Abstract

This paper proposes a novel approach to train word embeddings to capture antonyms. Word embeddings have shown to capture synonyms and analogies. Such word embeddings, however, cannot capture antonyms since they depend on the distributional hypothesis. Our approach utilizes supervised synonym and antonym information from thesauri, as well as distributional information from large-scale unlabelled text data. The evaluation results on the GRE antonym question task show that our model outperforms the state-of-the-art systems and it can answer the antonym questions in the F-score of 89%.

1 Introduction

Word embeddings have shown to capture synonyms and analogies (Mikolov et al., 2013b; Mnih and Kavukcuoglu, 2013; Pennington et al., 2014). Word embeddings have also been effectively employed in several tasks such as named entity recognition (Turian et al., 2010; Guo et al., 2014), adjectival scales (Kim and de Marneffe, 2013) and text classification (Le and Mikolov, 2014). Such embeddings trained based on *distributional hypothesis* (Harris, 1954), however, often fail to recognize antonyms since antonymous words, e.g. *strong* and *weak*, occur in similar contexts. Recent studies focuses on learning word embeddings for specific tasks, such as sentiment analysis (Tang et al., 2014) and dependency parsing (Bansal et al., 2014; Chen et al., 2014). These motivate a new approach to learn word embeddings to capture antonyms.

Recent studies on antonym detection have shown that thesauri information are useful in distinguishing antonyms from synonyms. The state-of-the-art systems achieved over 80% in F-score on GRE antonym tests. Yih et al. (2012) proposed a Polarity Inducing Latent Semantic Analysis (PILSA) that incorporated polarity information in two thesauri in constructing a matrix for latent semantic analysis. They additionally used context vectors to cover the out-of-vocabulary words; however, they did not use word embeddings. Recently, Zhang et al. (2014) proposed a Bayesian Probabilistic Tensor Factorization (BPTF) model to combine thesauri information and existing word embeddings. They showed that the usefulness of word embeddings but they used pre-trained word embeddings.

In this paper, we propose a novel approach to construct word embeddings that can capture antonyms. Unlike the previous approaches, our approach directly trains word embeddings to represent antonyms. We propose two models: a Word Embedding on Thesauri information (WE-T) model and a Word Embeddings on Thesauri and Distributional information (WE-TD) model. The WE-T model receives supervised information from synonym and antonym pairs in thesauri and infers the relations of the other word pairs in the thesauri from the supervised information. The WE-TD model incorporates corpus-based contextual information (distributional information) into the WE-T model, which enables the calculation of the similarities among in-vocabulary and out-of-vocabulary words.

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 984–989,
Denver, Colorado, May 31 – June 5, 2015.

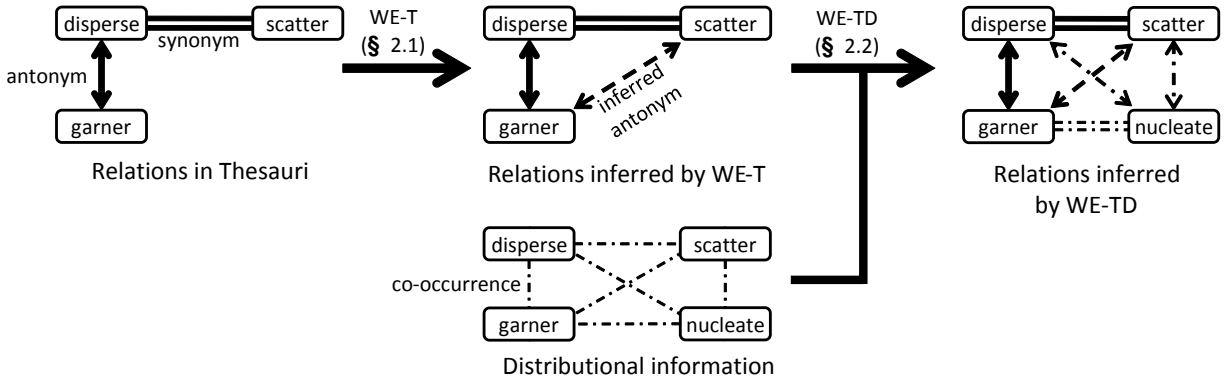

Figure 1: Overview of our approach. When we use the thesauri directly, *disperse* and *garner* are known to be antonymous and *disperse* and *scatter* are known to be synonymous, but the remaining relations are unknown. WE-T infers indirect relations among words in thesauri. Furthermore, WE-TD incorporates distributional information, and the relatedness among in-vocabulary and out-of-vocabulary words (*nucleate* here) are obtained.

2 Word embeddings for antonyms

This section explains how we train word embeddings from synonym and antonym pairs in thesauri. We then explain how to incorporate distributional information to cover out-of-vocabulary words. Figure 1 illustrates the overview of our approach.

2.1 Word embeddings using thesauri information

We first introduce a model to train word embeddings using thesauri information alone, which is called the WE-T model. We embed vectors to words in thesauri and train vectors to represent synonym and antonym pairs in the thesauri. More concretely, we train the vectors by maximizing the following objective function:

$$\begin{aligned} &\sum_{w \in V} \sum_{s \in S_w} \log \sigma(sim(w, s)) \\ &+\alpha \sum_{w \in V} \sum_{a \in A_w} \log \sigma(-sim(w, a)) \end{aligned} \quad (1)$$

V is the vocabulary in thesauri. S_w is a set of synonyms of a word w, and A_w is a set of antonyms of a word w. $\sigma(x)$ is the sigmoid function $\frac{1}{1+e^{-x}}$. α is a parameter to balance the effects of synonyms and antonyms. $sim(w_1, w_2)$ is a scoring function that measures a similarity between two vectors embedded to the corresponding words w_1 and w_2. We use the following asymmetric function for the scoring function:

$$sim(w_1, w_2) = \mathbf{v}_{w_1} \cdot \mathbf{v}_{w_2} + b_{w_1} \quad (2)$$

$\mathbf{v}_w$ is a vector embedded to a word w and b_w is a scalar bias term corresponding to w. This similarity score ranges from minus infinity to plus infinity and the sigmoid function in Equation (1) scales the score into the $[0, 1]$ range.

The first term of Equation (1) denotes the sum of the similarities between synonym pairs. The second term of Equation (1) denotes the sum of the dissimilarities between antonym pairs. By maximizing this objective, synonym and antonym pairs are tuned to have high and low similarity scores respectively, and indirect antonym pairs, e.g., synonym of antonym, will also have low similarity scores since the embeddings of the words in the pairs will be dissimilar. We use AdaGrad (Duchi et al., 2011) to maximize this objective function. AdaGrad is an online learning method using a gradient-based update with automatically-determined learning rate.

2.2 Word embeddings using thesauri and distributional information

Now we explain a model to incorporate corpus-based distributional information into the WE-T model, which is called the WE-TD model.

We hereby introduce Skip-Gram with Negative Sampling (SGNS) (Mikolov et al., 2013a), which the WE-TD model bases on. Levy and Goldberg (2014) shows the objective function for SGNS can

be rewritten as follows.

$$\sum_{w \in V} \sum_{c \in V} \{\#(w,c) \log \sigma(sim(w,c)) + k\#(w) P_0(c) \log \sigma(-sim(w,c))\} \quad (3)$$

The first term represents the co-occurrence pairs within a context window of C words preceding and following target words. $\#(w,c)$ stands for the number of appearances of a target word w and its context c. The second term represents the negative sampling. k is a number of negatively sampled words for each target word. $\#_p(w)$ is the number of appearances of w as a target word, and its negative context c is sampled from a modified unigram distribution P_0 (Mikolov et al., 2013a). We employ the subsampling (Mikolov et al., 2013a), which discards words according to the probability of $P(w) = 1 - \sqrt{\frac{t}{p(w)}}$. $p(w)$ is the proportion of occurrences of a word w in the corpus, and t is a threshold to control the discard. When we use a large-scale corpus directly, the effects of rare words are dominated by the effects of frequent words. Subsampling alleviates this problem by discarding frequent words more often than rare words.

To incorporate the distributional information into the WE-T model, we propose the following objective function, which simply adds this objective function to Equation 1 with an weight β:

$$\begin{aligned} &\beta\{\sum_{w \in V} \sum_{s \in S_w} \log \sigma(sim(w,s)) \\ &+\alpha \sum_{w \in V} \sum_{a \in A_w} \log \sigma(-sim(w,a))\} \\ &+ \sum_{w \in V} \sum_{c \in V} \{\#(w,c) \log \sigma(sim(w,c)) \\ &+k\#(w) P_0(c) \log \sigma(-sim(w,c))\} \end{aligned} \quad (4)$$

This function can be further arranged as

$$\sum_{w \in V} \sum_{c \in V} \{A_{w,c} \log \sigma(sim(w,c)) + B_{w,c} \log \sigma(-sim(w,c))\} \quad (5)$$

Here, the coefficients $A_{w,c}$ and $B_{w,c}$ are sums of corresponding coefficients in Equation 4. These terms can be pre-calculated by using the number of appearances of contextual word pairs, unigram distributions, and synonym and antonym pairs in thesauri.

The objective is maximized by using AdaGrad. We skip some updates according to the coefficients $A_{w,c}$ and $B_{w,c}$ to speed up the computation; we ignore the terms with extremely small coefficients ($< 10^{-5}$) and we sample the terms according to the coefficients when the coefficients are less than 1.

3 Experiments

3.1 Evaluation settings

This section explains the task setting, resource for training, parameter settings, and evaluation metrics.

3.1.1 GRE antonym question task

We evaluate our models and compare them with other existing models using GRE antonym question dataset originally provided by Mohammad et al. (2008). This dataset is widely used to evaluate the performance of antonym detection. Each question has a target word and five candidate words, and the system has to choose the most contrasting word to the target word from the candidate words (Mohammad et al., 2013). All the words in the questions are single-token words. This dataset consists of two parts, development and test, and they have 162 and 950 questions, respectively. Since the test part contains 160 development data set, We will also report results on 790 (950-160) questions following Mohammad et al. (2013).

In evaluating our models on the questions, we first calculated similarities between a target word and its candidate words. The similarities were calculated by averaging asymmetric similarity scores using the similarity function in Equation 2. We then chose a word which had the lowest similarity among them. When the model did not contain any words in a question, the question was left unanswered.

3.1.2 Resource for training

For supervised dataset, we used synonym and antonym pairs in two thesauri: WordNet (Miller, 1995) and Roget (Kipfer, 2009). These pairs were provided by Zhang et al. (2014)[1]. There were 52,760 entries (words), each of which had 11.7 synonyms on average, and 21,319 entries, each of which had 6.5 antonyms on average.

Table 1: Results on the GRE antonym question task. [†] is from Yih et al. (2012), [‡] is from Zhang et al. (2014), and [§] is from Mohammad et al. (2013). [¶] slightly differs from the result in Zhang et al. (2014) since thesauri can contain multiple candidates as antonyms and the answer is randomly selected for the candidates.

Error Type	Description	# Errors	Example Target	Example Gold	Example Predicted
Contrasting	Predicted answer is contrasting, but not antonym.	7	reticence dussuade	loquaciousness exhort	storm extol
Degree	Both answers are antonyms, but gold has a higher degree of contrast.	3	postulate	verify	reject
Incorrect gold	Gold answer is incorrect.	2	flinch	extol	advance
Wrong expansion	Gold and predicted answers are both in the expanded thesauri.	1	hapless	fortunate	happy
Incorrect	Predicted answer is not contrasting.	1	sessile	obile	ceasing
Total		14	—	—	—

Table 2: Error types by WE-TD on the development set.

We obtained raw texts from Wikipedia on November 2013 for unsupervised dataset. We lowercased all words in the text.

3.1.3 Parameter settings

The parameters were tuned using the development part of the dataset. In training the WE-T model, the dimension of embeddings was set to 300, the number of iteration of AdaGrad was set to 20, and the initial learning rate of AdaGrad was set to 0.03. α in Equation 1 were set to 3.2, according to the proportion of the numbers of synonym and antonym pairs in the thesauri. In addition to these parameters, when we trained the WE-TD model, we added the top 100,000 frequent words appearing in Wikipedia into the vocabulary. The parameter β was set to 100, the number of negative sampling k was set as 5, the context window size C was set to 5, the threshold for subsampling[2] was set to 10^{-8}.

3.1.4 Evaluation metrics

We used the *F-score* as a primary evaluation metric following Zhang et al. (2014). The *F-score* is the harmonic mean of *precision* and *recall*. *Precision* is the proportion of correctly answered questions over answered questions. *Recall* is the proportion of correctly answered questions over the questions.

[2]This small threshold is because this was used to balance the effects of supervised and unsupervised information.

3.2 Results

Table 1 shows the results of our models on the GRE antonym question task. This table also shows the results of previous systems (Yih et al., 2012; Zhang et al., 2014; Mohammad et al., 2013) and models trained on Wikipedia without thesauri (WE-D) for the comparison.

The low performance of WE-D illuminates the problem of distributional hypothesis. Word embeddings trained by using distributional information could not distinguish antonyms from synonyms.

Our WE-T model achieved higher performance than the baselines that only look up thesauri. In the thesauri information we used, the synonyms and antonyms have already been extended for the original thesauri by some rules such as ignoring part of speech (Zhang et al., 2014). This extension contributes to the larger coverage than the original synonym and antonym pairs in the thesauri. This improvement shows that our model not only captures the information of synonyms and antonyms provided by the supervised information but also infers the relations of other word pairs more effectively than the rule-based extension.

Our WE-TD model achieved the highest score among the models that use both thesauri and distributional information. Furthermore, our model has small differences in the results on the development and test parts compared to the other models.

3.3 Error Analysis

We analyzed the 14 errors on the development set, and summarized the result in Table 2.

Half of the errors (i.e., seven errors) were caused in the case that the predicted word is contrasting to some extent but not antonym ("Contrasting"). This might be caused by some kind of semantic drift. In order to predict these gold answers correctly, constraints of the words, such as part of speech and selectional preferences, need to be used. For example, "venerate" usually takes "person" as its object, while "magnify" takes "god." Three of the errors were caused by the degree of contrast of the gold and the predicted answers ("Degree"). The predicted word can be regarded as an antonym but the gold answer is more appropriate. This is because our model does not consider the degree of antonymy, which is out of our focus. One of the questions in the errors had an incorrect gold answer ("Incorrect gold"). We found that in one case both gold and predicted answers are in the expanded antonym dictionary ("Wrong expansion"). In expanding dictionary entries, the gold and predicted answers were both included in the word list of an antonym entries. In one case, the predicted answer was simply wrong ("Incorrect").

4 Conclusions

This paper proposed a novel approach that trains word embeddings to capture antonyms. We proposed two models: WE-T and WE-TD models. WE-T trains word embeddings on thesauri information, and WE-TD incorporates distributional information into the WE-T model. The evaluation on the GRE antonym question task shows that WE-T can achieve a higher performance over the thesauri lookup baselines and, by incorporating distributional information, WE-TD showed 89% in F-score, which outperformed the conventional state-of-the-art performances. As future work, we plan to extend our approaches to obtain word embeddings for other semantic relations (Gao et al., 2014).

Abstract

Vectorial representations of words derived from large current events datasets have been shown to perform well on word similarity tasks. This paper shows vectorial representations derived from substantially smaller explanatory text datasets such as English Wikipedia and Simple English Wikipedia preserve enough lexical semantic information to make these kinds of category judgments with equal or better accuracy.

1 Introduction

Vectorial representations derived from large current events datasets such as Google News have been shown to perform well on word similarity tasks (Mikolov, 2013; Levy & Goldberg, 2014). This paper shows vectorial representations derived from substantially smaller explanatory text datasets such as English Wikipedia and Simple English Wikipedia preserve enough lexical semantic information to make these kinds of category judgments with equal or better accuracy. Analysis shows these results may be driven by a prevalence of commonsense facts in explanatory text. These positive results for relatively small datasets suggest vectors derived from slower but more accurate analyses of these resources may be practical for lexical semantic applications.

2 Background

2.1 Wikipedia

Wikipedia is a free Internet encyclopedia website and the largest general reference work over the Internet.[1] As of December 2014, Wikipedia contained over 4.6 million articles[2] and 1.6 billion words. Wikipedia as a corpus has been heavily used to train various NLP models. Features of Wikipedia are well exploited in research like semantic web (Lehmann et al, 2014) and topic modeling (Dumais, 1988; Gabrilovich, 2007), but more importantly Wikipedia has been a reliable source for word embedding training because of its sheer size and coverage (Qiu, 2014), as recent word embedding models (Mikolov et al, 2013; Pennington et al, 2014) all use Wikipedia as an important corpus to build and evaluate their algorithms for word embedding creation.

2.2 Simple English Wikipedia

Simple English Wikipedia[3] is a Wikipedia database where all articles are written using simple English words and grammar. It is created to help adults and children who are learning English to look for encyclopedic information. Compared with full English Wikipedia, Simple English Wikipedia is much smaller. It contains around 120,000 articles and 20 million words, which is almost one fortieth the number of articles and one eightieth the number of words compared to full English Wikipedia, so the average length of articles is also shorter. Simple English Wikipedia is often used in simplification research (Coster, 2011; Napoles, 2010) where sentences from full English Wikipedia are matched to sentences from Simple English Wikipedia to explore techniques to simplify sentences. It would be

[1] See https://en.wikipedia.org/wiki/Wikipedia
[2] See http://en.wikipedia.org/wiki/Wikipedia:Size_of_Wikipedia
[3] See http://simple.wikipedia.org/wiki/Main_Page

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 990–994,
Denver, Colorado, May 31 – June 5, 2015.

reasonable to expect that the small vocabulary size of Simple English Wikipedia may be disadvantageous when trying to create word embeddings using co-occurrence information, but it may also be true that despite the much smaller vocabulary size and overall size, because of the explanatory nature of its text, Simple English Wikipedia would still preserve enough information to allow the performance of models trained with Simple English Wikipedia to be comparable to models trained on full Wikipedia, and perform equally well or better than non-explanatory texts like the Google News corpus.

2.3 Word2Vec

The distributed representation of words, or word embeddings, has gained significant attention in the research community, and one of the more discussed works is Mikolov's (2013) word representation estimation research. Mikolov proposed two neusral network based models for word representation: Continuous Bag-of-Words (CBOW) and Skip-gram. CBOW takes advantage of context words surrounding a given word to predict the word by summing all the context word vectors together to represent the word; whereas Skip-gram uses the word to predict the context word vectors for skip-gram positions, therefore making the model sensitive to positions of context words. Both of the models scale well to large quantities of training data, however it is noted by Mikolov that Skip-gram works well with small amounts of training data and provides good representations for rare words, and CBOW would perform better and have higher accuracy for frequent words if trained on larger corpora. The purpose of this paper is not to compare the models, but to use the models to compare training corpora to see how different arrangement of information may impact the quality of the word embeddings.

3 Task Description

To evaluate the effectiveness of full English Wikipedia and Simple English Wikipedia as training corpora for word embeddings, the word similarity-relatedness task described by Levy & Goldberg (2014) is used. As pointed out by Agirre et al (2009) and Levy & Goldberg (2014), relatedness may actually be measuring topical similarity and be better predicted by a bag-of-words model, and similarity may be measuring functional or syntactic similarity and be better predicted by a context-window model. However, when the models are constant, the semantic information of the test words in the training corpora is crucial to allowing the model to build semantic representations for the words. It may be argued that when the corpus is explanatory, more semantic information about the target words is present; whereas when the corpus is non-explanatory, information around the words is merely related to the words. The WordSim353 (Agirre, 2009) dataset is used as the test dataset. This dataset contains pairs of words that are decided by human annotators to be either similar or related, and a similarity or relatedness gold standard score is also given to every pair of words. There are 100 similar word pairs, 149 related pairs and 104 pairs of words with very weak or no relation. In the evaluation task, the unrelated word pairs are discarded from the dataset.

The objective of the task is to rank the similar word pairs higher than related ones. The retrieval/ranking procedure is as follows. First, the cosine similarity scores are calculated using word embeddings from a certain model; then the scores are sorted from the highest to the lowest. The retrieval step is then carried out by locating the last pair of the first n% of the pairs of similar words in the sorted list of scores and determining the percentage of similar word pairs in the sub-list delimited by the last pair of similar words. In other words, the procedure treats similar word pairs as successful retrievals and determines the accuracy rate when the recall rate is n%. Because the accuracy rate would always fall to the percentage of similar word pairs in all word pairs, it is expected that the later and more suddenly it falls, the better the model is performing in this task.

4 Models

The word2vec python implementation provided by gensim (Rehurek et al, 2010) package is used to train all the word2vec models. For Skip-gram and CBOW, a 5-word window size is used to allow them to get the same amount of raw information, also words appearing 5 times or fewer are filtered out. The dimensions of the word embeddings from Skip-gram and CBOW are all 300. Both full English Wikipedia and Simple English Wikipedia are used as training corpora with minimal preprocessing procedures: XML tags are removed and

infoboxes are filtered out, thus yielding four models: Full English Wikipedia – CBOW(FW-CBOW), Full English Wikipedia – Skip-gram(FW-SG), Simple English Wikipedia – CBOW(SW-CBOW) and Simple English Wikipedia – Skip-gram(SW-SG). The pre-trained Google News skip-gram model with 300-dimensional vectors (GN-SG) is also downloaded from the Google word2vec website for comparison. This model is trained on the Google News dataset with 100 billion words, which is 30 times as large as the full English Wikipedia and 240 times as large as Simple English Wikipedia.

5 Results

Table 1 shows the accuracy rate at every recall rate point, with the sum of all the accuracy rates as the cumulative score. It is shown that GN-SG, although not far behind, is not giving the best performance despite being trained on the largest dataset. In fact, it is clear that it never excels at any given recall rate point. It outperforms various models at certain recall rate points by a small margin, but there is no obvious advantage gained from training using a much larger corpus even when compared with the models trained on Simple English Wikipedia, despite the greater risk of sparse data problems on this smaller data set.

For models trained on Simple English Wikipedia and full English Wikipedia, it is also interesting to see that the models almost perform equally well. The FW-CBOW trained on full English Wikipedia performs the best among the models overall, but for the first few recall rate points, it performs equally well or slightly worse than either SW-CBOW or SW-SG trained on Simple English Wikipedia. At the later points, it is also clear that although FW-CBOW is generally better than all the other models most of the time, the margin could be considered narrow and furthermore it is equally as good as SW-CBOW at the first two recall points.

Comparing FW-SG with SW-SG and SW-CBOW, there is almost no sign of performance gain from training using full Wikipedia instead of the much smaller Simple Wikipedia. FW-SG performs equally well or often slightly worse than both Simple Wikipedia models.

The main observation in this paper is that Google News is not out-performing other systems substantially and that full Wikipedia systems are not out-performing Simple Wikipedia substantially (that is, comparing the CBOW models to one another and the Skip-gram models to one another). The main result from the table is not that smaller training datasets yield better systems, but that systems trained using significantly smaller training datasets of explanatory text have very close performances in this task compared with systems trained on very large datasets, despite the big training data size difference.

6 Analysis

As mentioned previously, similarity may be better predicted by a context-window model because it measures functional or syntactic similarity. However, it is not clear in these models that the syntactic information is a major component in the word embeddings. Instead, it may be that the main factor for the performance level of the models is the general explanatory content of the Wikipedia articles, as opposed to the current events content of Google News.

For similar words such as synonyms or hyponyms, the crucial information making them similar is shared general semantic features of the words. For example, for the word pair *physics : chemistry*, the shared semantic features might be that they are both academic subjects, both studied in institutions and both composed of different subfields, as shown in Table 2. The '@' sign in table 2 connects a context word with its position relative to the word in the center of the window. These shared properties

Model	10% Recall Rate	20% Recall Rate	30% Recall Rate	40% Recall Rate	50% Recall Rate	60% Recall Rate	70% Recall Rate	80% Recall Rate	90% Recall Rate	100% Recall Rate	Cumulative Score
FW-CBOW	**0.91**	**0.95**	0.89	**0.83**	**0.72**	**0.74**	**0.61**	**0.51**	**0.46**	0.40	**7.03**

FW-SG	**0.91**	**0.95**	0.79	0.75	0.63	0.61	0.53	0.49	0.43	0.40	6.50
SW-SG	**0.91**	**0.95**	**0.91**	0.70	0.62	0.57	0.54	0.45	0.42	0.40	6.47
GN-SG	0.85	0.84	0.82	0.79	0.70	0.64	0.57	0.48	0.43	0.40	6.51

Table 1: Performance of Different Models at Different Recall Rate Points

of the core semantic identities for these words may contribute greatly to the similarity judgments for humans and machines alike, and these shared properties may be considered general knowledge about the words. For the related words, for example *computer : keyboard*, it may be difficult to pinpoint the semantic overlap between the components which build up the core semantic identities of these words, and none is observed in the data.

General knowledge of a certain word may be found in explanatory texts about the word like dictionaries or encyclopedias, but rarely found in texts other than that. It would be assumed by the writers of informative non-explanatory texts like news articles that the readers are well acquainted with all the basic semantic information about the words, therefore repetition of such information would be unnecessary. For a similarity/relatedness judgment task where basic and compositional semantic information may prove to be useful, using a corpus like Google News, where information or context for a particular word assumes one is already conversant with it, would not be as effective as using a corpus like Wikipedia where general knowledge about a word may be available and repeated. Also, the smaller vocabulary size of Wikipedia compared with Google News would suggest that general knowledge may be conveyed more efficiently with less data sparsity.

In the Simple Wikipedia vs. full Wikipedia case, both corpora are explanatory texts. Despite the much smaller size, the general semantic overlap between each pair of similar words seems as evident in Simple Wikipedia as in full Wikipedia. For measurements like cosine similarity where large values in the same dimensions are favored, the basic semantic components which contribute to the similarity judgments for the words are the same comparatively across two different corpora. This may not be surprising because although more information may be present in full Wikipedia, because of its explanatory nature, the core semantic components which make a concept distinct still dominate over new and sparser information added to it. In Simple Wikipedia, the size of the articles

and vocabulary may restrict it to be basic and precise to explain a certain concept with fewer presumptions of what the readers already know, and it is suggested by the analysis that such style is also reflected in full Wikipedia, leading to the domination of general knowledge over specific facts.

7 Conclusion

This paper has shown vectorial representations derived from substantially smaller explanatory text datasets such as Wikipedia and Simple Wikipedia preserve enough lexical semantic information to make these kinds of category judgments with equal or better accuracy than news corpora. Analysis shows these results may be driven by a prevalence of commonsense facts in explanatory text. These positive results for small datasets suggest vectors derived from slower but more accurate analysis of these resources may be practical for lexical semantic applications, and we hope by providing this result, future researchers may be more aware of the viability of smaller-scale resources like Simple English Wikipedia (or presumably Wikipedia in other languages which are substantially smaller in size than English Wikipedia), that can still produce high quality vectors despite a much smaller size.

Abstract

This paper addresses the problem of morphological modeling in statistical speech-to-speech translation for English to Iraqi Arabic. An analysis of user data from a real-time MT-based dialog system showed that generating correct verbal inflections is a key problem for this language pair. We approach this problem by enriching the training data with morphological information derived from source-side dependency parses. We analyze the performance of several parsers as well as the effect on different types of translation models. Our method achieves an improvement of more than a full BLEU point and a significant increase in verbal inflection accuracy; at the same time, it is computationally inexpensive and does not rely on target-language linguistic tools.

1 Introduction

SMT from a morphologically poor language like English into a language with richer morphology continues to be a problem, in particular when training data is sparse and/or the SMT system has insufficient modeling capabilities for morphological variation in the target language. Most previous approaches to this problem have utilized a translate-and-inflect method, where a first-pass SMT system is trained on lemmatized forms, and the correct inflection for every word is predicted in a second pass by statistical classifiers trained on a combination of source and target language features. This paper looks at morphological modeling from a different perspective, namely to improve SMT in a real-time speech-to-speech translation system. Our focus is on resolving those morphological translation errors that are most likely to cause confusions and misunderstandings in machine-translation mediated human-human dialogs. Due to the constraints imposed by a real-time system, previous approaches that rely on elaborate feature sets and multi-pass processing strategies are unsuitable for this problem. The language pair of interest in this study is English and Iraqi Arabic (IA). The latter is a spoken dialect of Arabic with few existing linguistic resources. We therefore develop a low-resource approach that relies on source-side dependency parses only. We analyze its performance in combination with different types of parsers and different translation models. Results show a significant improvement in translation performance in both automatic and manual evaluations. Moreover, the proposed method is sufficiently fast for a real-time system.

2 Prior Work

Much work in SMT has addressed the issue of translating from morphologically-rich languages by preprocessing the source and/or target data by e.g., stemming and morphological decomposition (Popovic and Ney, 2004; Goldwater and McClosky, 2005), compound splitting (Koehn and Knight, 2003), or various forms of tokenization (Lee, 2004; Habash and Sadat, 2006). In (Minkov et al., 2007; Toutanova et al., 2008) morphological generation was applied as a postprocessing step for translation *into* morphologically-rich languages. A maximum-entropy Markov model was trained to predict the correct inflection for every stemmed word in the

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 995–1000,
Denver, Colorado, May 31 – June 5, 2015.

machine translation output from a first-pass system, conditioned on a set of lexical, morphological and syntactic features. More recently, (Chahuneau et al., 2013) applied a similar translate-and-inflect approach, utilizing unsupervised in addition to supervised morphological analyses. Inflection generation models were also used by (Fraser et al., 2012; Weller et al., 2013) for translation into German, and by (El Kholy and Habash, 2012) for Modern Standard Arabic. (Sultan, 2011) added both syntactic information on the source side that was used in filtering the phrase table, plus postprocessing on the target side for English-Arabic translation. Still other approaches enrich the translation system with morphology-aware feature functions or specific agreement models (Koehn and Hoang, 2007; Green and DeNero, 2012; Williams and Koehn, 2011).

In contrast to the above studies, which have concentrated on text translation, this paper focuses on spoken language translation within a bilingual human-human dialog system. Thus, our main goal is not to predict the correct morphological form of every word, but to prevent communication errors resulting from the mishandling of morphology. The intended use in a real-time dialog system imposes additional constraints on morphological modeling: any proposed approach should not add a significant computational burden to the overall system that might result in delays in translation or response generation. Our goal is also complicated by the fact that our target language is a spoken dialect of Arabic, for which few linguistic resources (training data, lexicons, morphological analyzers) exist. Lastly, Arabic written forms are morphologically highly ambiguous due to the lack of short vowel markers that signal grammatical categories.

3 Dialog System and Analysis

The first step in the dialog system used for this study consists of an automatic speech recognition (ASR) component that produces ASR hypotheses for the user's speech input. Several error detection modules then identify likely out-of-vocabulary and misrecognized words. This information is used by a clarification module that asks the user to rephrase these error segments; another module then combines the user's answers into a merged, corrected representation before sending it to the translation engine. A machine translation error detection module analyzes the translation to check for errors, such as unknown words. If an error is found, another clarification subdialog is initiated; otherwise, the translation is sent to a text-to-speech engine to produce the acoustic output in the other language. A schematic representation is shown in Figure 1. More details about the system can be found in (et al., 2013). The system was evaluated in live mode with native IA speakers as part of the DARPA BOLT Phase-II benchmark evaluations. The predefined scenarios included military and humanitarian assistance/disaster relief scenarios as well as general topics. All system interactions were logged and evaluated by bilingual human assessors.

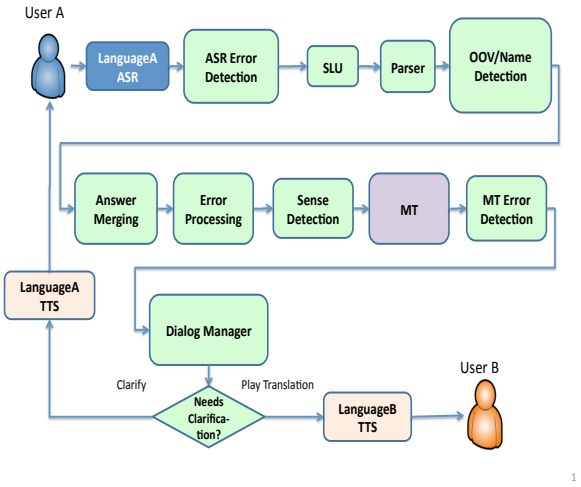

Figure 1: Dialog system used in this work.

During debriefing sessions with the users, some users voiced dissatisfaction with the translation quality, and a subsequent detailed error analysis was conducted on the logs of 30 interactions. Similar to previous studies (Condon et al., 2010) we found that a frequently recurring problem was wrong morphological verb forms in the IA output. Some examples are shown in Table 1. In Example 1, *to make sure* should be translated by a first-person plural verb but it is translated by a second-person plural form, changing the meaning to (*you (pl.) make sure*). The desired verb form would be *ntAkd*. Similarly, in Example 2 the translation of *transport* should agree with the translations of *someone* and the preceding

1	*you need to tell the locals to evacuate the area so we can secure the area* **to make sure** *no one gets hurt* *lAzm tqwl Alhm AhAly AlmnTqp bAlAxlA' AlmnTqp HtY nqdr nwmn AlmnTqp Elmwd* **ttAkdwn** *Anh mHd ytAY*
2	*do you have someone that can* **transport you** *to the nearest american base* *Endk wAHd yqdr* **nqlk** *lAqrb qAEdp Amrykyp*

Table 1: Examples of mistranslated morphology: English ASR hypotheses and IA translation hypotheses.

auxiliary verb *can* (*yqdr*). The correct form would be *yqlk* (*he/she transports you*) instead of *nqlk* (*we transport you*). Such translation errors are confusing to users as they affect the understanding of basic semantic roles. They tend to occur when translating English infinitival constructions (*to*+verb) or other syntactic constructions where English base verb forms need to be translated by a finite verb in IA. In these cases, explicit morphological features like person and number are required in Arabic but they are lacking in the English input.

4 Approach

An analysis of the SMT component showed that morphological translation errors primarily occur when a head word and its dependent (such as a verbal head and its subject noun dependent) are translated as part of different phrases or rules. In that case, insufficient context is available to produce the correct translation. Our approach is to annotate syntactic dependencies on the source side using a statistical parser. Based on the resulting dependency structures the source-side data is then tagged with explicit morphological verbal features using deterministic rules (e.g., subject nouns assign their person/number features to their verbal heads), and a new translation model is trained on this data. Our assumption is that words tagged with explicit morphological features will be aligned with their correct translations during training and will thus produce correctly inflected forms during testing even when the syntactic context is not available in the same phrase/rule. For instance, the input sentence in Example 1 in Table 1 would be annotated as:
you need-2sg to tell-2sg the locals to evacuate-3pl the area so we can-1pl secure-1pl the area to make-1pl sure no one gets-3sg hurt.
This approach avoids the costly extraction of multiple features, subsequent statistical classification, and inflection generation during run time; moreover, it does not require target-side annotation tools, an advantage when dealing with under-resourced spoken dialects. There are, however, several potential issues with this approach. First, introducing tags fragments the training data: the same word may receive multiple different tags, either due to genuine ambiguity or because of parser errors. As a result, word alignment and phrase extraction may suffer from data sparsity. Second, new word-tag combinations in the test data that were not observed in the training data will not have an existing translation. Third, the performance of the model is highly dependent on the accuracy of the parser. Finally, we make the assumption that the expression of person and number categories are matched across source and target language – in practice, we have indeed seen very few mismatched cases where e.g., a singular noun phrase in English is translated by a plural noun phrase in IA (see Section 6 below).

To address the first point the morph-tagged translation model can be used in a backoff procedure rather than as an alternative model. In this case the baseline model is used by default, and the morph-tagged model is only used whenever heads and dependents are translated as part of different phrases. Unseen translations for particular word-tag combinations in the test set could in principle be addressed by using a morphological analyzer to generate novel word forms with the desired inflections. However, this would require identifying the correct stem for the word in question, generating all possible morphological forms, and either selecting one or providing all options to the SMT system, which again increases system load. We analyzed unseen word-tag combination in the test data but found that their percentage was very small ($< 1\%$). Thus, for these forms we back off to the untagged counterparts rather than generating new inflected forms. To obtain better insight into the effect of parsing accuracy we compared the performance of two parsers in our

annotation pipeline: the Stanford parser (de Marneffe et al., 2006) (version 3.3.1) and the Macaon parser (Nasr et al., 2014). The latter is an implementation of graph-based parsing (McDonald et al., 2005) where a projective dependency tree maximizing a score function is sought in the graph of all possible trees using dynamic programming. It uses a 1st-order decoder, which is more robust to speech input as well as out-of-domain training data. The features implemented reflect those of (Bohnet, 2010) (based on lexemes and part-of-speech tags). The parser was trained on Penn-Treebank data transformed to match speech (lower-cased, no punctuation), with one iteration of self-training on the Transtac training set. We also use the combination of both parsers, where source words are only tagged if the tags derived independently from each parser agree with each other.

5 Data and Baseline Systems

Development experiments were carried out on the Transtac corpus of dialogs in the military and medical domain. The number of sentence pairs is 762k for the training set, 6.9k for the dev set, 2.8k for eval set 1, and 1.8k for eval set 2. Eval set 1 has one reference per sentence, eval set 2 has four references. For the development experiments we used a phrase-based Moses SMT system with a hierarchical reordering model, tested on Eval set 1. The language model was a backoff 6-gram model trained using Kneser-Ney discounting and interpolation of higher- and lower-order n-grams. In addition to automatic evaluation we performed manual analyses of the accuracy of verbal features in the IA translations on a subset of 65 sentences (containing 143 verb forms) from the live evaluations described above. This analysis counts a verb form as correct if its morphological features for person and number are correct, although it may have the wrong lemma (e.g., wrong word sense). The development experiments were designed to identify the setup that produces the highest verbal inflection accuracy. For final testing we used a more advanced SMT engine on Eval set 2.This system is the one used in the real-time dialog system; it contains a hierarchical phrase-based translation model, sparse features, and a neural network joint model (NNJM) (Devlin et al., 2014).

	BLEU		Acc (%)	
Parser	std	bo	std	bo
Baseline	16.8	N/A	37.1	N/A
Stanford	16.9	17.0	60.1	59.4
Macaon	17.0	17.1	**67.1**	62.9
Combined	17.1	17.1	59.4	57.3

Table 2: BLEU scores on Transtac eval set 1 and accuracy of verbal morphological features on manual eval set. *std* = standard, *bo* = backed-off system.

6 Experiments and Results

Results in Table 2 show the comparison between the baseline, different parsers, and the combined system. We see that verbal inflection accuracy increases substantially from the baseline performance and is best for the Macaon parser. Improvements over the baseline system without morphology are statistically significant; differences between the individual parsers are not (not, however, that the sample size for manual evaluation was quite small).

BLEU is not affected negatively but even increases slightly - thus, data fragmentation does not seem to be a problem overall. This may be due to the nature of the task and domain, which is results in fairly short, simple sentence constructions that can be adequately translated by a concatenation of shorter phrases rather than requiring longer phrases. Back-off systems (indicated by *bo*) and the combined system improve BLEU only trivially while decreasing verbal inflection accuracy by varying amounts. For testing within the dialog system we thus choose the Macaon parser and utilize a standard translation model rather than a backoff model. An added benefit is that the Macaon parser is already used in other components in the dialog system. Using this setup we ran two experiments with dialog system's SMT engine: first, we re-extracted phrases and rules based on the morph-tagged data and re-optimized the feature weights. In the second experiment, we additionally applied the NNJM to the morph-tagged source text. To this end we include all the morphological variants of the original vocabulary that was used for the NNJM in the untagged baseline system. Table 3 shows the results. The morph-tagged data improves the BLEU score under both conditions: in Experiment 1, the improve-

ment is almost a full BLEU point (0.91); in Experiment 2 the improvement is even larger (1.13), even though the baseline performance is stronger. Both results are statistically significant at p = 0.05, using a paired bootstrap resampling test. The combination of morph-tagged data and the more advanced modeling options (sparse features, NNJM) in this system seem to be beneficial. Improved translation performance may also be captured by the four reference translations as opposed to one in Eval set 1. In order to assess the added computation cost

System	no NNJM	with NNJM
Baseline	34.38	36.17
Morph tags	**35.29**	**37.30**

Table 3: BLEU on Eval set 2 using dialog system's SMT engine.

of our procedure we computed the decoding speed of the MT component in the dialog system for both the baseline and the morpho-tag systems. In the baseline MT system (with NNJM) without morpho-tags, decoding takes 0.01572 seconds per word or 0.15408 seconds per sentence – these numbers were obtained on a Dell Precision M4800 Laptop with a quad-core Intel i7-4930MX Processor and 32GB of RAM. Morpho-tagging only adds 0.00031 seconds per word or 0.0024 seconds per sentence. Thus, our procedure is extremely efficient.

An analysis of the remaining morphological translation errors not captured by our approach showed that in about 34% of all cases these were due to part-of-speech tagging or parser errors, i.e. verbs were mistagged as nouns rather than verbs and thus did not receive any morphological tags, or the parser hypothesized wrong dependency relations. In 53% of the cases the problem is the lack of more extensive discourse or contextual knowledge. This includes constructions where there is no overt subject for a verb in the current utterance, and the appropriate underlying subject must be inferred from the preceding discourse or from knowledge of the situational context. This is an instance of the more general problem of control (see e.g.,(Landau, 2013) for an overview of research in this area). It is exemplified by cases such as the following:

1. *The first step is to make sure that all personnel are in your debrief.*

Here, the underlying subject of "to make sure" could be a range of different candidates (*I*, *you*, *we*, etc.) and must be inferred from context.

2. *I can provide up to one platoon to help you guys cordon off the area.*

In this case the statistical parser identified *I* as the subject of *help*, but *platoon* is more likely to be the controller and was in fact identified as the underlying subject by the annotator. Such cases could potentially be resolved during the parsing step by integrating semantic information, e.g. as in (Bansal et al., 2014). However, initial investigations with semantic features in the Macaon parser resulted in a significant slow-down of the parser. In other cases, more sophisticated modeling of the entities and their relationships in the situational context will be required. This clearly is an area for future study.

Finally, in 13% of the cases, mistranslations are caused by a mismatch of number features across languages (e.g. number features for nouns such as *family* or *people*).

7 Conclusion

We have shown that significant gains in BLEU and verbal inflection accuracy in speech-to-speech translation for English-IA can be achieved by incorporating morphological tags derived from dependency parse information in the source language. The proposed method is fast, low-resource, and can easily be incorporated into a real-time dialog system. It adds negligible computational cost and does not require any target-language specific annotation tools. Possible areas for future study include the use of discourse or and other contextual information to determine morphological agreement, application to other languages pairs/morphological agreement types, and learning the annotation rules from data.

firstname.surname@lium.univ-lemans.fr

Abstract

This paper gives a detailed experiment feedback of different approaches to adapt a statistical machine translation system towards a targeted translation project, using only small amounts of parallel in-domain data. The experiments were performed by professional translators under realistic conditions of work using a computer assisted translation tool. We analyze the influence of these adaptations on the translator productivity and on the overall post-editing effort. We show that significant improvements can be obtained by using the presented adaptation techniques.

1 Introduction

Language service providers (LSP) and human professional translators currently use machine translation (MT) technology as a tool to increase their productivity. For this, MT is closely integrated into computer-assisted translation (CAT) tool. The MT system suggests an automatic translation of the input sentence which is then post-edited by the human professional translators. They generally work on a project-based pace, *i.e.* a set of documents (the project) have to be translated in a certain period of time. It is well know that an MT system has to be adapted to the target task and domain in order to achieve the best performances. This process of adaptation can be separated into two different steps. First, an adaptation is performed before the beginning of the translation process,. This aims to specialize the system to the targeted domain: we will to this adaptation as *domain adaptation*.

Then, another adaptation is performed during the translation process with the aim of iteratively integrating users' feedback into the MT system. The adaptation can be performed at two different frequencies: (i) the system can continuously learn from post-edited segments, the models being immediately updated, or (ii) all the available project-specific data is used after each day of work to adapt the MT engine. This scheme is more related to document level adaptation; we will refer to it as *project adaptation*. The experimental work described in this paper fits into the latter adaptation scheme.

As part of the MATECAT project[1], we analyze project adaptation performed over several days. All experiments were performed with professional human translators under realistic conditions of work. The motivations of this work are detailed in section 2 and related work is discussed. In sections 3 and 4 we present both the experimental protocol and framework before presenting the corresponding results in section 5.

2 Motivations

This work is a continuation of earlier research on adaptation of a statistical MT (SMT) system Cettolo et al., 2014). More precisely, it was motivated by remaining opened questions. First, what does the learning curve look like for an iterative usage of the daily adaptation procedure? Even if the efficiency of the project adaptation scheme has been established, it has not been tested yet over multiple days. Does it reaches a plateau or do the translation

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1001–1005,
Denver, Colorado, May 31 – June 5, 2015.

quality continue to improve? What are the causes for the observed gains? Are they due to the familiarization of the users with both the system and the task, or are they due to real efficiency of the adaptation scheme? In previous work, the protocol did not allow to clearly measure the adaptation performance. In order to avoid this issue, a specific experimental protocol has been defined as described in section 3. Moreover, in addition to answer these new questions, we assessed a project adaptation scheme which take advantage of continuous space language modeling (CSLM) as explained in section 4. As far as we know, this is the first time that a neural network LM is integrated into a professional environment workflow, and that adaptation in such an approach is considered.

3 Evaluation Protocol

We defined an adaptation protocol with the goal to assess the same task with and without adaptation procedure. Like in (Guerberof, 2009; Plitt and Masselot, 2010), three professional translators were involved in a two parts experiment: during the first part, translators receive MT suggestions from a state-of-the-art domain-adapted engine built with the Moses toolkit (Koehn et al., 2007), without being adapted with the data generated during the translation of the project.For the second part, the MT suggestions are provided by a MT system which was previously adapted to the current project using the human translations of prior working days. Since we asked the same translators to post-edit the same document twice (*i.e.* with and without MT adaptation), the second run was launched after a sufficient delay: the human memory impact is reduced since translators worked on other projects in between.

To measure the user productivity, we considered two performance indicators: (i) the post-editing effort measured with TER (Snover et al., 2006) which corresponds to the number of edits made individually by each translator, (ii) the time-to-edit rate expressed in number of translated words per hour. In addition to these two key indicators, we evaluated the translation quality using an automatic measure, namely BLEU score (Papineni et al., 2002). This measure is used to make sure that no regression in the translation quality is observed after several days of work due to overfitting of the project adaptation (since previous working days are used to adapt the models).

Moreover, in order to respect realistic working conditions, we decided to set up a unique user-specific Moses engine per translator. By these means, any inter-user side-effects due to personal choices or stylistic edits are avoided. In addition, we obtain multiple references for assessing the results of the test. Consequently, it was required for the assessment that human translators work in a synchronized manner, *i.e.* the same amount of data is translated every day by each translator. The systems are then adapted, individually for each translator, using previous days of work, and used by the translators during the next day, and so on.

4 Experimental framework

We ran contrastive experiments by asking the translators to post-edit translations of a Legal document from English into French (about 15k words) over five days (*i.e.* about 3k words/day). An in-domain adapted (DA) system was used as baseline system for the first day, before project adapted (PA) systems have taken over.

4.1 Domain adapted system

Before the human translator starts working, our DA system is trained using an extracted subset of bilingual training data that is mostly relevant to our specific domain. The extraction process, widely known as *data selection*, is applied using cross-entropy difference algorithm proposed by (Axelrod et al., 2011)[2]. In order to augment the amount of training data[3] (about 22M words) we also select a bilingual subset from *Europarl*, *JRC-Acquis*, *news commentary*, *software manuals of the OPUS corpus*, *translation memories* and the *United Nations corpus*. About 700M additional newspaper monolingual data selected from WMT evaluation campaign are also used for language modeling.

4.2 Project adapted system

Our project-adaptation scenario, which is repeated iteratively during the lifetime of the translation

[2]We used the XenC tool for data selection

[3]DGT+ECB corpora (see http://opus.lingfil.uu.se)

project, is achieved as follows: the new daily amount of specific data is added to the development set, and new monolingual and bilingual data selections are performed with it. The new SMT system built on these selected data is then optimized on the new development set.

When performing project adaptation of an SMT system, we assume that the documents of a project are quite close and then, adapting the SMT system using the n-th days could be helpful to translate the $n+1$ day. However, we need to be careful to not overfit to a particular day of the project. This is particularly risky since the daily amount of specific data is relatively small (about 3k words). Therefore, we chose to add three times the daily data to our existing in-domain development set. This factor of three was empirically determined during prior lab tests. Also, all the previous days are used, *i.e.* when we adapt after three days of work, we used all the data from the first three days.

4.3 Continuous Space Language Model

Over the last years, there has been significantly increasing interest in using neural networks in SMT. As mentioned above, we used this technology into our project adaptation scheme. Fully integrated to the MT systems, it was used by our three SMT systems dedicated to the translators.

A continuous space LM (CSLM) (Schwenk, 2010; Schwenk, 2013) is trained on the same data than a classical n-gram back-off LM and is used to rescore the n-best list. In our case, and after each day of work, the daily generated data (3k words) is used to perform the adaptation of the CSLM by continuing its training (see (Ter-Sarkisov et al., 2014) for details). An important advantage of this approach is that the adaptation can be performed in a couple of minutes.

5 Experimental results and discussion

All the results presented in this section have been extracted from the edit logs provided by the MATECAT CAT tool.

5.1 Post-editing effort

In terms of post-editing effort, the results for each translator according to several SMT systems are shown in Table 1. Several TER scores are computed between the SMT system output and various sets of references. This score reveals the number of edits performed by the translator in order to obtain a suitable translation. The first column indicates the day of the experiment. The second column represents three SMT systems, namely: the baseline system adapted to the domain (DA), the same system with a CSLM (DA+CSLM) and the project adapted system (all models were updated, including the CSLM) noted "PA+CSLM-adapt". The third, fourth and fifth columns represent respectively the TER scores for the three translators. The first score is calculated using the reference produced by the translator himself. It could be considered as HTER (Snover et al., 2009). The second score (in parenthesis) is calculated using the three references produced by the translators. The third score (in brackets) is calculated according to an official "generic" reference provided by the European Commission. By these additional results, we aim to assess whether their is a tendency of the systems to adapt strongly to the particular style of one translator, or whether they still perform well with respect to independent references. On day 1, only the DA and DA+CSLM systems are presented since the project adaptation can only start after the first working day.

First of all, we can notice that the use of CSLM significantly decrease the TER scores for all translators. We can also remark that the third translator has a much higher TER than the two other translators during the first two days. Then, the system seems to learn his style and the TER reaches a comparable level at day 3. We can observe that project adaptation always lowers the TER with respect to the individual reference. The only exception can be observed for the first translator for days 2, 4 and 5. However, the project-adapted system is better or identical in most cases when multiple references are used. It is also interesting to note that our adaptation procedure improves the post-editing effort with respect to the independent reference translation in nine out of twelve cases. Overall, it can be clearly seen that the adaptation scheme is very effective. The difference between the baseline system (DA+CSLM) and the fully adapted system (PA+CSLM-adapt) reaches 9 TER points in some conditions.

A quite similar tendency can be observed when

day	method	translator 1	translator 2	translator 3
1	**DA**	33.34 (28.10) **[54.59]**	32.99 (28.10) **[54.59]**	48.62 (28.10) **[54.59]**

	PA+CSLM-adapt	31.52 **(24.43)** [53.08]	**26.19 (22.34) [53.16]**	**30.46 (23.71) [54.31]**

Table 1: TER scores for English-French data of the Legal domain for the three translators over 5 days. Parenthesized scores are calculated using the references of all three translators, while scores in brackets are calculated using a generic reference provided by the European Commission.

analyzing translation quality in terms of BLEU score (results not presented here). Like for the prior TER results, the BLEU scores for translator 3 are much worse than the scores of the two other ones. After the third day, the scores reach the same level. Again, this could indicate that the adaptation process has learned his particular style.

5.2 Translation speed

Table 2 reports, for each translator, the translation speed, expressed in number of post-edited words per hour. The results are given for the two conditions of our experiment, along with the percentage of relative improvement. We can observe a very high productivity gain for all translators between the two sessions of our test, from 18.5% to 38.3%. The huge gain for translator T3 could be biased by the low working speed of the translator, even if we had confirmed that all the translators are experts with the post-editing process. We assume that either T3 had some difficulties with the legal domain or he had just taken his time to perform the test, or both. This could partially explain the huge improvement in productivity which is doubled.

User ID	Translation speed (words/hour) DA+CSLM	PA+CSLM-adapt	Δ
T1	928	1283	38.3%
T2	1533	1816	18.5 %
T3	308	704	128.5%

Table 2: Overall translation speed for all translators. Measurements are taken on post-edits performed with the domain-adapted MT system (DA+CSLM) and the project-adapted MT system (PA+CSLM-adapt).

6 Conclusion

Several studies have also shown that the close integration of MT into a CAT tool can increase the productivity of human translators. In this work, we extended these works in several aspects. We have observed systematic improvements of the translation quality and speed when adapting the systems with data generated during the translation project (spanning several days). The MT system does not only adapt to the style of the human translator who post-edit the automatic translations. In all cases, we observed improved translation quality with respect to an independent reference translation. Finally, we have shown that neural network LMs can be used in an operational SMT system and that they can be adapted very quickly to small amount of data. Although the use of neural networks in SMT is drawing a lot of attention, we are not aware at any other

deployment in real applications.

Acknowledgments

We thank the post-editors who took part to this experiment, as well as our anonymous reviewers for their feedback and suggestions. This work has been partially supported by the EC-funded project MATECAT (ICT-2011.4.2-287688).

Abstract

Word embedding has been found to be highly powerful to translate words from one language to another by a simple linear transform. However, we found some inconsistence among the objective functions of the embedding and the transform learning, as well as the distance measurement. This paper proposes a solution which normalizes the word vectors on a hypersphere and constrains the linear transform as an orthogonal transform. The experimental results confirmed that the proposed solution can offer better performance on a word similarity task and an English-to-Spanish word translation task.

1 Introduction

Word embedding has been extensively studied in recent years (Bengio et al., 2003; Turian et al., 2010; Collobert et al., 2011; Huang et al., 2012). Following the idea that the meaning of a word can be determined by 'the company it keeps' (Baroni and Zamparelli, 2010), i.e., the words that it co-occurs with, word embedding projects discrete words to a low-dimensional and continuous vector space where co-occurred words are located close to each other. Compared to conventional discrete representations (e.g., the one-hot encoding), word embedding provides more robust representations for words, particulary for those that infrequently appear in the training data. More importantly, the embedding encodes syntactic and semantic content implicitly, so that relations among words can be simply computed as the distances among their embeddings, or word vectors. A well-known efficient word embedding approach was recently proposed by (Mikolov et al., 2013a), where two log-linear models (CBOW and skip-gram) are proposed to learn the neighboring relation of words in context. A following work proposed by the same authors introduces some modifications that largely improve the efficiency of model training (Mikolov et al., 2013c).

An interesting property of word vectors learned by the log-linear model is that the relations among relevant words seem linear and can be computed by simple vector addition and substraction (Mikolov et al., 2013d). For example, the following relation approximately holds in the word vector space: Paris - France + Rome = Italy. In (Mikolov et al., 2013b), the linear relation is extended to the bilingual scenario, where a linear transform is learned to project semantically identical words from one language to another. The authors reported a high accuracy on a bilingual word translation task.

Although promising, we argue that both the word embedding and the linear transform are ill-posed, due to the inconsistence among the objective function used to learn the word vectors (maximum likelihood based on inner product), the distance measurement for word vectors (cosine distance), and the objective function used to learn the linear transform (mean square error). This inconsistence may lead to

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1006–1011,
Denver, Colorado, May 31 – June 5, 2015.

suboptimal estimation for both word vectors and the bilingual transform, as we will see shortly.

This paper solves the inconsistence by normalizing the word vectors. Specifically, we enforce the word vectors to be in a unit length during the learning of the embedding. By this constraint, all the word vectors are located on a hypersphere and so the inner product falls back to the cosine distance. This hence solves the inconsistence between the embedding and the distance measurement. To respect the normalization constraint on word vectors, the linear transform in the bilingual projection has to be constrained as an orthogonal transform. Finally, the cosine distance is used when we train the orthogonal transform, in order to achieve full consistence.

2 Related work

This work largely follows the methodology and experimental settings of (Mikolov et al., 2013b), while we normalize the embedding and use an orthogonal transform to conduct bilingual translation.

Multilingual learning can be categorized into projection-based approaches and regularization-based approaches. In the projection-based approaches, the embedding is performed for each language individually with monolingual data, and then one or several projections are learned using multilingual data to represent the relation between languages. Our method in this paper and the linear projection method in (Mikolov et al., 2013b) both belong to this category. Another interesting work proposed by (Faruqui and Dyer, 2014) learns linear transforms that project word vectors of all languages to a common low-dimensional space, where the correlation of the multilingual word pairs is maximized with the canonical correlation analysis (CCA).

The regularization-based approaches involve the multilingual constraint in the objective function for learning the embedding. For example, (Zou et al., 2013) adds an extra term that reflects the distances of some pairs of semantically related words from different languages into the objective funtion. A similar approach is proposed in (Klementiev et al., 2012), which casts multilingual learning as a multitask learning and encodes the multilingual information in the interaction matrix.

All the above methods rely on a multilingual lexicon or a word/pharse alignment, usually from a machine translation (MT) system. (Blunsom et al., 2014) proposed a novel approach based on a joint optimization method for word alignments and the embedding. A simplified version of this approach is proposed in (Hermann and Blunsom, 2014), where a sentence is represented by the mean vector of the words involved. Multilingual learning is then reduced to maximizing the overall distance of the parallel sentences in the training corpus, with the distance computed upon the sentence vectors.

3 Normalized word vectors

Taking the skip-gram model, the goal is to predict the context words with a word in the central position. Mathematically, the training process maximizes the following likelihood function with a word sequence $w_1, w_2 ... w_N$:

$$\frac{1}{N}\sum_{i=1}^{N}\sum_{-C\leq j\leq C, j\neq 0} logP(w_{i+j}|w_i) \qquad (1)$$

where C is the length of the context in concern, and the prediction probability is given by:

$$P(w_{i+j}|w_i) = \frac{\exp(c_{w_{i+j}}^T c_{w_i})}{\sum_w \exp(c_w^T c_{w_i})} \qquad (2)$$

where w is any word in the vocabulary, and c_w denotes the vector of word w. Obviously, the word vectors learned by this way are not constrained and disperse in the entire M-dimensional space, where M is the dimension of the word vectors. An inconsistence with this model is that the distance measurement in the training is the inner product $c_w^T c_{w'}$, however when word vectors are applied, e.g., to estimate word similarities, the metric is often the cosine distance $\frac{c_w^T c_{w'}}{||c_w|| ||c_{w'}||}$. A way to solve this consistence is to use the inner product in applications, however using the cosine distance is a convention in natural language processing (NLP) and this measure does

show better performance than the inner product in our experiments.

We therefore perform in an opposite way, i.e., enforcing the word vectors to be unit in length. Theoretically, this changes the learning of the embedding to an optimization problem with a quadratic constraint. Solving this problem by Lagrange multipliers is possible, but here we simply divide a vector by its l-2 norm whenever the vector is updated. This does not involve much code change and is efficient enough.[1]

The consequence of the normalization is that all the word vectors are located on a hypersphere, as illustrated in Figure 1. In addition, by the normalization, the inner product falls back to the cosine distance, hence solving the inconsistence between the embedding learning and the distance measurement.

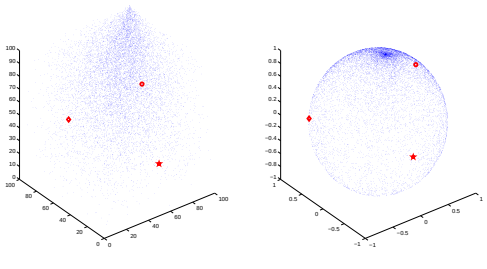

Figure 1: The distributions of unnormalized (left) and normalized (right) word vectors. The red circles/stars/diamonds represent three words that are embedded in the two vector spaces respectively.

4 Orthogonal transform

The bilingual word translation provided by (Mikolov et al., 2013b) learns a linear transform from the source language to the target language by the linear regression. The objective function is as follows:

$$\min_W \sum_i ||Wx_i - z_i||^2 \tag{3}$$

[1]For efficiency, this normalization can be conducted every n mini-batches. The performance is expected to be not much impacted, given that n is not too large.

where W is the projection matrix to be learned, and x_i and z_i are word vectors in the source and target language respectively. The bilingual pair (x_i, z_i) indicates that x_i and z_i are identical in semantic meaning. A high accuracy was reported on a word translation task, where a word projected to the vector space of the target language is expected to be as close as possible to its translation (Mikolov et al., 2013b). However, we note that the 'closeness' of words in the projection space is measured by the cosine distance, which is fundamentally different from the Euler distance in the objective function (3) and hence causes inconsistence.

We solve this problem by using the cosine distance in the transform learning, so the optimization task can be redefined as follows:

$$\max_W \sum_i (Wx_i)^T z_i. \tag{4}$$

Note that the word vectors in both the source and target vector spaces are normalized, so the inner product in (4) is equivalent to the cosine distance. A problem of this change, however, is that the projected vector Wx_i has to be normalized, which is not guaranteed so far.

To solve the problem, we first consider the case where the dimensions of the source and target vector spaces are the same. In this case, the normalization constraint on word vectors can be satisfied by constraining W as an orthogonal matrix, which turns the unconstrained problem (4) to a constrained optimization problem. A general solver such as SQP can be used to solve the problem. However, we seek a simple approximation in this work. Firstly, solve (4) by gradient descendant without considering any constraint. A simple calculation shows that the gradient is as follows:

$$\bigtriangledown_W = \sum_i x_i y_i^T, \tag{5}$$

and the update rule is simply given by:

$$W = W + \alpha \bigtriangledown_W \tag{6}$$

where α is the learning rate. After the update, W is orthogonalized by solving the following constrained quadratic problem:

$$\min_{\bar{W}} ||W - \bar{W}|| \quad s.t. \;\; \bar{W}^T\bar{W} = I. \qquad (7)$$

One can show that this problem can be solved by taking the singular value decomposition (SVD) of W and replacing the singular values to ones.

For the case where the dimensions of the source and target vector spaces are different, the normalization constraint upon the projected vectors is not easy to satisfy. We choose a pragmatic solution. First, we extend the low-dimensional vector space by padding a small tunable constant at the end of the word vectors so that the source and target vector spaces are in the same dimension. The vectors are then renormalized after the padding to respect the normalization constraint. Once this is done, the same gradient descendant and orthognalization approaches are ready to use to learn the orthogonal transform.

5 Experiment

We first present the data profile and configurations used to learn monolingual word vectors, and then examine the learning quality on the word similarity task. Finally, a comparative study is reported on the bilingual word translation task, with Mikolov's linear transform and the orthogonal transform proposed in this paper.

5.1 Monolingual word embedding

The monolingual word embedding is conducted with the data published by the EMNLP 2011 SMT workshop (WMT11)[2]. For an easy comparison, we largely follow Mikolov's settings in (Mikolov et al., 2013b) and set English and Spanish as the source and target language, respectively. The data preparation involves the following steps. Firstly, the text was tokenized by the standard scripts provided by WMT11[3], and then duplicated sentences were removed. The numerical expressions were tokenized as 'NUM', and special characters (such as !?,:) were removed.

The word2vector toolkit[4] was used to train the word embedding model. We chose the skip-gram model and the text window was set to 5. The training resulted in embedding of 169k English tokens and 116k Spanish tokens.

5.2 Monolingual word similarity

The first experiment examines the quality of the learned word vectors in English. We choose the word similarity task, which tests to what extent the word similarity computed based on word vectors agrees with human judgement. The WordSimilarity-353 Test Collection[5] provided by (Finkelstein et al., 2002) is used. The dataset involves 154 word pairs whose similarities are measured by 13 people and the mean values are used as the human judgement. In the experiment, the correlation between the cosine distances computed based on the word vectors and the humane-judged similarity is used to measure the quality of the embedding. The results are shown in Figure 2, where the dimension of the vector space varies from 300 to 1000. It can be observed that the normalized word vectors offer a high correlation with human judgement than the unnormalized counterparts.

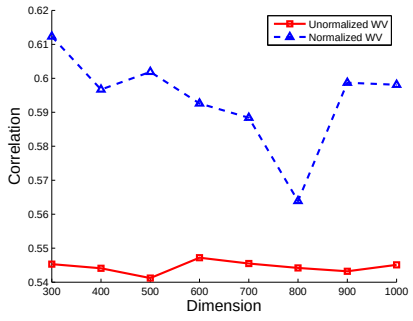

Figure 2: Results on the word similarity task with the normalized and unnormalized word vectors. A higher correlation indicates better quality.

[4]https://code.google.com/p/word2vec

[5]http://www.cs.technion.ac.il/ gabr/resources/data/wordsim353/

5.3 Bilingual word translation

The second experiment focuses on bilingual word translation. We select 6000 frequent words in English and employ the online Google's translation service to translate them to Spanish. The resulting 6000 English-Spanish word pairs are used to train and test the bilingual transform in the way of cross validation. Specifically, the 6000 pairs are randomly divided into 10 subsets, and at each time, 9 subsets are used for training and the rest 1 subset for testing. The average of the results of the 10 tests is reported as the final result. Note that not all the words translated by Google are in the vocabulary of the target language; the vocabulary coverage is 99.5% in our test.

5.3.1 Results with linear transform

We first reproduce Mikolov's work with the linear transform. A number of dimension settings are experimented with and the results are reported in Table 1. The proportions that the correct translations are in the top 1 and top 5 candidate list are reported as P@1 and P@5 respectively. As can be seen, the best dimension setting is 800 for English and 200 for Spanish, and the corresponding P@1 and P@5 are 35.36% and 53.96%, respectively. These results are comparable with the results reported in (Mikolov et al., 2013b).

D-EN	D-ES	P@1	P@5
300	300	30.43%	49.43%
500	500	25.76%	44.29%
700	700	20.69%	39.12%
800	200	35.36%	53.96%

Table 1: Performance on word translation with unnormalized embedding and linear transform. 'D-EN' and 'D-ES' denote the dimensions of the English and Spanish vector spaces, respectively.

5.3.2 Results with orthogonal transform

The results with the normalized word vectors and the orthogonal transform are reported in Table 2. It can be seen that the results with the orthogonal transform are consistently better than those reported in Table1 which are based on the linear transform. This confirms our conjecture that bilingual translation can be largely improved by the normalized embedding and the accompanied orthogonal transform.

D-EN	D-ES	P@1	P@5
300	300	38.99%	59.16%
500	500	39.91%	59.82%
700	700	41.04%	59.38%
800	200	40.06%	60.02%

Table 2: Performance on word translation with normalized embedding and orthogonal transform. 'D-EN' and 'D-ES' denote the dimensions of the English and Spanish vector spaces, respectively.

6 Conclusions

We proposed an orthogonal transform based on normalized word vectors for bilingual word translation. This approach solves the inherent inconsistence in the original approach based on unnormalized word vectors and a linear transform. The experimental results on a monolingual word similarity task and an English-to-Spanish word translation task show clear advantage of the proposal. This work, however, is still preliminary. It is unknown if the normalized embedding works on other tasks such as relation prediction, although we expect so. The solution to the orthogonal transform between vector spaces with mismatched dimensions is rather ad-hoc. Nevertheless, locating word vectors on a hypersphere opens a door to study the properties of the word embedding in a space that is yet less known to us.

Fast and Accurate Preordering for SMT using Neural Networks

Abstract

We propose the use of neural networks to model source-side preordering for faster and better statistical machine translation. The neural network trains a logistic regression model to predict whether two sibling nodes of the source-side parse tree should be swapped in order to obtain a more monotonic parallel corpus, based on samples extracted from the word-aligned parallel corpus. For multiple language pairs and domains, we show that this yields the best reordering performance against other state-of-the-art techniques, resulting in improved translation quality and very fast decoding.

1 Introduction

Preordering is a pre-processing task in translation that aims to reorder the source sentence so that it best resembles the order of the target sentence. If done correctly, it has a doubly beneficial effect: it allows a better estimation of word alignment and translation models which results in higher translation quality for distant language pairs, *and* it speeds up decoding enormously as less word movement is required.

Preordering schemes can be automatically learnt from source-side parsed, word-aligned parallel corpora. Recently Jehl et al (2014) described a scheme based on a feature-rich logistic regression model that predicts whether a pair of sibling nodes in the source-side dependency tree need to be permuted. Based on the node-pair swapping probability predictions of this model, a branch-and-bound search returns the best ordering of nodes in the tree.

We propose using a neural network (NN) to estimate this node-swapping probability. We find that this straightforward change to their scheme has multiple advantages:

1. The superior modeling capabilities of NNs achieve better performance at preordering and overall translation quality when using the same set of features.
2. There is no need to manually define which feature combinations are to be considered in training.
3. Preordering is even faster as a result of the previous point. Our results in translating from English to Japanese, Korean, Chinese, Arabic and Hindi support these findings by comparing against two other preordering schemes.

1.1 Related Work

There is a strong research and commercial interest in preordering, as reflected by the extensive previous work on the subject (Collins et al., 2005; Xu et al., 2009; DeNero and Uszkoreit, 2011; Neubig et al., 2012). We are interested in practical, language-independent preordering approaches that rely only on automatic source-language parsers (Genzel, 2010). The most recent work in this area uses large-scale feature-rich discriminative models, effectively treating preordering either as a learning to rank (Yang et al., 2012), multi-classification (Lerner and Petrov, 2013) or logistic regression (Jehl et al., 2014) problem. In this paper we incorporate NNs into the latter approach.

Lately an increasing body of work that uses NNs for various NLP tasks has been published, including language modeling (Bengio et al., 2003), POS

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1012–1017,
Denver, Colorado, May 31 – June 5, 2015.

tagging (Collobert et al., 2011), or dependency parsing (Chen and Manning, 2014). In translation, NNs have been used for improved word alignment (Yang et al., 2013; Tamura et al., 2014; Songyot and Chiang, 2014), to model reordering under an ITG grammar (Li et al., 2013), and to define additional feature functions to be used in decoding (Sundermeyer et al., 2014; Devlin et al., 2014). End-to-end translation systems based on NNs have also been proposed (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Bahdanau et al., 2014).

Despite the gains reported, only the approaches that do not dramatically affect decoding times can be directly applied to today's commercial SMT systems. Our paper is a step towards this direction, and to the best of our knowledge, it is the first one to describe the usage of NNs in preordering for SMT.

2 Preordering as node-pair swapping

Jehl et al (2014) describe a preordering scheme based on a logistic regression model that predicts whether a pair of sibling nodes in the source-side dependency tree need to be permuted in order to have a more monotonically-aligned parallel corpus. Their method can be briefly summarised by the pseudocode of Figure 1.

Let N be the set of nodes in the source tree, and let C_n be the set of children nodes of node n. For each node with at least two children, first extract the node features (lines 1-2). Then, for each pair of its children nodes: extract their respective features (lines 4-5), produce all relevant feature combinations (line 6), and store the node-pair swapping probability predicted by a logistic regression model based on all available features (line 7). Once all pair-wise probabilities are stored, search for the best global permutation and sort C_n accordingly (lines 9-10).

As features, Jehl et al (2014) use POS tags and dependency labels, as well as the identity and class of the head word (for the parent node) or the left/rightmost word (for children nodes). These are combined into *conjunctions* of 2 or 3 features to create new features. For logistic regression, they train a L1-regularised linear model using LIBLINEAR (Fan et al., 2008). The training samples are either positive/negative depending on whether swapping the nodes reduces/increases the number of crossed links in the aligned parallel corpus.

2.1 Applying Neural Networks

"A (feedforward) neural network is a series of logistic regression models stacked on top of each other, with the final layer being either another logistic regression model or a linear regression model" (Murphy, 2012).

Given this, we propose a straightforward alternative to the above framework: replace the linear logistic regression model by a neural network (NN). This way a superior modeling performance of the node-swapping phenomenon is to be expected. Additionally, feature combination need not be engineered anymore because that is *learnt* by the NN in training (line 6 in Figure 1 is skipped).

Training the neural network requires the same labeled samples that were used by Jehl et al (2014). We use the NPLM toolkit out-of-the-box (Vaswani et al., 2013). The architecture is a feed-forward neural network (Bengio et al., 2003) with four layers. The first layer i contains the input embeddings. The next two hidden layers (h_1, h_2) use rectified linear units; the last one is the softmax layer (o). We did not experiment with deeper NNs.

For our purposes, the input vocabulary of the NN is the set of all possible feature indicator names that are used for preordering[1]. There are no OOVs. Given the sequence of $\sim$ 20 features seen by the

[1]Using a vocabulary of the 5K top-frequency English words, 50 word classes, approximately 40 POS tags and 50 dependency labels, the largest input vocabulary in our experiments is roughly 30,000.

preorderer, the NN is trained to predict whether the nodes should be reordered or not, i.e. $|o| = 2$. For the rest of the layers, we use $|i| = 50$, $|h_1| = 100$, $|h_2| = 50$. We set the learning rate to 1, the mini-batch size to 64 and the number of epochs to 20.

3 Experiments

3.1 Data and setup

We report translation results in English into Japanese, Korean, Chinese, Arabic and Hindi. For each language pair, we use generic parallel data extracted from the web. The number of words is about 100M for Japanese and Korean, 300M for Chinese, 200M for Arabic and 9M for Hindi.

We use two types of dev/test sets: in-domain and mix-domain. The in-domain sets have 2K sentences each and were created by randomly extracting parallel sentences from the corpus, ensuring no repetitions remained. The mix-domain sets have about 1K sentences each and were created to evenly represent 10 different domains, including world news, chat/SMS, health, sport, science, business, and others.

Additionally, we report results on the English-to-Hindi WMT 2014 shared task (Bojar et al., 2014a) using the data provided[2]. The dev and test sets have 520 and 2507 sentences each. All dev and test sets have one single reference. We use SVMTool (Giménez and Màrquez, 2004) for POS Tagging, and MaltParser (Nivre et al., 2007) for dependency parsing.

3.2 Intrinsic reordering evaluation

We evaluate the intrinsic preordering task on a random 5K-sentence subset of the training data which is excluded from model estimation. We report the normalized crossing score c/s, where c is the number of crossing links (Genzel, 2010; Yang et al., 2012) in the aligned parallel corpus, and s is the number of source (e.g. English) words. Ideally we would like this metric to be zero, meaning a completely monotonic parallel corpus[3]; the more monotonic the corpus, the better the translation models will be and the faster decoding will run as less distortion will be needed.

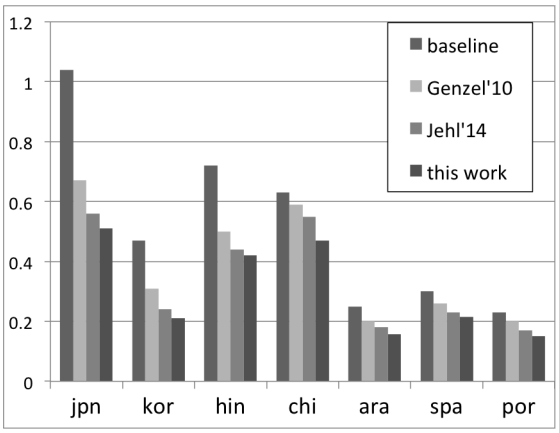

Figure 2: Normalized crossing score for English into Japanese, Korean, Hindi, Chinese, Arabic, Spanish and Portuguese.

Normalizing over the number of source words allows us to compare this metric across language pairs, and so the potential impact of preordering in translation performance becomes apparent. See Figure 2 for results across several language pairs. In all cases our proposed NN-based preorderer achieves the lowest normalized crossing score among all preordering schemes.

3.3 Translation performance

For translation experiments, we use a phrase-based decoder that incorporates a set of standard features and a hierarchical reordering model (Galley and Manning, 2008). The decoder stack size is set to 1000. Weights are tuned using MERT to optimize BLEU on the dev set. In English-to-Japanese and Chinese we use character-BLEU instead. To minimise optimization noise, we tune all our systems from flat parameters three times and report average BLEU score and standard deviation on the test set.

Table 1 contrasts the performance obtained by the system when using no preordering capabilities (baseline), and when using three alternative preordering schemes: the rule-based approach of Genzel (2010), the linear-model logistic-regression approach of Jehl et al (2014) and our NN-based preorderer. We report two baselines: one with distortion limit $d = 10$ and another with $d = 3$. For systems

[2]HindEndCorp v0.5 (Bojar et al., 2014b)

[3]However this may not be achievable given the alignment links and parse tree available. In this approach, only permutations of sibling nodes in the single source parse tree are permitted.

				best WMT14 constrained system			11.1

Table 1: Translation performance for various language pairs using no preordering (baseline), and three alternative preordering systems. Average test BLEU score and standard deviation across 3 independent tuning runs. Speed ratio is calculated with respect to the speed of the slower baseline that uses a $d = 10$. Stack size is 1000. For eng-jpn and eng-chi, character-based BLEU is used.

with preordering we only report $d = 3$, as increasing d does not improve performance.

As shown, our preorderer obtains the best BLEU scores for all reported languages and domains, proving that the neural network is modeling the dependency tree node-swapping phenomenon more accurately, and that the reductions in crossing score reported in the previous section have a positive impact in the final translation performance.

The bottom right-most column reports results on the WMT 2014 English-to-Hindi task. Our system achieves better results than the best score reported for this task[4]. In this case, the two logistic regression preorderers perform similarly, as standard deviation is higher, possibly due to the small size of the dev set.

3.4 Decoding Speed

The main purpose of preordering is to find a better translation performance in fast decoding conditions. In other words, by preordering the text we expect to be able to decode with less distortion or phrase reordering, resulting in faster decoding. This is shown in Table 1, which reports the speed ratio between each system and the speed of the top-most baseline, as measured in English-to-Japanese in-domain[5]. We find that decoding with a $d = 3$ is about 3 times faster than for $d = 10$.

We now take this further by reducing the stack size from 1000 to 50; see results in Table 2. As expected, all systems accelerate with respect to our initial baseline. However, this usually comes at a cost in BLEU with respect to using a wider beam, *unless* preordering is used. In fact, the logistic regression preorderers achieve the same performance while decoding over 60 times faster than the baseline.

Interestingly, the NN-based preorderer turns out to be slightly faster than any of the other preordering approaches. This is because there is no need to explicitly create thousands of feature combinations for each node pair; simply performing the forward matrix multiplications given the input sequence of ∼20 features is more efficient. Similar observations have been noted recently in the context of dependency parsing with NNs (Chen and Manning, 2014). Note also that, on average, only 25 pair-wise probabilities are queried to the logistic regression model per source sentence. Overall, we incorporate the benefits of neural networks for preordering at no compu-

Table 2: Translation performance for maximum stack size of 50. The figures in parentheses indicate the difference in BLEU scores due to using a smaller stack size, that is, compared to the same systems in Table 1. Speed ratio is calculated with respect to the speed of the slower baseline that uses a stack of 1000, eg. the first row in Table 1.

tational cost.

Currently, our preorderer takes 6.3% of the total decoding time (including 2.6% for parsing and 3.7% for actually preordering). We believe that further improvements in preordering will result in more translation gains and faster decoding, as the distortion limit is lowered.

4 Conclusions

To the best of our knowledge, this is the first paper to describe the usage of NNs in preordering for SMT. We show that simply replacing the logistic regression node-swapping model with an NN model improves both crossing scores and translation performance across various language pairs. Feature combination engineering is avoided, which also results in even faster decoding times.

Abstract

We present APRO, a new method for machine translation tuning that can handle large feature sets. As opposed to other popular methods (e.g., MERT, MIRA, PRO), which involve randomness and require multiple runs to obtain a reliable result, APRO gives the same result on any run, given initial feature weights. APRO follows the pairwise ranking approach of PRO (Hopkins and May, 2011), but instead of ranking a small sampled subset of pairs from the k-best list, APRO efficiently ranks *all* pairs. By obviating the need for manually determined sampling settings, we obtain more reliable results. APRO converges more quickly than PRO and gives similar or better translation results.

1 Introduction

Machine translation tuning seeks to find feature weights that maximize translation quality. Recent efforts have focused on methods that scale to large numbers of features (Cherry and Foster, 2012), and among these, PRO has gained popularity (Pairwise Ranking Optimization, Hopkins and May (2011)).

PRO's goal is to find feature weights such that the resulting k-best list entries are ranked in the same way that an evaluation function (e.g., BLEU, Papineni et al. (2002)) ranks them. To do this, it labels pairs of translations for each sentence as *positive* or *negative*, depending on the gold ranking of the two pair elements given by BLEU. A binary classifier is trained on these labeled examples, resulting in new feature weights, and the procedure is iterated. This procedure would ordinarily be too expensive since there are $\mathcal{O}(k^2)$ pairs per sentence, where both k and the number of sentences can be in the thousands, so billions of training examples would be produced per iteration. Therefore, Hopkins and May (2011) use subsampling to consider a small percentage of all pairs per sentence.

We present APRO (All-Pairs Ranking Optimization), a tuning approach that, like PRO, uses pairwise ranking for tuning. Unlike PRO, it is not limited to optimizing a small percentage of pairs per sentence. Based on an efficient ranking SVM formulation (Airola et al. (2011), Lee and Lin (2014)), we find, in each iteration, feature weights that minimize ranking errors for *all* pairs of translations per sentence. This tuning method inherits all the advantages of PRO—it is scalable, effective, easy to implement—and removes its limitations. It does not require meta-tuning of sampling parameters since no sampling is used; it does not need to be run multiple times to obtain reliable results, like MERT (Och, 2003), PRO, MIRA (Chiang et al., 2008) and others, since it uses global optimization and is deterministic given initial feature weights; and it converges quickly.

2 Notation and Definitions

For both PRO and APRO, we use the following definitions: A tuning dataset contains S source sentences $x^1, \ldots, x^S$. Let $\mathcal{Y}^s$ be the space of all translations of x^s. It contains one or more known reference translations $\boldsymbol{y}^s_+$. Each translation $y^s_i \in \mathcal{Y}^s$ has a fea-

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1018–1023,
Denver, Colorado, May 31 – June 5, 2015.

ture representation[1] $\boldsymbol{f}(x^s, y_i^s)$, or for short, $\boldsymbol{f}_i^s$, and a linear classification score $h_i^s = \mathbf{w}^T \boldsymbol{f}_i^s$, where $\mathbf{w}$ is a feature weight vector. Given a source sentence x^s, a translation decoder can search (often a subset of) $\mathcal{Y}^s$ and return the k translations $y_1^s, \ldots, y_k^s$ with the highest classification scores. A k-best list is the list of $y_1^s, \ldots, y_k^s, \forall s$. For each translation y_i^s we can obtain an evaluation score $b(y_i^s, \boldsymbol{y}_+^s)$, or for short, b_i^s, which can be the BLEU+1 score (Lin and Och, 2004).[2] For a given source sentence x^s, let (i, j) denote a pair of translations (y_i^s, y_j^s).

3 PRO

We now describe PRO, before constrasting it with our new approach, APRO. For each iteration t from $t = 1 \ldots T$, PRO performs the following steps:

1. Given current feature weights $\mathbf{w}_t$, obtain a k-best list, as defined above, from the translation decoder. For each x^s, add to its k-best entries the k-best entries from previous iterations, so that x^s now has k_s translations; the overall list is called an *accumulated* k-best list.

2. For each source sentence x^s, first sample up to Γ candidate pairs from its translations in the k-best list. Less similar pairs are more likely to become candidate pairs. Similarity in a pair (i, j) here means a small absolute difference d_{ij}^s between b_i^s and b_j^s. The most similar pairs ($d_{ij}^s < \beta$) are discarded. Then select the Ξ least similar pairs among the remaining candidate pairs.

3. For each pair (i, j) from the Ξ selected pairs, add the difference vector $(\boldsymbol{f}_i^s - \boldsymbol{f}_j^s)$ with class label 1 if $b_i^s > b_j^s$, otherwise add it with class label -1. Also add $(\boldsymbol{f}_j^s - \boldsymbol{f}_i^s)$ with the opposite label.

4. Train any classifier on the labeled data, resulting in a new weights vector $\mathbf{w}'$. Set $\mathbf{w}_{t+1} = \Psi \cdot \mathbf{w}' + (1 - \Psi) \cdot \mathbf{w}_t$.

Dependencies between tuning iterations are introduced by the use of accumulated k-best lists and the interpolation of weight vectors in step 4, using an interpolation factor Ψ. Translation quality varies with different choices for Γ, Ξ, β, Ψ, see Figure 1. The quality varies even when PRO is run multiple times with the *same* parameters, due to the sampling step. Practitioners would have to perform an expensive grid search multiple times to be sure to obtain good results. APRO seeks to remedy this problem. One could try to improve PRO by experimenting with other pair selection heuristics; APRO circumvents the problem by efficiently selecting *all* pairs.

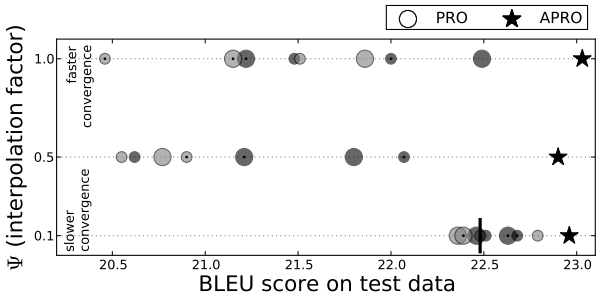

Figure 1: PRO versus APRO (eng-swe) for 3 settings of Ψ. PRO: 8 sampling settings per Ψ setting.[4] APRO: no sampling. Vertical line indicates settings from H&M (2011). Not shown: PRO outlier with BLEU =7.9 at $\Psi = 0.5$.

4 APRO

Our method APRO is, like PRO, a ranking method. We believe that learning to rank is a suitable method for MT tuning because it matches the test-time requirements of correctly predicting the best translations or correctly ranked k-best lists of translations.

Compared to PRO, we simplify the procedure by removing sampling and labeling steps 2 and 3, thereby removing some of PRO's implementation complexity and manually set parameters. We run only two steps, corresponding to PRO's steps 1 and 4: In each tuning iteration, we obtain an accumulated k-best list, then directly find a new $\mathbf{w}'$ that minimizes the loss on that k-best list, which corresponds to PRO's running of a classifier. APRO's classification model is an efficient ranking SVM (Airola et al. (2011), Lee and Lin (2014)), described as follows.

4.1 Model

For each sentence x^s, we define the set of preference pairs as the set of ordered translation pairs for which the evaluation score prefers the first element:

$$\mathcal{P}^s = \{(i, j) \ : \ b_i^s > b_j^s\} \tag{1}$$

[1] For simplicity, we leave out nuisance variables like alignments, segmentations, or parse trees, from this description, which may be part of the feature space.

[2] But see Nakov et al. (2013) for variants.

[4] PRO settings: $\Gamma = \{5k, 8k\} = \{\text{small, large}\}$, $\Xi = \{50, 100\} = \{\text{light, dark}\}$, $\beta = \{.03, .05\} = \{\text{no dot, dot}\}$.

Following Lee and Lin (2014), we define the loss (or, error) of any sentence s as the sum of its pairwise squared hinge losses:

$$L^s_{\mathbf{w}} = \sum_{(i,j)\in\mathcal{P}^s} \max(0, 1-h^s_i+h^s_j)^2 \quad (2)$$

That is, no loss is contributed by preference pairs for which the classification score correctly prefers the first element by a large-enough margin, i.e., $h^s_i \geq h^s_j+1$; all other preference pairs contribute some loss. We seek to find a weight vector that minimizes the regularized overall loss:

$$\mathbf{w}' = \operatorname*{argmin}_{\mathbf{w}} R_{\mathbf{w}} + C\cdot\frac{1}{N}\sum_s L^s_{\mathbf{w}} \quad (3)$$

where $R_{\mathbf{w}} = \frac{1}{2}\mathbf{w}^T\mathbf{w}$ is a Gaussian regularizer to prevent overfitting and C a constant controlling the relative regularization amount. We divide by $N = \sum_s k_s$ to account for the increasing sizes of accumulated k-best lists between tuning iterations, which leads to increased sentence losses. If this were not done, the relative amount of regularization would decrease in subsequent iterations of tuning.

Any gradient-based optimization method can be used to find $\mathbf{w}'$. Since the loss is convex, the weights we find given a particular k-best list are optimal. This is different from PRO and Bazrafshan et al. (2012), where the resulting weights depend on the pairs sampled; MIRA, where they depend on the order of sentences processed; and MERT, where optimization is greedy and depends on initial weights.

4.2 Efficient Computation

How do we efficiently compute $L^s_{\mathbf{w}}$ per sentence? In this and the following subsection, we leave out all sentence indices s for ease of notation; it is understood that we operate on a given sentence.

A straightforward algorithm to compute $L_{\mathbf{w}}$ would iterate over all preference pairs $(i,j) \in \mathcal{P}$ and add up their losses (Joachims, 2002). However, since there are $\mathcal{O}(k^2)$ pairs per sentence, with potentially thousands of sentences, this would be extremely inefficient. PRO's solution to this problem is subsampling. The alternative solution we apply is to make the sums over translation pairs efficient by carefully rearranging the terms of the sentence loss, making use of quantities that can be precomputed efficiently (Airola et al. (2011), Lee and Lin (2014)).

Definitions. Let us define those quantities. For a given sentence s, let the set $\mathcal{Q}$ contain all members of $\mathcal{P}$ that contribute a positive loss to the overall loss term:

$$\mathcal{Q} = \{(i,j) : (i,j) \in \mathcal{P} \wedge (1-h_i+h_j > 0)\} \quad (4)$$

We also define an index notation into $\mathcal{Q}$:

$$\mathcal{Q}_{i\bullet} = \{(i,j) \in \mathcal{Q}, \forall j\} \quad q_{i\bullet} = |\mathcal{Q}_{i\bullet}| \quad (5)$$
$$\mathcal{Q}_{\bullet j} = \{(i,j) \in \mathcal{Q}, \forall i\} \quad q_{\bullet j} = |\mathcal{Q}_{\bullet j}| \quad (6)$$
$$r_{i\bullet} = \sum_{(i,j)\in\mathcal{Q}_{i\bullet}} h_j \quad (7)$$

The bullet ($\bullet$) can be read as *any*. Example: $\mathcal{Q}_{\bullet 3}$ contains pairs $\in \mathcal{Q}$ whose second element is translation 3. $q_{i\bullet}$ and $q_{\bullet j}$ denote corresponding set sizes.

Rearrangement. We use these definitions to express the loss as a sum over only $\mathcal{O}(k)$ elements.

First, we simplify the loss expression by summing only over elements from $\mathcal{Q}$, i.e., pairs from $\mathcal{P}$ that contribute a positive loss, so the max becomes unnecessary:

$$L_{\mathbf{w}} = \sum_{(i,j)\in\mathcal{P}} \max(0, 1-h_i+h_j)^2 \quad (8)$$
$$= \sum_{(i,j)\in\mathcal{Q}} (1-h_i+h_j)^2 \quad (9)$$
$$= \sum_{(i,j)\in\mathcal{Q}} h_i^2-2h_i+1+h_j^2+2h_j-2h_ih_j \quad (10)$$

We then use the precomputed quantities defined above to rewrite the sum over $\mathcal{O}(k^2)$ pairs to a sum over just $\mathcal{O}(k)$ elements:

$$L_{\mathbf{w}} = \sum_{i=1}^{k} q_{i\bullet}(h_i^2-2h_i+1)+q_{\bullet i}(h_i^2+2h_i) - 2\, r_{i\bullet}\, h_i \quad (11)$$

This step is described in detail below. Our new formulation is simpler but equivalent to Lee and Lin

(2014). Using order statistics trees (Cormen et al., 2001), the quantities $q_{i\bullet}$, $q_{\bullet i}$, and $r_{i\bullet}$ can be precomputed in $\mathcal{O}(k \log k)$ time (see details in Lee and Lin (2014)). This precomputation, together with the rearranged loss, allows APRO to make efficient weight updates without having to subsample.

Detailed derivation. We explain how to derive Equation 11 from Equation 10.
First, let us define the following equalities:

$$\sum_{(1,j)\in\mathcal{Q}} h_1 = q_{1\bullet}\cdot h_1$$
$$\sum_{(2,j)\in\mathcal{Q}} h_2 = q_{2\bullet}\cdot h_2$$
$$\ldots$$

If we do not fix the first pair element to a particular value, we have:

$$\sum_{(i,j)\in\mathcal{Q}} h_i = \sum_i q_{i\bullet}\cdot h_i \tag{12}$$

Similarly:

$$\sum_{(j,1)\in\mathcal{Q}} h_1 = q_{\bullet 1}\cdot h_1$$
$$\sum_{(j,2)\in\mathcal{Q}} h_2 = q_{\bullet 2}\cdot h_2$$
$$\ldots$$

If we do not fix the second element of each pair to a particular value, we have:

$$\sum_{(j,i)\in\mathcal{Q}} h_i = \sum_i q_{\bullet i}\cdot h_i \tag{13}$$

We split Equation 10 into separate sums and perform a change of variables in the second sum:

$$\begin{aligned} L_{\mathbf{w}} = &\sum_{(i,j)\in\mathcal{Q}} h_i^2 - 2h_i + 1 + \sum_{(j,i)\in\mathcal{Q}} h_i^2 + 2h_i \\ &-2\sum_{(i,j)\in\mathcal{Q}} h_i h_j \end{aligned} \tag{14}$$

We introduce one more equality, where (16) follows from the definition of $r_{i\bullet}$ in Equation 7:

$$\sum_{(i,j)\in\mathcal{Q}} h_i h_j = \sum_i h_i \left(\sum_{(i,j)\in\mathcal{Q}_{i\bullet}} h_j \right) \tag{15}$$

Lang.	Train	Dev	Test
Ara-Eng	14.4M	66K	37K
Chi-Eng	142.9M	61K	29K
Eng-Swe	100.1M	21K	22K
Eng-Fra	100.0M	63K	20K
Ita-Eng	102.8M	21K	20K
Pol-Eng	90.5M	21K	19K

Table 1: Number of words in the used data sets.

$$= \sum_i h_i \; r_{i\bullet} \tag{16}$$

We now use equalities 12, 13, and 16 to arrive at Equation 11:

$$\begin{aligned} L_{\mathbf{w}} = &\sum_i q_{i\bullet}(h_i^2 - 2h_i + 1) + \sum_i q_{\bullet i}(h_i^2 + 2h_i) \\ &-2\sum_i r_{i\bullet}\, h_i \\ = &\sum_i q_{i\bullet}(h_i^2 - 2h_i + 1) + q_{\bullet i}(h_i^2 + 2h_i) \\ &-2 r_{i\bullet}\, h_i \end{aligned}$$

5 Experiments

5.1 Experimental Setup

We validate APRO on 6 diverse language pairs. For each one, we perform HMM-based word alignment (Vogel et al., 1996) and phrase rule extraction on the training data. We use 20 standard features, incl. 8 reordering features, plus the sparse features listed for PBTM systems in Hopkins and May (2011).[5]

For Ara-Eng and Chi-Eng, we use BOLT Y2 data sets.[6] For all other languages, we sample train, dev, and test sets from in-house data. Table 1 describes the different data set sizes. We use 5-gram LMs trained on the target side of the training data; for Ara-Eng and Chi-Eng, we add 2 LMs trained on English Gigaword and other sources.

We tune on dev data. In each tuning run, we use $k = 500$, except for Ara-Eng ($k = 1500$). We use the same weight initialization for every tuning run, where most features are initialized to 0 and some dense features are initialized to 1 or -1. During tuning, we use case-insensitive BLEU+1. We tune for

[5] We use the 500 most frequent words for word pair features.
[6] For ara-eng, a subset of the training data was chosen whose source side has maximum similarity to the test source side.

	PRO		APRO

Pol-Eng	(22.4) 23.0	(0.95) 0.99	(23.3) 23.3	(1.00) 0.99

Table 2: PRO versus APRO after 10 iterations (small in parentheses) and at convergence ($\leq$ 30 iterations). Good results after 10 iterations indicate fast convergence. PRO: mean over 2 runs (average BLEU standard deviation was 0.1); APRO: single run. LR: length ratio.

up to 30 iterations,[7] where we reset the accumulated k-best list after 10 iterations.[8] For PRO, we use Γ=5000, Ξ=50, β=0.05, Ψ=0.1, and (MegaM) regularization strength λ=1 as described in Hopkins and May (2011). For APRO, we use regularization strength C=0.01 and Ψ=1, which effectively removes the weight interpolation step. We repeat each PRO tuning twice and report the mean of length ratios and case-sensitive BLEU scores on test data. For APRO, no repeated runs are necessary; it gives the same result on any run given initial feature weights.

For APRO, we optimize using the implementation by Lee and Lin, which uses a truncated Newton method.[9]

5.2 Results

We measure the runtime of PRO and APRO. For an accumulated k-best list containing s=2,748 sentences with an average k_s=3,600 translation, PRO and APRO take 13 and 8 minutes, respectively. Table 2 shows translation quality after 10 iterations and at convergence. We observe that APRO converges quickly: After running for 10 iterations, it gives higher BLEU scores and better length ratios than PRO for five out of six language pairs. At convergence, PRO has caught up, but for all language pairs APRO performs similar or better.

One of APRO's advantages are stable results: Figure 1 compares PRO and APRO for 3 values of Ψ: For each value, we run PRO eight times with different sampling settings and APRO once. We observe that the different PRO settings result in different BLEU scores. Cherry and Foster (2012) report that they could not find one PRO setting that worked across all language pairs. This suggests that practitioners may have to run expensive grid searches to find optimal PRO performance; this is not necessary with APRO. While PRO performs best with $\Psi = 0.1$, APRO gets good results for Ψ=1, which is the reason for its fast convergence (Table 2).

6 Conclusions

We have presented APRO, a new tuning method for machine translation. Like PRO, APRO is a batch pairwise ranking method, and as such, it inherits PRO's advantages of being effective, scalable to large feature sets and easy to fit into the standard batch MT tuning framework. We remove PRO's sampling step and learn a pairwise ranking over the whole k-best list in $\mathcal{O}(k \log k)$ time. We have shown that PRO's different sampling settings result in different final results; by removing these settings we get more reliable results. We find that PRO's weight interpolation is not necessary for APRO, resulting in faster convergence. At convergence, APRO's translation quality was found to be similar or better than PRO's. APRO's use of global optimization and the lack of randomness lead to more stable tuning with deterministic results.

[7] Like Hopkins and May (2011), we stop earlier when the accumulated k-best list does not change anymore.

[8] This removes bad translations from early iterations and provides good initial weights for the last 20 iterations. This did not decrease but sometimes increase final performance.

[9] See `http://goo.gl/CVmnoZ`. No change to the software is necessary; but in each iteration it must be called with $C' = \frac{C}{N}$, see Equation 3. We have also experimented with a change to the software that scales the loss of each sentence by the number of translation pairs for that sentence; this did not give reliable BLEU improvements over Equation 3.

Abstract

Supervised morphological paradigm learning by identifying and aligning the longest common subsequence found in inflection tables has recently been proposed as a simple yet competitive way to induce morphological patterns. We combine this non-probabilistic strategy of inflection table generalization with a discriminative classifier to permit the reconstruction of complete inflection tables of unseen words. Our system learns morphological paradigms from labeled examples of inflection patterns (inflection tables) and then produces inflection tables from unseen lemmas or base forms. We evaluate the approach on datasets covering 11 different languages and show that this approach results in consistently higher accuracies vis-à-vis other methods on the same task, thus indicating that the general method is a viable approach to quickly creating high-accuracy morphological resources.

1 Introduction

Use of detailed and sophisticated morphological features has been found to be crucial for many downstream NLP tasks, including part-of-speech tagging and parsing (Tseng et al., 2005; Spoustová et al., 2007). However, creating an accurate wide-coverage morphological analyzer for a new language that can be used in tandem with other higher-level analyses is an arduous task.

Learning word inflection patterns by organizing related word-forms into morphological paradigms based on the longest common subsequence (LCS) found in an inflection table has recently been proposed as a method for supervised and semi-supervised induction of morphological processing tools from labeled data (Ahlberg et al., 2014). Also, the argument that the LCS shared by different inflected forms of a word—even if discontinuous within a word—corresponds strongly to a cross-linguistic notion of a 'stem' has later been advanced independently on grounds of descriptive economy and minimum description length (Lee and Goldsmith, 2014).

We used this idea in (Ahlberg et al., 2014) to create a relatively simple-to-implement system that learns paradigms from example inflection tables and is then able to reconstruct inflection tables for unseen words by comparing suffixes of new base forms to base forms seen during training. The system performs well on available datasets and results in human-readable and editable output. The longest common subsequence strategy itself shows little bias toward any specific morphological process such as prefixation, suffixation, or infixation. Using the model, we argued, a selection of ready-inflected tables could be quickly provided by a linguist, allowing rapid development of morphological resources for languages for which few such resources exist.

Potentially, however, the model's commitment to a simple suffix-based learner is a weakness. To assess this, we evaluate a similar LCS-based generalization system with a more refined discriminative classifier that takes advantage of substrings in the example data and performs careful feature selection. We show that much higher accuracies can be achieved by combining the LCS paradigm generalization strategy with such a feature-based classi-

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1024–1029,
Denver, Colorado, May 31 – June 5, 2015.

fier that assigns unknown words to the LCS-learned paradigm based on substring features taken from word edges. This holds in particular for languages where paradigmatic behavior is triggered by material in the beginning of a word (e.g. German verbs).

We present experiments on 18 datasets in 11 languages varying in morphological complexity. In all the experiments, the task is to reconstruct a complete inflection table from a base form, which usually corresponds to the lemma or dictionary form of a noun, verb, or adjective. The experiments are divided into two sets. In the first, we use an earlier dataset (Durrett and DeNero, 2013) of Finnish, German, and Spanish to compare against other methods of paradigm learning. In the second, we use a more comprehensive and complex dataset we have developed for 8 additional languages. This new dataset is less regular and intended to be more realistic in that it also features defective or incomplete inflection tables and inflection tables containing various alternate forms, naturally making the classification task substantially more difficult.[1]

Overall, supervised and semi-supervised learning of morphology by generalizing patterns from inflection tables is an active research field. Recent work sharing our goals includes Toutanova and Cherry (2009), Dreyer and Eisner (2011), which works with a fully Bayesian model, Dinu et al. (2012), Eskander et al. (2013), which attempts to learn lexicons from morphologically annotated corpora, and Durrett and DeNero (2013), who train a discriminative model that learns transformation rules between word forms. We directly compare our results against the last using the same dataset.

The paper is organized as follows: section 2 contains the experimental setup, section 3 the datasets, and section 4 the results and discussion.

2 Method

As a first step, our system converts inflection tables into paradigms using a procedure given in Hulden (2014). The system generalizes concrete inflection tables by associating the common symbol subsequences shared by the words (the LCS) with variables. These variables represent abstractions that at table reconstruction time can correspond to any sequence of one or more symbols. As many inflection tables of different words are identical after assigning the common parts to 'variables,' this procedure results in a comparatively small number of paradigms after being input a large number of inflection tables. The process is illustrated in Figure 1. During generalization, the forms that gave rise to a particular paradigm are stored and later used for training a classifier to assign unknown base forms to paradigms. Having a number of paradigms at our disposal by this generalization method, the task of reconstructing an inflection table for an unseen base form in effect means picking the correct paradigm from among the ones generalized, a standard classification task of choosing the right/best paradigm.

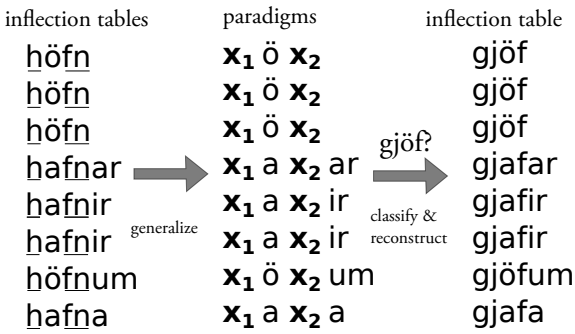

Figure 1: General overview of the system, exemplified using Icelandic nouns. First, a large number of inflection tables are generalized into a smaller number of paradigms; the generalization of the table for **höfn** 'harbor' into a paradigm is illustrated here. At classification time, an unknown base form is classified into one of the learned paradigms and its inflection table is reconstructed, illustrated here by **gjöf** 'present'.

After seeing a number of inflection tables generalized into abstract paradigms as described above, the task we evaluate is how well complete inflection tables can be reconstructed from only seeing an unknown base form. To this end, we train a "one-vs-the-rest" linear multi-class support vector machine (SVM).[2] For each example base form wb_i that is a member of paradigm p_j, we extract all substrings from wb_i from the left and right edges, and use those as binary features corresponding to the paradigm p_j.

[1] The data and the code is available at our website `https://svn.spraakbanken.gu.se/clt/naacl/2015/extract`

[2] Using LIBLINEAR (Fan et al., 2008) with L2-regularization.

For example, during training, the German verb **lesen** would have the following binary features activated: {#l, #le, #les, #lese, #lesen, #lesen#, lesen#, esen#, sen#, en#, n#}.

Before applying the classifier to an unseen base form and reconstructing the corresponding inflection table, many competing paradigms can be ruled out as being ill-matched simply by inspecting the base form. For example, the infinitive for the paradigm containing the English verb **sing** is generalized as x_1+**i**+x_2. At classification time of a verb like **run**, this paradigm can be ruled out due to incompatibility, as there is no **i** in **run**, and so the infinitive cannot be generated. Likewise, the Icelandic paradigm seen in Figure 1 can be ruled out for the base form **hest** 'horse', as the base form does not contain **ö**. The SVM-classifier may indeed suggest such paradigm assignments, but such classifications are ignored and the highest scoring compatible paradigm is selected instead. These additional constraints on possible base form-paradigm pairings are a general feature of the LCS-strategy and are not at all tied to the classification method here.

2.1 Feature selection

In order to eliminate noise features, we performed feature selection using the development set. We simultaneously tuned the SVM soft-margin penalty parameter C, as well as the length and type (prefix/suffix) of substrings to include as features. More concretely, we explored the values using a grid search over $C = 0.01 \ldots 5.0$, with a growing sequence gap (Hsu et al., 2003), as well as tuning the maximum length of anchored substring features to use $(3 \ldots 9)$, and whether to include prefix-anchored substrings at all $(0/1)$. In the second experiment, where cross-validation was used, we performed the same tuning procedure on each fold's development set.

3 Data

For the first experiment, we use the datasets provided by Durrett and DeNero (2013). This dataset contains complete inflection tables for German nouns and verbs (DE-NOUNS, DE-VERBS), Finnish verbs and nouns combined with adjectives (FI-VERBS, FI-NOUNADJ), and Spanish verbs (ES-VERBS). The number of inflection tables in this set ranges from 2,027 (DE-VERBS) to 7,249 (FI-VERBS). From these tables, 200 were held out for development and 200 for testing, following the splits that previous authors have used (Durrett and DeNero, 2013; Ahlberg et al., 2014) to ensure a fair baseline.[3]

For the second experiment, we collected additional inflection tables from Catalan (CA), English (EN), French (FR), Galician (GL), Italian (IT), Portuguese (PT), Russian (RU) (all from the FreeLing project (Padró and Stanilovsky, 2012)) and Maltese (MT) (Camilleri, 2013).[4] These inflection tables are often incomplete or defective and some contain very rarely occurring grammatical forms. Many alternate forms are also given. To avoid having to account for rare or historical forms, we filtered out grammatical forms (slots) that occur in less than $\sim$1% of all inflection tables. We also performed an independent cross-check with Wiktionary and removed some inflection table slots that did not appear in that resource. We further limited the number of inflection tables to 5,000. In the second experiment, we also split each dataset into 5 folds for cross-validation (maximally 4,000 tables for training, 500 for development and 500 for testing for each fold).

4 Results and discussion

In the main results tables 1, 2, and 3 we report the per table accuracy and per form accuracy in reconstructing complete inflection tables from unseen base forms. The per table accuracy is the percentage of inflection tables that are perfectly reconstructed from the base form. The per form accuracy is the percentage of correct forms in the reconstructed table. The associated oracle scores, which independently provide a measure of generalization power of the LCS-method, represent the maximal percentage achievable by an oracle classifier that always picks

[3] The development and test data for the first experiment had been filtered to not contain any of the 200 most frequently occurring forms in the language (Durrett and DeNero, 2013); this may result in an easier classification task because the maneuver in effect ensures that words belonging to irregular paradigms—i.e. those which would otherwise be difficult to classify correctly—are never evaluated against.

[4] The FreeLing data also included Russian verbs. However, this data set was deemed too incomplete to be useful and was left out.

the best learned paradigm for an unseen base form. In experiment 2, where the correct forms may consist of several alternatives, we only count a form as correct if all alternatives are given and all are correct. For example, the verb **dream** in English lists two alternative past participles, **dreamed** and **dreamt**, which both must be reconstructed for the past participle form to count as being correct.

Experiment 1

The accuracies obtained on the first three-language comparison experiment are shown in Table 1. Here, we see a consistent improvement upon the *max-suff*-strategy (AFH14) that simply picks the longest matching suffix among the base forms seen and assigns the unseen word to the same paradigm (breaking ties by paradigm frequency), as well as improvement over other learning strategies (D&DN13). Particularly marked is the improved accuracy on German verbs. We assume that this is because German verb prefixes, which are ignored in a suffix-based classifier, contain information that is useful in classifying verb behavior. German verbs that contain so-called inseparable prefixes like **miss-, ver-, wider-** do not prefix a **ge-** in the past participle form. For example: **kaufen** $\sim$ **gekauft**, **brauchen** $\sim$ **gebraucht**, **legen** $\sim$ **gelegt**, but **verkaufen** $\sim$ **verkauft**, **widerlegen** $\sim$ **widerlegt**, **missbrauchen** $\sim$ **missbraucht**, reflecting the replacement of the standard **ge-** by the inseparable prefix. There are many such inseparable prefixes that immediately trigger this behavior (although some prefixes only occasionally show inseparable behavior), yet this information is lost when only looking at suffixes at classification time. This analysis is supported by the fact that, during feature selection, German verbs was the only dataset in this first experiment where word prefixes were not removed by the feature selection process.

Experiment 2

The results of the second experiment are given in tables 2 (per table accuracy) and 3 (per form accuracy). The tables contain information about how many inflection tables were input on average over 5 folds to the learner (**#tbl**), how many paradigms this reduced to (**#par**), and how many forms (slots) each paradigm has (**#forms**). The **mfreq** column is a baseline where the classifier always picks the most populated paradigm, i.e. the paradigm that resulted from combining the largest number of different inflection tables by the LCS process. The **AFH14** shows the performance of a maximal suffix matching classifier, identical to that used in Ahlberg et al. (2014).

Discussion

Overall, the results support earlier claims that the LCS-generalization appears to capture paradigmatic behavior well, especially if combined with careful classification into paradigms. There is a clear and consistent improvement over baselines that use the same data sets. In addition, the SVM-classifier yields results comparable, and in many cases better, to using a maximum suffix classifier and additionally having access to raw corpus data in the language, a semi-supervised experiment reported separately in Ahlberg et al. (2014). In this work we have not attempted to extend the current method to such a semi-supervised scenario, although such an extension seems both interesting and possible.

Table 3: Per form accuracy results on the second experiment. 5-fold cross-validation is used throughout. The **#forms**-column shows the number of different slots in the paradigms. Other columns are as in table 2.

In some cases, we see a significant drop between the per-form and the per-table accuracy. For example, in the case of Russian nouns, per table accuracy is at 66.36%, while the per-form accuracy is 89.35%. This effect is explained—not only in the Russian case but in many others—by the existence of similar paradigms that differ only in very few forms. If the classifier picks an incorrect, but closely related paradigm, most forms may be produced correctly although the entire reconstructed table counts as wrong if even a single form is incorrect.

A few outliers remain. The Maltese verbs, which exhibit Semitic interdigitation in some paradigms, seem to generalize fairly well, and have a per form oracle score of 95.49 (shown in table 3). However, this is not reflected in the relatively low per form accuracy (61.15), which warrants further analysis. It may be an indication of that the correct paradigm is simply difficult to ascertain based only on the lemma form, or that additional features could be developed, perhaps ones that are discontinuous in the word.

An obvious extension to the current method is to inspect a suggested reconstructed table holistically, i.e., not relying only on base form features. That is, one could avoid making a commitment to a particular paradigm based solely on the features of the base form, and instead also include features from all the forms that a paradigm would generate. Such features are of course available in the training data in the various forms in an inflection table. Features from the seen forms could be used to rate compatibility since an incorrect reconstruction of an inflection table may likely be identified by its tendency to produce phonotactic patterns rarely or never seen in the training data.

With relatively few paradigms learned from collections of word forms, one can achieve fairly high coverage on unseen data. In principle, for example, the 13 most frequently used paradigms of Spanish verbs suffice to cover 90% of all verbs (per token). A useful application of this is rapid language resource development—one can elicit from a speaker a small number of well-chosen inflection tables, e.g. all forms of specific nouns, verbs, adjectives; generalize these inflection tables into paradigms; and use this information to deduce the possible morphological classes for a majority of unseen word forms.

Abstract

We present the first dynamic programming (DP) algorithm for shift-reduce constituency parsing, which extends the DP idea of Huang and Sagae (2010) to context-free grammars. To alleviate the propagation of errors from part-of-speech tagging, we also extend the parser to take a tag lattice instead of a fixed tag sequence. Experiments on both English and Chinese treebanks show that our DP parser significantly improves parsing quality over non-DP baselines, and achieves the best accuracies among empirical linear-time parsers.

1 Introduction

Incremental parsing has gained popularity in both dependency (Nivre, 2004; Zhang and Clark, 2008) and constituency parsing (Zhu et al., 2013; Wang and Xue, 2014). However, the greedy or beam search algorithms used in these parsers can only explore a tiny fraction of trees among exponentially many candidates. To alleviate this problem, Huang and Sagae (2010) propose a dynamic programming (DP) algorithm, reducing the search space to a polynomial size by merging equivalent states. This idea has been extended by Kuhlmann et al. (2011) and Cohen et al. (2011) to other dependency parsing paradigms.

In constituency parsing, however, DP has not yet been applied to incremental parsing, and the bigger search space in constituency parsing suggests a potentially even bigger advantage by DP. However, with unary rules and more-than-binary branchings, constituency parsing presents challenges not found in dependency parsing that must be addressed before applying DP. Thus, we first present an odd-even shift-reduce constituency parser which always finishes in same number of steps, eliminating the complicated asynchronicity issue in previous work (Zhu et al., 2013; Wang and Xue, 2014), and then develop dynamic programming on top of that. Secondly, to alleviate the error propagation from POS tagging, we also extends the algorithm to take a tagging sausage lattice as input, which is a compromise between pipeline and joint approaches (Hatori et al., 2011; Li et al., 2011; Wang and Xue, 2014).

Our DP parser achieves state-of-the-art performances on both Chinese and English treebanks (at 90.8% on PTB and 83.9% on CTB, the latter being the highest in literature).

2 Odd-Even Shift-Reduce CFG Parser

One major challenge in constituency parsing is unary rules. Unlike dependency parsing where shift-reduce always finishes in $2n-1$ steps, existing incremental constituency parsers (Zhu et al., 2013; Wang and Xue, 2014) reach the goal state (full parse tree) in different steps due to different number of unary rules. So we propose a new, synchronized, "odd-even" system to reach the goal in the same $4n-2$ steps. A *state* is notated $p = \langle S, Q \rangle$, where S is a stack of trees ..., s_1, s_0, and Q is a queue of word-tag pairs. At even steps (when step index is even) we can choose one of the three standard actions

- sh: shift the head of Q, a word-tag pair (t, w), onto S as a singleton tree $t(w)$;
- $\mathsf{re}^x_{\curvearrowleft}$: combine the top two trees on the stack and replace them with a new tree $x(s_1, s_0)$, x being the root nonterminal, headed on s_0;
- $\mathsf{re}^x_{\curvearrowright}$: similar to $\mathsf{re}^x_{\curvearrowleft}$ but headed on s_1;

and at odd steps we can choose two new actions:

$$\text{input}\ \ (t_1, w_1)\ ...\ (t_n, w_n)$$

$$\text{axiom}\ 0 : \langle \epsilon, (t_1, w_1)\ ...\ (t_n, w_n) \rangle : 0$$

$$\textsf{sh}\quad \frac{l : \langle S, (t,w)|Q \rangle : c}{l{+}1 : \langle S|t(w), Q \rangle : c{+}c_{\textsf{sh}}}\ l \text{ is even}$$

$$\textsf{re}^x_{\curvearrowleft}\quad \frac{l : \langle S|s_1|s_0, Q \rangle : c}{l{+}1 : \langle S|x(s_1, s_0), Q \rangle : c{+}c_{\textsf{re}^x_{\curvearrowleft}}}\ l \text{ is even}$$

$$\textsf{un}^x\quad \frac{l : \langle S|s_0, Q \rangle : c}{l{+}1 : \langle S|x(s_0), Q \rangle : c{+}c_{\textsf{un}^x}}\ l \text{ is odd}$$

$$\textsf{st}\quad \frac{l : \langle S|s_0, Q \rangle : c}{l{+}1 : \langle S|s_0, Q \rangle : c{+}c_{\textsf{st}}}\ l \text{ is odd}$$

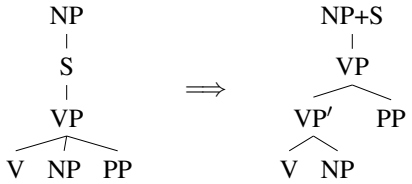
$$\text{goal}\ \ 2(2n-1) : \langle s_0, \epsilon \rangle : c$$

Figure 1: Shift-reduce system, omitting $\textsf{re}^x_{\curvearrowright}$. c is the model score, and $c_{\textsf{sh}}$, $c_{\textsf{re}^x_{\curvearrowleft}}$, etc. are the action scores.

- $\textsf{un}^x$: replace s_0 with a new tree $x(s_0)$ with x being the root nonterminal;
- $\textsf{st}$: no action.

Figure 1 shows the deductive system. Note that we alternate between standard shift-reduce actions in even steps and unary actions ($\textsf{un}^x$ or $\textsf{st}$) in odd steps, and the first action must be $\textsf{sh}$, followed by a $\textsf{un}^x$ or $\textsf{st}$, and followed by another $\textsf{sh}$. Continuing this procedure, we can always achieve the goal in $2(2n-1)$ steps.

In practice, we have larger than two-way rules and multi-level unary rules, so we binarize them and collapse multi-level unary rules into one level, for example,



Following Huang and Sagae (2010), we represent **feature templates** as functions $\mathbf{f}(\cdot, \cdot)$ on stack S and queue Q. Table 1 shows the 43 feature templates we use in this paper, all adopted from Zhu et al. (2013). They are combinations of the 32 **atomic features** $\tilde{\mathbf{f}}(S, Q)$ (e.g. s_0.t and s_0.c denote the head tag and

$$\textsf{sh}\quad \frac{l : \langle S, (t,w)|Q \rangle : (c, v)}{l{+}1 : \langle S|t(w), Q \rangle : (c{+}c_{\textsf{sh}}, 0)}\ l \text{ is even}$$

$$\textsf{re}^x_{\curvearrowleft}\quad \frac{\overset{\text{state } p\text{:}}{l' : \langle S'|s'_1, Q' \rangle : (c', v')}\quad \overset{\text{state } q\text{:}}{l : \langle S|s_1|s_0, Q \rangle : (c, v)}}{l{+}1 : \langle S'|x(s'_1, s_0), Q \rangle : (c'{+}v{+}\delta, v'{+}v{+}\delta)}$$
$$l \text{ and } l' \text{ are even}, p \in \pi(q)$$

$$\textsf{un}^x\ \frac{l : \langle S|s_0, Q \rangle : (c, v)}{l{+}1 : \langle S|x(s_0), Q \rangle : (c{+}c_{\textsf{un}^x}, v + c_{\textsf{un}^x})}\ l \text{ is odd}$$

Figure 2: DP shift-reduce, omitting $\textsf{re}^x_{\curvearrowright}$ and $\textsf{st}$. c and v are prefix and inside scores, and $\delta = c_{\textsf{sh}}(p) + c_{\textsf{re}^x_{\curvearrowleft}}(q)$. State equivalence is defined below in Section 3.

syntactic category of tree s_0, resp., and s_0.lc.w is the head word of its leftmost child).

3 Dynamic Programming

The key idea towards DP is the merging of equivalent states, after which the stacks are organized in a "graph-structured stack" (GSS)(Tomita, 1988). Following Huang and Sagae (2010), "equivalent states" $\sim$ in a same beam are defined by the atomic features $\tilde{\mathbf{f}}(S, Q)$ and the span of s_0:

$$\langle S, Q \rangle \sim \langle S', Q' \rangle$$
$$\Leftrightarrow \tilde{\mathbf{f}}(S, Q) = \tilde{\mathbf{f}}(S', Q') \text{ and } s_0.span = s'_0.span.$$

Similarly, for each state p, $\pi(p)$ is a set of **predictor states**, each of which can be combined with p in a $\textsf{re}^x_{\curvearrowleft}$ or $\textsf{re}^x_{\curvearrowright}$ action. For each action, we have different operations on $\pi(p)$. If a state p makes a $\textsf{sh}$ action and generates a state p', then $\pi(p') = \{p\}$. If two shifted states p' and p'' are equivalent, $p' \sim p''$, we merge $\pi(p')$ and $\pi(p'')$. If a state p makes a reduce ($\textsf{re}^x_{\curvearrowleft}$ or $\textsf{re}^x_{\curvearrowright}$) action, p tries to combine with every $p' \in \pi(p)$, and each combination generates a state r with $\pi(r) = \pi(p')$. If two reduced states are equivalent, we only keep one predictor states, as their predictor states are identical. If a state p fires an $\textsf{un}^x$ or a $\textsf{st}$ action resulting in a state u, we copy the predictor states $\pi(u) = \pi(p)$. Similar to reduce actions, if two resulting states after applying an $\textsf{un}^x$ or a $\textsf{st}$ action are equivalent, we only keep the best one with highest score (the recombined ones are only useful for searching k-best trees).

Figure 3: Extended shift-reduce deductive system with tagging sausage lattice, only showing sh.

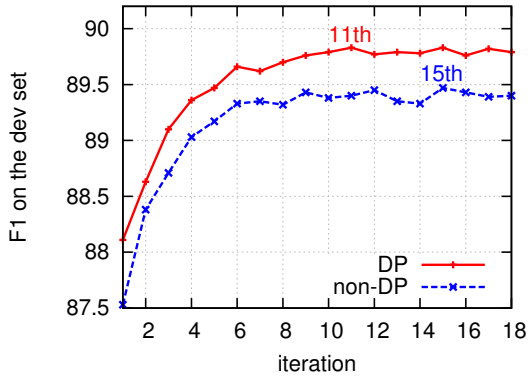

Figure 4: The learning curves of non-DP and DP parsers on the development set. DP achieves the best performance at 11th iteration with 89.8%, while non-DP gets its optimal iteration at 15th with a lower F1 89.5%.

In order to compute all the scores in GSS, for each state p, we calculate the prefix score, c, which is the total cost of the best action sequence from the initial state to the end of state p, and the inside score v, which is the score since the last shift (Figure 2).

The new mechanism beyond Huang and Sagae (2010) is the non-trivial dynamic programming treatment of unary actions ($\textsf{un}^x$ and st), which is not found in dependency parsing. Note that the score calculation is quite different from shift in the sense that unary actions are more like reduces.

4 Incorporating Tag Lattices

It is easy to extend our deductive system to take tagging sausage lattices as input. The key difference is that the tag t associated with each word in the input sequence becomes a set of tags T. Thus, in the sh action, we split the state with all the possible tags t' in the tagset T' for the **second** word on the queue. Figure 3 shows the deductive system, where we only change the sh action, input and axiom. For simplicity reasons we only present one word look ahead (we just need to know the tag of the first word on the queue), but in practice, we use a look ahead of 4 words ($q_0..q_3$, see Table 1), so each shift actually splits the tagset of the 5th word on the queue (q_4).

5 Experiments

We evaluate our parsers on both Penn English Treebank (PTB) and Chinese Treebank (CTB). For PTB, we use sections 02-21 as the training, section 24 as the dev set, and section 23 as the test. For CTB, we use the version of 5.1, articles 001-270 and 440-1151 as the training data, articles 301-325 as the dev set, and articles 271-300 as the test set.

Besides training with gold POS tags, we add k-best automatic tagging results to the training set using a MaxEnt model with ten-way jackknifing (Collins, 2000). And we automatically tag the dev and test sets with k-best tagging sequences us-

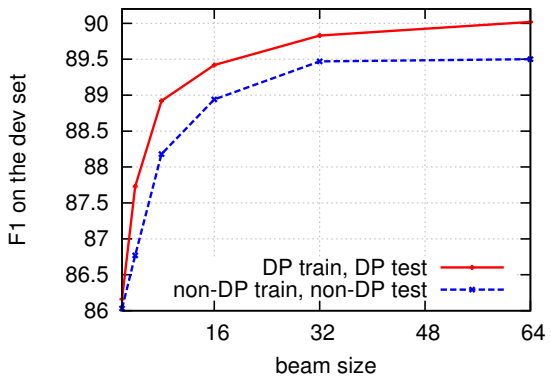

Figure 5: The F1 curves of non-DP and DP parsers (train and test consistently) on the dev set.

ing the MaxEnt POS tagger (at 97.1% accuracy on English, and 94.5% on Chinese) trained on the training set. We set k to 20 for English. And we run two sets of experiments, 1-best vs. 20-best, for Chinese to address the tagging issue. We train our parsers using "max-violation perceptron" (Huang et al., 2012) (which has been shown to converge much faster than "early-update" of Collins and Roark (2004)) with minibatch parallelization (Zhao and Huang, 2013) on the head-out binarized and unary-collapsed training set. We finally debinarize the trees to recover the collapsed unary rules.

We evaluate parser performance with EVALB including labeled precision (LP), labeled recall (LR), and bracketing F1. We use a beam size of 32, and pick the optimal iteration number based on the performances on the dev set.

Our baseline is the shift-reduce parser without state recombination (henceforth "non-DP"), and our dynamic programming parser (henceforth "DP") is the extension of the baseline.

5.1 Learning Curves and Search Quality

Figure 4 shows the learning curves on the PTB dev set. With a same beam width, DP parser achieves a better performance (89.8%, peaking at the 11th iteration) and converges faster than non-DP. Picking the optimal iterations for DP and non-DP models, we test each with various beam size, and plot the F1 curves in Figure 5. Again, DP is always better than non-DP, with 0.5% difference at beam of 64.

non-DP (20-best POS)	83.3	83.2	83.2	95.5
DP (20-best POS)	**83.6**	**84.2**	**83.9**	**95.6**

Table 3: Results on Chinese (CTB) 5.1 test set.

5.2 Final Results on English

Table 2 shows the final results on the PTB test set. The last column shows the empirical time complexity. Our baseline parser achieves a competitive score, which is higher than Berkeley even with a linear time complexity, and is comparable to Zhu et al. (2013). Our DP parser improves the F1 score by 0.5 points over the non-DP, and achieves the best F1 score among empirical linear-time parsers.

5.3 Sausage Lattice Parsing

To alleviate the propagation of errors from POS tagging, we run sausage lattice parsing on both Chinese and English, where Chinese tagging accuracy significantly lag behind English.

Table 3 shows the F1 score and POS tagging accuracy of all parsing models on the Chinese 5.1 test set. Our MaxEnt POS tagger achieves an accuracy of 94.5% on 1-best outputs, and an oracle score of 97.1% on 20-best results. The average number of

tags for each word in the 20-best list is 1.1.

The joint tagging and parsing approach of Wang and Xue (2014) improves the F1 score from 80.1% to 83.6% (see lines 4 and 5). We instead use sausage lattices, a much cheaper way. The non-DP (1-best POS) and non-DP (20-best POS) lines show the effectiveness of using sausage lattices (+1.1 for tagging and +2.6 for parsing). As Wang and Xue (2014) is a non-DP model, it is comparable to our non-DP results. With the help of 20-best tagging lattices, we achieve the same tagging accuracy at 95.5%, but still 0.4 worse on the F1 score than the joint model. It suggests that we need a larger k to catch up the gap. But our DP model boosts the performance further to the best score at 83.9% with a similar set of features.

The last two lines (non-DP and DP) in Table 2 show our English lattice parsing results. So we run another baseline with the non-DP English parser on 1-best POS tags, and the baseline achieves a tagging accuracy at 97.11 and an F1 score at 90.1. Comparing to the tagging accuracy (97.15) and F1 score (90.3) of our non-DP lattice parser, sausage lattice parsing doesn't help the tagging accuracy, but helps parsing a little by 0.2 points. The statistics show that 2 percent of POS tags in the lattice parsing result are different from the baseline, and those differences lead to a slight improvement on parsing.

6 Conclusions

In this paper, we present a dynamic programming algorithm based on graph-structured stack (GSS) for shift-reduce constituency parsing, and extend the algorithm to take tagging sausage lattices as input. Experiments on both English and Chinese treebanks show that our DP parser outperforms almost all other parsers except of Carreras et al. (2008), which runs in a much higher time complexity.

Abstract

Transcribing documents from the printing press era, a challenge in its own right, is more complicated when documents interleave multiple languages—a common feature of 16th century texts. Additionally, many of these documents precede consistent orthographic conventions, making the task even harder. We extend the state-of-the-art historical OCR model of Berg-Kirkpatrick et al. (2013) to handle word-level code-switching between multiple languages. Further, we enable our system to handle spelling variability, including now-obsolete shorthand systems used by printers. Our results show average relative character error reductions of 14% across a variety of historical texts.

1 Introduction

Transcribing documents printed on historical printing presses poses a number of challenges for OCR technology. Berg-Kirkpatrick et al. (2013) presented an unsupervised system, called *Ocular*, that handles the types of noise that are characteristic of pre-20th century documents and uses a fixed monolingual language model to guide learning. While this approach is highly effective on English documents from the 18th and 19th centuries, problems arise when it is applied to older documents that feature code-switching between multiple languages and obsolete orthographic characteristics.

In this work, we address these issues by developing a new language model for *Ocular*. First, to handle multilingual documents, we replace *Ocular's* simple n-gram language model with an unsupervised model of intrasentential code-switching that allows joint transcription and word-level language identification. Second, to handle orthographic variation, we provide an interface that allows individuals familiar with relevant languages to guide the language model with targeted orthographic information. As a result, our system handles inconsistent spelling, punctuation, and diacritic usage, as well as now-obsolete shorthand conventions used by printers.

We evaluate our model using documents from the *Primeros Libros* project, a digital archive of books printed in the Americas prior to 1601 (Dolan, 2012). These texts, written in European and indigenous languages, often feature as many as three languages on a single page, with code-switching occurring on the chapter, sentence, and word level. Orthographic variations are pervasive throughout, and are particularly difficult with indigenous languages, for which writing systems were still being developed.

Our results show improvements across a range of documents, yielding an average 14% relative character error reduction over the previous state-of-the-art, with reductions as high as 27% on particular texts.

2 Data

Writing during the early modern period in Europe was characterized by increasing use of vernacular languages alongside Latin, Greek, and Hebrew. In the colonies, this was matched by the development of grammars and alphabetic writing systems for indigenous languages (see Eisenstein (1979) and Mignolo (1995)). In all cases, orthographies were regionally variable and subject to the limited resources of the printing houses; this is particularly true in the Americas, where resources were scarce,

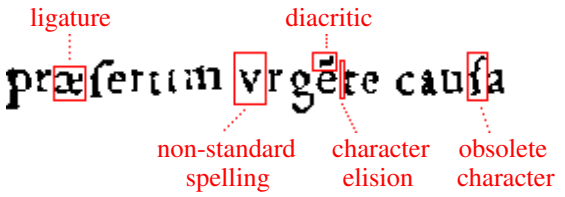
Denver, Colorado, May 31 – June 5, 2015.



Input: præſertim vrgẽte cauſa
Language model: praesertim urgente causa

Figure 1: An example OCR input showing the original image and an example of an equivalent modernized text similar to data used to train the LM.

and where indigenous-language orthographies were first being developed (Baddeley and Voeste, 2013).

The 349 digital facsimiles in the *Primeros Libros* collection are characteristic of this trend. Produced during the first century of Spanish colonization, they represent the introduction of printing technology into the Americas, and reflect the (sometimes conflicted) priorities of the nascent colony, from religious orthodoxy to conversion and education.

For our experiments, we focus on multilingual documents in three languages: Spanish, Latin, and Nahuatl. As Berg-Kirkpatrick et al. (2013) show, a language model built on contemporaneous data will perform better than modern data. For this reason, we collected 15–17th century texts from Project Gutenberg,[1] producing Spanish and Latin corpora of more than one million characters each. Due to its relative scarcity, we augmented the Nahuatl corpus with a private collection of transcribed colonial documents.

3 Baseline System

The starting point for our work is the *Ocular* system described by Berg-Kirkpatrick et al. (2013). The fonts used in historical documents are usually unknown and can vary drastically from document to document. *Ocular* deals with this problem by learning the font in an unsupervised fashion – directly from the input historical document. In order to accomplish this, the system uses a specialized generative model that reasons about the main sources of variation and noise in historical printing. These include the shapes of the character glyphs, the horizontal spacing between characters, and the vertical offset of each character from a common baseline. Additionally, since documents exhibit variable inking levels (where individual characters are often faded or smeared with blotched ink) the system also models the amount of ink applied to each type piece.

The generative process operates as follows. First, a sequence of character tokens is generated by a character n-gram language model. Then, bounding boxes for each character token are generated, conditioned on the character type, followed by vertical offsets and inking levels. Finally, the pixels in each bounding box are generated, conditioned on the character types, vertical offsets, and inking levels. In this work, we focus on improving the language model, and leave the rest of the generative process untouched.

4 Language Model

We present a new language model for *Ocular* that is designed to handle issues that are characteristic of older historical documents: code-switching and orthographic variability. We extend the conventional character n-gram language model and its training procedure to deal with each of these problems in turn.

4.1 Code-Switching

Because *Ocular*'s character n-gram language model (LM) is fixed and monolithic, even when it is trained on corpora from multiple languages, it treats all text as a single "language"—a multilingual blur at best. As a result, the system cannot model the fact that different contiguous blocks of text correspond to specific languages and thus follow specific statistical patterns. In order to transcribe documents that feature intrasentential code-switching, we replace *Ocular*'s simple n-gram LM with one that directly models code-switching by representing language segmentation as a latent variable.

Our code-switching LM generates a sequence of pairs (e_i, ℓ_i) where e_i is the current character and ℓ_i is the current language. The sequence of languages ℓ_i specifies the segmentation of generated text into language regions. Our LM is built from several component models: First, for each language type ℓ, we incorporate a standard monolingual character n-gram model trained on data from language ℓ. The com-

[1] http://www.gutenberg.org/

ponent model corresponding to language ℓ is called P_ℓ^{CHAR}. Second, our LM also incorporates a model that governs code-switching between languages. We call this model P^{LANG}. The generative process for our LM works as follows. For the ith character position, we first generate the current language ℓ_i conditioned on the previous character e_{i-1} and the previous language ℓ_{i-1} using P^{LANG}. Then, conditioned on the current language l_i and the previous $n-1$ characters, we generate the current character e_i using $P_{\ell_i}^{\text{CHAR}}$. This means that the probability of pair (e_i,ℓ_i) given its context is computed as:

$$P^{\text{LANG}}(\ell_i \mid e_{i-1}, \ell_{i-1}) \cdot P_{\ell_i}^{\text{CHAR}}(e_i \mid e_{i-1} \ldots e_{i-n+1})$$

We parameterize P^{LANG} in a way that enforces two constraints. First, to ensure that each word is assigned a single language, we only allow language transitions for characters directly following whitespace (a space character or a page margin, unless the character follows a line-end hyphen). Second, to resist overly frequent code-switching (and encourage longer spans), we let a Bernoulli parameter κ specify the probability of choosing to draw a new language at a word boundary (instead of deterministically staying in the same language). By setting κ low, we indicate a strong belief that language switches should be infrequent, while still allowing a switch if sufficient evidence is found in the image.[2] Finally, we parameterize the frequency of each language in the text. Specifically, for each language ℓ, a multinomial parameter θ_ℓ specifies the probability of transitioning to ℓ when you draw a new language. We learn this group of multinomial parameters, θ_ℓ for each language, in an unsupervised fashion, and in doing so, adapt to the proportions of languages found in the particular input document. Thus, using our parameterization, the probability of transitioning from language ℓ to ℓ', given previous character e, is:

$$P^{\text{LANG}}(\ell' \mid e, \ell) = \begin{cases} (1-\kappa) + \kappa \cdot \theta_{\ell'} & \text{if } e = \textit{space} \text{ and } \ell = \ell' \\ \kappa \cdot \theta_{\ell'} & \text{if } e = \textit{space} \text{ and } \ell \neq \ell' \\ 1 & \text{if } e \neq \textit{space} \text{ and } \ell = \ell' \\ 0 & \text{if } e \neq \textit{space} \text{ and } \ell \neq \ell' \end{cases}$$

[2]We use $\kappa = 10^{-6}$ across all experiments.

Finally, because our code-switching LM uses multiple separate language-specific n-gram models P_ℓ^{CHAR}, we are able to maintain a distinct set of valid characters for each language. By restricting each language's model to the set of characters in the corpus for that language, we can push the model away from incompatible languages during transcription if it is confident about certain rare characters, and limit the search space by reducing the number of character combinations considered for any given position. We also include, for all languages, a set of punctuation symbols such as ¶ and § that appear in printed books but not in the LM training data.

4.2 Orthographic Variability

The component monolingual n-gram LMs must be trained on monolingual corpora in their respective languages. However, due to the lack of codified orthographic conventions concerning spelling, diacritic usage, and spacing, compounded by the liberal use of now-obsolete shorthand notations by printers, statistics gleaned from available modern corpora provide a poor representation of the language used in the printed documents. Even 16th century texts on Project Gutenberg tend to be written, for the benefit of the reader, using modern spellings. The disconnect between the orthography of the original documents and modern texts can be seen in Figure 1. To address these issues, we introduced an interface for

incorporating orthographic variability into the training procedure for the component LMs.

For our experiments, we built Latin, Nahuatl, and Spanish variability rulebanks by asking language experts to identify spelling anomalies from among several sample pages from *Primeros Libros* documents, and specify *rewrite rules* that map modern spellings back to variant spellings; we also drew on data from paleographic textbooks. Example rules can be seen in Table 1. These rules are used to rewrite corpus text before the LMs are trained; for instance, every nth occurrence of *en* in the Spanish corpus might be rewritten as *ẽ*. This approach reintroduces historically accurate orthographic variability into the LM.

5 Experiments

We compare to *Ocular*, the state of the art for historical OCR.[3] Since *Ocular* only supports monolingual English OCR, we added support for alternative alphabets, including diacritics and ligatures, and trained a single mixed-language model on a combined Spanish/Latin/Nahuatl corpus.

We evaluate our model on five different books from the *Primeros Libros* collection, representing a variety of printers, presses, typefaces, and authors (Table 3). Each book features code-switching between Spanish, Latin, and Nahuatl. For each book, a font was trained on ten (untranscribed) pages using unsupervised learning procedure described by Berg-Kirkpatrick et al. (2013). The font was evaluated on a separate set of ten pages, manually transcribed.[4]

6 Results and Analysis

Our overall results (Table 2) show improvements on every book in our evaluation, achieving as high as 29% relative word-error (WER) reduction.

Replacing *Ocular*'s single mixed-language LM with our unsupervised code-switch model results in immediate improvements. An example of transcription output, including the language-assignments made by the model, can be seen in Figure 2.

Further improvements are seen by handling orthographic variation. Figure 3 gives an example of how a single spelling variation can lead to a cascade of transcription errors. Here, the baseline system, confused by the elision of the letter *n* in the word *mẽtira* (from *mentira*, "lie"), transcribed it with an entirely different word (*merita*, "merit"). When our handling of alternate spellings is employed, the LM has good statistics for character sequences including the character *ẽ*, and is able to decode the word correctly.

There are several explanations for the differences in results among the five evaluation books. First, the two oldest texts, *Gante* and *Anunciación*, use Gothic fonts that are more difficult to read and feature capital letters that are nearly impossible for the model to recognize (see Table 3). This contributes to the high character error rates for those books.

Second, the word error rate metric is complicated by the inconsistent use of spaces in Nahuatl writ-

		no variation handling	mentira	merita
handling variation	mentira	mẽtira

Figure 3: Two variants of the same word (*mentira*), pulled from the same page of text. The form *mentira* appears in the LM training corpus, but the shorthand *mẽtira* does not. Without special handling, the model does not know that *mẽtira* is valid.

ing, falsely claiming "word" errors when all *characters* are correct. Use of spaces is not standardized across the printed books, or across the digitized LM training corpora, and is still in fact a contested issue among modern Nahuatl scholars. While it is important for the transcription process to insert spaces appropriately into the Spanish and Latin text (even when the printer left little, as with *ypara* in Figure 2), it is difficult to assess what it means for a space to be "correctly" inserted into Nahuatl text. *Rincón* and *Bautista* contain relatively less Nahuatl text and are affected less by this problem.

A final source of errors arises when our model "corrects" the original document to match modern conventions, as with diacritics, whose usages were less conventionalized at the time these books were printed. For example, the string *numero* is often transcribed as *número*, the correct modern spelling.

7 Conclusions and Future Work

We have demonstrated an unsupervised OCR model that improves upon Berg-Kirkpatrick et al. (2013)'s state-of-the-art *Ocular* system in order to effectively handle the code-switching and orthographic variability prevalent in historical texts. In addition to transcribing documents, our system also implicitly assigns language labels to words, allowing their usage in downstream tasks. We have also presented a new corpus, with transcriptions, for the evaluation of multilingual historical OCR systems.

Our system, as currently designed, attempts to faithfully transcribe text. However, for the purposes of indexability and searchability of these documents, it may be desirable to also produce *canonicalized* transcriptions, for example collapsing spelling variants to their modern forms. Fortunately, this can be done in our approach by running the variability rewrite rules "backward" as a post-processing step.

Further technical improvements may be made by having the system automatically attempt to bootstrap the identification of spelling variants, a process that could complement our approach through an active learning setup. Additionally, since even our relatively simple unsupervised code-switch language modeling approach yielded improvements to OCR performance, it may be justified to attempt the adaptation of more complex code-switch recognition techniques (Solorio et al., 2014).

The automatic transcription of the *Primeros Libros* collection has significant implications for scholars of the humanities interested in the role that inscription and transmission play in colonial history. For example, there are parallels between the way that the Spanish transformed indigenous languages into Latin-like writing systems (removing "noise" like phonemes that do not exist in Latin), and the way that the OCR tool transforms historical printed documents into unicode (removing "noise" like artifacts of the printing process and physical changes to the pages); in both instances, arguably important information is lost. We present some of these ideas at the American Comparative Literature Association's annual meeting, where we discuss the relationship between sixteenth century indigenous orthography and *Ocular*'s code-switching language models (Alpert-Abrams and Garrette, 2015).

Matching Citation Text and Cited Spans in Biomedical Literature: a Search-Oriented Approach

Arman Cohan, Luca Soldaini, Nazli Goharian
Georgetown University, Information Retrieval Lab, Computer Science Department
{arman, luca, nazli}@ir.cs.georgetown.edu

Abstract

Citation sentences (citances) to a reference article have been extensively studied for summarization tasks. However, citances might not accurately represent the content of the cited article, as they often fail to capture the context of the reported findings and can be affected by epistemic value drift. Following the intuition behind the TAC (Text Analysis Conference) 2014 Biomedical Summarization track, we propose a system that identifies text spans in the reference article that are related to a given citance. We refer to this problem as citance-reference spans matching. We approach the problem as a retrieval task; in this paper, we detail a comparison of different citance reformulation methods and their combinations. While our results show improvement over the baseline (up to 25.9%), their absolute magnitude implies that there is ample room for future improvement.

1 Introduction

The size of scientific literature has increased dramatically during recent decades. In biomedical domain for example, PubMed – the largest repository of biomedical literature – contains more than 24 million articles. Thus, there is a need for concise presentation of important findings in the scientific articles being published. Text summarization of scientific articles is a method for such presentation. One obvious form of scientific summaries, is the abstract of the articles. Another type of scientific summaries relates to citance-based summaries which are summaries created using the set of citations to a reference article. This kind of summary covers some aspects of the reference article which might not be present in its abstract (Elkiss et al., 2008).

Citances often cover important and novel insights about findings or aspects of a paper that others have found interesting; thus, they capture contributions that had an impact on the research community (Elkiss et al., 2008; Qazvinian and Radev, 2008).

Reference Article

(Voorhoeve et al., 2006): *"These miRNAs neutralize p53-mediated CDK inhibition, **possibly** through direct inhibition of the expression of the tumor suppressor LATS2."*

Citing Article

(Okada et al., 2011): *"Two oncogenic miRNAs, miR-372 and miR-373, **directly inhibit** the expression of Lats2, **thereby** allowing tumorigenic growth in the presence of p53 (Voorhoeve et al., 2006)."*

Figure 1: Example of epistemic value drift from (De Waard and Maat, 2012). The claim in (Voorhoeve et al., 2006) becomes fact in (Okada et al., 2011).

In the past, many have focused on citance extraction and citance-based summarization. Example of citance extraction include (Siddharthan and Teufel, 2007), who used a machine learning approach with linguistic, lexical, statistical and positional features, and (Kaplan et al., 2009), who studied a coreference resolution based approach. Citance extraction has been also studied in the context of automatic summarization. For example, (Qazvinian and Radev, 2010) proposed a framework based on probabilistic inference to identify citances, while (Abu-Jbara and Radev, 2011) approached the problem as a classification task. In the biomedical domain, the use of citances was first studied by (Nakov et al., 2004).

While useful, citances by themselves lack the appropriate evidence to capture the exact content of the original paper, such as circumstances, data and assumptions under which certain findings were obtained. Citance-based summaries might also modify the epistemic value of a claim presented in the cited work (De Waard and Maat, 2012); that is, they might report a preliminary result or a claim as a definite fact (example in figure 1).

Recently, a new track at TAC has been introduced to explore ways to generate better citance-based

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1042–1048,
Denver, Colorado, May 31 – June 5, 2015.

summaries[1]. One way to achieve this, is to link citances to text spans in the reference article to obtain a more informative collection of sentences representing the reference article (figure 2). A framework designed to solve such problem requires two components: (*i*) a method to identify the most relevant spans of text in the reference text and (*ii*) a system to automatically generate a summary given a set of citances and reference spans.

In this paper, we propose an information retrieval approach designed to address the first task. We explore the impact of several query reformulation techniques – some domain independent, others tailored to biomedical literature – on the performance of the system. Furthermore, we apply combined reformulations, which yields an additional improvement over any single method (25% over the baseline).

As a related area, passage retrieval in biomedical articles has been studied in the context of the genomics track (Hersh et al., 2006; Hersh et al., 2007) and in following efforts (Urbain et al., 2008; Urbain et al., 2009; Chen et al., 2011). In these works, the goal is to find passages that relate to a given term or keyword (e.g. GeneRIF). In contrast, our system considers citances as queries, which are substantially longer than keyword-based queries and have a syntactical structure.

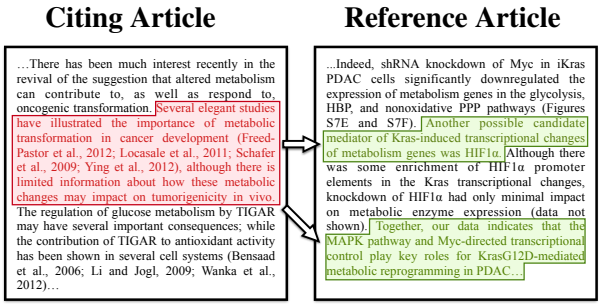
In summary, our contributions are: (*i*) A search-based, unsupervised (thus easily scalable to other domains) approach to citance-reference spans matching and (*ii*) adaptation of various query reformulation techniques for the citatnce-refrence span matching.

2 Methodology

The goal of the proposed system is to retrieve text spans from the reference paper that match the finding(s) each citance is referring to. We approach this problem as a search task. That is we consider the citance as a query and the reference text spans as documents. Then, using a retrieval model along with query reformulation, we find the most relevant text spans to a given citance. Our methodology consist of the following steps:

1. Create sentence level index from the reference article.

[1]http://www.nist.gov/tac/2014/BiomedSumm/



(Cheung et al., 2013) (Ying et al., 2012)

Figure 2: Example of a citance/reference article pair from the TAC training set[1]. The text in the red box on the left is referred to as the citance text, while the text in the green boxes on the right is referred to as the reference text.

2. Apply query reformulation to the given citance and retrieve the most relevant spans.
3. Rerank and merge the retrieved spans that correctly describe the citance.

We will describe each step in the following sections.

2.1 Creating the index

To create an index of spans, each reference article is tokenized at a sentence level using the Punkt tokenize (Kiss and Strunk, 2006). Because each relevant reference span in the reference text can be formed by several consecutive sentences (according to the annotation guidelines, each span can consist of one up to five consecutive sentences), we index text spans comprised of one up to five sentences.

2.2 Retrieval model

We evaluated the performance of several retrieval models during experimentation, i.e. vector space model (Salton et al., 1975), probabilistic BM25 (Robertson and Zaragoza, 2009), divergence from randomness (DFR) (Amati and Van Rijsbergen, 2002), and language models (Ponte and Croft, 1998) with Dirichlet priors. All models showed very similar performances (with only DFR constantly underperforming all other models) and we did not observe any statistically significant differences between each set of runs. Therefore, we opted for the vector space model as our retrieval model.

2.3 Query reformulation

We apply several query reformulation techniques to the citance to better retrieve the related text spans. We leverage both general and domain specific query reformulations for this purpose. Specifically,

we use biomedical concepts, ontology information, keyphrases and the syntactic structure of the citance.

2.3.1. Unmodified query (*baseline*): The citance after removing stop words, numeric values and citation markers (i.e. the actual indicator of the citation) serves as our baseline.

2.3.2. Biomedical concepts (UMLS-*reduce*): We remove from the query those terms that do not map to any medical concept in the UMLS[1] metathesaurus. We use MetaMap (Aronson, 2001) to map biomedical expressions in the citances to UMLS concepts. More specifically, our heuristic greedily matches the longest expressions in the citance to concepts in the UMLS metathesaurus; such strategy was deemed the most appropriate after experimenting with various matching approaches. We limited the scope of UMLS-reduce to SNOMED Clinical Terms (Bos et al., 2006) collection of UMLS and the "preferred concepts" (i.e., concepts that are determined by the National Library of Medicine to provide the best representation for a concept); terms that are not mapped to any UMLS concept were removed.

2.3.3. Noun phrases (*NP*): Citances include many important biological concepts, often appearing as noun phrases. For this reason, we reformulate citance by only keeping noun phrases and filtering out other parts of speech. We retain noun phrases that consist of up to 3 terms, as longer phrases were empirically determined to be too specific. Stopwords are removed from noun phrases.

2.3.4. Keyword based (*KW*): We consider a statistical measure for identifying key terms in the citance. Specifically, we computed the *idf*[2] of the terms in the citance in a domain-specific corpus to evaluate their importance. Given the domain of our dataset, we used the Open Access Subset of PubMed Central[3]. We filter out the terms whose *idf* value is less than a fixed threshold (after empirical evaluation, this threshold was set to 2.5).

2.3.5. Biomedical expansion (UMLS-*expand*): The terminology used by the citing author and the referenced author is not necessarily identical. Multiple terms or multi-word expressions can be mapped to the same concepts and each author might use their own choice of terms for describing a concept. In this approach, we add related terminology to the important concepts in the citance to solve this issue. Since our dataset consists of articles from biomedical literature, we took advantage of the UMLS metathesaurus to expand terms or multi-word expressions with their synonyms. We did not enforce any threshold for the number of terms added by UMLS-*expand*. However, in order to prevent query drift, we expanded citances using only UMLS's "preferred concepts" and concepts from the "SNOMED Clinical Terms" (SNOMED CT) terminology.

2.3.6. Combined reformulation: Due to the narrative structure of citances and their relative long length, using all citance terms for expansion is likely to cause query drift. Therefore, we first reduce the citance using one of previously described reduction approaches and then apply query expansion. In detail, we evaluated the combination of noun phrases and UMLS expansion, as well as UMLS reduction and expansion.

2.4 Combining retrieved spans

Due to our indexing strategy described in section 2.1, some text spans retrieved by the search engine could overlap with each other. Intuitively, if a span containing multiple contiguous sentences $\{s_1, \ldots, s_l\}$ is retrieved alongside any of its constituent sentences s_i, its relevance score should be increased to account for the relevance of s_i.

We exploited such intuition by adding the score of each span with the score of any of the constituent sentences or sub-spans retrieved alongside it. After the score is updated, the constituent sentences or sub-spans are removed from the list of retrieved results. Finally, because the number of reference spans indicated by the annotators in our data set is at most three, the system returns the top three results.

It is worth mentioning that we also looked at some other query reformulation approaches such as pseudo relevance feedback (Buckley et al., 1995) and Wikipedia based biomedical term filtering (Cohan et al., 2014); however, our experimentations should that these methods performed substantially worse than the baseline, consequently, we do not report those results nor their relevant discussions.

[1] http://www.nlm.nih.gov/research/umls/
[2] Inverted Document Frequency
[3] http://www.ncbi.nlm.nih.gov/pmc/

Type of agreement	Count	Average overlap
Full agreement	2	100%
Partial agreement between all annotators	66	$21.7 \pm 15.4\%$
Partial agreement between a majority of annotators	121	$19.2 \pm 11.4\%$
Partial agreement between a minority of annotators	113	$27.0 \pm 15.9\%$
No agreement at all	11	0%

Table 1: Levels of agreement between annotators. The 4 annotators fully agree on just 2 of the 313 annotations. In most cases, a majority (3 annotators) or a minority (2 annotators) agrees on a portion of reference spans, indicating that the task is not trivial even for domain experts.

3 Evaluation and Dataset

The system was evaluated on TAC 2014 Biomedical Summarization track training dataset. It consists of 20 topics, each of which contains between 10 to 20 citing articles and 1 reference article. For each topic, four domain experts were asked to identify the appropriate reference spans for each citance in the reference text. To better understand the dataset, we analyzed the agreement between annotators (table 1). This table shows that the overall agreement is relatively low.

We used two sets of metrics for evaluation of the task. The first one is based on the weighted overlaps between the retrieved spans and the correct spans designated by annotators and is meant to reward spans overlapping with the ground truth. Weighted recall and precision for a system returning span S with respect to a set of M annotators, consisting of gold spans G_1, ..., G_M are defined as follows:

$$\text{Recall} \stackrel{\text{def}}{=} \frac{\sum_{i=1}^{M} |S \cap G_i|}{\sum_{i=1}^{M} |G_i|} \quad \text{Prec} \stackrel{\text{def}}{=} \frac{\sum_{i=1}^{M} |S \cap G_i|}{M \times |S|} \quad (1)$$

The overall score of the system is the mean F-1 (harmonic mean of the weighted precision and recall) over all the topics.

Based on the weighted F-1 score, a method could be penalized for retrieving any spans that are not indicated as gold spans by the annotators. Even if those spans are semantically similar to the gold spans, they will not receive any score. This is not ideal because, as the high disagreement shown in table 1 implies, gold spans by offset locations are highly controversial. For this reason, we also considered ROUGE-L (Lin, 2004) as another evaluation metric, as it rewards a method for retrieving spans that are similar to the gold spans. Specifically, ROUGE-L, takes into account the sentence similarity by considering the longest in sequence n-grams between the retrieved spans and gold spans.

4 Results and discussion

The problem of matching citations with cited spans in scientific articles is a new task and to the best of our knowledge, there is no prior work on this task. Thus to evaluate the effectiveness of our different methods, we compared the performance of our proposed approaches against the unmodified query baseline. The results are shown in Table 2.

Interestingly, we observe that UMLS-*reduce* performs worse than the baseline in terms of F-1. This can be attributed to the fact that multiple expressions in the biomedical literature can be used to refer to the same concept. Such diversity is not captured by UMLS-*reduce*, as it only performs query reduction. Moreover, a citance often contains expressions that, while not mapping to any biomedical concepts, provide useful context and therefore are fundamental in conveying the meaning of the citance (we will refer to such expressions as *supporting expressions* in the reminder of the paper). These supporting expressions are not captured by UMLS-*reduce*.

NP outperforms the baseline (+18.8% F-1). This outcome is expected, as most important biomedical concepts in the citance are noun phrases. Moreover, supporting expressions are also captured, as most of them are noun phrases.

KW also shows promising results (+11.5% F-1 and +15.2% ROUGE-L F-1 improvement), proving that the *idf* of the terms in citance over a large biomedical corpus is a valid measure of their informativeness for this task.

When comparing *KW* and *NP*, we notice that the former obtains higher precision values than the latter; this outcome is reversed with respect to recall (i.e., *NP*'s recall is higher than *KW*'s). Such behavior can be motivated by the fact that *NP*, as it extracts noun phrases that are likely to appear in the gold reference span, has a higher chance of retrieving relevant sections of the reference text. However, *NP* is more likely to retrieve non-relevant spans, as the extracted noun phrases, which are often describing the main findings of the cited paper, are preva-

	Recall	Precision	F-1	ROUGE-L Recall	ROUGE-L Prec	ROUGE-L F-1
baseline	0.169	0.152	0.156	0.496	0.200	0.280
UMLS-*reduce*	0.132 (-22.0%)	0.146 (-4.08%)	0.136 (-12.5%)	0.496 (0.0%)	0.224* (12.0%)	0.293 (4.8%)
KW	0.173* (3.0%)	0.193** (27.6%)	0.174** (11.5%)	0.491 (-0.1%)	0.273** (36.3%)	0.323** (15.2%)
NP	0.199** (18.3%)	0.178** (17.6%)	0.185** (18.8%)	0.550** (11.1 %)	0.211* (5.5 %)	0.280 (0.0%)
UMLS-*expand*	0.182** (8.1%)	0.148 (-2.1%)	0.160* (3.2 %)	0.498 (0.5%)	0.245** (22.2%)	0.315** (12.3%)
UMLS-*reduce* + UMLS-*expand*	**0.201** (19.6%)**	0.179** (18.0%)	0.187** (20.0%)	**0.558** (12.6 %)**	0.209** (4.4 %)	0.293* (4.4%)
NP + UMLS-*expand*	0.180* (7.1%)	**0.224** (47.8%)**	**0.196** (25.9%)**	0.501 (1.13%)	**0.280** (39.9%)**	**0.333** (18.8%)**

Table 2: Results for reference span matching; *KW*: reduction using KeyWords; *NP*: reduction using Noun Phrases; UMLS-*expand*: expansion using UMLS; UMLS-*reduce*: reduction using UMLS; * (**) indicates statistical significance at $p < 0.05$ ($p < 0.01$) using student's t-test over the baseline.

lent throughout the reference article. On the other hand, *KW* selects highly discriminative terms which are highly effective in retrieving some relevant reference spans, but might not appear in others.

We observe that UMLS-*expand*, by adding related concepts to the query, achieves significant improvement over the baseline in terms of recall (+8.1%). Such improvement is expected, as UMLS-*expand* augments the citance with all possible formulations of the detected biomedical concepts. However, its precision is only comparable with the baseline, as it does not remove any noisy terms from the citance. Interestingly, we notice that its ROUGE-L precision greatly outperforms the baseline (+22.2%). This behavior is motivated by the fact that UMLS-*expand*, even when not retrieving all the correct reference spans, extracts certain parts of the reference articles that share many biomedical concepts with the gold spans, thus achieving high structural similarity.

The two combined methods (*NP* + UMLS-*expand* and UMLS-*reduce* + UMLS-*expand*) obtain the best overall performance compared to the baseline. UMLS-*reduce* + UMLS-*expand* obtains the highest recall among all methods. This outcome directly depends on the fact that all the synonyms of a certain biomedical concept are captured using UMLS-*expand*. However, unlike UMLS-*expand*, this combined method also achieves statistically significant improvement in terms of precision, as UMLS-*reduce* removes terms that can cause query drift.

NP + UMLS-*expand* has the highest overall performance, achieving a 25.9% increase over the baseline in terms of F-1, and an 18.8% increase in terms of ROUGE-L F-1. As previously mentioned, noun phrases are highly effective in identifying relevant biomedical concepts, as well as supporting expressions. Given the addition of UMLS-*expand*, synonyms of the extracted noun phrases are also considered, further increasing the chance of retrieving relevant reference spans.

The limited performance of all methods in terms of the overall weighted F-1 and ROUGE-L scores is expected due to the difficulty of the task, as further corroborated by the low agreement between annotators. As previously stated, this makes the task particularly challenging for any system, as identifying the most appropriate reference spans is highly nontrivial even for domain experts. Nevertheless, while full agreement between domain experts is not present, as it is shown in table 1, more than 60% of the time, annotators agree – at least partially – on the position of the reference spans. This makes the task worth exploring.

5 Conclusion

In this paper, we propose an information retrieval approach for the problem of matching reference text spans with citances. Our approach takes advantage of several general and domain specific query reformulation techniques. Our best performing method obtains a significant increase over the baseline (25.9% F-1). However, as the absolute performance of the system indicates, the task of identifying matching reference spans to a given citance is highly non trivial. This fact is also reflected by the high disagreement between domain experts annotations and suggests that further exploration of the task is needed.

Abstract

A major opportunity for NLP to have a real-world impact is in helping educators score student writing, particularly content-based writing (i.e., the task of automated short answer scoring). A major challenge in this enterprise is that scored responses to a particular question (i.e., labeled data) are valuable for modeling but limited in quantity. Additional information from the scoring guidelines for humans, such as exemplars for each score level and descriptions of key concepts, can also be used. Here, we explore methods for integrating scoring guidelines and labeled responses, and we find that stacked generalization (Wolpert, 1992) improves performance, especially for small training sets.

1 Introduction

Educational applications of NLP have considerable potential for real-world impact, particularly in helping to score responses to assessments, which could allow educators to focus more on instruction.

We focus on the task of analyzing short, content-focused responses from an assessment of reading comprehension, following previous work on short answer scoring (Leacock and Chodorow, 2003; Mohler et al., 2011; Dzikovska et al., 2013). This task is typically defined as a text regression or classification problem: we label student responses that consist of one or more sentences with scores on an ordinal scale (e.g. correct, partially correct, or incorrect; 1–5 score range, etc.). Importantly, in addition to the student response itself, we may also have available other information such as reference answers or descriptions of key concepts from the scoring guidelines for human scorers. Such information can be cheap to acquire since it is often generated as part of the assessment development process.

Generally speaking, most work on short answer scoring takes one of the following approaches:

- A **response-based** approach uses detailed features extracted from the student response itself (e.g., word n-grams, etc.) and learns a scoring function from human-scored responses.
- A **reference-based** approach compares the student response to reference texts, such as exemplars for each score level, or specifications of required content from the assessment's scoring guidelines. Various text similarity methods (Agirre et al., 2013) can be used.

These two approaches can, of course, be combined. However, to our knowledge, the issues of how to combine the approaches and when that is likely to be useful have not been thoroughly studied.

A challenge in combining the approaches is that the response-based approach produces a large set of sparse features (e.g., word n-gram indicators), while the reference-based approach produces a small set of continuous features (e.g., similarity scores between the response and exemplars for different score levels). A simple combination method is to train a model on the union of the feature sets (§3.3). However, the dense reference features may be lost among the many sparse response features.

*Work done when Keisuke Sakaguchi was an intern at ETS. Michael Heilman is now a data scientist at Civis Analytics.

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1049–1054,
Denver, Colorado, May 31 – June 5, 2015.

Therefore, we apply stacked generalization (i.e. stacking) (Wolpert, 1992; Sakkis et al., 2001; Torres Martins et al., 2008) to build an ensemble of the response- and reference-based approaches. To our knowledge, there is little if any research investigating the value of stacking for NLP applications such as automated scoring.[1]

The contributions of this paper are as follows: (1) we investigate various reference-based features for short answer scoring, (2) we apply stacking (Wolpert, 1992) in order to combine the reference- and response-based methods, and (3) we demonstrate that the stacked combination outperforms other models, especially for small training sets.

2 Task and Dataset

We conduct our experiments on short-answer questions that are developed under the *Reading for Understanding* (RfU) assessment framework. This framework is designed to measure the reading comprehension skills of students from grades 6 through 9 by attempting to assess whether the reader has formed a coherent mental model consistent with the text discourse. A more detailed description is provided by Sabatini and O'Reilly (2013).

We use 4 short-answer questions based on two different reading passages. The first passage is a 1300-word short story. A single question ("Q1" hereafter) asks the reader to read the story and write a 5–7 sentence synopsis in her own words that includes all the main characters and action from the story but does *not* include any opinions or information from outside the story. The second passage is a 700-word article that describes the experiences of European immigrants in the late 19th and early 20th centuries. There are 3 questions associated with this passage: two that ask the reader to summarize one section each in the article ("Q2" and "Q4") and a third that asks to summarize the entire article ("Q3"). These 3 questions ask the reader to restrict his or her responses to 1–2 sentences each.

Each question includes the following:

- **scored responses**: short responses written by students, scored on a 0 to 4 scale for the first question, and 0 to 3 for the other 3.
- **exemplars**: one or two exemplar responses for each score level, and
- **key concepts**: several ($\leq$ 10) sentences briefly expressing key concepts in a correct answer.

The data for each question is split into a training and testing sets. For each question, we have about 2,000 scored student responses.

Following previous work on automatic scoring (Shermis and Burstein, 2013), we evaluate performance using the quadratically weighted κ (Cohen, 1968) between human and machine scores (rounded and trimmed to the range of the training scores).

3 Models for Short Answer Scoring

Next, we describe our implementations of the response- and reference-based scoring methods. All models use support vector regression (SVR) (Smola and Schölkopf, 2004), with the complexity parameter tuned by cross-validation on the training data.[2]

3.1 Response-based

Our implementation of the response-based scoring approach ("resp" in §4) uses SVR to estimate a model to predicts human scores for text responses. Various sparse binary indicators of linguistic features are used:

- binned response length (e.g. the `length-7` feature fires when the character contains 128-255 characters.)
- word n-grams from $n = 1$ to 2
- character n-grams from $n = 2$ to 5, which is more robust than word n-gram regarding spelling errors in student responses
- syntactic dependencies in the form of Parent-Label-Child (e.g. `boy-det-the` for "the boy")
- semantic roles in the form of PropBank[3] style (e.g. `say.01-A0-boy` for "(the) boy said")

[1] Some applications have used stacking but not analyzed its value. For example, many participants used stacking in the ASAP2 competition `http://http://www.kaggle.com/c/asap-sas`. Also, Heilman and Madnani (2013) used stacking for Task 7 of SemEval 2013.

[2] We used the implementation of SVR in scikit-learn (Pedregosa et al., 2011) via SKLL (`https://github.com/EducationalTestingService/skll`) version 0.27.0. Other than the complexity parameter, we used the defaults.

[3] `http://verbs.colorado.edu/~mpalmer/projects/ace.html`

The syntactic and semantic features were extracted using the ClearNLP parser.[4] We used the default models and options for the parser. We treat this model as a strong baseline to which we will add reference-based features.

3.2 Reference-based

Our implementation of the reference-based approach ("ref" in §4) uses SVR to estimate a model to predict human scores from various measures of the similarity between the response and information from the scoring guidelines provided to the human scorers. Specifically, we use the following information from §2: (a) sentences expressing key concepts that should be present in correct responses, and (b) small sets of exemplar responses for each score level. For each type of reference, we use the following similarity metrics:

- **BLEU**: the BLEU machine translation metric (Papineni et al., 2002), with the student response as the translation hypothesis. When using BLEU to compare the student response to the (much shorter) sentences containing key concepts, we ignore the brevity penalty.
- **word2vec cosine**: the cosine similarity between the averages of the word2vec vectors (Mikolov et al., 2013) of content words in the response and reference texts (e.g., exemplar), respectively.[5,6]
- **word2vec alignment**: the alignment method below with word2vec word similarities.
- **WordNet alignment**: the alignment method below with the Wu and Palmer (1994) WordNet (Miller, 1995) similarity score.

The WordNet and word2vec alignment metrics are computed as follows, where S is a student response, R is one of a set of reference texts, W_s and W_r are content words in S and R, respectively, and $Sim(W_s, W_r)$ is the word similarity function:

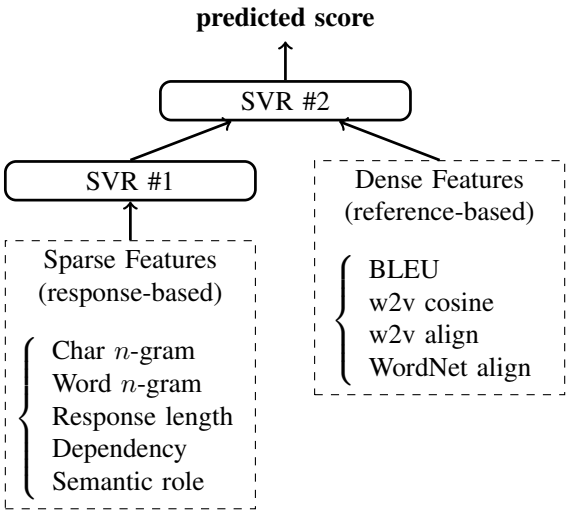

Figure 1: Stacking model for short answer scoring

$$\frac{1}{len(S)} \sum_{W_s} \max_{W_r \in R} Sim(W_s, W_r) \quad (1)$$

When R is one of a set of reference texts (e.g., one of multiple exemplars available for a given score point), we use the maximum similarity over available values of R. In our data, there are multiple exemplars per score point, but only one text (usually, a single sentence) per key concept. In other words, we select the most similar exemplar response for each score level.

3.3 Simple Model Combination

One obvious way to combine the response- and reference-based models is to simply train a single model that uses both the sparse features of the student response and the dense, real-valued similarity features. Our experiments (§4) include such a model as a strong baseline, using SVR to estimate feature weights.

3.4 Model Combination with Stacking

In preliminary experiments with the training data, we observed no gains for the simple combination model over the component models. One potential challenge of combining the two scoring approaches is that the weights for the dense, reference-based features may be difficult to properly esti-

[4] `http://www.clearnlp.com`, v2.0.2

[5] The word2vec model was trained on the English Wikipedia as of June 2012, using gensim (`http://radimrehurek.com/gensim/`) with 100 dimensions, a context window of 5, a minimum count of 5 for vocabulary items, and the default skip-gram architecture.

[6] We define content words as ones whose POS tags begin with "N" (nouns), "V" (verbs), "J" (adjectives), or "R" (adverbs).

mate due to regularization[7] and the large number of sparse, mostly irrelevant linguistic features from the response-based approach. In fact, the reference-based sparse features constitute almost 90% of the entire feature set, while the response-based dense features constitute the remaining 10%.

This leads us to explore stacking (Wolpert, 1992), an ensemble technique where a top-layer model makes predictions based on predictions from lower-layer models. Here, we train a lower-layer model to aggregate the sparse response-based features into a single "response-based prediction" feature, and then train an upper-layer SVR model that includes that feature along with all of the reference-based features. Figure 1 shows the details.[8]

For training our stacking model, we first train the response-based regression model (SVR #1 in Figure 1), and then train the reference-based regression model (SVR #2) with an additional prediction feature value from the response-based model. Specifically, the lower-layer model concentrates sparse and binary features into a single continuous value, which accords with reference-based dense features in the upper-layer model. In training the lower-layer SVR on the training data, computing the response-based prediction feature (i.e., output of the lower-layer SVR) from the sparse features is similar to k-fold cross-validation ($k = 10$ here): the prediction feature values are computed for each fold by response-based SVR models trained on the remaining folds. In training the upper-layer SVR on the testing data, this prediction feature is computed by a single model trained on the entire training set.

4 Experiments

This section describes two experiments: an evaluation of reference-based similarity metrics, and an evaluation of methods for combining the reference- and response-based features by stacking. As mentioned in §2, we evaluate performance using quadratically weighted κ between the human and predicted scores.

[7] Another possible combination approach would be to use the combination method from §3.3 but apply less regularization to the reference-based features, or, equivalently, scale them by a large constant. We only briefly explored this through training set cross-validation. The stacking approach seemed to perform at least as well in general.

[8] It would also be possible to also make a lower-layer model for the reference-based features, though doing this did not show benefits in preliminary experiments.

	Q1	Q2	Q3	Q4
BLEU	.72	.45	.60	.52
word2vec cosine	.75	.45	.61	.52
word2vec alignment	.76	.47	.61	.51
WordNet alignment	.73	.49	.59	.51
All ("ref")	.78	.52	.66	.59
length	.68	.42	.59	.51
response-based ("resp")	.82	.72	.75	.74

Table 1: Training set cross-validation performance of reference-based models, in quadratically weighted κ, with baselines for comparison. The response-based ("resp") model is a stronger baseline as described in §3.3. Note that each reference-based model includes the length bin features for a fair comparison to "resp".

4.1 Similarity Metrics

We first evaluate the similarity metrics from §3.2 using 10-fold cross-validation on the training data. We evaluated SVR models for each metric individually as well as a model combining all features from all metrics. In all models, we included the response length bin features (§3.1) as a proxy for response-based features. We compare to the response-based model (§3.1) and to a model consisting of only the response length bin feature.

The results are shown in Table 1. Each similarity metric by itself does not always improve the performance remarkably from the baseline (i.e., the response length bin features). However, when we incorporate all the similarity features, we obtained substantial gain in all 4 questions. In the subsequent model combination experiment, therefore, we used all similarity features to represent the reference-based approach because it outperformed the other similarity models.

4.2 Model Combination

Next, we tested models that use both response- and reference-based features on a held-out test set, which contains 400 responses per question. We evaluated the response-based ("resp", §3.1) and reference-based ("ref", §3.2) individual models as well as the two combination methods ("ref+resp", §3.3 and "ref+resp stacking", §3.4). We also eval-

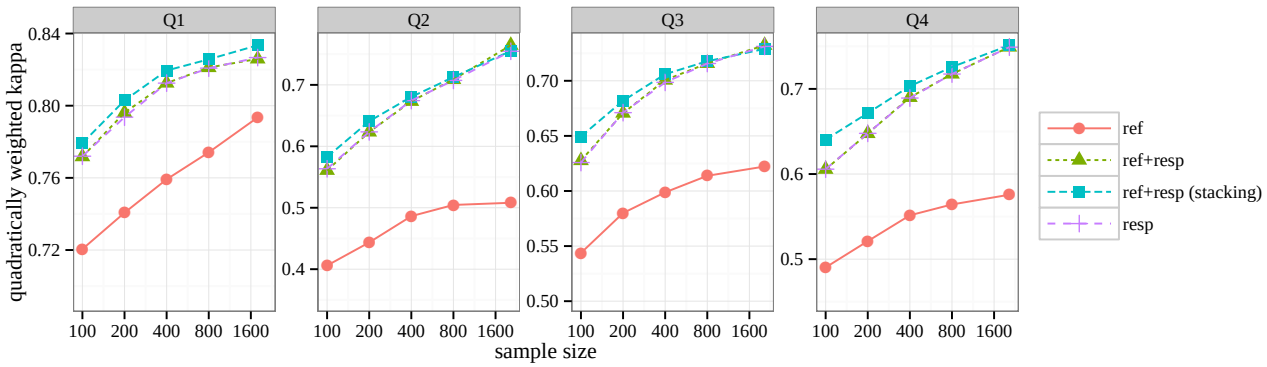

Figure 2: Test set results for various models trained on differently sized random samples of the training data. Each point represents an average over 20 runs, except for the rightmost points for each question, which correspond to training on the full training set. Note that the "resp" and "ref+resp" lines mostly overlap.

uated models trained on differently sized subsets of the training data. For each subset size, we averaged over 20 samples. The results are in Figure 2.

The performance of all models increased as training data grew, though there were diminishing returns (note the logarithmic scale). Also, the models with response-based features outperform those with just reference-based features, as observed previously by Heilman and Madnani (2013).

Most importantly, while all models with response-based features perform about the same with 1,000 training examples or higher, the stacked model tended to outperform the other models for cases where the number of training examples was very limited.[9] This indicates that stacking enables learning better feature weights than a simple combination when the feature set contains a mixture of sparse as well as dense features, particularly for smaller data sizes.

5 Conclusion

In this paper, we explored methods for using different sources of information for automatically scoring short, content-based assessment responses. We combined a response-based method that uses sparse features (e.g., word and character n-grams) with a reference-based method that uses a small number of features for the similarity between the response and information from the scoring guidelines (exemplars and key concepts).

On four reading comprehension assessment questions, we found that a combined model using stacking outperformed a non-stacked combination, particularly for the most practically relevant cases where training data was limited. We believe that such an approach may be useful for dealing with diverse feature sets in other automated scoring tasks as well as other NLP tasks.

As future work, it might be interesting to explore a more sophisticated model where the regression models in different layers are trained simultaneously by back-propagating the error of the upper-layer, as in neural networks.

[9] We are not aware of an appropriate significance test for experiments where subsets of the training data are used. However, the benefits of stacking seem unlikely to be due to chance. For all 4 items, stacking outperformed the non-stacking combination for 18 or more of the 20 200-response training subsets (note that under a binomial test, this would be significant with $p < 0.001$). Also, for the 100-response training subsets, stacking was better for 16 or more of the 20 subsets ($p < 0.01$).

Acknowledgments

We would like to thank John Sabatini and Kietha Biggers for providing us with the RfU datasets. We would also like to thank Dan Blanchard, Aoife Cahill, Swapna Somasundaran, Anastassia Loukina, Beata Beigman Klebanov, and the anonymous reviewers for their help.

Socially-Informed Timeline Generation for Complex Events

Lu Wang **Claire Cardie** **Galen Marchetti**

Abstract

Existing timeline generation systems for complex events consider only information from traditional media, ignoring the rich social context provided by user-generated content that reveals representative public interests or insightful opinions. We instead aim to generate socially-informed timelines that contain both news article summaries and selected user comments. We present an optimization framework designed to balance topical cohesion between the article and comment summaries along with their informativeness and coverage of the event. Automatic evaluations on real-world datasets that cover four complex events show that our system produces more informative timelines than state-of-the-art systems. In human evaluation, the associated comment summaries are furthermore rated more insightful than editor's picks and comments ranked highly by users.

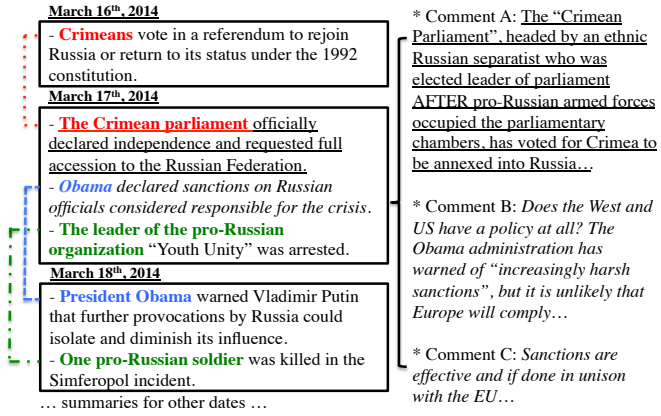

Figure 1: A snippet of the event timeline on Ukraine Crisis is displayed on the left. On the right, we display a set of representative comments addressing the article summary of March 17^{th}. Comment A (underlined) brings a perspective on "Crimean parliament passes declaration of independence" (the article sentence is also underlined on the left). Comments B and C focus on Obama's sanctions on Ukrainian and Russian officials. Sentences linked by edges belong to the same event thread, which is centered on the entities with the same color.

1 Introduction

Social media sites on the Internet provide increasingly more, and increasingly popular, means for people to voice their opinions on trending events. Traditional news media — the New York Times and CNN, for example — now provide online mechanisms that allow and encourage readers to share reactions, opinions, and personal experiences relevant to a news story. For complex emerging events, in particular, user comments can provide relevant, interesting and insightful information beyond the facts reported in the news. But their large volume and tremendous variation in quality make it impossible for readers to efficiently digest the user-generated content, much less integrate it with reported facts from the dozens or hundreds of news reports produced on the event each day.

In this work, we present a *socially-informed timeline generation system* that jointly generates a news article summary and a user comment summary for each day of an ongoing complex event. A sample (gold standard) timeline snippet for Ukraine Crisis is shown in Figure 1. The event timeline is on the left; the comment summary for March 17^{th} is on the right.

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1055–1065,
Denver, Colorado, May 31 – June 5, 2015.

While generating timelines from news articles and summarizing user comments have been studied as separate problems (Yan et al., 2011; Ma et al., 2012), their joint summarization for timeline generation raises new challenges. Firstly, there should be a tight connection between the article and comment portion of the timeline. By definition, users comment on socially relevant events. So the important part of articles and insightful comments should both cover these events. Moreover, good reading experience requires that the article summary and comment summary demonstrate evident connectivity. For example, Comment C in Figure 1 ("Sanctions are effective and if done in unison with the EU") is obscure without knowing the context that "sanctions are imposed by U.S". Simply combining the outputs from a timeline generation system and a comment summarization system may lead to timelines that lack cohesion. On the other hand, articles and comments are from intrinsically different genres of text: articles emphasize facts and are written in a professional style; comments reflect opinions in a less formal way. Thus, it could be difficult to recognize the connections between articles and comments. Finally, it is also challenging to enforce continuity in timelines with many entities and events.

To address the challenges mentioned above, we formulate the timeline generation task as an optimization problem, where we maximize topic cohesion between the article and comment summaries while preserving their ability to reflect *important* concepts and subevents, adequate *coverage* of mentioned topics, and *continuity* of the timeline as it is updated with new material each day. We design a novel alternating optimizing algorithm that allows the generation of a high quality article summary and comment summary via mutual reinforcement. We demonstrate the effectiveness of our algorithm on four disparate complex event datasets collected over months from the New York Times, CNN, and BBC. Automatic evaluation using ROUGE (Lin and Hovy, 2003) and gold standard timelines indicates that our system can effectively leverage user comments to outperform state-of-the-art approaches on timeline generation. In a human evaluation via Amazon Mechanical Turk, the comment summaries generated by our method were selected as the best in terms of informativeness and insightfulness in 66.7% and 51.7% of the evaluations (vs. 26.7% and 30.0% for randomly selected editor's-picks).

Especially, our optimization framework relies on two scoring functions that estimate the importance of including individual article sentences and user comments in the timeline. Based on the observation that entities or events frequently discussed in the user comments can help with identify summary-worthy content, we show that the scoring functions can be learned jointly by utilizing graph-based regularization. Experiments show that our joint learning model outperforms state-of-the-art ranking algorithms and other joint learning based methods when evaluated on sentence ranking and comment ranking. For example, we achieve an NDCG@3 of 0.88 on the Ukraine crisis dataset, compared to 0.77 from Yang et al. (2011) which also conducts joint learning between articles and social context using factor graphs.

Finally, to encourage continuity in the generated timeline, we propose an entity-centered event threading algorithm. Human evaluation demonstrates that users who read timelines with event threads write more informative answers than users who do not see the threads while answering the same questions. This implies that our system constructed threads can help users better navigate the timelines and collect relevant information in a short time.

For the rest of the paper, we first describe data collection (Section 2). We then introduce the joint learning model for importance prediction (Section 3). The full timeline generation system is presented in Section 4, which is followed by evaluations (Section 5). Related work and conclusion are in Sections 6 and 7.

2 Data Collection and Preprocessing

We crawled news articles from New York Times (NYT), CNN, and BBC on four trending events: the missing Malaysia Airlines Flight MH370 (MH370), the political unrest in Ukraine (Ukraine), the Israel-Gaza conflict (Israel-Gaza), and the NSA surveillance leaks (NSA). For each event, we select a set of key words (usually entities' name), which are used to filter out irrelevant articles. We collect comments for NYT articles through NYT community API, and comments for CNN articles via Disqus

API. [1] NYT comments come with information on whether a comment is an editor's-pick. The statistics on the four datasets are displayed in Table 1.[2]

	Time Span	# Articles	# Comments
MH370	03/08 - 06/30	955	406,646
Ukraine	03/08 - 06/30	3,779	646,961
Israel-Gaza	07/20 - 09/30	909	322,244
NSA	03/23 - 06/30	145	60,481

Table 1: Statistics on the four event datasets.

We extract parse trees, dependency trees, and coreference resolution results of articles and comments with Stanford CoreNLP (Manning et al., 2014). Sentences in articles are labeled with timestamps using SUTime (Chang and Manning, 2012).

We also collect all articles with comments from NYT in 2013 (henceforth NYT2013) to form a training set for learning importance scoring functions on articles sentences and comments (see Section 3). NYT2013 contains $3,863$ articles and $833,032$ comments.

3 Joint Learning for Importance Scoring

We first introduce a joint learning method that uses *graph-based regularization* to simultaneously learn two functions — a SENTENCE scorer and a COMMENT scorer — that predict the importance of including an individual news article sentence or a particular user comment in the timeline.

We train the model on the aforementioned NYT2013 dataset, where 20% of the articles and their comments are reserved for parameter tuning. Formally, the training data consists of a set of articles $D = \{d_i\}_{i=0}^{|D|-1}$. Each article d_i contains a set of sentences $x_{s_{d_i}} = \{x_{s_{d_i},j}\}_{j=0}^{|s_{d_i}|-1}$ and a set of associated comments $x_{c_{d_i}} = \{x_{c_{d_i},k}\}_{k=0}^{|c_{d_i}|-1}$, where $|s_{d_i}|$ and $|c_{d_i}|$ are the numbers of sentences and comments for d_i. For simplicity, we use x_s or x_c to denote a sentence or a comment wherever there is no ambiguity.

In addition, each article has a human-written abstract. We use the ROUGE-2 (Lin and Hovy, 2003) score of each sentence computed against the associated abstract as its gold-standard importance score. Each comment is assigned a gold-standard value of 1.0 if it is an editor's pick, or 0.0 otherwise.

The SENTENCE and COMMENT scorers rely on two classifiers, each designed to handle the special characteristics of news and user comments, respectively; and a graph-based regularizing constraint that encourages similarity between selected sentences and comments. We describe each component below.

Article SENTENCE **Importance.** Each sentence x_s in a news article is represented as a k-dimensional feature vector $\mathbf{x_s} \in \mathbb{R}^k$, with a gold-standard label y_s. We denote the training set as a feature matrix $\tilde{\mathbf{X}}_\mathbf{s}$, with a label vector $\tilde{\mathbf{Y}}_\mathbf{s}$. To produce the SENTENCE scoring function $f_s(x_s) = \mathbf{x_s} \cdot \mathbf{w_s}$, we use ridge regression to learn a vector $\mathbf{w_s}$ that minimizes $||\tilde{\mathbf{X}}_\mathbf{s}\mathbf{w_s} - \tilde{\mathbf{Y}}_\mathbf{s}||_2^2 + \beta_s \cdot ||\mathbf{w_s}||_2^2$. Features used in the model are listed in Table 2. We also impose the following *position-based regularizing constraint* to encode the fact that the first sentence in a news article usually conveys the most essential information: $\lambda_s \cdot \sum_{d_i} \sum_{x_{s_{d_i},j}, j\neq 0} ||(\mathbf{x_{s_{d_i},0}} - \mathbf{x_{s_{d_i},j}}) \cdot \mathbf{w_s} - (y_{s_{d_i},0} - y_{s_{d_i},j})||_2^2$, where $x_{s_{d_i},j}$ is the j-th sentence in document d_i. Term $(\mathbf{x_{s_{d_i},0}} - \mathbf{x_{s_{d_i},j}}) \cdot \mathbf{w_s}$ measures the difference in predicted scores between the first sentence and any other sentence. This value is expected be close to the true difference. We further construct $\tilde{\mathbf{X}}'_\mathbf{s}$ to contain all difference vectors $(\mathbf{x_{s_{d_i},0}} - \mathbf{x_{s_{d_i},j}})$, with $\tilde{\mathbf{Y}}'_\mathbf{s}$ as label difference vector. The objective function to minimize becomes

$$J_s(\mathbf{w_s}) = \\ ||\tilde{\mathbf{X}}_\mathbf{s}\mathbf{w_s} - \tilde{\mathbf{Y}}_\mathbf{s}||_2^2 + \lambda_s \cdot ||\tilde{\mathbf{X}}'_\mathbf{s}\mathbf{w_s} - \tilde{\mathbf{Y}}'_\mathbf{s}||_2^2 + \beta_s \cdot ||\mathbf{w_s}||_2^2 \quad (1)$$

User COMMENT **Importance.** Similarly, each comment x_c is represented as an $l-$dimensional feature vector $\mathbf{x_c} \in \mathbb{R}^l$, with label y_c. Comments in the training data are denoted with a feature matrix $\tilde{\mathbf{X}}_\mathbf{c}$ with a label vector $\tilde{\mathbf{Y}}_\mathbf{c}$. Likewise, we learn $f_c(x_c) = \mathbf{x_c} \cdot \mathbf{w_c}$ by minimizing $||\tilde{\mathbf{X}}_\mathbf{c}\mathbf{w_c} - \tilde{\mathbf{Y}}_\mathbf{c}||_2^2 + \beta_c \cdot ||\mathbf{w_c}||_2^2$. Features are listed in Table 3. We apply a *pairwise preference-based regularizing constraint* (Joachims, 2002) to incorporate a bias toward editor's picks: $\lambda_c \cdot \sum_{d_i} \sum_{x_{c_{d_i},j} \in \mathbf{E_{d_i}}, x_{c_{d_i},k} \notin \mathbf{E_{d_i}}} ||(\mathbf{x_{c_{d_i},j}} - \mathbf{x_{c_{d_i},k}}) \cdot \mathbf{w_c} - 1||_2^2$, where $\mathbf{E_{d_i}}$ are the editor's picks for d_i. Term $(\mathbf{x_{c_{d_i},j}} - \mathbf{x_{c_{d_i},k}}) \cdot \mathbf{w_c}$ enforces the separation of editor's picks from regular comments. We further construct $\tilde{\mathbf{X}}'_\mathbf{c}$ to contain all the pairwise differences

[1] BBC comment volume is low, so we do not collect it.

[2] The datasets are available at `http://www.cs.cornell.edu/~luwang/data.html`.

$(\mathbf{x_{c_{d_i},j}} - \mathbf{x_{c_{d_i},k}})$. $\tilde{\mathbf{Y}}'_{\mathbf{c}}$ is a vector of same size as $\tilde{\mathbf{X}}'_{\mathbf{c}}$ with each element as 1. Thus, the objective function to minimize is:

$$J_c(\mathbf{w_c}) = \\ ||\tilde{\mathbf{X}}_{\mathbf{c}}\mathbf{w_c} - \tilde{\mathbf{Y}}_{\mathbf{c}}||_2^2 + \lambda_c \cdot ||\tilde{\mathbf{X}}'_{\mathbf{c}}\mathbf{w_c} - \tilde{\mathbf{Y}}'_{\mathbf{c}}||_2^2 + \beta_c \cdot ||\mathbf{w_c}||_2^2 \quad (2)$$

Graph-Based Regularization. The regularizing constraint is based on two mutually reinforcing hypotheses: (1) the importance of a sentence depends partially on the availability of sufficient insightful comments that touch on topics in the sentence; (2) the importance of a comment depends partially on whether it addresses notable events reported in the sentences. For example, we want our model to bias $\mathbf{w_s}$ to predict a high score for a sentence with high similarity to numerous insightful comments.

We first create a bipartite graph from sentences and comments on the same articles, where edge *weights* are based on the content similarity between a sentence and a comment (TF-IDF similarity is used). Let $\tilde{\mathbf{R}}$ be an $N \times M$ adjacency matrix, where N and M are the numbers of sentences and comments. R_{sc} is the similarity between sentence x_s and comment x_c. We normalize $\tilde{\mathbf{R}}$ by $\tilde{\mathbf{Q}} = \tilde{\mathbf{D}}^{-\frac{1}{2}}\tilde{\mathbf{R}}\tilde{\mathbf{D}'}^{-\frac{1}{2}}$, where $\tilde{\mathbf{D}}$ and $\tilde{\mathbf{D}}'$ are diagonal matrices: $\tilde{\mathbf{D}} \in \mathbb{R}^{N\times N}$, $D_{i,i} = \sum_{j=1}^{M} R_{i,j}$; $\tilde{\mathbf{D}}' \in \mathbb{R}^{M\times M}$, $D'_{j,j} = \sum_{i=1}^{N} R_{i,j}$. The interplay between the two types of data is encoded in the following regularizing constraint:

$$J_{s,c}(\mathbf{w_s}, \mathbf{w_c}) = \\ \lambda_{sc} \cdot \sum_{d_i} \sum_{x_s \in x_{s_{d_i}}, x_c \in x_{c_{d_i}}} Q_{x_s,x_c} \cdot (\mathbf{x_s} \cdot \mathbf{w_s} - \mathbf{x_c} \cdot \mathbf{w_c})^2 \quad (3)$$

Full Objective Function. Thus, the full objective function consists of the three parts discussed above:

$$J(\mathbf{w_s}, \mathbf{w_c}) = J_s(\mathbf{w_s}) + J_c(\mathbf{w_c}) + J_{s,c}(\mathbf{w_s}, \mathbf{w_c}) \quad (4)$$

Furthermore, using the following notation,

$$\tilde{\mathbf{X}} = \begin{bmatrix} \tilde{\mathbf{X}}_{\mathbf{s}} & \mathbf{0} \\ \mathbf{0} & \tilde{\mathbf{X}}_{\mathbf{c}} \end{bmatrix} \quad \tilde{\mathbf{Y}} = \begin{bmatrix} \tilde{\mathbf{Y}}_{\mathbf{s}} \\ \tilde{\mathbf{Y}}_{\mathbf{c}} \end{bmatrix} \quad \tilde{\mathbf{X}}' = \begin{bmatrix} \tilde{\mathbf{X}}'_{\mathbf{s}} & \mathbf{0} \\ \mathbf{0} & \tilde{\mathbf{X}}'_{\mathbf{c}} \end{bmatrix} \quad \tilde{\mathbf{Y}}' = \begin{bmatrix} \tilde{\mathbf{Y}}'_{\mathbf{s}} \\ \tilde{\mathbf{Y}}'_{\mathbf{c}} \end{bmatrix}$$

$$\tilde{\boldsymbol{\beta}} = \begin{bmatrix} \beta_s\mathbf{I_k} & \mathbf{0} \\ \mathbf{0} & \beta_c\mathbf{I_l} \end{bmatrix} \quad \tilde{\boldsymbol{\lambda}} = \begin{bmatrix} \lambda_s\mathbf{I}_{|\mathbf{X}'_{\mathbf{s}}|} & \mathbf{0} \\ \mathbf{0} & \lambda_c\mathbf{I}_{|\mathbf{X}'_{\mathbf{c}}|} \end{bmatrix}$$

$$\tilde{\mathbf{L}} = \begin{bmatrix} \lambda_{sc}\mathbf{I}_{|\mathbf{X_s}|} & -\lambda_{sc}\tilde{\mathbf{Q}} \\ -\lambda_{sc}\tilde{\mathbf{Q}}^{\mathbf{T}} & \lambda_{sc}\mathbf{I}_{|\mathbf{X_c}|} \end{bmatrix} \quad \mathbf{w} = \begin{bmatrix} \mathbf{w_s} \\ \mathbf{w_c} \end{bmatrix}$$

we can show a **closed form solution** to Equation 4 as follows:

$$\hat{\mathbf{w}} = \\ (\tilde{\mathbf{X}}^{\mathbf{T}}\tilde{\mathbf{L}}\tilde{\mathbf{X}} + \tilde{\mathbf{X}}^{\mathbf{T}}\tilde{\mathbf{X}} + \tilde{\mathbf{X}}'^{\mathbf{T}}\tilde{\boldsymbol{\lambda}}\tilde{\mathbf{X}}' + \tilde{\boldsymbol{\beta}})^{-1}(\tilde{\mathbf{X}}^{\mathbf{T}}\tilde{\mathbf{Y}} + \tilde{\mathbf{X}}'^{\mathbf{T}}\tilde{\boldsymbol{\lambda}}\tilde{\mathbf{Y}}') \quad (5)$$

4 Timeline Generation

Now we present an optimization framework for timeline generation. Formally, for each day, our system takes as input a set of sentences V_s and a set of comments V_c to be summarized, and the (automatically generated) timeline $\mathcal{T}$ (represented as threads) for days prior to the current day. It then identifies a subset $S \subseteq V_s$ as the article summary and a subset $C \subseteq V_c$ as the comment summary by maximizing the following function:

$$\mathcal{Z}(S, C; \mathcal{T}) = \mathcal{S}_{qual}(S; \mathcal{T}) + \mathcal{C}_{qual}(C) + \delta\mathcal{X}(S, C) \quad (6)$$

where $\mathcal{S}_{qual}(S; \mathcal{T})$ measures the quality of the article summary S in the context of the historical timeline represented as event threads $\mathcal{T}$; $\mathcal{C}_{qual}(C)$ computes the quality of the comment summary C; and $\mathcal{X}(S, C)$ estimates the connectivity between S and C.

We solve this maximization problem using an alternating optimization algorithm which is outlined

in Section 4.4. In general, we alternately search for a better article summary S with hill climbing search and a better comment summary C with Ford-Fulkerson algorithm until convergence.

In the rest of this section, we first describe an *entity-centered event threading* algorithm to construct event threads $\mathcal{T}$ which are used to boost article timeline continuity. Then we explain how to compute $\mathcal{S}_{qual}(S;\mathcal{T})$ and $\mathcal{C}_{qual}(C)$ in Section 4.2, followed by $\mathcal{X}(S,C)$ in Section 4.3.

4.1 Entity-Centered Event Threading

We present an event threading process where each thread connects sequential events centered on a set of relevant *entities*. For instance, the following thread connects events about *Obama*'s action towards the annexation of Crimea by *Russia*:

Day 1: *Obama* declared sanctions on *Russian officials*.
Day 2: *President Obama* warned *Russian*.
Day 3: *Obama* urges *Russian* to move back its troops.
Day 4: *Obama* condemns *Russian* aggression in Ukraine.

We first collect relation extractions as *(entity, relation, entity)* triples from OLLIE (Mausam et al., 2012), a dependency relation based open information extraction system. We retain extractions with confidence scores higher than 0.5. We further design syntactic patterns based on Fader et al. (2011) to identify relations expressed as a combination of a verb and nouns. Each relation contains at least one event-related word (Ritter et al., 2012).

The *entity-centered event threading* algorithm works as follows: on the first day, each sentence in the summary becomes an individual cluster; thereafter, each sentence in the current day's article summary either gets attached to an existing thread or starts a new thread. The updated threads then become the input to next day's summary generation process. On day n, we have a set of threads $\mathcal{T} = \{\tau : \mathbf{s_1}, \mathbf{s_2}, \cdots, \mathbf{s_{n-1}}\}$ constructed from previous $n-1$ days, where $\mathbf{s_i}$ represents the set of sentences attached to thread τ from day i. The *cohesion* between a new sentence $s \in S$ and a thread τ is denoted as $cohn(s,\tau)$. s is attached to $\hat{\tau}$ if there exists $\hat{\tau} = \max_{\tau \in T} cohn(s,\tau)$ and $cohn(s,\hat{\tau}) > 0.0$. Otherwise, s becomes a new thread. We define $cohn(s,\tau) = \min_{\mathbf{s_i}\in\tau, \mathbf{s_i}\neq\emptyset} tfsimi(\mathbf{s_i}, s)$, where $tfsimi(\mathbf{s_i}, s)$ measures the TF similarity between $\mathbf{s_i}$ and s. We consider unigrams/bigrams/trigrams generated from the entities of our event extractions.

4.2 Summary Quality Measurement

Recall that we learned two separate importance scoring functions for sentences and comments, which will be denoted here as $imp_s(s)$ and $imp_c(c)$. With an article summary S and threads $\mathcal{T} = \{\tau_i\}$, the **article summary quality** function $\mathcal{S}_{qual}(S;\mathcal{T})$ has the following form:

$$\mathcal{S}_{qual}(S;\mathcal{T}) = \sum_{s\in S} imp(s)$$
$$+\theta_{cov} \sum_{s'\in V_s} \min(\sum_{s\in S} tfidf(s,s'), \alpha \sum_{\hat{s}\in V_s} tfidf(\hat{s},s'))$$
$$+ \theta_{cont} \sum_{\tau\in\mathcal{T}} \max_{s_k\in S} cohn(s_k,\tau)$$

$tfidf(\cdot,\cdot)$ is the TF-IDF similarity function. $\mathcal{S}_{qual}(S;\mathcal{T})$ captures three desired qualities of an article summary: *importance* (first item), *coverage* (second item), and the *continuity* of the current summary to previously generated summaries. The coverage function has been used to encourage summary diversity and reduce redundancy (Lin and Bilmes, 2011; Wang et al., 2014). The continuity function considers how well article summary S can be attached to each event thread, thus favors summaries that can be connected to multiple threads.

Parameters θ_{cov} and α are tuned on multi-document summarization dataset DUC 2003 (Over and Yen, 2003). Experiments show that system performance peaks and is stable for $\theta_{cont} \in [1.0, 5.0]$. We thus fix θ_{cont} to 1.0. We discard sentences with more than 80% of content words covered by historical summaries. We use BASIC to denote a system that only optimizes on importance and coverage (i.e. first two items in $\mathcal{S}_{qual}(S;\mathcal{T})$). The system optimizing $\mathcal{S}_{qual}(S;\mathcal{T})$ is henceforth called THREAD.

The **comment summary quality** function simply takes the form $\mathcal{C}_{qual}(C) = \sum_{c\in C} imp_c(c)$.

4.3 Connectivity Measurement

We encode two objectives in the connectivity function $\mathcal{X}(S,C)$: (1) encouraging topical cohesion (i.e. connectivity) between article summary and comment summary; and (2) favoring comments that cover diversified events.

Let $conn(s,c)$ measure content similarity between a sentence $s \in S$ and a comment $c \in C$. Connectivity between article summary S and comment summary C is computed as follows. We build a bipartite graph $\mathcal{G}$ between S and C with edge weight as $conn(s,c)$.

We then find an edge set $\mathcal{M}$, the best matching of $\mathcal{G}$. $\mathcal{X}(S, C)$ is defined as the sum over edge weights in $\mathcal{M}$, i.e. $\mathcal{X}(S, C) = \sum_{e \in \mathcal{M}} weight(e)$. An example is illustrated in Figure 2.

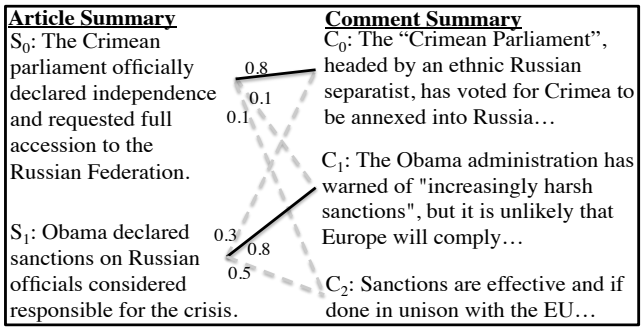

Figure 2: An example on computing the connectivity between an article summary (left) and a comment summary (right) via best matching in bipartite graph. Number on each edge indicates the content similarity between a sentence and a comment. Solid lines are edges in the best matching graph. For this example, the connectivity $\mathcal{X}(S, C)$ is $0.8 + 0.8 = 1.6$.

We consider two options for $conn(s, c)$. One is *lexical similarity* which is based on TF-IDF vectors. Another is *semantic similarity*. Let $R_s = \{(a_s, r_s, b_s)\}$ and $R_c = \{(a_c, r_c, b_c)\}$ be the sets of dependency relations in s and c. $conn(s, c)$ is calculated as:

$$\sum_{(a_s, r_s, b_s) \in R_s} \max_{\substack{(a_c, r_c, b_c) \in R_c \\ r_s = r_c}} simi(a_s, a_c) \times simi(b_s, b_c)$$

where $simi(\cdot, \cdot)$ is a word similarity function. We experiment with shortest path based similarity defined on WordNet (Miller, 1995) and Cosine similarity with word vectors trained on Google news (Mikolov et al., 2013). Systems using the three metrics that optimize $\mathcal{Z}(S, C; \mathcal{T})$ are henceforth called THREAD+OPT$_{\texttt{TFIDF}}$, THREAD+OPT$_{\texttt{WordNet}}$ and THREAD+OPT$_{\texttt{WordVec}}$.

4.4 An Alternating Optimization Algorithm

To maximize the full objective function $\mathcal{Z}(S, C; \mathcal{T})$, we design a novel alternating optimization algorithm (Alg. 1) where we alternately find better S and C.

We initialize S_0 by a greedy algorithm (Lin and Bilmes, 2011) with respect to $\mathcal{S}_{qual}(S; \mathcal{T})$. Notice that $\mathcal{S}_{qual}(S; \mathcal{T})$ is a submodular function, so that the greedy solution is a $1 - 1/e$ approximation to the optimal solution of $\mathcal{S}_{qual}(S; \mathcal{T})$. Fixing S_0, we model the problem of finding C_0 that maximizes $\mathcal{C}_{qual}(C) + \delta \mathcal{X}(S_0, C)$ as a maximum-weight bipartite graph matching problem. This problem can be reduced to a maximum network flow problem, and then be solved by Ford-Fulkerson algorithm (details are discussed in (Kleinberg and Tardos, 2005)). Thereafter, for each iteration, we alternately find a better S_t with regard to $\mathcal{S}_{qual}(S; \mathcal{T}) + \delta \mathcal{X}(S, C_{t-1})$ using hill climbing, and an exact solution C_t to $\mathcal{C}_{qual}(C) + \delta \mathcal{X}(S_t, C)$ with Ford-Fulkerson algorithm. Iteration stops when the increase of $\mathcal{Z}(S, C)$ is below threshold ϵ (set to 0.01). System performance is stable when we vary $\delta \in [1.0, 10.0]$, so we set $\delta = 1.0$.

Input : sentences V_s, comments V_c, threads $\mathcal{T}$, δ, threshold ϵ, functions $\mathcal{Z}(S, C; \mathcal{T})$, $\mathcal{S}_{qual}(S; \mathcal{T})$, $\mathcal{C}_{qual}(C)$, $\mathcal{X}(S, C)$
Output: article summary S, comment summary C

```
/* Initialize S and C by greedy algorithm
   and Ford-Fulkerson algorithm                */
```
$S_0 \leftarrow \max_S \mathcal{S}_{qual}(S; \mathcal{T})$;
$C_0 \leftarrow \max_C \mathcal{C}_{qual}(C) + \delta \mathcal{X}(S_0, C)$;
$t \leftarrow 1$;
$\Delta \mathcal{Z} \leftarrow \infty$;
while $\Delta \mathcal{Z} > \epsilon$ **do**
```
  /* Step 1: Hill climbing algorithm    */
```
  $S_t \leftarrow \max_S \mathcal{S}_{qual}(S; \mathcal{T}) + \delta \mathcal{X}(S, C_{t-1})$;
```
  /* Step 2: Ford-Fulkerson algorithm   */
```
  $C_t \leftarrow \max_C \mathcal{C}_{qual}(C) + \delta \mathcal{X}(S_t, C)$;
  $\Delta \mathcal{Z} = \mathcal{Z}(S_t, C_t; \mathcal{T}) - \mathcal{Z}(S_{t-1}, C_{t-1}; \mathcal{T})$;
  $t \leftarrow t + 1$;
end

Algorithm 1: Generate article summary and comment summary for a given day via alternating optimization .

Algorithm 1 is guaranteed to find a solution at least as good as S_0 and C_0. It progresses only if Step 1 finds S_t that improves upon $\mathcal{Z}(S_{t-1}, C_{t-1}; \mathcal{T})$, and Step 2 finds C_t where $\mathcal{Z}(S_t, C_t; \mathcal{T}) \geq \mathcal{Z}(S_t, C_{t-1}; \mathcal{T})$.

5 Experimental Results

5.1 Evaluation of SENTENCE and COMMENT Importance Scorers

We test importance scorers (Section 3) on single document *sentence ranking* and *comment ranking*.

For both tasks, we compare with two previous systems on joint ranking and summarization of news articles and tweets. *Yang et al. (2011)* employ supervised learning based on factor graphs to model content similarity between the two types of data. We use the same features for this model. *Gao et al. (2012)* summarize by including the complementary information between articles and

tweets, which is estimated by an unsupervised topic model.[3] We also consider two state-of-the-art rankers: *RankBoost* (Freund et al., 2003) and *LambdaMART* (Burges, 2010). Finally, we use a *position baseline* that ranks sentences based on their position in the article, and a *rating baseline* that ranks comments based on positive user ratings.

We evaluate using normalized discounted cumulative gain at top 3 returned results (NDCG@3). Sentences are considered relevant if they have ROUGE-2 scores larger than 0.0 (computed against human abstracts), and comments are considered relevant if they are editor's picks.[4] Figure 3 demonstrates that our joint learning model uniformly outperforms all the other comparisons for both ranking tasks. In general, supervised learning based approaches (e.g. our method, Yang et al. (2011), RankBoost, and LambdaMART) produce better results than unsupervised method (e.g. Gao et al. (2012)).[5]

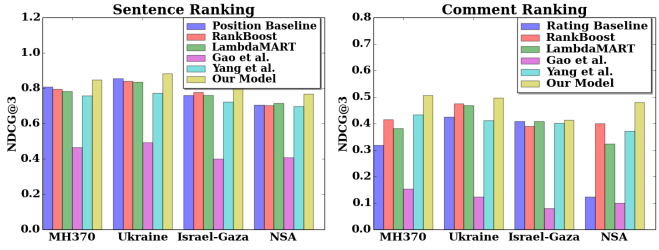

Figure 3: Evaluation of sentence and comment ranking on the four datasets by using normalized discounted cumulative gain at top 3 returned results (NDCG@3). Our joint learning based approach uniformly outperforms all the other comparisons.

5.2 Leveraging User Comments

In this section, we test if our system can leverage comments to produce better article-based summaries for event timelines. We collect **gold-standard timelines** for each of the four events from the corresponding Wikipedia page(s), NYT topic page, or BBC news page.

We consider two existing timeline creation systems that only utilize news articles, and a timeline generated from single-article human abstracts: (1) CHIEU AND LEE (2004) select sentences with high "interestingness" and "burstiness" using a likelihood ratio test to compare word distributions of sentences with articles in neighboring days. (2) YAN ET AL. (2011) design an evolutionary summarization system that selects sentences based on on coverage, coherence, and diversity. (3) We construct a timeline from the human ABSTRACTs provided with each article: we sort them chronologically according to article timestamps and add abstract sentences into each daily summary until reaching the word limit.

We test on five variations of our system. The first two systems generate article summaries with no comment information by optimizing $S_{qual}(S;\mathcal{T})$ using a greedy algorithm: BASIC ignores event threading; THREAD considers the threads. THREAD+OPT$_{\texttt{TFIDF}}$, THREAD+OPT$_{\texttt{WordNet}}$ and THREAD+OPT$_{\texttt{WordVec}}$ (see Section 4.3) leverage user comments to generate article summaries as well as comment summaries based on alternating optimization of Equation 3. Although comment summaries are generated, they are not used in the evaluation.

For all systems, we generate daily article summaries of at most 100 words, and select 5 comments for the corresponding comment summary. We employ ROUGE (Lin and Hovy, 2003) to automatically evaluate the content coverage (in terms of ngrams) of the article-based timelines vs. gold-standard timelines. ROUGE-2 (measures bigram overlap) and ROUGE-SU4 (measures unigram and skip-bigrams separated by up to four words) scores are reported in Table 4. As can be seen, under the alternating optimization framework, our systems, employing both articles and comments, consistently yield better ROUGE scores than the three baseline systems and our systems that do not leverage comments. Though constructed from single-article abstracts, baseline ABSTRACT is found to contain redundant information and thus limited in content coverage. This is due to the fact that different media tend to report on the same important events.

5.3 Evaluating Socially-Informed Timelines

We evaluate the full article+comment-based timelines on Amazon Mechanical Turk. Turkers are presented with a timeline consisting of five consecutive days' article summaries and four variations of the accompanying comment summary:

[3] We thank Zi Yang and Peng Li for providing the code.

[4] We experiment with all articles for sentence ranking, and NYT comments (with editor's picks) for comment ranking.

[5] Similar results are obtained with mean reciprocal rank.

	MH370		Ukraine		Israel-Gaza		NSA	
	R-2	*R-SU4*	*R-2*	*R-SU4*	*R-2*	*R-SU4*	*R-2*	*R-SU4*
CHIEU AND LEE	6.43	10.89	4.64	8.87	3.38	**7.32**	6.14	9.73
YAN ET AL.	6.37	10.35	4.57	8.67	2.39	5.78	3.99	7.73
ABSTRACT	6.16	10.62	3.85	8.40	2.21	5.42	7.03	8.65
- Greedy Algorithm								
BASIC	6.59	9.80	5.31	9.23	3.15	6.20	3.81	7.58
THREAD	6.55	10.86	5.73	9.75	3.16	6.16	6.29	10.09
- Alternating Optimization (leveraging comments)								
THREAD+OPT$_{\texttt{TFIDF}}$	*8.74*	11.63	*9.10*	*12.59*	3.78	6.45	*8.07*	*10.31*
THREAD+OPT$_{\texttt{WordNet}}$	*8.73*	***11.87***	*8.67*	*12.10*	**4.11**	6.64	***8.63***	***11.12***
THREAD+OPT$_{\texttt{WordVec}}$	***9.29***	11.63	***9.16***	***12.72***	3.75	6.38	*8.29*	*10.36*

Table 4: ROUGE-2 (R-2) and ROUGE-SU4 (R-SU4) scores (multiplied by 100) for different timeline generation approaches on four event datasets. Systems that statistically significantly outperform the three baselines ($p < 0.05$, paired $t-$test) are in *italics*. Numbers in **bold** are the highest score for each column.

RANDOMly selected comments, USER'S-PICKS (ranked by positive user ratings), *randomly* selected EDITOR'S-PICKS and timelines produced by the THREAD+OPT$_{\texttt{WordVec}}$ version of OUR SYSTEM. We also include one noisy comment summary (i.e. irrelevant to the question) to avoid spam. We display two comments per day for each system.[6]

Turkers are asked to rank the comment summary variations according to *informativeness* and *insightfulness*. For informativeness, we ask the Turkers to judge based only on knowledge displayed in the timeline, and to rate each comment summary based on how much relevant information they learn from it. For insightfulness, Turkers are required to focus on insights and valuable opinions. They are requested to leave a short explanation of their ranking.

15 five-day periods are randomly selected. We solicit four distinct Turkers located in the U.S. to evaluate each set of timelines. An inter-rater agreement of Krippendorff's α of 0.63 is achieved for informativeness ranking and α is 0.50 for insightfulness ranking.

Table 5 shows the percentage of times a particular method is selected as producing the best comment portion of the timeline, as well as the micro-average rank of each method, for both informativeness and insightfulness. Our system is selected as the best in 66.7% of the evaluations for informativeness and 51.7% for insightfulness. In both cases, we statistically significantly outperform ($p < 0.05$ using a Wilcoxon signed-rank test) the editor's-picks and user's-picks. Turkers' explanations indicate that they prefer our comment summaries mainly because they are "very informative and insightful to what was happening", and "show the sharpness of the commenter". Turkers sometimes think the summaries randomly selected from editor's-picks "lack connection", and characterize user's-picks as "the information was somewhat limited".

[6]For our system, we select the two comments with highest importance scores from the comment summary.

	Informativeness		Insightfulness	
	% Best	Avg Rank	% Best	Avg Rank
Random	1.7%	3.67	3.3%	3.58
User's-picks	5.0%	2.83	15.0%	2.55
Editor's-picks	26.7%	2.05	30.0%	2.22
Our system	**66.7%**	**1.45**	**51.7%**	**1.65**

Table 5: Human evaluation results on the comment portion of socially-informed timelines. **Boldface** indicates statistical significance vs. other results in the same column using a Wilcoxon signed-rank test ($p < 0.05$). On average, the output from our system is ranked higher than all other alternatives.

Figure 4 shows part of the timeline generated by our system for the Ukraine crisis.

Article Summary	Comment Summary
2014-03-17 Obama administration froze the U.S. assets of seven Russian officials, while similar sanctions were imposed on four Ukrainian officials. . . .	Theodore Roosevelt said that the worst possible thing you can do in diplomacy is "soft hitting". That is what the US and the EU are doing in these timid "sanctions" against people without any overseas accounts. . .
2014-03-18 Ukraine does not recognize a treaty signed in Moscow on Tuesday making its Crimean peninsula a part of Russia. . .	Though there were many in Crimea who supported annexation, there were certainly some who did not. what about those people?. . .
2014-03-19 The head of NATO warned on Wednesday that Russian President Vladimir Putin may not stop with the annexation of Crimea . . .	If you look at a real map , Crimea is an island and has always been more connected to Russia than to Ukraine. . .
2014-03-20 The United States on Thursday expanded its sanctions on Russians. . .	The US and EU should follow up economic sanctions with concrete steps to strengthen NATO. . .

Figure 4: A snippet of timeline generated by our system THREAD+OPT$_{\texttt{WordVec}}$ for the Ukraine crisis. Due to space limitations, we only display partial summaries.

5.4 Human Evaluation of Event Threading

Here we evaluate on the utility of event threads for high-level information access guidance: *can event threads allow users to easily locate and absorb information with a specific interest in mind?*

We first sample a 10-day timeline for each dataset from those produced by the THREAD+OPT$_{\texttt{WordVec}}$

variation of our system. We designed one question for each timeline. Sample questions are: "describe the activities for searching for the missing flight MH370", and "describe the attitude and action of Russian Government on Eastern Ukraine". We recruited 10 undergraduate and graduate students who are native speakers of English. Each student first read one question and its corresponding timeline for 5 minutes. The timeline was then removed, and the student wrote down an answer for the question. We asked each student to answer the question for each of four timelines (one for each event dataset). Two timelines are displayed with threads, and two without threads. We presented threads by adding a thread number in front of each sentence.

We then used Amazon Mechanical Turk to evaluate the informativeness of students' answers. Turkers were asked to read all 10 answers for the same question, with five answers based on timelines with threads and five others based on timelines without threads. After that, they rated each answer with an informativeness score on a 1-to-5 rating scale (1 as "not relevant to the query", and 5 as "very informative"). We also added two quality control questions. Table 6 shows that the average rating for answers written after reading timelines *with threads* is 3.29 (43% are rated ≥ 4), higher than the 2.58 for the timelines with *no thread* exhibited (30% are rated ≥ 4).

Answer Type	**Avg $\pm$ STD**	**Rated 5 (%)**	**Rated 4 (%)**
No Thread	2.58 ± 1.20	7%	23%
With Threads	3.29 ± 1.28	17%	26%

Table 6: Human evaluation on the informativeness of answers written after reading timelines *with threads* vs. with *no thread*. Answers written with access to threads are rated higher (3.29) than the ones with no thread (2.58).

6 Related Work

There is a growing interest in generating article summaries informed by social context. Existing work focuses on learning users' interests from comments and incorporates the learned information into a news article summarization system (Hu et al., 2008). Zhao et al. (2013) instead estimate word distributions from tweets, and bias a Page Rank algorithm to give higher restart probability to sentences with similar distributions. Generating tweet+article summaries has been recently investigated in Yang et al. (2011). They propose a factor graph to allow sentences and tweets to mutually reinforce each other. Gao et al. (2012) exploit a co-ranking model to identify sentence-tweet pairs with complementary information estimated from a topic model. These efforts handle a small number of documents and tweets, while we target a larger scale of data.

In terms of timeline summarization, the Chieu and Lee (2004) system ranks sentences according to "burstiness" and "interestingness" estimated by a likelihood ratio test. Yan et al. (2011) explore an optimization framework that maximizes the relevance, coverage, diversity, and coherence of the timeline. Neither system has leveraged the social context. Our event threading algorithm is also inspired by work on topic detection and tracking (TDT) (Allan et al., 1998), where efforts are made for document-level link detection and topic tracking. Similarly, Nallapati et al. (2004) investigate event threading for articles, where they predict linkage based on causal and temporal dependencies. Shahaf et al. (2012) instead seek for connecting articles into one coherent graph. To the best of our knowledge, we are the first to study sentence-level event threading.

7 Conclusion

We presented a socially-informed timeline generation system, which constructs timelines consisting of article summaries and comment summaries. An alternating optimization algorithm is designed to maximize the connectivity between the two sets of summaries as well as their importance and information coverage. Automatic and human evaluations showed that our system produced more informative timelines than state-of-the-art systems. Our comment summaries were also rated as very insightful.

Movie Script Summarization as Graph-based Scene Extraction

Philip John Gorinski and **Mirella Lapata**
Institute for Language, Cognition and Computation
School of Informatics, University of Edinburgh
10 Crichton Street, Edinburgh EH8 9AB
P.J.Gorinski@sms.ed.ac.uk, mlap@inf.ed.ac.uk

Abstract

In this paper we study the task of movie script summarization, which we argue could enhance script browsing, give readers a rough idea of the script's plotline, and speed up reading time. We formalize the process of generating a shorter version of a screenplay as the task of finding an optimal chain of scenes. We develop a graph-based model that selects a chain by jointly optimizing its logical progression, diversity, and importance. Human evaluation based on a question-answering task shows that our model produces summaries which are more informative compared to competitive baselines.

1 Introduction

Each year, about 50,000 screenplays are registered with the WGA[1], the Writers Guild of America. Only a fraction of these make it through to be considered for production and an even smaller fraction to the big screen. How do producers and directors navigate through this vast number of scripts available? Typically, production companies, agencies, and studios hire script readers, whose job is to analyze screenplays that come in, sorting the hopeful from the hopeless. Having read the script, a reader will generate a coverage report consisting of a logline (one or two sentences describing the story in a nutshell), a synopsis (a two- to three-page long summary of the script), comments explaining its appeal or problematic aspects, and a final verdict as to whether the script merits further consideration. A script excerpt from "Silence of the Lambs", an American thriller released in 1991, is shown in Figure 1.

```
We can't get a good glimpse of his face, but
his body is plump, above average height; he
is in his mid 30's.  Together they easily
lift the chair into the truck.
                MAN (O.S.)
        Let's slide it up, you mind?
CUT TO:
INT. THE PANEL TRUCK - NIGHT
He climbs inside the truck, ducking under a
small hand winch, and grabs the chair.  She
hesitates again, but climbs in after him.
                   MAN
          Are you about a size 14?
                CATHERINE
                (surprised)
                   What?
Suddenly, in the shadowy dark, he clubs her
over the back of her head with his cast.
```

Figure 1: Excerpt from "The Silence of the Lambs". The scene heading `INT. THE PANEL TRUCK - NIGHT` denotes that the action takes place inside the panel truck at night. Character cues (e.g., `MAN`, `CATHERINE`) preface the lines the actors speak. Action lines describe what the camera sees (e.g., `We can't get a good glimpse of his face, but his body...`).

Although there are several screenwriting tools for authors (e.g., Final Draft is a popular application which automatically formats scripts to industry standards, keeps track of revisions, allows insertion of notes, and writing collaboratively online), there is a lack of any kind of script reading aids. Features of such a tool could be to automatically grade the quality of the script (e.g., thumbs up or down), generate

[1] The WGA is a collective term representing US TV and film writers.

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1066–1076,
Denver, Colorado, May 31 – June 5, 2015.

synopses and loglines, identify main characters and their stories, or facilitate browsing (e.g., "show me every scene where there is a shooting"). In this paper we explore whether current NLP technology can be used to address some of these tasks. Specifically, we focus on script summarization, which we conceptualize as the process of generating a shorter version of a screenplay, ideally encapsulating its most informative scenes. The resulting summaries can be used to enhance script browsing, give readers a rough idea of the script's content and plotline, and speed up reading time.

So, what makes a good script summary? According to modern film theory, "all films are about nothing — nothing but character" (Monaco, 1982). Beyond characters, a summary should also highlight major scenes representative of the story and its progression. With this in mind, we define a script summary as a *chain of scenes* which conveys a narrative and smooth transitions from one scene to the next. At the same time, a good chain should incorporate some *diversity* (i.e., avoid redundancy), and focus on *important* scenes and characters. We formalize the problem of selecting a good summary chain using a graph-theoretic approach. We represent scripts as (directed) bipartite graphs with vertices corresponding to scenes and characters, and edge weights to their strength of correlation. Intuitively, if two scenes are connected, a random walk starting from one would reach the other frequently. We find a chain of highly connected scenes by jointly optimizing logical progression, diversity, and importance.

Our contributions in this work are three-fold: we introduce a novel summarization task, on a new text genre, and formalize scene selection as the problem of finding a chain that represents a film's story; we propose several novel methods for analyzing script content (e.g., identifying important characters and their interactions); and perform a large-scale human evaluation study using a question-answering task. Experimental results show that our method produces summaries which are more informative compared to several competitive baselines.

2 Related Work

Computer-assisted analysis of literary text has a long history, with the first studies dating back to the 1960s (Mosteller and Wallace, 1964). More recently, the availability of large collections of digitized books and works of fiction has enabled researchers to observe cultural trends, address questions about language use and its evolution, study how individuals rise to and fall from fame, perform gender studies, and so on (Michel et al., 2010). Most existing work focuses on low-level analysis of word patterns, with a few notable exceptions. Elson et al. (2010) analyze 19th century British novels by constructing a conversational network with vertices corresponding to characters and weighted edges corresponding to the amount of conversational interaction. Elsner (2012) analyzes characters and their emotional trajectories, whereas Nalisnick and Baird (2013) identify a character's enemies and allies in plays based on the sentiment of their utterances. Other work (Bamman et al., 2013, 2014) automatically infers latent character types (e.g., villains or heroes) in novels and movie plot summaries.

Although we are not aware of any previous approaches to summarize screenplays, the field of computer vision is rife with attempts to summarize video (see Reed 2004 for an overview). Most techniques are based on visual information and rely on low-level cues such as motion, color, or audio (e.g., Rasheed et al. 2005). Movie summarization is a special type of video summarization which poses many challenges due to the large variety of film styles and genres. A few recent studies (Weng et al., 2009; Lin et al., 2013) have used concepts from social network analysis to identify lead roles and role communities in order to segment movies into scenes (containing one or more shots) and create more informative summaries. A surprising fact about this line of work is that it does not exploit the movie script in any way. Characters are typically identified using face recognition techniques and scene boundaries are presumed unknown and are automatically detected. A notable exception are Sang and Xu (2010) who generate video summaries for movies, while taking into account character interaction features which they estimate from the corresponding screenplay.

Our own approach is inspired by work in egocentric video analysis. An egocentric video offers a first-person view of the world and is captured from a wearable camera focusing on the user's activities,

	# Movies	AvgLines	AvgScenes	AvgChars
Drama	665	4484.53	79.77	60.94
Thriller	451	4333.10	91.84	52.59
Comedy	378	4303.02	66.13	57.51
Action	288	4255.56	101.82	59.99

Figure 2: ScriptBase corpus statistics. Movies can have multiple genres, thus numbers do not add up to 1,276.

social interactions, and interests. Lu and Grauman (2013) present a summarization model which extracts subshot sequences while finding a balance of important subshots that are both diverse and provide a natural progression through the video, in terms of prominent visual objects (e.g., bottle, mug, television). We adapt their technique to our task, and show how to estimate character-scene correlations based on linguistic analysis. We also interpret movies as social networks and extract a rich set of features from character interactions and their sentiment which we use to guide the summarization process.

3 ScriptBase: A Movie Script Corpus

We compiled ScriptBase, a collection of 1,276 movie scripts, by automatically crawling web-sites which host or link entire movie scripts (e.g., `imsdb.com`). The retrieved scripts were then cross-matched against Wikipedia[2] and IMDB[3] and paired with corresponding user-written summaries, plot sections, loglines and taglines (taglines are short snippets used by marketing departments to promote a movie). We also collected meta-information regarding the movie's genre, its actors, the production year, etc. ScriptBase contains movies comprising 23 genres; each movie is on average accompanied by 3 user summaries, 3 loglines, and 3 taglines. The corpus spans years 1909–2013. Some corpus statistics are shown in Figure 2.

The scripts were further post-processed with the Stanford CoreNLP pipeline (Manning et al., 2014) to perform tagging, parsing, named entity recognition and coreference resolution. They were also annotated with semantic roles (e.g., ARG0, ARG1), using the MATE tools (Björkelund et al., 2009). Our summarization experiments focused on comedies and thrillers. We randomly selected 30 movies for training/development and 65 movies for testing.

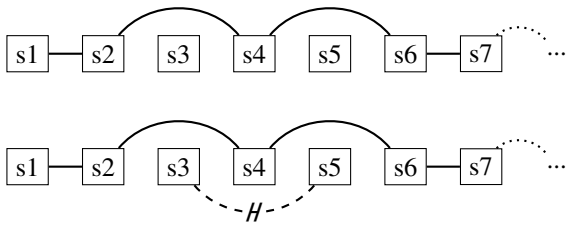

Figure 3: Example of consecutive chain (top). Squares represent scenes in a screenplay. The bottom chain would not be allowed, since the connection between $s3$ and $s5$ makes it non-consecutive.

4 The Scene Extraction Model

As mentioned earlier, we define script summarization as the task of selecting a chain of scenes representing the movie's most important content. We interpret the term scene in the screenplay sense. A scene is a unit of action that takes place in one location at one time (see Figure 1). We therefore need not be concerned with scene segmentation; scene boundaries are clearly marked, and constitute the basic units over which our model operates.

Let $M = (S, C)$ represent a screenplay consisting of a set $S = \{s_1, s_2, \ldots, s_n\}$ of scenes, and a set $C = \{c_1, \ldots, c_m\}$ of characters. We are interested in finding a list $S' = \{s_i, \ldots s_k\}$ of *ordered, consecutive* scenes subject to a compression rate m (see the example in Figure 3). A natural interpretation of m in our case is the percentage of scenes from the original script retained in the summary. The extracted chain should contain (a) *important* scenes (i.e., critical for comprehending the story and its development); (b) *diverse* scenes that cover different aspects of the story; and (c) scenes which highlight the story's *progression* from beginning to end. We therefore find the chain S' maximizing the objective function $Q(S')$ which is the weighted sum of three terms: the story progression P, scene diversity D, and scene importance I:

$$S^* = \underset{S' \subset S}{arg\,max}\, Q(S') \quad (1)$$

$$Q(S') = \lambda_P P(S') + \lambda_D D(S') + \lambda_I I(S') \quad (2)$$

In the following, we define each of the three terms.

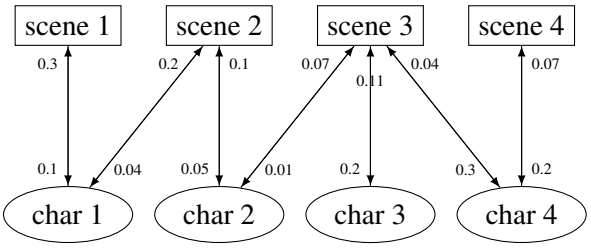

Figure 4: Example of a bipartite graph, connecting a movie's scenes with participating characters.

Scene-to-scene Progression The first term in the objective is responsible for selecting chains representing a logically coherent story. Intuitively, this means that if our chain includes a scene where a character commits an action, then scenes involving affected parties or follow-up actions should also be included. We operationalize this idea of progression in a story in terms of how strongly the characters in a selected scene s_i influence the transition to the next scene s_{i+1}:

$$P(S') = \sum_{i=0}^{|S'|-1} \sum_{c \in C_i} INF(s_i, s_{i+1}|c) \tag{3}$$

We represent screenplays as weighted, bipartite graphs connecting scenes and characters:

$$B = (V,E) : V = C \cup S$$

$$E = \{(s,c,w_{s,c})|s \in S,\, c \in C,\, w_{s,c} \in [0,1]\} \cup$$

$$\{(c,s,w_{c,s})|c \in C,\, s \in S,\, w_{c,s} \in [0,1]\}$$

The set of vertices V corresponds to the union of characters C and scenes S. We therefore add to the bipartite graph one node per scene and one node per character, and two directed edges for each scene-character and character-scene pair. An example of a bipartite graph is shown in Figure 4. We further assume that two scenes s_i and s_{i+1} are tightly connected in such a graph if a random walk with restart (RWR; Tong et al. 2006; Kim et al. 2014) which starts in s_i has a high probability of ending in s_{i+1}.

In order to calculate the random walk stationary distributions, we must estimate the weights between a character and a scene. We are interested in how important a character is generally in the movie, and specifically in a particular scene. For $w_{c,s}$, we consider the probability of a character being important, i.e., of them belonging to the set of main characters:

$$w_{c,s} = P(c \in main(M)),\ \forall (c,s,w_{c,s}) \in E \tag{4}$$

where $P(c \in main(M))$ is some probability score associated with c being a main character in script M. For $w_{s,c}$, we take the number of interactions a character is involved in relative to the total number of interactions in a specific scene as indicative of the character's importance in that scene. Interactions refer to conversational interactions as well as relations between characters (e.g., who does what to whom):

$$w_{s,c} = \frac{\sum\limits_{c' \in C_s} inter(c,c')}{\sum\limits_{c_1,c_2 \in C_s} inter(c_1,c_2)},\ \forall (s,c,w_{s,c}) \in E \tag{5}$$

We defer discussion of how we model probability $P(c \in Main(M))$ and obtain interaction counts to Section 5. Weights $w_{s,c}$ and $w_{c,s}$ are normalized:

$$w_{s,c} = \frac{w_{s,c}}{\sum_{(s,c',w'_{s,c})} w'_{s,c}},\ \forall (s,c,w_{s,c}) \in E \tag{6}$$

$$w_{c,s} = \frac{w_{c,s}}{\sum_{(c,s',w'_{c,s})} w'_{c,s}},\ \forall (c,s,w_{c,s}) \in E \tag{7}$$

We calculate the stationary distributions of a random walk on a transition matrix T, enumerating over all vertices v (i.e., characters *and* scenes) in the bipartite graph B:

$$T(i,j) = \begin{cases} w_{i,j} \text{ if } (v_i, v_j, w_{i,j} \in E^B) \\ 0 \text{ otherwise} \end{cases} \tag{8}$$

We measure the *influence* individual characters have on scene-to-scene transitions as follows. The stationary distribution r_k for a RWR walker starting at node k is a vector that satisfies:

$$r_k = (1-\varepsilon)Tr_k + \varepsilon e_k \tag{9}$$

where T is the transition matrix of the graph, e_k is a *seed vector*, with all elements 0, except for element k which is set to 1, and ε is a restart probability parameter. In practice, our vectors r_k and e_k are indexed by the scenes and characters in a movie, i.e., they have length $|S| + |C|$, and their n_{th} element corresponds either to a known scene or character. In cases where

graphs are relatively small, we can compute r directly[4] by solving:

$$r_k = \varepsilon(I-(1-\varepsilon)T)^{-1}e_k \quad (10)$$

The lth element of r then equals the probability of the random walker being in state l in the stationary distribution. Let r_k^c be the same as r_k, but with the character node c of the bipartite graph being turned into a sink, i.e., all entries for c in the transition matrix T are 0. We can then define how a single character influences the transition between scenes s_i and s_{i+1} as:

$$INF(s_i, s_{i+1}|c) = r_{s_i}[s_{i+1}] - r^c_{s_i}[s_{i+1}] \quad (11)$$

where $r_{s_i}[s_{i+1}]$ is shorthand for that element in the vector r_{s_i} that corresponds to scene s_{i+1}. We use the INF score directly in Equation (3) to determine the progress score of a candidate chain.

Diversity The diversity term $D(S')$ in our objective should encourage chains which consist of more dissimilar scenes, thereby avoiding redundancy. The diversity of chain S' is the sum of the diversities of its successive scenes:

$$D(S') = \sum_{i=1}^{|S'|-1} d(s_i, s_{i+1}) \quad (12)$$

The diversity $d(s_i, s_{i+1})$ of two scenes s_i and s_{i+1} is estimated taking into account two factors: (a) do they have any characters in common, and (b) does the sentiment change from one scene to the next:

$$d(s_i, s_{i+1}) = \frac{d_{char}(s_i, s_{i+1}) + d_{sen}(s_i, s_{i+1})}{2} \quad (13)$$

where $d_{char}(s_i, s_{i+1})$ and $d_{sen}(s_i, s_{i+1})$ respectively denote character and sentiment similarity between scenes. Specifically, $d_{char}(s_i, s_{i+1})$ is the relative character overlap between scenes s_i and s_{i+1}:

$$d_{char}(s_i, s_{i+1}) = 1 - \frac{|C_{s_i} \cap C_{s_{i+1}}|}{|C_{s_i} \cup C_{s_{i+1}}|} \quad (14)$$

d_{char} will be 0 if two scenes share the same characters and 1 if no characters are shared. Analogously, we define d_{sen}, the sentiment overlap between two scenes as:

$$d_{sen}(s_i, s_{i+1}) = 1 - \frac{k \cdot dif(s_i, s_{i+1})}{k - k \cdot dif(s_i, s_{i+1}) + 1} \quad (15)$$

$$dif(s_i, s_{i+1}) = \frac{1}{1 + |sen(s_i) - sen(s_{i+1})|} \quad (16)$$

where the sentiment $sen(s)$ of scene s is the aggregate sentiment score of all interactions in s:

$$sen(s) = \sum_{c,c' \in C_s} sen(inter(c, c')) \quad (17)$$

We explain how interactions and their sentiment are computed in Section 5. Again, d_{sen} is larger if two scenes have a less similar sentiment. $dif(s_i, s_{i+1})$ becomes 1 if the sentiments are identical, and increasingly smaller for more dissimilar sentiments. The sigmoid-like function in Equation (15) scales d_{sen} within range $[0, 1]$ to take smaller values for larger sentiment differences (factor k adjusts the curve's smoothness).

Importance The score $I(S')$ captures whether a chain contains important scenes. We define $I(S')$ as the sum of all scene-specific importance scores $imp(s_i)$ of scenes contained in the chain:

$$I(S') = \sum_{i=1}^{|S'|} imp(s_i) \quad (18)$$

The importance $imp(s_i)$ of a scene s_i is the ratio of lead to support characters within that scene:

$$imp(s_i) = \frac{\sum_{c:\, c \in C_{s_i} \wedge c \in main(M)} 1}{\sum_{c:\, c \in C_{s_i}} 1} \quad (19)$$

where C_{s_i} is the set of characters present in scene s_i, and $main(M)$ is the set of main characters in the movie.[5] $I(s_i)$ is 0 if a scene does not contain any main characters, and 1 if it contains only main characters (see Section 5 for how $main(M)$ is inferred).

Optimal Chain Selection We use Linear Programming to efficiently find a good chain. The objective is to maximize Equation (2), i.e., the sum of the terms for progress, diversity and importance,

[4] We could also solve for r recursively which would be preferable for large graphs, since the performed matrix inversion is computationally expensive.

[5] Whether scenes are important if they contain many main characters is an empirical question in its own right. For our purposes, we assume that this relation holds.

subject to their weights λ. We add a constraint corresponding to the compression rate, i.e., the number of scenes to be selected and enforce their linear order by disallowing non-consecutive combinations. We use GLPK[6] to solve the linear problem.

5 Implementation

In this section we discuss several aspects of the implementation of the model presented in the previous section. We explain how interactions are extracted and how sentiment is calculated. We also present our method for identifying main characters and estimating the weights $w_{s,c}$ and $w_{c,s}$ in the bipartite graph.

Interactions The notion of interaction underlies many aspects of the model defined in the previous section. For instance, interaction counts are required to estimate the weights $w_{s,c}$ in the bipartite graph of the progression term (see Equation (5)), and in defining diversity (see Equations (15)–(17)). As we shall see below, interactions are also important for identifying main characters in a screenplay.

We use the term interaction to refer to *conversations* between two characters, as well as their *relations* (e.g., if a character kills another). For conversational interactions, we simply need to identify the *speaker* generating an utterance and the *listener*. Speaker attribution comes for free in our case, as speakers are clearly marked in the text (see Figure 1). Listener identification is more involved, especially when there are multiple characters in a scene. We rely on a few simple heuristics. We assume that the previous speaker in the same scene, who is different from the current speaker, is the listener. If there is no previous speaker, we assume that the listener is the closest character mentioned in the speaker's utterance (e.g., via a coreferring proper name or a pronoun). In cases where we cannot find a suitable listener, we assume the current speaker is the listener.

We obtain character relations from the output of a semantic role labeler. Relations are denoted by verbs whose ARG0 and ARG1 roles are character names. We extract relations from the dialogue but also from scene descriptions. For example, in Figure 1 the description `Suddenly, [...] he clubs her over the head` contains the relation `clubs(MAN,CATHERINE)`. Pronouns are resolved to their antecedent using the Stanford coreference resolution system (Lee et al., 2011).

Sentiment We labeled lexical items in screenplays with sentiment values using the AFINN-96 lexicon (Nielsen, 2011), which is essentially a list of words scored with sentiment strength within the range $[-5,+5]$. The list also contains obscene words (which are often used in movies) and some Internet slang. By summing over the sentiment scores of individual words, we can work out the sentiment of an interaction between two characters, the sentiment of a scene (see Equation (17)), and even the sentiment between characters (e.g., who likes or dislikes whom in the movie in general).

Main Characters The progress term in our summarization objective crucially relies on characters and their importance (see the weight $w_{c,s}$ in Equation (4)). Previous work (Weng et al., 2009; Lin et al., 2013) extracts social networks where nodes correspond to roles in the movie, and edges to their co-occurrence. Leading roles (and their communities) are then identified by measuring their centrality in the network (i.e., number of edges terminating in a given node).

It is relatively straightforward to obtain a social network from a screenplay. Formally, for each movie we define a *weighted* and *undirected* graph:

$$G = \{C,E\}, : C = \{c_1, \ldots c_n\},$$
$$E = \{(c_i, c_j, w) | c_i, c_j \in C, w \in \mathbb{N}_{>0}\}$$

where vertices correspond to movie characters[7], and edges denote character-to-character interactions. Figure 5 shows an example of a social network for "The Silence of the Lambs". Due to lack of space, only main characters are displayed, however the actual graph contains *all* characters (42 in this case). Importantly, edge weights are not normalized, but directly reflect the strength of association between different characters.

We do not solely rely on the social network to identify main characters. We estimate $P(c \in main(M))$, the probability of c being a leading character in movie M, using a Multi Layer

[6] https://www.gnu.org/software/glpk/

[7] We assume one node per *speaking role* in the script.

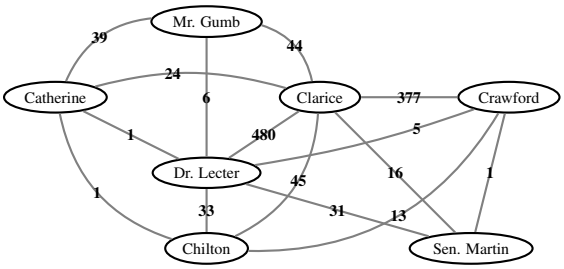

Figure 5: Social network for "The Silence of the Lambs"; edge weights correspond to absolute number of interactions between nodes.

Perceptron (MLP) and several features pertaining to the structure of the social network and the script text itself. A potential stumbling block in treating character identification as a classification task is obtaining training data, i.e., a list of main characters for each movie. We generate a gold-standard by assuming that the characters listed under Wikipedia's *Cast* section (or an equivalent section, e.g., *Characters*) are the main characters in the movie.

Examples of the features we used for the classification task include the barycenter of a character (i.e., the sum of its distance to all other characters), PageRank (Page et al., 1999), an eigenvector-based centrality measure, absolute/relative interaction weight (the sum of all interactions a character is involved in, divided by the sum of all interactions in the network), absolute/relative number of sentences uttered by a character, number of times a character is described by other characters (e.g., `He is a monster` or `She is nice`), number of times a character talks about other characters, and type-token-ratio of sentences uttered by the character (i.e., rate of unique words in a character's speech). Using these features, the MLP achieves an F1 of 79.0% on the test set. It outperforms other classification methods such as Naive Bayes or logistic regression. Using the full-feature set, the MLP also obtains performance superior to any individual measure of graph connectivity.

Aside from Equation (4), lead characters also appear in Equation (19), which determines scene importance. We assume a character $c \in main(M)$ if it is predicted by the MLP with a probability ≥ 0.5.

6 Experimental Setup

Gold Standard Chains The development and tuning of the chain extraction model presented in Section 4 necessitates access to a gold standard of key scene chains representing the movie's most important content. Our experiments concentrated on a sample of 95 movies (comedies and thrillers) from the ScriptBase corpus (Section 3). Performing the scene selection task for such a big corpus manually would be both time consuming and costly. Instead, we used distant supervision based on Wikipedia to automatically generate a gold standard.

Specifically, we assume that Wikipedia plots are representative of the most important content in a movie. Using the alignment algorithm presented in Nelken and Shieber (2006), we align script sentences to Wikipedia plot sentences and assume that scenes with at least one alignment are part of the *gold chain* of scenes. We obtain many-to-many alignments using features such as lemma overlap and word stem similarity. When evaluated on four movies[8] (from the training set) whose content was manually aligned to Wikipedia plots, the aligner achieved a precision of .53 at a recall rate of .82 at deciding whether a scene should be aligned. Scenes are ranked according to the number of alignments they contain. When creating gold chains at different compression rates, we start with the best-ranked scenes and then successively add lower ranked ones until we reach the desired compression rate.

System Comparison In our experiments we compared our scene extraction model (SceneSum) against three baselines. The first baseline was based on the *minimum* overlap (MinOv) of characters in consecutive scenes and corresponds closely to the diversity term in our objective. The second baseline was based on the *maximum* overlap (MaxOv) of characters and approximates the importance term in our objective. The third baseline selects scenes at random (averaged over 1,000 runs). Parameters for our models were tuned on the training set, weights for the terms in the objective were optimized to the following values: $\lambda_P = 1.0$, $\lambda_D = 0.3$, and $\lambda_I = 0.1$. We set the restart probability of our random walker

to $\varepsilon = 0.5$, and the sigmoid scaling factor in our diversity term to $k = -1.2$.

Evaluation We assessed the output of our model (and comparison systems) automatically against the gold chains described above. We performed experiments with compression rates in the range of 10% to 50% and measured performance in terms of F1. In addition, we also evaluated the quality of the extracted scenes as perceived by humans, which is necessary, given the approximate nature of our gold standard. We adopted a question-answering (Q&A) evaluation paradigm which has been used previously to evaluate summaries and document compression (Morris et al., 1992; Mani et al., 2002; Clarke and Lapata, 2010). Under the assumption that the summary is to function as a replacement for the full script, we can measure the extent to which it can be used to find answers to questions which have been derived from the entire script and are representative of its core content. The more questions a hypothetical system can answer, the better it is at summarizing the script as a whole.

Two annotators were independently instructed to read scripts (from our test set) and create Q&A pairs. The annotators generated questions relating to the plot of the movie and the development of its characters, requiring an unambiguous answer. They compared and revised their Q&A pairs until a common agreed-upon set of five questions per movie was reached (see Table 1 for an example). In addition, for every movie we asked subjects to name the main characters, and summarize its plot (in no more than four sentences). Using Amazon Mechanical Turk (AMT)[9], we elicited answers for eight scripts (four comedies and thrillers) in four summarization conditions: using our model, the two baselines based on minimum and maximum character overlap, and the random system. All models were assessed at the same compression rate of 20% which seems realistic in an actual application environment, e.g., computer aided summarization. The scripts were preselected in an earlier AMT study where participants were asked to declare whether they had seen the movies in our test set (65 in total). We chose the screenplays which had received the least viewings so as to avoid eliciting answers based on familiarity with the movie. A total of 29 participants, all self-reported native English speakers, completed the Q&A task. The answers provided by the subjects were scored against an answer key. A correct answer was marked with a score of one, and zero otherwise. In cases where more answers were required per question, partial scores were awarded to each correct answer (e.g., 0.5). The score for a summary is the average of its question scores.

SceneSum	0.23	0.37	0.50	0.60	0.68
Random	0.10	0.20	0.30	0.40	0.50

Table 2: Model performance on automatically generated gold standard (test set) at different compression rates.

7 Results

Table 2 shows the performance of SceneSum, our scene extraction model, and the three comparison systems (MaxOv, MinOv, Random) on the automatic gold standard at five compression rates. As can be seen, MaxOv performs best in terms of F1, followed by SceneSum. We believe this is an artifact due to the way the gold standard was created. Scenes with large numbers of main characters are more likely to figure in Wikipedia plot summaries and will thus be more frequently aligned. A chain based on maximum character overlap will focus on such scenes and will agree with the gold standard better compared to chains which take additional script properties into account.

We further analyzed the scenes selected by SceneSum and the comparison systems with respect to their position in the script. Table 3 shows the av-

	Beginning	Middle	End
MaxOv	33.95	34.89	31.16
MinOv	34.30	33.91	31.80
SceneSum	35.30	33.54	31.16
Random	34.30	33.91	31.80

Table 3: Average percentage of scenes taken from the beginning, middle and ends of movies, on automatic gold standard test set.

erage percentage of scenes selected from the beginning, middle, and end of the movie (based on an equal division of the number of scenes in the screenplay). As can be seen, the number of selected scenes tends to be evenly distributed across the entire movie. SceneSum has a slight bias towards the beginning of the movie which is probably natural, since leading characters appear early on, as well as important scenes introducing essential story elements (e.g., setting, points of view).

The results of our human evaluation study are summarized in Table 4. We observe that SceneSum summaries are overall more informative compared to those created by the baselines. In other words, AMT participants are able to answer more questions regarding the story of the movie when reading SceneSum summaries. In two instances ("A Nightmare on Elm Street 3" and "Mumford"), the overlap models score better, however, in this case the movies largely consist of scenes with the same characters and relatively little variation ("A Nightmare on Elm Street 3"), or the camera follows the main lead in his interactions with other characters ("Mumford"). Since our model is not so character-centric, it might be thrown off by non-character-based terms in its objective, leading to the selection of unfavorable scenes. Table 4 also presents a break down of the different types of questions answered by our participants. Again, we see that in most cases a larger percentage is answered correctly when reading SceneSum summaries.

Overall, we observe that SceneSum extracts chains which encapsulate important movie content across the board. We should point out that although our movies are broadly classified as comedies and thrillers, they have very different structure and content. For example, "Little Athens" has a very loose plotline, "Living in Oblivion" has multiple dream sequences, whereas "While She was Out" contains only a few characters and a series of important scenes towards the end. Despite this variety, SceneSum performs consistently better in our task-based evaluation.

Movies	MaxOv	MinOv	SceneSum	Random
Nightmare 3	69.18	**74.49**	60.24	56.33
Little Athens	34.92	31.75	**36.90**	33.33
Living in Oblivion	40.95	35.00	**60.00**	30.24
Mumford	**72.86**	60.00	30.00	54.29
One Eight Seven	47.30	38.89	**67.86**	30.16
Anniversary Party	45.39	56.35	**62.46**	37.62
We Own the Night	28.57	32.14	**52.86**	28.57
While She Was Out	72.86	75.71	**85.00**	45.71
All Questions	51.51	50.54	**56.91**	39.53
Five Questions	51.00	53.13	**57.38**	36.88
Plot Question	60.00	56.88	**73.75**	55.00
Characters Question	**45.54**	37.34	37.75	31.29

Table 4: Percentage of questions answered correctly.

8 Conclusions

In this paper we have developed a graph-based model for script summarization. We formalized the process of generating a shorter version of a screenplay as the task of finding an optimal chain of scenes, which are diverse, important, and exhibit logical progression. A large-scale evaluation based on a question-answering task revealed that our method produces more informative summaries compared to several baselines. In the future, we plan to explore model performance in a wider range of movie genres as well as its applicability to other NLP tasks (e.g., book summarization or event extraction). We would also like to automatically determine the compression rate which should presumably vary according to the movie's length and content. Finally, our long-term goal is to be able to generate loglines as well as movie plot summaries.

Acknowledgments We would like to thank Rik Sarkar, Jon Oberlander and Annie Louis for their valuable feedback. Special thanks to Bharat Ambati, Lea Frermann, and Daniel Renshaw for their help with system evaluation.

Toward Abstractive Summarization Using Semantic Representations

Abstract

We present a novel abstractive summarization framework that draws on the recent development of a treebank for the Abstract Meaning Representation (AMR). In this framework, the source text is parsed to a set of AMR graphs, the graphs are transformed into a summary graph, and then text is generated from the summary graph. We focus on the graph-to-graph transformation that reduces the source semantic graph into a summary graph, making use of an existing AMR parser and assuming the eventual availability of an AMR-to-text generator. The framework is data-driven, trainable, and not specifically designed for a particular domain. Experiments on gold-standard AMR annotations and system parses show promising results. Code is available at: https://github.com/summarization

1 Introduction

Abstractive summarization is an elusive technological capability in which textual summaries of content are generated *de novo*. Demand is on the rise for high-quality summaries not just for lengthy texts (e.g., books; Bamman and Smith, 2013) and texts known to be prohibitively difficult for people to understand (e.g., website privacy policies; Sadeh et al., 2013), but also for non-textual media (e.g., videos and image collections; Kim et al., 2014; Kuznetsova et al., 2014; Zhao and Xing, 2014), where extractive and compressive summarization techniques simply do not suffice. We believe that the challenge of abstractive summarization deserves renewed attention and propose that recent developments in semantic analysis have an important role to play.

We conduct the first study exploring the feasibility of an abstractive summarization system based on transformations of semantic representations such as the Abstract Meaning Representation (AMR; Banarescu et al., 2013). Example sentences and their AMR graphs are shown in Fig. 1. AMR has much in common with earlier formalisms (Kasper, 1989; Dorr et al., 1998); today an annotated corpus comprised of over 20,000 AMR-analyzed English sentences (Knight et al., 2014) and an automatic AMR parser (JAMR; Flanigan et al., 2014) are available.

In our framework, summarization consists of three steps illustrated in Fig. 1: (1) parsing the input sentences to individual AMR graphs, (2) combining and transforming those graphs into a single summary AMR graph, and (3) generating text from the summary graph. This paper focuses on step 2, treating it as a structured prediction problem. We assume text documents as input[1] and use JAMR for step 1. We use a simple method to read a bag of words off the summary graph, allowing evaluation with ROUGE-1, and leave full text generation from AMR (step 3) to future work.

The graph summarizer, described in §4, first merges AMR graphs for each input sentence through a *concept merging* step, in which coreferent nodes of the graphs are merged; a *sentence conjunction* step, which connects the root of each sentence's AMR graph to a dummy "ROOT" node; and an optional

[1] In principle, the framework could be applied to other inputs, such as image collections, if AMR parsers became available for them.

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1077–1086,
Denver, Colorado, May 31 – June 5, 2015.

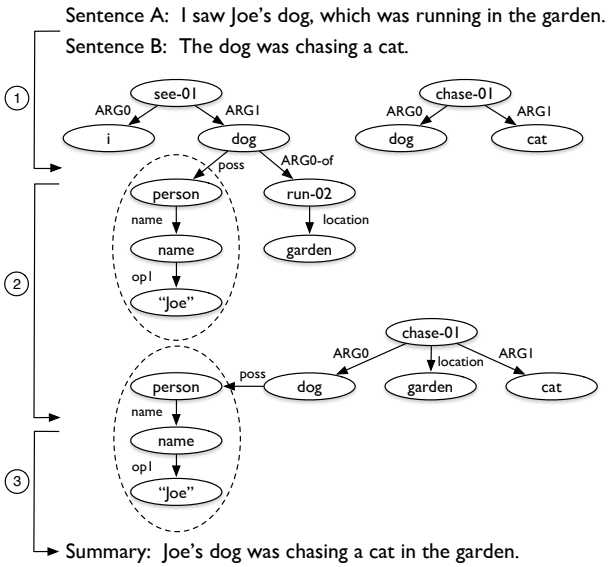

Figure 1: A toy example. Sentences are parsed into individual AMR graphs in step 1; step 2 conducts graph transformation that produces a single summary AMR graph; text is generated from the summary graph in step 3.

graph expansion step, where additional edges are added to create a fully dense graph on the sentence-level. These steps result in a single connected *source graph*. A subset of the nodes and arcs from the source graph are then selected for inclusion in the *summary graph*. Ideally this is a condensed representation of the most salient semantic content from the source.

We briefly review AMR and JAMR (§2), then present the dataset used in this paper (§3). The main algorithm is presented in §4, and we discuss our simple generation step in §5. Our experiments (§6) measure the intrinsic quality of the graph transformation algorithm as well as the quality of the terms selected for the summary (using ROUGE-1). We explore variations on the transformation and the learning algorithm, and show oracle upper bounds of various kinds.

2 Background: Abstract Meaning Representation and JAMR

AMR provides a whole-sentence semantic representation, represented as a rooted, directed, acyclic graph (Fig. 1). Nodes of an AMR graph are labeled with *concepts*, and edges are labeled with *relations*. Concepts can be English words ("dog"), PropBank event predicates ("chase-01," "run-02"), or special keywords ("person"). For example, "chase-01" represents a PropBank roleset that corresponds to the first sense of "chase". According to Banarescu et al. (2013), AMR uses approximately 100 relations. The rolesets and core semantic relations (e.g., ARG0 to ARG5) are adopted from the PropBank annotations in OntoNotes (Hovy et al., 2006). Other semantic relations include "location," "mode," "name," "time," and "topic." The AMR guidelines[2] provide more detailed descriptions. Banarescu et al. (2013) describe AMR Bank, a 20,341-sentence corpus annotated with AMR by experts.

Step 1 of our framework converts input document sentences into AMR graphs. We use a statistical semantic parser, JAMR (Flanigan et al., 2014), which was trained on AMR Bank. JAMR's current performance on our test dataset is 63% F-score.[3] We will analyze the effect of AMR parsing errors by comparing JAMR output with gold-standard annotations of input sentences in the experiments (§6).

In addition to predicting AMR graphs for each sentence, JAMR provides alignments between spans of words in the source sentence and fragments of its predicted graph. For example, a graph fragment headed by "date-entity" could be aligned to the tokens "April 8, 2002." We use these alignments in our simple text generation module (step 3; §5).

3 Dataset

To build and evaluate our framework, we require a dataset that includes inputs and summaries, each with gold-standard AMR annotations.[4] This allows us to use a statistical model for step 2 (graph summarization) and to separate its errors from those in step 1 (AMR parsing), which is important in determining whether this approach is worth further investment.

Fortunately, the "proxy report" section of the AMR Bank (Knight et al., 2014) suits our needs. A

[2] `http://www.isi.edu/~ulf/amr/help/amr-guidelines.pdf`

[3] AMR parse quality is evaluated using smatch (Cai and Knight, 2013), which measures the accuracy of concept and relation predictions. JAMR was trained on the in-domain training portion of LDC2014T12 for our experiments.

[4] Traditional multi-document summarization datasets, such as the ones used in DUC and TAC competitions, do not have gold-standard AMR annotations.

	# Docs.	Ave. # Sents.		Source Graph		
		Summ.	Doc.	Nodes	Edges	Expand
Train	298	1.5	17.5	127	188	2,670
Dev.	35	1.4	19.2	143	220	3,203
Test	33	1.4	20.5	162	255	4,002

Table 1: Statistics of our dataset. "Expand" shows the number of edges after performing graph expansion. The numbers are averaged across all documents in the split. We use the official split, dropping one training document for which no summary sentences were annotated.

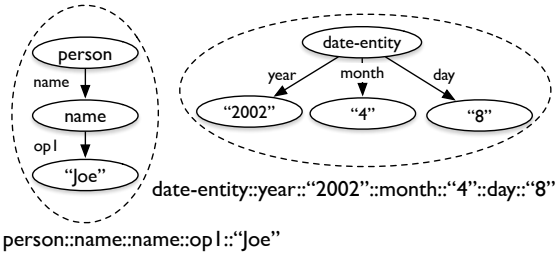

Figure 2: Graph fragments are collapsed into a single concept and assigned a new concept label.

proxy report is created by annotators based on a single newswire article, selected from the English Gigaword corpus. The report header contains metadata about date, country, topic, and a short summary. The report body is generated by editing or rewriting the content of the newswire article to approximate the style of an analyst report. Hence this is a single document summarization task. All sentences are paired with gold-standard AMR annotations. Table 1 provides an overview of our dataset.

4 Graph Summarization

Given AMR graphs for all of the sentences in the input (step 1), graph summarization transforms them into a single summary AMR graph (step 2). This is accomplished in two stages: source graph construction (§4.1); and subgraph prediction (§4.2).

4.1 Source Graph Construction

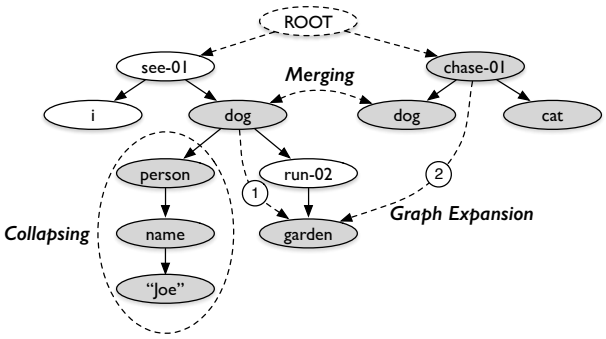
The "source graph" is a single graph constructed using the individual sentences' AMR graphs by merging identical concepts. In the AMR formalism, an entity or event is canonicalized and represented by a single graph fragment, regardless of how many times it is referred to in the sentence. This principle can be extended to multiple sentences, ideally resulting in a source graph with no redundancy. Because repeated mentions of a concept in the input can signal its importance, we will later encode the frequency of mentions as a feature used in subgraph prediction.

Concept merging involves collapsing certain graph fragments into a single concept, then merging all concepts that have the same label. We collapse the graph fragments that are headed by either a date-entity ("date-entity") or a named entity ("name"), if the fragment is a flat structure. A collapsed named entity is further combined with its parent (e.g., "person") into one concept node if it is the only child of the parent. Two such graph fragments are illustrated in Fig. 2. We choose named and date entity concepts since they appear frequently, but most often refer to different entities (e.g., "April 8, 2002" vs. "Nov. 17"). No further collapsing is done. A collapsed graph fragment is assigned a new label by concatenating the consisting concept and edge labels. Each fragment that is collapsed into a new concept node can then only be merged with other identical fragments. This process won't recognize coreferent concepts like "Barack Obama" = "Obama" and "say-01" = "report-01," but future work may incorporate both entity coreference resolution and event coreference resolution, as concept nodes can represent either.

Due to the concept merging step, a pair of concepts may now have multiple labeled edges between them. We merge all such edges between a given pair of concepts into a single unlabeled edge. We remember the two most common labels in such a group, which are used in the edge "Label" feature (Table 3).

To ensure that the source graph is connected, we add a new "ROOT" node and connect it to every concept that was originally the root of a sentence graph (see Fig. 3). When we apply this procedure to the documents in our dataset (§3), source graphs contain 144 nodes and 221 edges on average.

We investigated how well these automatically constructed source graphs cover the gold-standard summary graphs produced by AMR annotators. Ideally, a source graph should cover all of the gold-standard edges, so that summarization can be accomplished by selecting a subgraph of the source



Sentence A: I saw Joe's dog, which was running in the garden.
Sentence B: The dog was chasing a cat.

Figure 3: A source graph formed from two sentence AMR graphs. Concept collapsing, merging, and graph expansion are demonstrated. Edges are unlabeled. A "ROOT" node is added to ensure connectivity. (1) and (2) are among edges added through the optional expansion step, corresponding to sentence- and document-level expansion, respectively. Concept nodes included in the summary graph are shaded.

	Summary Edge Coverage (%)			
			Expand	
	Labeled	Unlabeled	Sent.	Doc.
Train	64.8	67.0	75.5	84.6
Dev.	77.3	78.6	85.4	91.8
Test	63.0	64.7	75.0	83.3

Table 2: Percentage of summary edges that can be covered by an automatically constructed source graph.

graph (§4.2). In Table 2, columns one and two report labeled and unlabeled edge coverage. 'Unlabeled' counts edges as matching if both the source and destination concepts have identical labels, but ignores the edge label.

In order to improve edge coverage, we explore expanding the source graph by adding every possible edge between every pair of concepts within the same sentence. We also explored adding every possible edge between every pair of concepts in the entire source graph. Edges that are newly introduced during expansion receive a default label 'null'. We report unlabeled edge coverage in Table 2, columns three and four, respectively. Subgraph prediction became infeasable with the document-level expansion, so we conducted our experiments using only sentence-level expansion. Sentence-level graph expansion increases the average number of edges by a factor of 15, to 3,292. Fig. 3 illustrates the motivation. Document-level expansion covers the gold-standard summary edge "chase-01" → "garden," yet the expansion is computationally prohibitive; sentence-level expansion adds an edge "dog" → "garden," which enables the prediction of a structure with similar semantic meaning: "Joe's dog was in the garden chasing a cat."

4.2 Subgraph Prediction

We pose the selection of a summary subgraph from the source graph as a structured prediction problem that trades off among including important information without altering its meaning, maintaining brevity, and producing fluent language (Nenkova and McKeown, 2011). We incorporate these concerns in the form of features and constraints in the statistical model for subgraph selection.

Let $G = (V, E)$ denote the merged source graph, where each node $v \in V$ represents a unique concept and each directed edge $e \in E$ connects two concepts. G is a connected, directed, node-labeled graph. Edges in this graph are unlabeled, and edge labels are not predicted during subgraph selection. We seek to maximize a score that factorizes over graph nodes and edges that are included in the summary graph. For subgraph (V', E'):

$$score(V', E'; \boldsymbol{\theta}, \boldsymbol{\psi}) = \sum_{v \in V'} \boldsymbol{\theta}^\top \mathbf{f}(v) + \sum_{e \in E'} \boldsymbol{\psi}^\top \mathbf{g}(e) \quad (1)$$

where $\mathbf{f}(v)$ and $\mathbf{g}(e)$ are the feature representations of node v and edge e, respectively. We describe node and edge features in Table 3. $\boldsymbol{\theta}$ and $\boldsymbol{\psi}$ are vectors of empirically estimated coefficients in a linear model.

We next formulate the selection of the subgraph using integer linear programming (ILP; §4.2.1) and describe supervised learning for the parameters (coefficients) from a collection of source graphs paired with summary graphs (§4.2.2).

4.2.1 Decoding

We cast decoding as an ILP whose constraints ensure that the output forms a connected subcomponent of the source graph. We index source graph concept nodes by i and j, giving the "ROOT" node

Node Features	Concept	Identity feature for concept label
	Freq	Concept freq in the input sentence set; one binary feature defined for each frequency threshold $\tau = 0/1/2/5/10$
	Depth	Average and smallest depth of node to the root of the sentence graph; binarized using 5 depth thresholds
	Position	Average and foremost position of sentences containing the concept; binarized using 5 position thresholds
	Span	Average and longest word span of concept; binarized using 5 length thresholds; word spans obtained from JAMR
	Entity	Two binary features indicating whether the concept is a named entity/date entity or not
	Bias	Bias term, 1 for any node
Edge Features	Label	First and second most frequent edge labels between concepts; relative freq of each label, binarized by 3 thresholds
	Freq	Edge frequency (w/o label, non-expanded edges) in the document sentences; binarized using 5 frequency thresholds
	Position	Average and foremost position of sentences containing the edge (without label); binarized using 5 position thresholds
	Nodes	Node features extracted from the source and target nodes (all above node features except the bias term)
	IsExpanded	A binary feature indicating the edge is due to graph expansion or not; edge freq (w/o label, all occurrences)
	Bias	Bias term, 1 for any edge

Table 3: Node and edge features (all binarized).

index 0. Let N be the number of nodes in the graph. Let v_i and $e_{i,j}$ be binary variables. v_i is 1 iff source node i is included; $e_{i,j}$ is 1 iff the directed edge from node i to node j is included.

The ILP objective to be maximized is Equation 1, rewritten here in the present notation:

$$\sum_{i=1}^{N} v_i \underbrace{\boldsymbol{\theta}^\top \mathbf{f}(i)}_{\text{node score}} + \sum_{(i,j)\in E} e_{i,j} \underbrace{\boldsymbol{\psi}^\top \mathbf{g}(i,j)}_{\text{edge score}} \quad (2)$$

Note that this objective is linear in $\{v_i, e_{i,j}\}_{i,j}$ and that features and coefficients can be folded into node and edge scores and treated as constants during decoding.

Constraints are required to ensure that the selected nodes and edges form a valid graph. In particular, if an edge (i, j) is selected ($e_{i,j}$ takes value of 1), then both its endpoints i, j must be included:

$$v_i - e_{i,j} \geq 0, \quad v_j - e_{i,j} \geq 0, \quad \forall i, j \leq N \quad (3)$$

Connectivity is enforced using a set of single-commodity flow variables $f_{i,j}$, each taking a non-negative integral value, representing the flow from node i to j. The root node sends out up to N units of flow, one to reach each included node (Equation 4). Each included node consumes one unit of flow, reflected as the difference between incoming and outgoing flow (Equation 5). Flow may only be sent over an edge if the edge is included (Equation 6).

$$\sum_i f_{0,i} - \sum_i v_i = 0, \quad (4)$$

$$\sum_i f_{i,j} - \sum_k f_{j,k} - v_j = 0, \quad \forall j \leq N, \quad (5)$$

$$N \cdot e_{i,j} - f_{i,j} \geq 0, \quad \forall i, j \leq N. \quad (6)$$

The AMR representation allows graph reentrancies (concept nodes having multiple parents), yet reentrancies are rare; about 5% of edges are reentrancies in our dataset. In this preliminary study we force the summary graph to be tree-structured, requiring that there is at most one incoming edge for each node:

$$\sum_j e_{i,j} \leq 1, \quad \forall j \leq N. \quad (7)$$

Interestingly, the formulation so far equates to an ILP for solving the prize-collecting Steiner tree problem (PCST; Segev, 1987), which is known to be NP-complete (Karp, 1972). Our ILP formulation is modified from that of Ljubić et al. (2006). Flow-based constraints for tree structures have also previously been used in NLP for dependency parsing (Martins et al., 2009) and sentence compression (Thadani and McKeown, 2013). In our experiments, we use an exact ILP solver,[5] though many approximate methods are available.

Finally, an optional constraint can be used to fix the size of the summary graph (measured by the number of edges) to L:

$$\sum_i \sum_j e_{i,j} = L \quad (8)$$

The performance of summarization systems depends strongly on their compression rate, so systems are only directly comparable when their compression rates are similar (Napoles et al., 2011). L is supplied to the system to control summary graph size.

[5] http://www.gurobi.com

4.2.2 Parameter Estimation

Given a collection of input and output pairs (here, source graphs and summary graphs), a natural starting place for learning the coefficients $\boldsymbol{\theta}$ and $\boldsymbol{\psi}$ is the structured perceptron (Collins, 2002), which is easy to implement and often performs well. Alternatively, incorporating factored cost functions through a structured hinge loss leads to a structured support vector machine (SVM; Taskar et al., 2004) which can be learned with a very similar stochastic optimization algorithm. In our scenario, however, the gold-standard summary graph may not actually be a subset of the source graph. In machine translation, *ramp loss* has been found to work well in situations where the gold-standard output may not even be in the hypothesis space of the model (Gimpel and Smith, 2012). The structured perceptron, hinge, and ramp losses are compared in Table 4.

We explore learning by minimizing each of the perceptron, hinge, and ramp losses, each optimized using Adagrad (Duchi et al., 2011), a stochastic optimization procedure. Let β be one model parameter (coefficient from $\boldsymbol{\theta}$ or $\boldsymbol{\psi}$). Let $g^{(t)}$ be the subgradient of the loss on the instance considered on the t^{th} iteration with respect to β. Given an initial step size η, the update for β on iteration t is:

$$\beta^{(t+1)} \leftarrow \beta^{(t)} - \frac{\eta}{\sqrt{\sum_{\tau=1}^{t}(g^{(\tau)})^2}} g^{(t)} \qquad (9)$$

5 Generation

Generation from AMR-like representations has received some attention, e.g., by Langkilde and Knight (1998) who described a statistical method. Though we know of work in progress driven by the goal of machine translation using AMR, there is currently no system available.

We therefore use a heuristic approach to generate a bag of words. Given a predicted subgraph, a system summary is created by finding the most frequently aligned word span for each concept node. (Recall that the JAMR parser provides these alignments; §2). The words in the resulting spans are generated in no particular order. While this is not a natural language summary, it is suitable for unigram-based summarization evaluation methods like ROUGE-1.

6 Experiments

In Table 5, we report the performance of subgraph prediction and end-to-end summarization on the test set, using gold-standard and automatic AMR parses for the input. Gold-standard AMR annotations are used for model training in all conditions. During testing, we apply the trained model to source graphs constructed using either gold-standard or JAMR parses. In all of these experiments, we use the number of edges in the gold-standard summary graph to fix the number of edges in the predicted subgraph, allowing direct comparison across conditions.

Subgraph prediction is evaluated against the gold-standard AMR graphs on summaries. We report precision, recall, and F_1 for nodes, and F_1 for edges.[6]

Oracle results for the subgraph prediction stage are obtained using the ILP decoder to minimize the cost of the output graph, given the gold-standard. We assign wrong nodes and edges a score of -1, correct nodes and edges a score of 0, then decode with the same structural constraints as in subgraph prediction. The resulting graph is the best summary graph in the hypothesis space of our model, and provides an upper bound on performance achievable within our framework. Oracle performance on node prediction is in the range of 80% when using gold-standard AMR annotations, and 70% when using JAMR output. Edge prediction has lower performance, yielding 52.2% for gold-standard and 31.1% for JAMR parses. When graph expansion was applied, the numbers increased to 64% and 46.7%, respectively. The uncovered summary edge (i.e., those not covered by source graph) is a major source for low recall values on edge prediction (see Table 2); graph expansion slightly alleviates this issue.

Summarization is evaluated by comparing system summaries against reference summaries, using ROUGE-1 scores (Lin, 2004)[7]. System summaries are generated using the heuristic approach presented in §5: given a predicted subgraph, the approach finds the most frequently aligned word span for each concept node, and then puts them together as a bag of words. ROUGE-1 is particularly usefully for eval-

[6] Precision, recall, and F_1 are equal since the number of edges is fixed.

[7] ROUGE version 1.5.5 with options '-e data -n 4 -m -2 4 -u -c 95 -r 1000 -f A -p 0.5 -t 0 -a -x'

Structured perceptron loss:	$-score(G^*)$	$+ \max_G score(G)$
Structured hinge loss:	$-score(G^*)$	$+ \max_G (score(G) + cost(G; G^*))$
Structured ramp loss:	$-\max_G (score(G) - cost(G; G^*))$	$+ \max_G (score(G) + cost(G; G^*))$

Table 4: Loss functions minimized in parameter estimation. G^* denotes the gold-standard summary graph. $score(\cdot)$ is as defined in Equation 1. $cost(G; G^*)$ penalizes each vertex or edge in $G \cup G^* \setminus (G \cap G^*)$. Since *cost* factors just like the scoring function, each $\max$ operation can be accomplished using a variant of ILP decoding (§4.2.1) in which the cost is incorporated into the linear objective while the constraints remain the same.

		Subgraph Prediction				**Summarization**		
		Nodes			**Edges**	**ROUGE-1**		
		P (%)	R (%)	F (%)	F (%)	P (%)	R (%)	F (%)

	Oracle	64.1	74.8	68.9	31.1	87.5	43.7	57.8
	Oracle + Expand	66.9	76.4	71.2	46.7			

Table 5: Subgraph prediction and summarization (to bag of words) results on test set. Gold-standard AMR annotations are used for model training in all conditions. "+ Expand" means the result is obtained using source graph with expansion; edge performance is measured ignoring labels.

uating such less well-formed summaries, such as those generated from speech transcripts (Liu and Liu, 2013).

Oracle summaries are produced by taking the gold-standard AMR parses of the reference summary, obtaining the most frequently aligned word span for each unique concept node using the JAMR aligner (§2), and then generating a bag of words summary. Evaluation of oracle summaries is performed in the same manner as for system summaries. The above process does not involve graph expansion, so summarization performance is the same for the two conditions "Oracle" and "Oracle + Expand."

We find that JAMR parses are a large source of degradation of edge prediction performance, and a smaller but still significant source of degradation for concept prediction. Surprisingly, using JAMR parses leads to slightly improved ROUGE-1 scores. Keep in mind, though, that under our bag-of-words generator, ROUGE-1 scores only depend on concept prediction and are unaffected by edge prediction. The oracle summarization results, 65.8% and 57.8% F_1 scores for gold-standard and JAMR parses, respectively, further suggest that improved graph summarization models (step 2) might benefit from future improvements in AMR parsing (step 1).

Across all conditions and both evaluations, we find that incorporating a cost-aware loss function (hinge vs. perceptron) has little effect, but that using ramp loss leads to substantial gains.

In Table 5, we show detailed results with and without graph expansion. "+ Expand" means the results are obtained using the expanded source graph. We find that graph expansion only marginally affects system performance. Graph expansion slightly hurts the system performance on edge prediction. For example, using ramp loss with JAMR parser as input, we obtained 50.7% and 19.0% for node and edge prediction with graph expansion; 51.5% and 20.0%

without edge expansion. On the other hand, it increases the oracle performance by a large margin. This suggests that with more training data, or a more sophisticated model that is able to better discriminate among the enlarged output space, graph expansion still has promise to be helpful.

7 Related and Future Work

According to Dang and Owczarzak (2008), the majority of competitive summarization systems are extractive, selecting representative sentences from input documents and concatenating them to form a summary. This is often combined with sentence compression, allowing more sentences to be included within a budget. ILPs and approximations have been used to encode compression and extraction (McDonald, 2007; Martins and Smith, 2009; Gillick and Favre, 2009; Berg-Kirkpatrick et al., 2011; Almeida and Martins, 2013; Li et al., 2014). Other decoding approaches have included a greedy method exploiting submodularity (Lin and Bilmes, 2010), document reconstruction (He et al., 2012), and graph cuts (Qian and Liu, 2013), among others.

Previous work on abstractive summarization has explored user studies that compare extractive with NLG-based abstractive summarization (Carenini and Cheung, 2008). Ganesan et al. (2010) propose to construct summary sentences by repeatedly searching the highest scored graph paths. (Gerani et al., 2014) generate abstractive summaries by modifying discourse parse trees. Our work is similar in spirit to Cheung and Penn (2014), which splices and recombines dependency parse trees to produce abstractive summaries. In contrast, our work operates on semantic graphs, taking advantage of the recently developed AMR Bank.

Also related to our work are graph-based summarization methods (Vanderwende et al., 2004; Erkan and Radev, 2004; Mihalcea and Tarau, 2004). Vanderwende et al. (2004) transform input to logical forms, score nodes using PageRank, and grow the graph from high-value nodes using heuristics. In Erkan and Radev (2004) and Mihalcea and Tarau (2004), the graph connects surface terms that co-occur. In both cases, the graphs are constructed based on surface text; it is not a representation of propositional semantics like AMR. However, future work might explore similar graph-based calculations to contribute features for subgraph selection in our framework.

Our constructed source graph can easily reach ten times or more of the size of a sentence dependency graph. Thus more efficient graph decoding algorithms, e.g., based on Lagrangian relaxation or approximate algorithms, may be explored in future work. Other future directions may include jointly performing subgraph and edge label prediction; exploring a full-fledged pipeline that consists of an automatic AMR parser, a graph-to-graph summarizer, and a AMR-to-text generator; and devising an evaluation metric that is better suited to abstractive summarization.

Many domains stand to eventually benefit from summarization. These include books, audio/video segments, and legal texts.

8 Conclusion

We have introduced a statistical abstractive summarization framework driven by the Abstract Meaning Representation. The centerpiece of the approach is a structured prediction algorithm that transforms semantic graphs of the input into a single summary semantic graph. Experiments show the approach to be promising and suggest directions for future research.

Abstract

Previous work on text coherence was primarily based on matching multiple mentions of the same entity in different parts of the text; therefore, it misses the contribution from semantically related but not necessarily coreferential entities (e.g., ***Gates*** and ***Microsoft***). In this paper, we capture such semantic relatedness by leveraging world knowledge (e.g., ***Gates*** *is the person who created* ***Microsoft***), and use two existing evaluation frameworks. First, in the unsupervised framework, we introduce semantic relatedness as an enrichment to the original graph-based model of Guinaudeau and Strube (2013). In addition, we incorporate semantic relatedness as additional features into the popular entity-based model of Barzilay and Lapata (2008). Across both frameworks, our enriched model with semantic relatedness outperforms the original methods, especially on short documents.

1 Introduction

In a well-written document, sentences are organized and presented in a logical and coherent form, which makes the text fluent and easily understood. Therefore, coherence is a fundamental aspect of high text quality, and the evaluation of coherence is a crucial component of many NLP applications, such as essay scoring (Miltsakaki and Kukich, 2004), story generation (McIntyre and Lapata, 2010), and document summarization (Barzilay et al., 2002).

A particularly popular model for evaluating text coherence is the entity-based local coherence model of Barzilay and Lapata (2008) (B&L), which extracts mentions of entities in adjacent sentences, and captures local coherence in terms of the transitions in the grammatical role of each mention. Following this direction, a number of extensions have been proposed (Elsner and Charniak, 2008; Elsner and Charniak, 2011; Lin et al., 2011; Feng et al., 2014), the majority of which focus on enriching the original entity features. An exception is the unsupervised model of Guinaudeau and Strube (2013) (G&S), which converts the document into a graph of sentences, and evaluates the text coherence by computing the average out-degree over the entire graph.

However, despite the apparent success of these methods, they rely merely on matching mentions of the same entity, but neglect the contribution from semantically related but not necessarily coreferential entities. For example, the text in Figure 1a[1] has no common entity in s_2 and s_3. However, the transition between them is perfectly coherent, because there exists close semantic relatedness between two distinct entities, ***Gates*** in s_2 and ***Microsoft*** in s_3, which can be captured by the world knowledge that ***Gates*** *is the person who created* ***Microsoft*** (represented by ***Gates-create-Microsoft***). In fact, the issue of absence of common entities between adjacent sentences is quite prevalent. Analyzing the CoNLL 2012 dataset (Pradhan et al., 2012), we found that 42.34% of the time, adjacent sentences do not share common entities. As a result, methods which rely on strict entity matching would fail on these cases.

*This work was partly done while the first author was visiting University of Toronto.

Denver, Colorado, May 31 – June 5, 2015.

s_1: In 1980, [Gates]$_S$ licensed [86-DOS]$_O$ from [Tim Paterson]$_X$ for $50,000, which marketed it as [PC-DOS]$_X$.
s_2: [Gates' smartest move]$_S$ was retaining [ownership of the source code]$_O$ of what he and [Allen]$_X$ would develop as [MS-DOS]$_X$.
s_3: [Microsoft]$_S$ got a [licensing fee]$_O$ every time [IBM]$_S$ sold a [PC]$_O$.

(a) A fragment of news text

	Gates	86-DOS	Paterson	PC-DOS	Move	Ownership	Source	Code	MS-DOS	Microsoft	Fee	Time	IBM	PC
s_1	S	O	X	X	-	-	-	-	-	-	-	-	-	-
s_2	S	-	-	-	S	O	O	O	O	-	-	-	-	-
s_3	-	-	-	-	-	-	-	-	-	S	O	X	S	O

(b) The corresponding entity grid

Figure 1: A news text fragment with its corresponding entity grid constructed following B&L (2008). Although s_2 and s_3 share no entity, their transition is still coherent, because ***Gates*** and ***Microsoft*** are semantically related by the knowledge ***Gates-create-Microsoft***.

We wish to incorporate semantic relatedness between different entities into existing models to tackle the problem described above. In particular, we propose to capture such semantic relatedness between different entities with world knowledge represented as triples, e.g., ***Gates-create-Microsoft***. Given a text to be evaluated, we first retrieve relevant world knowledge from multiple sources. For the unsupervised framework of G&S, we integrate knowledge into the original graph-based document representation, in which sentences are the nodes and edges are formed by shared entities and our world knowledge. Then, we adopt a dynamic programming algorithm to produce a coherence score for the text. For the supervised framework of B&L, we incorporate the world knowledge as a novel set of features into the original entity-based model, and train a model to discriminate different degrees of text coherence.

To evaluate the impact of incorporating semantic relatedness, we conduct experiments on two datasets, each of which resembles a real sub-task in the text coherence modeling: **sentence ordering** and **summary coherence rating**. On both tasks, across two frameworks, supervised and unsupervised, we perform a direct comparison between our enhanced model and the original one. On both tasks, our models are shown to be more powerful than the models relying on entity matching only. Moreover, for sentence ordering, world knowledge is shown to be especially useful on short documents.

2 Background

2.1 Entity-based local coherence modeling

The initial entity-based model was developed by B&L. It is based on the intuition that there exists a canonical order of how entities occur in the text. Therefore, we can model text coherence by measuring how mentions of various entities are distributed within the text. Specifically, for a given document d, an entity grid is constructed in which the rows represent the sentences and the columns represent entities. Each grid cell r_{ij} corresponds to the syntactic role of entity e_j in sentence s_i: subject (S), object (O), other (X), or nothing ($-$). For example, Figure 1b shows the entity grid of the text shown in Figure 1a. If an entity serves multiple syntactic roles in a sentence, its grammatical role is resolved according to the priority order: $S \succ O \succ X \succ -$.

Based on the entity grid representation, a local coherence transition is defined as a sequence $\{S, O, X, -\}^n$, representing the grammatical roles or absence of a particular entity across n adjacent sentences. Then, the document is encoded as a feature vector $\Phi(d) = (p_1(d), p_2(d), \ldots, p_m(d))$, where $p_t(d)$ is the normalized frequency of the transition t in the entity grid, and m is the number of predefined transitions. $p_t(d)$ is computed as the number of occurrences of transition t among all entities in the entity grid, divided by the total number of transitions of the same length. Using this feature encoding, the model is then trained as a preference ranking problem between documents of different degrees of coherence.

2.2 Graph-based local coherence modeling

As mentioned previously, most extensions to the entity-based local coherence model focus on enriching the feature set (Filippova and Strube, 2007; Elsner and Charniak, 2011; Lin et al., 2011; Feng et al., 2014), all of which follow a supervised learning framework. To the best of our knowledge, the only exception is the unsupervised method proposed by

G&S, which transforms the entity grid into a sentence graph and measures text coherence by computing the average out-degree of the graph. For a document d, its entity grid is constructed first, following the method described in Section 2.1. Then, a bipartite graph $G = (V_s, V_e, L, W)$ is constructed, where V_s is the set of nodes representing sentences in the text; V_e is the set of nodes representing entities; L is the set of edges associated with a weight $w \in W$. An edge exists between a sentence s_x and an entity e, if and only if e occurs in s_x. Each edge is further associated with a weight $w(e, s_x)$, determined by the grammatical role of the entity e in sentence s_x: 3 for subject (S), 2 for object (O), 1 for other (X), and 0 for nothing ($-$). Note that graph G consists of both sentence nodes and entity nodes.

Then, G is converted to another graph P, which consists of sentence nodes only, where an edge connects two sentence nodes if and only if at least one entity is shared between these two sentences. In P, the weight of each edge is computed by aggregating the edge weights in the original bipartite graph G:

$$w^{(P)}(s_x, s_y) = \sum_{e \in E_{xy}} w^{(G)}(e, s_x) * w^{(G)}(e, s_y), \quad (1)$$

where E_{xy} is the set of entities shared by two sentences s_x and s_y, and $w^{(G)}(e, s_x)$ is the weight of edge between entity e and sentence s_x as illustrated before. The coherence of the document is thus measured by the average out-degree of graph P.

Although this method is purely unsupervised, it achieves a performance comparable with its supervised counterparts, e.g., B&L. However, since this method still relies on matching multiple mentions of the same entity, it misses the important contribution from those semantically related yet distinct entities, e.g. ***Gates*** and ***Microsoft*** in Figure 1a.

3 Finding relevant world knowledge

To supplement existing models with information derived from semantic relatedness, given a document d to be evaluated, we first retrieve all world knowledge related to d. There are two major issues for this process: (1) **knowledge sources**: where can we obtain this knowledge?, and (2) **knowledge selection**: how do we pinpoint the most relevant ones?

Knowledge sources There are two main kinds of knowledge sources: (1) manually edited knowledge bases, such as YAGO (Hoffart et al., 2013), which consists of about 4 million human-edited instances from on-line encyclopedias such as WikiPedia (Denoyer and Gallinari, 2007) and FreeBase (Bollacker et al., 2008), and (2) automatically constructed knowledge bases, such as Reverb (Fader et al., 2011), which covers about 20 million instances extracted from raw texts. Generally speaking, manually edited knowledge bases have better accuracy but lower coverage, while automatically extracted knowledge bases are the opposite. To seek a good balance, we use both YAGO and Reverb as our knowledge sources. In addition, the automatically constructed knowledge bases can be extracted from raw texts of any domain, which makes our method adaptable. Both sources are presented in triples, $argument_1$-*predicate*-$argument_2$, (e.g., ***Gates-create-Microsoft***), where the two arguments are usually entities and the predicate is the relation between them (Zhang et al., 2014).

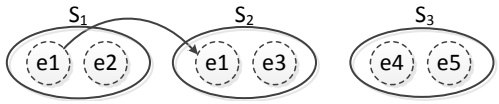
Knowledge selection For each document d, we then select the subset of relevant knowledge instances, in the sense that they represent relations between the entities in d. In particular, we extract all entities in d, and query the knowledge bases to obtain all the knowledge instances in which both of the two arguments, $argument_1$ and $argument_2$, match some of the entities in d.

One issue in knowledge selection is whether to retrieve knowledge instances using exact or partial matching. For a given pair of entities in the text, the chance is rather low to find instances in the knowledge bases where the two arguments perfectly match the pair of entities, because entities in the source document might appear in aliases or abbreviations. In contrast, partial matching between arguments and entities usually increases coverage but at risk of introducing more noise. In our work, to balance accuracy and coverage, when retrieving world knowledge, we use partial matching and form queries only for those entities realized as noun phrases in the text.

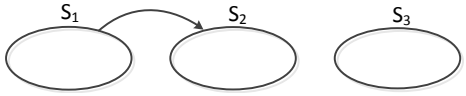
4 World knowledge encoding

4.1 Unsupervised graph-based framework

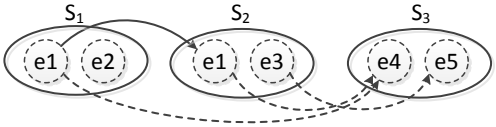
As described in Section 2.2, G&S represents the text as a graph and measures the coherence by the average out-degree of the graph. In this part, we describe



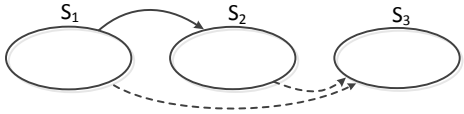
(a) Traditional entity graph relying on entity matching



(b) Traditional sentence graph converted from (a)



(c) Our entity graph encoding relatedness between entities



(d) Our sentence graph converted from (c)

Figure 2: (a) and (b) show the traditional entity and sentence graph based on matching multiple mentions of the same entity; while (c) and (d) represent our entity and sentence graph encoding semantic relatedness between those semantically related but not necessarily coreferential entities (e.g., ***Gates*** and ***Microsoft***) by adding *world-knowledge edges* (dashed lines) accroding to world knowledge (e.g., ***Gates-create-Microsoft***).

how we capture semantic relatedness by encoding world knowledge to the graph-based model. The outline of our method is as follows. Given a document d, we first retrieve relevant world knowledge from multiple sources (see Section 3). Then, we construct an *entity graph* with world knowledge to capture both the distribution information and semantic relatedness between entities (see Section 4.1.1). After that, we convert the entity graph into a *sentence graph* (see Section 4.1.2), in which two sentences are connected not only through common entities but also through world knowledge. Finally, we apply our novel *reachability score computation* **over the sentence graph** to produce a coherence score for the text to be evaluated (see Section 4.1.3).

4.1.1 Entity graph

As shown in Figure 2c, there are two kinds of edges in our *entity graph*: (1) *common-entity edges* (solid lines), which connect different mentions of the same entity, such as ***Gates*** in s_1 and ***Gates*** in s_2; (2) *world-knowledge edges* (dashed lines), which connect different entities through certain world knowledge, such as ***Gates*** in s_2 and ***Microsoft*** in s_3 related by ***Gates-create-Microsoft***. This representation captures not only the distribution information of individual entities but also the semantic relatedness between different entities. In contrast, the original graph-based model by G&S (Figures 2a and 2b) includes common-entity edges only and misses the semantic relatedness information. Formally, for a document d, we define its entity graph as $G = (V, L_m, L_k, W_m, W_k)$, where V denotes the nodes of entities; L_m denotes the set of common-entity edges and L_k denotes the set of world-knowledge edges; and W_m and W_k are the two sets of weights associated with L_m and L_k respectively.

Following G&S, for each common-entity edge $l_m \in L_m$, which connects two mentions of the same entity e appearing in different sentences s_x and s_y, we compute its weight as $w(e, s_x) \times w(e, s_y)$, where the value of $w(e, s_x)$ is based on the grammatical role of the entity e in the sentence s_x as follows: 3 for subject (S), 2 for object (O), 1 for other (X), and 0 for nothing($-$). When multiple mentions of the same entity appear with different grammatical roles in the same sentence, the role with the highest weight is chosen to represent the entity. For each world-knowledge edge $l_k \in L_k$, which connects two different entities e_{ix} and e_{jy} appearing in sentence s_x and s_y respectively, we consider three factors when assigning the weight to the edge: (1) semantic relatedness between e_{ix} and e_{jy}: higher relatedness leads to a higher weight; (2) the grammatical roles of e_{ix} and e_{jy} in s_x and s_y: different roles correspond to different weights; and (3) textual distance between e_{ix} and e_{jy}: longer distance results in a lower weight. Therefore we compute the weight of l_k between e_{ix} and e_{jy} as below:

$$w_k(e_{ix}, e_{jy}) = \frac{r(e_i, e_j) \times w(e_{ix}, s_x) \times w(e_{jy}, s_y)}{d(e_{ix}, e_{jy}) \times 2}, \quad (2)$$

where $w(e_{ix}, s_x)$ is associated to the grammatical role of e_{ix} in s_x as illustrated before; $d(e_{ix}, e_{jy})$ is the distance between e_{ix} and e_{jy}; and $r(e_i, e_j)$ is the semantic relatedness between e_{ix} and e_{jy} as shown in For-

mula 3 below. Note that the value of $r(e_i, e_j)$ is independent of the sentence in which e_i and e_j appear, so we denote it as $r(e_i, e_j)$ instead of $r(e_{ix}, e_{jy})$.

$$r(e_i, e_j) = \begin{cases} \dfrac{\log n(e_i, e_j)}{\max\limits_{l_{mn} \in L_k} \log n(e_m, e_n)} & \text{if } n(e_i, e_j) > 2, \\ 0 & \text{otherwise.} \end{cases} \tag{3}$$

where $n(e_i, e_j)$ corresponds to the number of world knowledge instances relating e_i and e_j. For instance, Figure 1a contains an edge between ***Gates*** (e_1 in s_1) and ***Microsoft*** (e_2 in s_3), in which $w(e_{11}, s_1)$ and $w(e_{23}, s_3)$ are 3, and $d(e_{11}, e_{23})$ is 2. Note that we consider the grammatical roles in both common edges and background knowledge edges because we treat them independently from each other. The grammatical information is important to both of these two kinds of edges.

4.1.2 Sentence graph

Figure 2d shows the sentence graph converted from the entity graph in Figure 2c. In our work, in order to incorporate world knowledge, we adopt an enriched representation of sentence graph, $G' = (V', L'_m, L'_k, W'_m, W'_k)$, where V' is the sentence nodes; L'_m denotes the set of common-entity edges (solid lines); L'_k denotes the set of world-knowledge edges (dashed lines), and W'_m and W'_k correspond to the weights associated with the edges in L'_m and L'_k.

Intuitively, the semantic relatedness between two sentences can be measured as the total relatedness of each entity pair in the two sentences. Therefore, in our enhanced sentence graph representation, for a pair of sentences s_x and s_y, the weight of their common-entity edge, $w'_m(s_x, s_y)$, is computed as $w'_m(s_x, s_y) = \sum_{e_i \in V_{xy}} w_m(e_{ix}, e_{iy})$, where V_{xy} is the set of entities shared by two sentences s_x and s_y, and $w_m(e_{ix}, e_{iy})$ is the weight of the corresponding common-entity edge in the entity graph (see Section 4.1.1). Similarly, the weight of their world-knowledge edge, $w'_k(s_x, s_y)$, is computed as $w'_k(s_x, s_y) = \sum_{e_i \in V_x, e_j \in V_y} w_k(e_{ix}, e_{jy})$, where V_x and V_y denote the set of entities in s_x and s_y respectively, and $w_k(e_{ix}, e_{jy})$ is the weight of the corresponding world-knowledge edge in the entity graph.

Algorithm 1: Reachability score computation.

Input: $G' = (V', L'_m, L'_k, W'_m, W'_k)$.
Output: The final reachability score S.

$n \leftarrow |V'|$
for $j = 1 \rightarrow n$ **do**
  $score(v'_j) \leftarrow 0$
for $j = 1 \rightarrow n$ **do**
  for $i = 0 \rightarrow j - 1$ **do**
    if $l'_m(i, j) \in L'_m$ **then**
      $score(v'_j) \leftarrow score(v'_i) + w'_m(i, j)$
    if $l'_k(i, j) \in L'_k$ **then**
      $score(v'_j) \leftarrow score(v'_i) + w'_k(i, j)$
return $S = \dfrac{\sum_{v'_j \in V' \wedge out(v'_j)=0} score(v'_j)}{|\{v'_j : v'_j \in V' \wedge out(v'_j) = 0\}|}$

4.1.3 Reachability score computation

Based on our sentence graph representation, we compute a reachability score for each sentence node. To produce a final coherence score for the text, we compute the ***average reachability score*** among those nodes whose out-degree is equal to 0 in the graph, rather than among all nodes, because of the intuition that, if a sentence node has no subsequent nodes, their reachability score therefore reflects the tightness between this sentence and the preceding part of the text. For a certain sentence node v'_j, its reachability score is defined as the sum of edge weights on all paths from the starting node (i.e., the first sentence) to v'_j, and the contribution of each path to the final reachability score depends on the total weight of that path as shown in Equation 4.

$$score(v'_j) = \sum_{v'_i \in V', v'_i \neq v'_j} (score(v'_i) + w'_m(i, j) + w'_k(i, j)) \tag{4}$$

where $score(v'_i)$ denotes the reachability score of v'_i, and $w'_m(i, j)$ and $w'_k(i, j)$ are the weights of the common-entity edge and the world-knowledge edge between v'_i and v'_j; if there is no such edge in the graph, the corresponding weight is set to 0.

Algorithm 1 summarizes our reachability score computation, in which the reachability score of each node is initially 0, and iteratively updated.

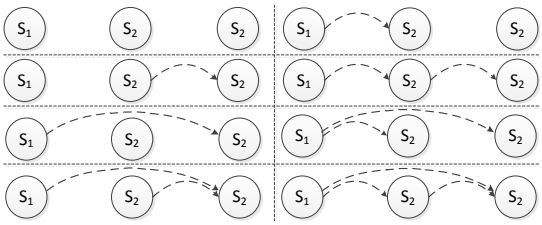


Figure 3: Eight patterns of how world knowledge is distributed among three adjacent sentences.

4.2 Supervised entity-based framework

As mentioned previously, numerous extensions have been proposed to the original entity-based model of B&L. However, those extensions mostly rely on entity matching and thus fail to incorporate the information from semantically related yet distinct entities. We propose a novel extension by introducing world knowledge to capture entity-wise relatedness.

Inspired by the original entity-based model, in which local coherence is reflected by the patterns of how entities act grammatically from one sentence to the next, we believe that local coherence can also be characterized by the patterns of how world knowledge relates a pair of sentences. Specifically, given a set of sentences, there are different patterns of how knowledge instances are distributed among them. We consider modeling those patterns within a window of 3 sentences, in which there are $2^3 = 8$ different distribution patterns, as shown in Figure 3. We then use the frequencies of these distribution patterns over the entire document as additional features into the entity-based model. In particular, for each particular distribution pattern b_k, its corresponding frequency $p(b_k) = \frac{|b_k|}{|V'| - 2}$, where $|b_k|$ is the number of occurrences of b_k in the sentence graph.

In addition to $p(b_k)$, we also compute another feature, $p(E)$, which is the frequency that two nodes are connected by certain world knowledge over the sentence graph, reflecting the overall semantic relatedness within the graph. $p(E)$ is computed as $p(E) = \frac{|L'_k|}{|V'|}$. With these world knowledge features incorporated into the original entity-based model, we obtain an enhanced model with an emphasis on semantic relatedness between different entities.

5 Experiments

To evaluate the impact of incorporating semantic relatedness, we conduct experiments on two datasets, each of which resembles a real sub-task in modeling text coherence: **sentence ordering** and **summary coherence rating**. Since text coherence is a relative concept rather than a binary distinction, in both tasks, we formulate the problem as pairwise preference ranking. Specifically, given a set of texts with different degrees of coherence, we train a ranker to prefer the more coherent text over the less coherent one. Performance is therefore measured as the fraction of correct pairwise rankings as recognized by the ranker. We use SVM^{light} (Joachims, 2002) with the ranking configuration to train and evaluate our models, with all parameters set to default values.

On both tasks, across two frameworks, supervised and unsupervised, we directly compare our modified model against the original one, i.e., B&L in the supervised framework and G&S in the unsupervised framework. In our experiments, we use the Stanford parser (Marneffe et al., 2006) to automatically extract the grammatical role for each entity mention.

5.1 Sentence ordering

The task of sentence ordering attempts to simulate the situation where, given a predefined set of information-bearing items, we need to determine the best order to arrange those items.

In this paper, we follow G&S and introduce CoNLL 2012[2] (Pradhan et al., 2012) as our dataset, which is composed of documents from multiple news sources. For each text, we randomly shuffle its sentences to generate 20 permutations with incorrect sentence order. For a fair comparison, we also evaluate our model on a filtered subset of documents with an average length of 31.8 sentences. Therefore, our dataset contains 72 documents and $72 \times 20 = 1440$ permutations, among which the shortest one contains 25 sentences. For our enhanced graph-based model (introduced in Section 4.1), which is purely unsupervised, we evaluate our model over the entire dataset. For our enhanced entity-based model (introduced in Section 4.2), which is purely supervised, we use half of the complete CoNLL dataset for training (237 documents plus permutations) and use half

[2]http://conll.cemantix.org/2012/data.html

of the filtered subset (36 documents plus permutations). The training and test sets do not overlap.

In this task, each training and test instance is composed of a pair of a source document and one of its permutations, and the source document is always considered more coherent than its permutation.

5.2 Summary coherence rating

The second task is summary coherence rating, in which, given a pair of summaries about the same set of source documents, we determine the ranking of these two summaries based on their degrees of coherence. The performance of the model is assessed by comparing model-induced rankings against the rankings given by human judges. We use the same dataset (DUC 2003) as B&L and G&S did, which consists of summaries generated either by human writers or by automatic summarization systems. Each summary was given a coherence score by averaging among seven judges. Often, machine-generated summaries receive low coherence scores because they contain sentences taken out of context and thus display problems with respect to coherence.

This dataset consists of 16 input document clusters, each of which is associated with five machine-generated summaries along with a human-written summary. In total, we have 96 summaries (for more details, see B&L). We form pairwise rankings by taking any two summaries originating from the same document cluster, given that the two summaries receive different coherence scores: 144 of the resulting rankings are used for training and 80 are for testing.

5.3 Experiment results

In this section, we demonstrate the performance of our models with world knowledge encoded in one of the two ways: paths in a sentence graph or features in an entity grid. We compare our models against the original graph-based model (G&S) and entity-based model (B&L). The evaluation is conducted on the two tasks, sentence ordering and summary coherence rating, and the accuracy is the fraction of correct pairwise rankings.

Table 1 shows the performance of various models on both tasks. The first section shows the results of G&S's graph-based local coherence model, including the performance reported in their original paper and that achieved by our re-implementation, representing the effect with no world knowledge encoded. The second section shows the performance of our two graph-based models with world knowledge encoded. *Graph model + K* is the basic model with world knowledge encoded, but coherence is simply measured as the average out-degree as in G&S's approach. *Graph model + K + Avg_R* replaces the out-degree measurement by our *average reachability score* (described in Section 4.1.3), which measures coherence in a more sophisticated way. The third section shows the results of B&L's entity-based local coherence model, including the originally reported performance and that obtained by our re-implementation, in which no world knowledge features are included. The last section, *Entity model + K*, shows the result of entity-based model with our world knowledge features encoded. Note that the random baseline of both tasks is 50%.

Model	**SO**	**SCR**
Graph model (G&S)	88.9	80.0
Graph model (Implemented)	89.6	48.8
Graph model + K	91.3**	50.0
Graph model + K + Avg_R	**93.4****	**55.0***
Entity model (B&L)	88.9	83.8
Entity model (Implemented)	93.7	90.0
Entity model + K	**95.1****	**91.3**

Table 1: Accuracies (%) of various models on the two tasks, sentence ordering (*SO*) and summary coherence rating (*SCR*). Models that perform significantly better than their corresponding re-implemented basic models are denoted by ** ($p < .01$) or * ($p < .05$), verified using paired *t*-test.

Firstly, for graph-based models, our *Graph model + K* outperforms the original models, suggesting that world knowledge is truly helpful for capturing more coherence information[3]. Moreover, by intro-

[3]The large discrepancy between the performance reported by G&S and that of our re-implementation in *Task 2* is due to the fact that G&S experimented with a set of specially formed summary pairs (see their paper for detail), which we have no access to. They also did not give sufficient details about how they constructed those summary pairs, which has a great impact on the final result. This made it difficult for us to fully re-implement their experiment. So we use B&L's set of summary pairs, which are generated randomly and are more difficult to distinguish, which explains our differing results from theirs.

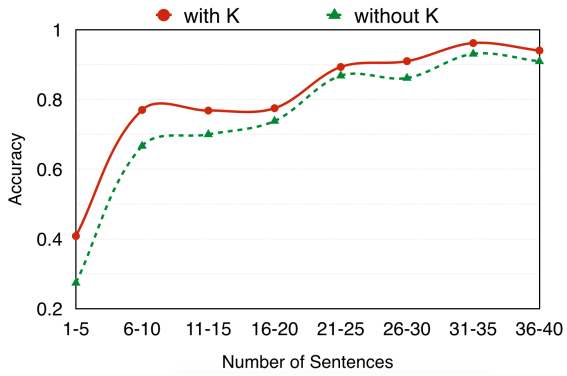

Figure 4: Graph-based models, with and without world knowledge (labeled as *With K* and *Without K*), tested on sets with different numbers of sentences.

ducing the scoring scheme of *average reachability score*, our *Graph model + K + Avg_R* achieves the best performance among all graph-based models.

Secondly, for entity-based models, our enhanced model with knowledge features encoded also achieves superior performance than our re-implemented model, again confirming the usefulness of world knowledge. Interestingly, we observe that our re-implementation obtains higher accuracy compared to the performance reported by B&L. This is partly due to the fact that the documents in our dataset have an average length of 31.5 sentences, which are longer than those used in B&L's experiments. We will further discuss this problem in Section 5.4 and show that document length is an important factor to the overall performance.

However, on the task of summary coherence rating, the difference between our extended models and the original ones is generally not significant, primarily due to the fact that the sample size for this task is too small, i.e., 80 pairwise rankings.

5.4 Effect of document length

5.4.1 Effect of document length on the overall performance

We further analyze the impact of document length on the task of sentence ordering. We partition our original dataset, which consists of 214 documents and their permutations, into 8 non-overlapping subsets, according to the length of documents: 1-5, 6-10,..., and 36-40 sentences. To illustrate the correlation between the performance and the length of document, we test our models with and without world knowledge encoded on each subset separately. Since the size of the available training data in each subset is relatively small, the supervised entity-based model suffers from sparsity. Therefore, we focus on the unsupervised graph-based models only.

Model	Accuracy (%)
Graph Model	27.4
Graph Model + K	**44.2**
Entity Model	65.8
Entity Model + K	**71.1**

Table 2: Performance of various models with and without world knowledge in the sentence ordering task, tested on short documents with 1–5 sentences.

Figure 4 shows the performance on different subsets. We can see that the performance of both models generally improves as the number of sentences increases. This observation is quite intuitive, because the longer a document is, the higher the chance is that, after being shuffled, adjacent sentences in the resulting permutation would be completely irrelevant to each other. Therefore, for longer documents, it is much easier for the model to distinguish a permutation from its source document.

5.4.2 Effect of document length on the model with world knowledge

Moreover, we also observe that the document length has a non-universal effect, in terms of how the model could benefit from incorporating world knowledge. Specifically, we find that world knowledge has a greater effect on short documents, as demonstrated in Table 2. Evaluated on a set of documents composed of 30 extremely short documents only (1–5 sentences), we see that our enhanced graph-based model is able to improve the performance by 16.8% over the basic model, and our enhanced entity-based model achieves 5.3% improvement (both differences are significant at $p < .01$). We postulate that it is primarily because a document with fewer sentences tends to shift to another subtopic immediately without elaborating on the previous one, and strict entity matching would find it difficult to establish coherent transitions between them. Therefore, the contribution from semantic relatedness tends to dominate the overall performance.

6 Conclusions and future work

In this paper, for the evaluation of text coherence, we go beyond strict entity matching and model the semantic relatedness between distinct entities through the use of world knowledge. Specifically, we incorporate world knowledge into two existing frameworks: (1) the unsupervised graph-based model (G&S), and (2) the supervised entity-grid model (B&L). Across the two frameworks, on both of our evaluation tasks, sentence ordering and summary coherence rating, our enhanced models with world knowledge encoded are shown to be stronger than the corresponding basic models, confirming that semantic relatedness is truly important for coherence modeling and such relatedness can be effectively captured by world knowledge. Moreover, we observe that world knowledge is particularly useful for short documents in sentence ordering, as it provides additional clues to relate sub-topics in the text.

In our future work, we wish to explore the effect of our world knowledge in conjunction with discourse relations. Specifically, we plan to incorporate world knowledge into the framework of discourse role matrix (Lin et al., 2011; Feng et al., 2014). In addition, we also plan to develop a more sophisticated feature encoding by distinguishing different types of predicates in world knowledge triples.

Chinese Event Coreference Resolution: An Unsupervised Probabilistic Model Rivaling Supervised Resolvers

Chen Chen and **Vincent Ng**

Abstract

Recent work has successfully leveraged the semantic information extracted from lexical knowledge bases such as WordNet and FrameNet to improve English event coreference resolvers. The lack of comparable resources in other languages, however, has made the design of high-performance non-English event coreference resolvers, particularly those employing unsupervised models, very difficult. We propose a generative model for the under-studied task of Chinese event coreference resolution that rivals its supervised counterparts in performance when evaluated on the ACE 2005 corpus.

1 Introduction

Event coreference resolution is the task of determining which event mentions in a text refer to the same real-world event. Compared to entity coreference, event coreference is not only much less studied, but it is arguably more challenging. Recall that for two event mentions to be coreferent, both their *triggers* (i.e., the words realizing the occurrence of the events) and their corresponding *arguments* (e.g., the times, places, and people involved in them) have to be compatible. However, identifying potential arguments (which is typically performed by an entity extraction system), linking arguments to their event mentions (which is typically performed by an event extraction system), and determining the compatibility between two event arguments (which is the job of an entity coreference resolver), are all non-trivial tasks. In other words, end-to-end event coreference resolution is complicated in part by the fact that an event coreference resolver has to rely on the noisy outputs produced by its upstream components in the standard information extraction (IE) pipeline.

In this paper, we examine Chinese event coreference resolution. While English event coreference is under-investigated, Chinese event coreference is much less studied than English event coreference. In terms of task definition, there is no difference between English and Chinese event coreference. However, the design of high-performance Chinese event coreference resolvers is complicated in part by the lack of large-scale lexical knowledge bases. Recent work by Bejan and Harabagiu (2010; 2014) has shown that the semantic information extracted from WordNet (Fellbaum, 1998) and FrameNet (Baker et al., 1998) significantly contributed to the performance of their English event coreference resolver.

While the lack of comparable lexical knowledge bases in Chinese can be mitigated in part by the use of event coreference annotated data, we focus on a challenging version of the task --- *unsupervised* Chinese event coreference resolution. Specifically, our goal is to learn an event coreference model *without* using data annotated with event coreference links. When evaluated on the Chinese portion of the ACE 2005 corpus, our unsupervised probabilistic model for event coreference resolution rivals its state-of-the-art supervised counterpart in performance. This, together with the fact that its underlying generative process is not language-dependent and does not rely on features extracted from lexical knowledge bases, potentially enables it to be applied to languages where neither annotated data nor large-scale

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1097–1107,
Denver, Colorado, May 31 – June 5, 2015.

knowledge bases are available.

Another feature of our model that deserves mention is that it performs joint event coreference resolution and anaphoricity determination. Anaphoricity determination, the task of determining whether a mention is anaphoric and hence needs to be resolved, is an issue common to both entity and event coreference resolution. However, determining the anaphoricity of an event mention is arguably more difficult than determining the anaphoricity of a pronoun. The reason is that while there exist lexical and syntactic cues that can be used to reliably identify pleonastic pronouns (Bergsma and Yarowsky, 2011), the lack of such cues in event mentions makes the identification of anaphoric event mentions challenging even in a supervised manner, let alone in an unsupervised manner. Note that ignoring anaphoricity determination and having our model attempt to resolve every event mention is not a viable option, as only 24.4% of the Chinese event mentions in our evaluation corpus (ACE 2005) are anaphoric. Our decision to jointly model anaphoricity determination and event coreference resolution was inspired by the difficulty of designing a standalone system for determining the anaphoricity of event mentions.

2 Related Work

Almost all existing approaches to event coreference are developed for English. These approaches can broadly be divided into three categories.

Within-document coreference is the most popularly investigated and arguably the most important event coreference task. While early work in MUC (e.g., Humphreys et al. (1997)) is limited to several scenarios, ACE takes a further step towards processing more fine-grained events. Most ACE event coreference resolvers are supervised, training a pairwise model to determine whether two event mentions are coreferent (e.g., Ahn (2006)).

Improvements to this standard approach include the use of *feature weighting* to train a better model (McConky et al., 2012), and *graph-based clustering algorithms* to produce event coreference clusters (Chen and Ji, 2009; Sangeetha and Arock, 2012). Chen et al. (2011) train multiple classifiers to handle coreference between event mentions of different syntactic types (e.g., verb-noun coreference, noun-noun coreference) on the OntoNotes corpus (Pradhan et al., 2007). However, OntoNotes is only partially annotated with event coreference links, and Chen et al. further make the simplifying assumption that event coreference chains are all and only those coreference chains that involve at least one verb.

More recently, Cybulska and Vossen (2012) and Goyal et al. (2013) have performed event coreference using semantic relations (e.g., hyponymy relations extracted from WordNet) and distributional semantic information, respectively, on the Intelligence Community (IC) corpus (Hovy et al., 2013). The IC corpus, which at the time of writing is not yet publicly available, is different from the MUC and ACE corpora in that it is annotated with not only *full* event coreference relations but also *partial* event coreference relations. Partial coreference is a term coined by Hovy et al. to refer to event relations that exhibit subtle deviation from the perfect identity of events (e.g., the subset relation, the membership relation). While all of the aforementioned work addresses the full event coreference task, a two-stage approach is recently proposed by Araki et al. (2014) to identify subevent relations from the IC corpus.

Cross-document coreference is first investigated by Bagga and Baldwin (1999), who represent an event mention as a vector of its context words and determine whether two event mentions are coreferent based on the cosine similarity of their vectors. Bejan and Harabagiu (2010; 2014) and Lee et al. (2012) propose nonparametric models and a joint entity and event coreference model respectively for within- and cross-document event coreference, evaluating their models on the ECB corpus. However, ECB "is annotated mainly for cross-document coreference" and many difficult cases of within-document coreference are not annotated (Liu et al., 2014).

Naughton (2009) and Elkhlifi and Faiz (2009) have worked on **sentence-level event coreference**, where the goal is to determine whether two sentences containing event mentions are coreferent. Somewhat unfortunately, simplifying assumptions have to be made when a sentence containing multiple non-coreferent event mentions is encountered.

Compared to English event coreference, there has been much less work on Chinese event coreference. SinoCoreferencer (Chen and Ng, 2014), a publicly-available ACE-style within-document event corefer-

ence resolver for Chinese that achieves state-of-the-art results, employs a supervised approach where a classifier is trained to determine whether two event mentions are coreferent. We will compare our unsupervised model against this supervised resolver.

3 ACE Event Coreference

In this section, we overview the ACE 2005 event coreference task, which is the version of the within-document event coreference task we focus on.

The ACE 2005 event coreference task requires that an event coreference resolver perform coreference on event mentions belonging to one of the ACE event types. More specifically, an event mention is composed of a *trigger* (i.e., the word realizing the event's occurrence) and a set of *arguments* (i.e., the event's participants). Each event trigger has a *type* and a *subtype*. In ACE 2005, eight event types are defined, which are further subcategorized into 33 subtypes. Each event argument has a semantic *role*. In ACE 2005, a set of argument roles is defined for each event type. That is, an event's type determines what roles its mentions' arguments can assume. Not surprisingly, two event mentions cannot be coreferent if their triggers have different subtypes or they have incompatible arguments (e.g., their dates or locations are different).

To better understand the ACE 2005 event coreference task, consider the sentence in Figure 1, which is taken from the ACE 2005 corpus. This example contains three event mentions belonging to the ACE event types. Specifically, these three mentions are triggered by the words 离 (leaving), 暗杀 (assassinated) and 攻击 (attack). 暗杀 and 攻击 have type LIFE and subtype DIE, whereas 离 has type MOVEMENT and subtype TRANSPORT. Note that 暗杀 and 攻击 refer to the same real-world event and are therefore coreferent.

沙米里与其子在上午交通尖峰时间 [离] 家时，遭到 [暗杀]。这次 [攻击] 再次显示叛乱分子能力。

Shameri and his son were [assassinated] during morning rush hour when [leaving] home. This [attack] once again demonstrated the insurgents' ability.

Figure 1: An excerpt from a Chinese document in the ACE 2005 corpus with the corresponding English translation. The event mentions are bracketed.

4 The Generative Model

In this section, we present our generative model.

4.1 Notation

We begin by introducing the notation that we use in the rest of this paper. We denote e to be the current event mention to be resolved (henceforth the *active* event mention). C, the set of candidate antecedents of e, contains all the event mentions preceding e in the associated text as well as a dummy candidate antecedent d (to which e will be resolved if it is non-anaphoric). Also, we define k to be the context surrounding e as well as every candidate antecedent c in C, and k_c to be the context surrounding e and candidate antecedent c. Moreover, we define l to be a binary variable indicating whether c is the correct antecedent of e. Finally, e_t and c_t denote e and c's respective trigger words.

4.2 Training

Our model estimates $P(e, k, c, l)$, the probability of seeing (1) the active event mention e; (2) the context k surrounding e and its candidate antecedents; (3) a candidate antecedent c of e; and (4) l, a binary value indicating whether c is e's correct antecedent. Since we estimate this probability from a raw, unannotated corpus, we are effectively treating e, k, and c as observed data and l as hidden data.

Owing to the presence of hidden data, we estimate the model parameters using the Expectation-Maximization (EM) algorithm (Dempster et al., 1977). Specifically, we use EM to iteratively estimate the model parameters from data in which each event mention is labeled with the probability that it corefers with each of its candidate antecedents, and apply the resulting model to relabel each event mention with the probability that it corefers with each of its candidate antecedents. Below we describe the details of the E-step and the M-step.

4.2.1 E-Step

The goal of the E-step is to compute $P(l{=}1|e, k, c)$, the probability that a candidate antecedent c is the correct antecedent of e given context k. Assuming that exactly one of the e's candidate antecedents is

its correct antecedent, we can rewrite $P(l{=}1|e,k,c)$ as follows:

$$P(l{=}1|e,k,c) = \frac{P(e,k,c,l{=}1)}{\sum_{c' \in C} P(e,k,c',l{=}1)} \quad (1)$$

As we can see from Equation (1), to compute $P(l{=}1|e,k,c)$, we need to compute $P(e,k,c,l{=}1)$, which can be rewritten using Chain Rule:

$$P(e,k,c,l{=}1) = P(e|k,c,l{=}1) * P(l{=}1|k,c) * P(c|k) * P(k) \quad (2)$$

Next, given $l = 1$ (i.e., c is the antecedent of e), we assume that we can generate e from c without looking at the context. Using this assumption and approximating e and c by their trigger words, we can rewrite $P(e|k,c,l{=}1)$ as follows:

$$P(e|k,c,l{=}1) \approx P(e_t|c_t,l{=}1) \quad (3)$$

Moreover, we assume that (1) given e and c's context, the probability of c being the antecedent of e is not affected by the context of the other candidate antecedents; and (2) k_c is sufficient for determining whether c is the antecedent of e. So,

$$P(l{=}1|k,c) \approx P(l{=}1|k_c,c) \approx P(l{=}1|k_c) \quad (4)$$

Next, applying Bayes Rule to $P(l{=}1|k_c)$, we get:

$$\frac{P(k_c|l{=}1)P(l{=}1)}{P(k_c|l{=}1)P(l{=}1) + P(k_c|l{=}0)P(l{=}0)} \quad (5)$$

Representing k_c as a set of n features $f_c^1, \ldots f_c^n$ and assuming that each f_c^i is conditionally independent given l, we can approximate Expression (5) as:

$$\frac{\prod_i P(f_c^i|l{=}1)P(l{=}1)}{\prod_i P(f_c^i|l{=}1)P(l{=}1) + \prod_i P(f_c^i|l{=}0)P(l{=}0)} \quad (6)$$

Given Equations (2), (3), (4) and (6), we can rewrite $P(l{=}1|e,k,c)$ as follows:

$$P(l{=}1|e,k,c) = \frac{P(e,k,c,l{=}1)}{\sum_{c' \in C} P(e,k,c',l{=}1)} \approx \frac{P(e_t|c_t,l{=}1) * \frac{\prod_i P(f_c^i|l{=}1)}{Z_c} * P(c|k)}{\sum_{c' \in C} P(e_t|c'_t,l{=}1) * \frac{\prod_i P(f_{c'}^i|l{=}1)}{Z_{c'}} * P(c'|k)} \quad (7)$$

where

$$Z_x = \prod_i P(f_x^i|l{=}1)P(l{=}1) + \prod_i P(f_x^i|l{=}0)P(l{=}0) \quad (8)$$

As we can see from Equation (7), our model has four groups of parameters, namely $P(e_t|c_t,l{=}1)$, $P(f_c^i{=}1|l)$, $P(l)$ and $P(c|k)$. With these four groups of parameters, we can apply Equation (7) to efficiently compute $P(l{=}1|e,k,c)$.

Two points deserve mention before we describe our M-step. First, among the four groups of parameters, $P(e_t|c_t,l{=}1)$ and $P(f_c^i|l)$ are estimated in the M-step described below; $P(l)$ is estimated in parameter initialization and used throughout the EM iterations (details on parameter initialization appear after the M-step); and $P(c|k)$ is computed heuristically. Intuitively, $P(c|k)$ is the prior probability of a candidate antecedent c given context k. The simplest way to model $P(c|k)$ is to assume that every candidate antecedent is equally likely given the context. In practice, however, some candidate antecedents are implausible given the context. To identify such candidate antecedents, we employ a simple heuristic, which considers a candidate antecedent implausible if its event subtype is different from that of e. Consequently, we model $P(c|k)$ as follows: if c is implausible, we set $P(c|k)$ to 0 and distribute the probability mass uniformly over all and only the plausible candidate antecedents. Since this heuristic is not applicable to dummy candidates, we assume for simplicity that they are all plausible.

Second, by including d as a dummy candidate antecedent for each e, we model anaphoricity determination and event coreference in a joint fashion. If the model resolves e to d, it means that the model posits e as non-anaphoric; on the other hand, if the model resolves e to a non-dummy candidate antecedent c, it means that the model posits e as anaphoric and c as e's correct antecedent. This joint modeling method has proven effective in earlier work on supervised entity coreference resolution (e.g., Rahman and Ng (2009; 2011)).

4.2.2 M-Step

Given $P(l{=}1|e,k,c)$, the goal of the M-step is to (re)estimate two of the four groups of parameters mentioned above, namely $P(e_t|c_t,l{=}1)$ and $P(f_c^i|l)$, using maximum likelihood estimation.

Specifically, $P(e_t|c_t, l{=}1)$ is estimated as follows:

$$P(e_t|c_t, l{=}1) = \frac{Count(e_t, c_t, l{=}1) + \theta}{Count(c_t, l{=}1) + \theta * |t|} \quad (9)$$

where $Count(c_t, l{=}1)$ is the expected number of times c has trigger word c_t when it is the antecedent of an event mention; and $|t|$ is the number of possible trigger words in the training data (we treat the "trigger word" of a dummy candidate antecedent as an unseen word). Also, θ is the Laplace smoothing parameter, which we set to 1, and $Count(e_t, c_t, l{=}1)$ is the expected number of times e has e_t as its trigger when its antecedent c has trigger c_t. Given trigger words e'_t and c'_t, we compute $Count(e'_t, c'_t, l{=}1)$ as follows:

$$Count(e'_t, c'_t, l{=}1) = \sum_{e,c:e_t=e'_t,c_t=c'_t} P(l{=}1|e, k, c) \quad (10)$$

The remaining group of parameters, $P(f_c^i|l)$, can be estimated in a similar fashion.

To start the induction process, we initialize all parameters with uniform values. Specifically, $P(e_t|c_t, l{=}1)$ is set to $\frac{1}{|t|}$, and $P(l{=}1|k_c)$ is set to 0.5. As noted before, $P(l)$ is also initialized here and used throughout the EM iterations. Recall that $P(l{=}1)$ is the fraction of event pairs that are coreferent. Since we assumed earlier that each event mention has exactly one (dummy or non-dummy) antecedent, $P(l{=}1)$ can be computed as the number of event mentions divided by the total number of event pairs. After initialization, we iteratively run the E-step and the M-step until convergence.

There is an important question we have not addressed: what features f_c^i should we use to represent context k_c, which we need to estimate $P(f_c^i|l)$? We defer the discussion of this question to Section 5.

4.3 Inference

After training, we can apply the resulting model to resolve event mentions. Given an event mention e, we determine its antecedent as follows:

$$\hat{c} = \arg\max_{c \in C} P(l{=}1|e, k, c) \quad (11)$$

where C is the set of candidate antecedents of e. In other words, we apply Equation (11) to each of e's candidate antecedents, and select the one that yields the largest probability. If c is a non-dummy candidate antecedent, we posit c as the antecedent of e; otherwise, we posit e as non-anaphoric.

5 Context Features

As mentioned at the end of Section 4.2.2, to fully specify our model, we need to describe the features f_c^i used to represent k_c, which is needed to compute $P(f_c^i|l)$. Recall that k_c encodes the context surrounding candidate antecedent c and active event mention e. We represent k_c using six features that encode the relationship between c and e, some of which are motivated by previous work on supervised event coreference resolution (e.g., Chen and Ji (2009)). Below we describe these six features, which can be broadly divided into three categories.

5.1 Trigger-Based Features

We employ two trigger-based features (Features 1 and 2), both of which are binary-valued and are computed based on e's and c's triggers.

Feature 1 encodes whether c_t and e_t, the trigger words of c and e, satisfy any of the following three conditions:

1. c_t and e_t are lexically identical;
2. c_t and e_t contain the same basic verb (BV) and their verb structures are compatible;
3. the similarity between c_t and e_t is greater than a certain threshold (which we set to 0.8 in our experiments).

Intuitively, Feature 1 is a recall-enhancing feature: it encodes a condition whose satisfaction can help discover many event coreference links. However, it is not designed to be precision-oriented, as it is computed based solely on the triggers and not their surrounding contexts. Below we explain conditions 2 and 3 in more detail.

Recall that condition 2 encodes our observation that an event coreference relation may exist between two non-identical trigger words having the same BV if their verb structures are compatible. To understand this condition, let us explain the notion of BVs and how we determine the compatibility of two verb structures. A BV is a single-character Chinese verb, which is the building block of all Chinese verbs.

Specifically, Li et al. (2012) observe that, with a few exceptions, a Chinese verb constructed out of a basic verb bv possesses one of six main *verb structures*: (1) bv (e.g., 逮 (arrest)); (2) bv + verb (e.g., 送到 (deliver), where bv is 送); (3) verb + bv (e.g., 离开 (leave), where bv is 开); (4) bv + complementation (e.g., 进了 (enter), where bv is 进); (5) bv + noun/adjective (e.g., 开枪 (shoot), where bv is 开); (6) noun/adjective + bv (e.g., 轻伤 (slight wound), where bv is 伤). Now, assuming that t_1 and t_2 are two lexically different trigger words containing the same BV (bv), we say that their verb structures (denoted as vs_1 and vs_2) are incompatible if one of the following conditions is satisfied: (1) bv appears in different positions in t_1 and t_2 (e.g., 开枪 (shoot) and 离开 (leave), where bv is 开); (2) both vs_1 and vs_2 have bv + verb or verb + bv as their verb structure (e.g., 送到 (deliver) and 赶到 (reach), where bv is 到); or (3) both vs_1 and vs_2 have noun/adjective + bv or bv + noun/adjective as their verb structure (e.g., 轻伤 (slight wound) and 重伤 (severe wound), where bv is 伤). Note that these three incompatibility conditions encode our commonsense knowledge of when two Chinese verbs having the same BV cannot have the same meaning.

Next, we explain how we compute the similarity between two trigger words in condition 3. To capture their semantic similarity, we first apply word2vec (Mikolov et al., 2013) to the Chinese Gigaword corpus (Parker et al., 2009) to obtain a vector representation of each word and then compute the cosine similarity between the two word vectors.

Feature 2, our second trigger-based feature, encodes whether two nominal event mentions are incompatible w.r.t. number. Specifically, its value is True if and only if (1) c and e are both nouns, and (2) one is singular and the other is plural. Intuitively, this feature encodes a non-coreference condition.

5.2 Argument-Based Features

We employ three argument-based features (Features 3−5), all of which are binary-valued and are computed based on c's and e's arguments.

Feature 3 encodes whether c and e possess two arguments that have the same semantic role but different semantic classes.[1] Intuitively, Feature 3 encodes a non-coreference condition: c and e cannot be coreferent if such arguments exist.

Feature 4 can be viewed as a generalized version of Feature 3, encoding whether c and e possess two arguments that have the same semantic role but are not coreferent.

Feature 5 encodes whether c and e possess two named entity (NE) arguments that both have VALUE as their NE type but are lexically different. Such event mentions have a good chance of being not coreferent.

5.3 Distance Feature

We employ one distance feature (Feature 6) that encodes how far c and e are apart from each other in terms of the number of event mentions. To reduce data sparseness during parameter estimation, however, we quantize the distance as follows. Let d be the distance between the first event mention and the last event mention in the document for which the distance feature will be computed. Note that the distance between an arbitrary pair of event mentions in this document will be between 0 and d. We divide the interval [0,d] into four equal-sized regions, and set the value of the distance feature based on which of the four bins it falls into.

5.4 Features for Dummy Candidates

Now that we can compute the aforementioned six features for a non-dummy candidate antecedent, we next specify how we compute these features for a dummy candidate antecedent d of active event mention e. For Feature 1, we set the feature value of d to True, whereas for Features 2−5, we set the feature value of d to False. To understand why these values are chosen, note that for each of these features the opposite value could be a strong indicator of non-coreference, potentially causing the model to have an overly strong bias against selecting d as the antecedent of e.

Finally, to compute Feature 6, we assume that d is the zero-th event mention of the associated document, and then compute the distance feature in the same way as described above. By letting d be the zero-th event mention, we make the probability of picking d as the correct antecedent (the probability of

[1] The possible semantic classes are the ACE 2005 entity types, i.e., PERSON, ORGANIZATION, GPE, FACILITY, and LOCATION.

classifying e as non-anaphoric) depend on e's position in the associated text. This makes sense because in general, the probability of e being non-anaphoric tends to be larger (smaller) when it appears earlier (later) in the document.

6 Evaluation

6.1 Experimental Setup

Dataset. For evaluation, we conduct five-fold cross-validation experiments on the 633 Chinese documents of the ACE 2005 training corpus. Statistics on the corpus are shown in Table 1.

Evaluation measures. We report results in terms of recall (R), precision (P), and F-score (F) using the commonly-used coreference evaluation measures given by the CoNLL scorer, namely the link-based MUC scorer (Vilain et al., 1995), the mention-based B^3 scorer (Bagga and Baldwin, 1998), the entity-based version of the CEAF scorer (Luo, 2005), and the Rand index-based BLANC scorer (Recasens and Hovy, 2011), after singleton event mentions are removed from the coreference partitions produced by our resolver. We use the latest version (version 8) of the CoNLL scorer[2], which fixes a bug in previous versions (Pradhan et al., 2014). In addition, we report the CoNLL score (Pradhan et al., 2011), which is the unweighted average of the MUC, B^3, and CEAF F-scores.

Evaluation setting. We perform an end-to-end evaluation, as it can more accurately reflect the performance of an event coreference resolver when it is used in practice.

More specifically, to extract the event mentions used in our evaluation, we employ SinoCoreferencer[3], which, as mentioned before, is an end-to-end ACE-style Chinese IE system that achieves state-of-the-art event coreference results. Specifically, the event triggers needed to compute the trigger-based context features are extracted using SinoCoreferencer's event extraction subsystem. The event subtypes needed to identify and filter out implausible candidate antecedents are also provided by its event extraction subsystem. The event arguments needed to compute the argument-based context features are first extracted and typed by its entity extraction subsystem, and then linked to their triggers by its event extraction subsystem. Finally, the entity coreference links and the semantic roles needed to compute Feature 4 are provided by its entity coreference subsystem and its event extraction subsystem, respectively.[4] Details of each of these subsystems can be found in Chen and Ng (2014).

Documents	633
Sentences	9,967

6.2 Results

We employ two supervised resolvers as baseline systems. The first baseline employs rote learning, simply positing two event mentions as coreferent if their corresponding triggers are annotated as coreferent in the training data. The second baseline is SinoCoreferencer, which has produced the best Chinese event coreference results to date on the ACE corpus.

Row 1 of Table 2 shows the results of the baseline that employs rote learning. As we can see, this baseline achieves a CoNLL score of 37.9. Row 2 shows the results of SinoCoreferencer. It performs significantly better than the rote-learning baseline w.r.t. all five scoring measures[5], achieving a CoNLL score of 39.2. Finally, row 3 shows the results of our model. Despite being unsupervised, it significantly outperforms the better baseline, SinoCoreferencer, w.r.t. all five scoring measures, achieving a CoNLL score of 41.5, which is 2.3 points higher than that of SinoCoreferencer. These results suggest that a generative approach to unsupervised event coreference holds promise.

6.3 Ablation Experiments

Recall that in our model eight probability terms play a major role: $P(e_t|c_t)$, $P(c|k)$, and $P(f_c^i|l)$ for each

[2] conll.github.io/reference-coreference-scorers/

[3] Downloadable from http://www.hlt.utdallas.edu/~yzcchen/coreference/

[4] We employ only those semantic roles that can be reliably determined by SinoCoreferencer's event extraction subsystem, namely, AGENT, ADJUDICATOR, DEFENDANT, GIVER, PERSON, PLACE, POSITION, ORGANIZATION, ORIGIN, and RECIPIENT.

[5] All significance tests are paired t-tests, with $p < 0.05$.

System	MUC			B^3			$CEAF_e$			BLANC			CoNLL
	R	P	F	R	P	F	R	P	F	R	P	F	F
Rote learning	42.6	36.4	39.3	41.4	32.3	36.3	37.0	39.7	38.3	27.4	20.0	23.1	37.9
SinoCoreferencer	42.7	38.3	40.4	41.5	34.7	37.8	39.9	39.2	39.5	28.1	23.7	25.7	39.2
Our model	43.1	42.4	42.8	41.4	39.1	40.2	40.7	42.6	41.6	27.5	26.4	26.9	41.5

Table 2: Five-fold cross-validation event coreference results on the ACE 2005 corpus.

of the six context features. To investigate the contribution of each probability term to overall performance, we conduct ablation experiments. Specifically, in each ablation experiment, we remove exactly one term from the model and retrain it.

Ablation results are shown in Table 3. Each row contains the F-scores obtained via the five evaluation measures. To facilitate comparison, the scores of the model in which all eight probability terms are used is shown in row 1. As we can see, Feature 1 is the most useful feature: its removal causes the CoNLL score to drop significantly by 5.3 points. A closer examination reveals that the drop in the CoNLL score is caused by a significant drop in recall w.r.t. all scorers. Recall that this feature encodes the conditions under which two triggers are likely to be coreferent. It is perhaps not surprising that its removal causes a significant drop in recall.

The second most useful feature is $P(c|k)$, which places zero probability mass on candidate antecedents whose event subtypes are different from that of the active event mention. Its removal causes the CoNLL score to drop significantly by 1.6 points. The removal of each other feature resulted in a small, insignificant drop in the CoNLL score.

System	MUC	B^3	$CEAF_e$	BLANC	CoNLL

6.4 Error Analysis

It is somewhat surprising that our unsupervised event coreference model outperforms the better supervised baseline, SinoCoreferencer. To understand why, we analyze the errors made by the two resolvers.

Our analysis proceeds as follows. First, to gain insights into the differences between the two resolvers, we examine those candidate event mentions that are correctly handled by one model but not the other (Section 6.4.1). Specifically, we consider a candidate event mention e correctly handled if (1) e is a correctly resolved anaphoric event mention; (2) e is an unresolved singleton event mention; or (3) e is an unresolved non-event mention (i.e., not a true event mention). Second, to understand how to improve event coreference, we identify the major sources of error made by both resolvers (Section 6.4.2).

6.4.1 Common Sources of Disagreement

There are 323 candidate event mentions that are correctly handled by one model but not the other in our dataset. Among these 323 cases, 205 (50 anaphoric + 79 singletons + 76 non-event) are correctly handled by the unsupervised model, and 118 (42 anaphoric + 52 singletons + 24 non-event) are correctly handled by SinoCoreferencer.

From these numbers, we can see that the unsupervised model performs far better than SinoCoreferencer in *not* resolving the singletons and the non-event mentions. This is perhaps not surprising given the unsupervised model's relatively stricter conditions on resolving a candidate event mention. Specifically, it is unlikely to posit two candidate event mentions as coreferent unless (1) their triggers have a BV match or a large word2vec similarity value and (2) none of the non-coreference conditions are satisfied. Overall, these results explain why the unsupervised model has a much higher precision than SinoCoreferencer.

Not only does the unsupervised model perform much better in not resolving singletons and non-event mentions, but it is also slightly more accurate

in resolving the anaphoric event mentions, which ultimately enables it to achieve a higher recall than SinoCoreferencer. In particular, it correctly resolves 50 anaphoric mentions that are incorrectly handled by SinoCoreferencer. The successful resolution of these anaphoric mentions can be attributed largely to its use of BV and word2vec, neither of which is exploited by SinoCoreferencer. However, while a BV match or a high word2vec similarity value is a good indicator of event coreference, they are by no means perfect. This partly explains why there are singletons and non-event mentions that are correctly handled by SinoCoreferencer but not the unsupervised model.

Despite the fact that SinoCoreferencer slightly lags behind the unsupervised model in resolving anaphoric mentions, it correctly resolves 42 anaphoric event mentions that are incorrectly handled by the unsupervised model. These are cases that cannot be handled simply by relying on BV match or word2vec similarity. More specifically, two of the unique features of SinoCoreferencer are primarily responsible for its successful resolution of these event mentions. First, it learns coreferent trigger pairs from the training data. These pairs proved to be useful for event coreference, as we saw from the competitive results provided by the rote-learning baseline. Second, unlike the unsupervised model, SinoCoreferencer can posit two event mentions as coreferent *without* considering their triggers. More specifically, SinoCoreferencer may posit two event mentions as coreferent if the corresponding arguments of the two event mentions (i.e., arguments having the same role) are coreferent. Neither of these two recall-enhancing features of SinoCoreferencer is a precise indicator of event coreference. In other words, employing them widens the precision gap between the two resolvers.

6.4.2 Common Sources of Error

Next, we discuss the major sources of error made by both our unsupervised model and SinoCoreferencer. Broadly, the errors can be divided into two categories, precision errors and recall errors.

Precision errors arise primarily from erroneous coreference links established between (1) one or more candidate event mentions that are not true event mentions; (2) two event mentions with incompatible latent attributes such as MODALITY, POLARITY, GENERICITY, and TENSE, since these attributes are not exploited by the two resolvers; (3) two event mentions with incompatible arguments, since these arguments fail to be extracted by the argument identification component; (4) two mentions representing events that occur at different times, since the event mentions are not timestamped[6]; and (5) two event mentions whose corresponding arguments are incorrectly posited by the entity coreference subsystem as coreferent.

On the other hand, recall errors arise primarily from missing coreference links attributed to (1) the trigger identification component's failure to detect one or both of the triggers involved in an event coreference link; (2) the entity coreference subsystem's failure to establish the link(s) between the corresponding arguments of two coreferent event mentions; (3) the lack of positive evidence of event coreference, such as BV match, high word2vec similarity, and coreferent arguments; and (4) the argument identification component's failure to extract one or more arguments of an event mention.

7 Conclusions

We presented a generative model for the relatively under-studied task of unsupervised Chinese event coreference resolution whose parameters were learned using EM from an unannotated corpus. When evaluated on the ACE 2005 corpus, our model significantly outperforms SinoCoreferencer, a state-of-the-art Chinese event coreference resolver.

Since the performance of our resolver is limited in part by the errors made by SinoCoreferencer's subsystems, we plan to mitigate this problem by performing joint inference for entity coreference, event extraction and event coreference in future work.

Acknowledgments

We thank the three anonymous reviewers for their detailed and insightful comments on an earlier draft of this paper. This work was supported in part by NSF Grants IIS-1147644 and IIS-1219142.

[6] Not all of these errors can be fixed by exploiting the TENSE attribute, as TENSE is only a crude approximation of time. For instance, in the phrases 首度被捕 (arrested for the first time) and 再度被捕 (arrested again), the two occurrences of 被捕 (arrested) are associated with different timestamps despite the fact that they have the same TENSE.

Abstract

Coreference is a core NLP problem. However, newswire data, the primary source of existing coreference data, lack the richness necessary to truly solve coreference. We present a new domain with denser references—quiz bowl questions—that is challenging and enjoyable to humans, and we use the quiz bowl community to develop a new coreference dataset, together with an annotation framework that can tag any text data with coreferences and named entities. We also successfully integrate active learning into this annotation pipeline to collect documents maximally useful to coreference models. State-of-the-art coreference systems underperform a simple classifier on our new dataset, motivating non-newswire data for future coreference research.

1 Introduction

Coreference resolution—adding annotations to an input text where multiple strings refer to the same entity—is a fundamental problem in computational linguistics. It is challenging because it requires the application of syntactic, semantic, and world knowledge (Ng, 2010).

For example, in the sentence *Monsieur Poirot assured Hastings that he ought to have faith in him*, the strings *Monsieur Poirot* and *him* refer to the same person, while *Hastings* and *he* refer to a different character.

There are a panoply of sophisticated coreference systems, both data-driven (Fernandes et al., 2012; Durrett and Klein, 2013; Durrett and Klein, 2014; Björkelund and Kuhn, 2014) and rule-based (Pradhan et al., 2011; Lee et al., 2011). Recent CoNLL shared tasks provide the opportunity to make a fair comparison between these systems. However, because all of these shared tasks contain strictly newswire data,[1] it is unclear how existing systems perform on more diverse data.

We argue in Section 2 that to truly solve coreference resolution, the research community needs high-quality datasets that contain many challenging cases such as nested coreferences and coreferences that can only be resolved using external knowledge. In contrast, newswire is deliberately written to contain few coreferences, and those coreferences should be easy for the reader to resolve. Thus, systems that are trained on such data commonly fail to detect coreferences in more expressive, non-newswire text.

Given newswire's imperfect range of coreference examples, can we do better? In Section 3 we present a specialized dataset that specifically tests a *human's* coreference resolution ability. This dataset comes from a community of trivia fans who also serve as enthusiastic annotators (Section 4). These data have denser coreference mentions than newswire text and present hitherto unexplored questions of what is coreferent and what is not. We also incorporate active learning into the annotation process. The result is a small but highly dense dataset of 400 documents with 9,471 mentions.

[1]We use "newswire" as an umbrella term that encompasses all forms of edited news-related data, including news articles, blogs, newsgroups, and transcripts of broadcast news.

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1108–1118,
Denver, Colorado, May 31 – June 5, 2015.

We demonstrate in Section 5 that our dataset is significantly different from newswire based on results from the effective, widely-used Berkeley system (Durrett and Klein, 2013). These results motivate us to develop a very simple end-to-end coreference resolution system consisting of a CRF-based mention detector and a pairwise classifier. Our system outperforms the Berkeley system when both have been trained on our new dataset. This result motivates further exploration into complex coreference types absent in newswire data, which we discuss at length in Section 7.

2 Newswire's Limitations for Coreference

Newswire text is widely used as training data for coreference resolution systems. The standard datasets used in the MUC (MUC-6, 1995; MUC-7, 1997), ACE (Doddington et al., 2004), and CoNLL shared tasks (Pradhan et al., 2011) contain only such text. In this section we argue why this monoculture, despite its many past successes, offer diminishing results for advancing the coreference subfield.

First, newswire text has sparse references, and those that it has are mainly identity coreferences and appositives. In the CoNLL 2011 shared task (Pradhan et al., 2007) based on OntoNotes 4.0 (Hovy et al., 2006),[2] there are 2.1 mentions per sentence; in the next section we present a dataset with 3.7 mentions per sentence.[3] In newswire text, most nominal entities (not including pronouns) are singletons; in other words, they do not corefer to anything. OntoNotes 4.0 development data contains 25.4K singleton nominal entities (Durrett and Klein, 2013), compared to only 7.6K entities which corefer to something (anaphora). On the other hand, most pronominals are anaphoric, which makes them easy to resolve as pronouns are single token entities. While it is easy to obtain a lot of newswire data, the amount of coreferent-heavy mention clusters in such text is not correspondingly high.

Second, coreference resolution in news text is trivial for humans because it rarely requires world knowledge or semantic understanding. Systems trained on news media data for a related problem—entity extraction—falter on non-journalistic texts (Poibeau and Kosseim, 2001). This discrepancy in performance can be attributed to the stylistic conventions of journalism. Journalists are instructed to limit the number of entities mentioned in a sentence, and there are strict rules for referring to individuals (Boyd et al., 2008). Furthermore, writers cannot assume that their readers are familiar with all participants in the story, which requires that each entity is explicitly introduced in the text (Goldstein and Press, 2004). These constraints make for easy reading and, as a side effect, easy coreference resolution. Unlike this simplified "journalistic" coreference, everyday coreference relies heavily on inferring the identities of people and entities in language, which requires substantial world knowledge.

While news media contains examples of coreference, the primary goal of a journalist is to convey information, not to challenge the reader's coreference resolution faculty. Our goal is to evaluate coreference systems on data that taxes even human coreference.

3 Quiz Bowl: A Game of Human Coreference

One example of such data comes from a game called *quiz bowl*. Quiz bowl is a trivia game where questions are structured as a series of sentences, all of which indirectly refer to the answer. Each question has multiple clusters of mutually-coreferent terms, and one of those clusters is coreferent with the answer. Figure 1 shows an example of a quiz bowl question where all answer coreferences have been marked.

A player's job is to determine[4] the entity ref-

[2] As our representative for "newswire" data, the English portion of the Ontonotes 4.0 contains professionally-delivered weblogs and newsgroups (15%), newswire (46%), broadcast news (15%), and broadcast conversation (15%).

[3] Neither of these figures include singleton mentions, as OntoNotes does not have gold tagged singletons. Our dataset has an even higher density when singletons are included.

[4] In actual competition, it is a race to see which team can identify the coreference faster, but we ignore that aspect here.

NW	Later, [they]$_1$ all met with [President Jacques Chirac]$_2$. [Mr. Chirac]$_2$ said an important first step had been taken to calm tensions.
NW	Around the time of the [Macau]$_1$ handover, questions that were hot in [the Western media]$_2$ were "what is Macaense"? And what is native [Macau]$_1$ culture?
NW	[MCA]$_1$ said that [it]$_1$ expects [the proposed transaction]$_2$ to be completed no later than November 10th.
QB	As a child, [this character]$_1$ reads [[his]$_1$ uncle]$_2$ [the column]$_3$ [*That Body of Yours*]$_3$ every Sunday.
QB	At one point, [these characters]$_1$ climb into barrels aboard a ship bound for England. Later, [one of [these characters]$_1$]$_2$ stabs [the Player]$_3$ with a fake knife.
QB	[One poet from [this country]$_2$]$_1$ invented the haiku, while [another]$_3$ wrote the [*Tale of Genji*]$_4$. Identify [this homeland]$_2$ of [Basho]$_1$ and [Lady Murasaki]$_3$.

Table 1: Three newswire sentences and three quiz bowl sentences with annotated coreferences and singleton mentions. These examples show that quiz bowl sentences contain more complicated types of coreferences that may even require world knowledge to resolve.

[The Canadian rock band by [this name]] has released such albums as Take A Deep Breath, Young Wild and Free, and Love Machine and had a 1986 Top Ten single with Can't Wait For the Night. [The song by [this name]] is [the first track on Queen's Sheer Heart Attack]. FTP, identify [the shared name of, most notably, [a novel by Graham Greene]].

Figure 1: An example quiz bowl question about the novel *Brighton Rock*. Every mention referring to the answer of the question has been marked; note the variety of mentions that refer to the same entity.

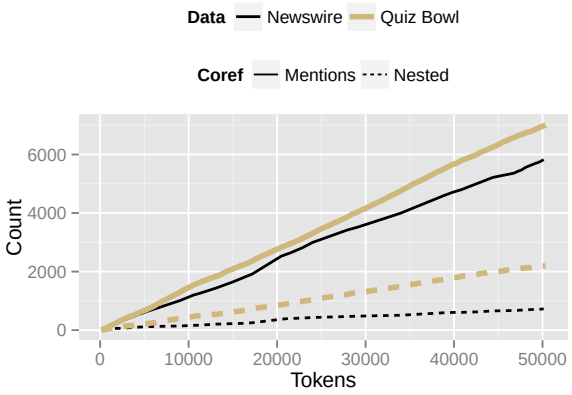

Figure 2: Density of quiz bowl vs. CoNLL coreference both for raw and nested mentions.

erenced by the question. Each sentence contains progressively more informative references and more well-known clues. For example, a question on Sherlock Holmes might refer to him as "he", "this character", "this housemate of Dr. Watson", and finally "this detective and resident of 221B Baker Street". While quiz bowl has been viewed as a classification task (Iyyer et al., 2014), previous work has ignored the fundamental task of coreference. Nevertheless, quiz bowl data are dense and diverse in coreference examples. For example, nested mentions, which are difficult for both humans and machines, are very rare in the newswire text of OntoNotes—0.25 mentions per sentence—while quiz bowl contains 1.16 mentions per sentence (Figure 2). Examples of nested mentions can be seen in in Table 1. Since quiz bowl is a game, it makes the task of solving coreference interesting and *challenging* for an annotator. In the next section, we use the intrinsic fun of this task to create a new annotated coreference dataset.

4 Intelligent Annotation

Here we describe our annotation process. Each document is a single quiz bowl question containing an average of 5.2 sentences. While quiz bowl

covers all areas of academic knowledge, we focus on questions about literature from Boyd-Graber et al. (2012), as annotation standards are more straightforward.

Our webapp (Figure 3) allows users to annotate a question by highlighting a phrase using their mouse and then pressing a number corresponding to the coreference group to which it belongs. Each group is highlighted with a single color in the interface. The webapp displays a single question at a time, and for some questions, users can compare their answers against gold annotations by the authors. We provide annotators the ability to see if their tags match the gold labels for a few documents as we need to provide a mechanism to help them learn the annotation guidelines as the annotators are crowdsourced volunteers. This improves inter-annotator agreement.

The webapp was advertised to quiz bowl players before a national tournament and attracted passionate, competent annotators preparing for the tournament. A leaderboard was implemented to encourage competitiveness, and prizes were given to the top five annotators.

Users are instructed to annotate all authors, characters, works, and the answer to the question (even if the answer is not one of the previously specified types of entities). We consider a coreference to be the maximal span that can be replaced by a pronoun.[5] As an example, in the phrase *this folk sermon by James Weldon Johnson*, the entire phrase is marked, not just *sermon* or *this folk sermon*. Users are asked to consider appositives as separate coreferences to the same entity. Thus, *The Japanese poet Basho* has two phrases to be marked, *The Japanese poet* and *Basho*, which both refer to the same group.[6] Users annotated prepositional phrases attached to a noun to capture entire noun phrases.

Titular mentions are mentions that refer to entities with similar names or the same name as a title, e.g., "The titular doctor" refers to the person "Dr. Zhivago" while talking about the book with the same name. For our purposes, all titular mentions refer to the same coreference group. We also encountered a few mentions that refer to multiple groups; for example, in the sentence *Romeo met Juliet at a fancy ball, and they get married the next day*, the word *they* refers to both *Romeo* and *Juliet*. Currently, our webapp cannot handle such mentions.

Number of ...	Quiz bowl	OntoNotes
documents[7]	400	1,667
sentences	1,890	44,687
tokens	50,347	955,317
mentions	9,471	94,155
singletons[8]	2,461	0
anaphora	7,010	94,155
nested ment.	2,194	11,454

Table 2: Statistics of both our quiz bowl dataset and the OntoNotes training data from the CoNLL 2011 shared task.

To illustrate how popular the webapp proved to be among the quiz bowl community, we had 615 documents tagged by seventy-six users within a month. The top five annotators, who between them tagged 342 documents out of 651, have an agreement rate of 87% with a set of twenty author-annotated questions used to measure tagging accuracy.

We only consider documents that have either been tagged by four or more users with a predetermined degree of similarity and verified by one or more author (150 documents), or documents tagged by the authors in committee (250 documents). Thus, our gold dataset has 400 documents.

Both our quiz bowl dataset and the OntoNotes dataset are summarized in Table 2. If coreference resolution is done by pairwise classification, our dataset has a total of 116,125 possible mention pairs. On average it takes about fifteen minutes to tag a document because often the annotator will not know which mentions co-refer

[5] We phrased the instruction in this way to allow our educated but linguistically unsavvy annotators to approximate a noun phrase.

[6] The datasets, full annotation guide, and code can be found at `http://www.cs.umd.edu/~aguha/qbcoreference`.

[7] This number is for the OntoNotes training split only.

[8] OntoNotes is not annotated for singletons.

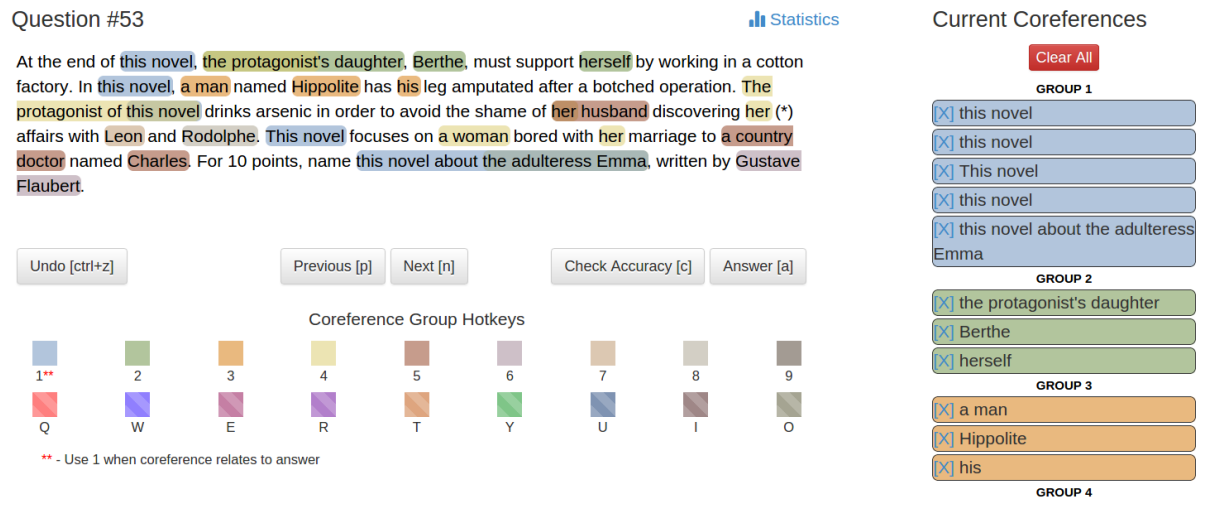

Figure 3: The webapp to collect annotations. The user highlights a phrase and then assigns it to a group (by number). Showing a summary list of coreferences on the right significantly speeds up user annotations.

to what group without using external knowledge. OntoNotes is 18.97 larger than our dataset in terms of tokens but only 13.4 times larger in terms of mentions.[9] Next, we describe a technique that allows our webapp to choose which documents to display for annotation.

4.1 Active Learning

Active learning is a technique that alternates between training and annotation by selecting instances or documents that are maximally useful for a classifier (Settles, 2010). Because of the large sample space and amount of diversity present in the data, active learning helps us build our coreference dataset. To be more concrete, the original corpus contains over 7,000 literature questions, and we want to tag only the useful ones. Since it can take a quarter hour to tag a single document and we want at least four annotators to agree on every document that we include in the final dataset, annotating all 7,000 questions is infeasible.

We follow Miller et al. (2012), who use active learning for document-level coreference rather than at the mention level. Starting from a seed set of a hundred documents and an evaluation set of fifty documents[10] we sample 250 more documents from our set of 7,000 quiz bowl questions. We use the Berkeley coreference system (described in the next section) for the training phase. In Figure 4 we show the effectiveness of our iteration procedure. Unlike the result shown by Miller et al. (2012), we find that for our dataset voting sampling beats random sampling, which supports the findings of Laws et al. (2012).

Voting sampling works by dividing the seed set into multiple parts and using each to train a model. Then, from the rest of the dataset we select the document that has the most variance in results after predicting using all of the models. Once that document gets tagged, we add it to the seed set, retrain, and repeat the procedure. This process is impractical with instance-level active learning methods, as there are 116,125 mention pairs (instances) for just 400 documents. Even with document-level sampling, the procedure of training on all documents in the seed set and then testing every document in the sample space is a slow task. Batch learning can speed up this process at the cost of increased document redundancy; we choose not to use it because we want a diverse collection of annotated documents. Active learning's advantage is that new documents are more likely to contain diverse

[9] These numbers do not include singletons as OntoNotes does not have them tagged, while ours does.

[10] These were documents tagged by the quiz bowl community, so we didn't have to make them wait for the active learning process to retrain candidate models.

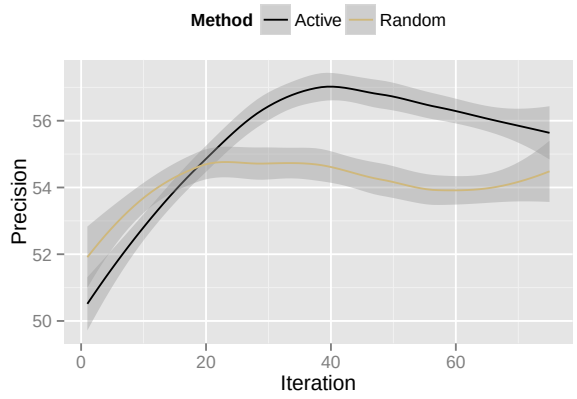

Figure 4: Voting sampling active learning works better than randomly sampling for annotation.

(and thus interesting) combinations of entities and references, which annotators noticed during the annotation process. Documents selected by the active learning process were dissimilar to previously-selected questions in both content and structure.

5 Experimental Comparison of Coreference Systems

We evaluate the widely used Berkeley coreference system (Durrett and Klein, 2013) on our dataset to show that models trained on newswire data cannot effectively resolve coreference in quiz bowl data. Training and evaluating the Berkeley system on quiz bowl data also results in poor performance. [11] This result motivates us to build an end-to-end coreference resolution system that includes a data-driven mention detector (as opposed to Berkeley's rule-based one) and a simple pairwise classifier. Using our mentions and only six feature types, we are able to outperform the Berkeley system on our data. Finally, we explore the linguistic phenomena that make quiz bowl coreference so hard and draw insights from our analysis that may help to guide the next generation of coreference systems.

[11] We use default options, including hyperparameters tuned on OntoNotes

5.1 Evaluating the Berkeley System on Quiz Bowl Data

We use two publicly-available pretrained models supplied with the Berkeley coreference system, *Surface* and *Final*, which are trained on the entire OntoNotes dataset. The difference between the two models is that *Final* includes semantic features. We report results with both models to see if the extra semantic features in *Final* are expressive enough to capture quiz bowl's inherently difficult coreferences. We also train the Berkeley system on quiz bowl data and compare the performance of these models to the pretrained newswire ones in Table 3. Our results are obtained by running a five-fold cross-validation on our dataset. The results show that newswire is a poor source of data for learning how to resolve quiz bowl coreferences and prompted us to see how well a pairwise classifier does in comparison. To build an end-to-end coreference system using this classifier, we first need to know which parts of the text are "mentions", or spans of a text that refer to real world entities. In the next section we talk about our mention detection system.

5.2 A Simple Mention Detector

Detecting mentions is done differently by different coreference systems. The Berkeley system does rule-based mention detection to detect every NP span, every pronoun, and every named entity, which leads to many spurious mentions. This process is based on an earlier work of Kummerfeld et al. (2011), which assumes that every maximal projection of a noun or a pronoun is a mention and uses rules to weed out spurious mentions. Instead of using such a rule-based mention detector, our system detects mentions via sequence labeling, as detecting mentions is essentially a problem of detecting start and stop points in spans of text. We solve this sequence tagging problem using the MALLET (McCallum, 2002) implementation of conditional random fields (Lafferty et al., 2001). Since our data contain nested mentions, the sequence labels are BIO markers (Ratinov and Roth, 2009). The features we use, which are similar to those used in Kummerfeld et al. (2011), are:

		MUC		
System	Train	P	R	F_1
Surface	OntoN	47.22	27.97	35.13
Final	OntoN	50.79	30.77	38.32
Surface	QB	**60.44**	31.31	41.2
Final	QB	60.21	**33.41**	**42.35**

Table 3: The top half of the table represents Berkeley models trained on OntoNotes 4.0 data, while the bottom half shows models trained on quiz bowl data. The MUC F_1-score of the Berkeley system on OntoNotes text is 66.4, which when compared to these results prove that quiz bowl coreference is significantly different than OntoNotes coreference.

- the token itself
- the part of speech
- the named entity type
- a dependency relation concatenated with the parent token[12]

Using these simple features, we obtain surprisingly good results. When comparing our detected mentions to gold standard mentions on the quiz bowl dataset using exact matches, we obtain 76.1% precision, 69.6% recall, and 72.7% F_1 measure. Now that we have high-quality mentions, we can feed each pair of mentions into a pairwise mention classifier.

5.3 A Simple Coref Classifier

We follow previous pairwise coreference systems (Ng and Cardie, 2002; Uryupina, 2006; Versley et al., 2008) in extracting a set of lexical, syntactic, and semantic features from two mentions to determine whether they are coreferent. For example, if *Sylvia Plath*, *he*, and *she* are all of the mentions that occur in a document, our classifier gives predictions for the pairs *he—Sylvia Plath*, *she—Sylvia Plath*, and *he—she*.

Given two mentions in a document, m_1 and m_2, we generate the following features and feed them to a logistic regression classifier:

- binary indicators for all tokens contained in m_1 and m_2 concatenated with their parts-of-speech
- same as above except for an n-word window before and after m_1 and m_2
- how many tokens separate m_1 and m_2
- how many sentences separate m_1 and m_2
- the cosine similarity of `word2vec` (Mikolov et al., 2013) vector representations of m_1 and m_2; we obtain these vectors by averaging the word embeddings for all words in each mention. We use publicly-available 300-dimensional embeddings that have been pretrained on 100B tokens from Google News.
- same as above except with publicly-available 300-dimensional `GloVe` (Pennington et al., 2014) vector embeddings trained on 840B tokens from the Common Crawl

The first four features are standard in coreference literature and similar to some of the surface features used by the Berkeley system, while the word embedding similarity scores increase our F-measure by about 5 points on the quiz bowl data. Since they have been trained on huge corpora, the word embeddings allow us to infuse world knowledge into our model; for instance, the vector for *Russian* is more similar to *Dostoevsky* than *Hemingway*.

Figure 5 shows that our logistic regression model (LR) outperforms the Berkeley system on numerous metrics when trained and evaluated on the quiz bowl dataset. We use precision, recall, and F_1, metrics applied to MUC, BCUB, and CEAFE measures used for comparing coreference systems.[13] We find that our LR model outperforms Berkeley by a wide margin when both are trained on the mentions found by our mention detector (CRF). For four metrics, the CRF mentions actually improve over training on the gold mentions.

Why does the LR model outperform Berkeley

[12]These features were obtained using the Stanford dependency parser (De Marneffe et al., 2006).

[13]The MUC (Vilain et al., 1995) score is the minimum number of links between mentions to be inserted or deleted when mapping the output to a gold standard key set. BCUB (Bagga and Baldwin, 1998) computes the precision and recall for all mentions separately and then combines them to get the final precision and recall of the output. CEAFE (Luo, 2005) is an improvement on BCUB and does not use entities multiple times to compute scores.

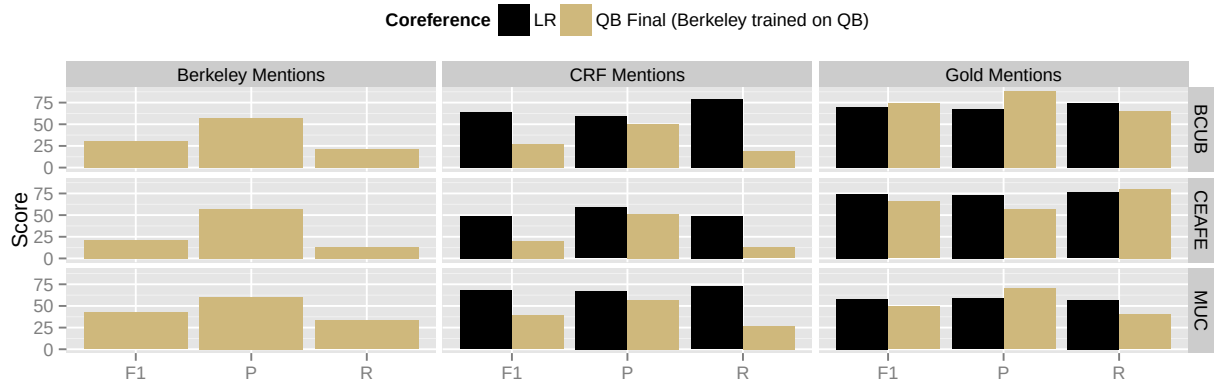

Figure 5: All models are trained and evaluated on quiz bowl data via five fold cross validation on F_1, precision, and recall. Berkeley/CRF/Gold refers to the mention detection used, LR refers to our logistic regression model and *QB Final* refers to the Berkeley model trained on quiz bowl data. Our model outperforms the Berkeley model on every metric when using our detected CRF mentions. When given gold mentions, LR outperforms Berkeley *QB Final* in five of nine metrics.

when both are trained on our quiz bowl dataset? We hypothesize that some of Berkeley's features, while helpful for sparse OntoNotes coreferences, do not offer the same utility in the denser quiz bowl domain. Compared to newswire text, our dataset contains a much larger percentage of complex coreference types that require world knowledge to resolve. Since the Berkeley system lacks semantic features, it is unlikely to correctly resolve these instances, whereas the pretrained word embedding features give our LR model a better chance of handling them correctly. Another difference between the two models is that the Berkeley system ranks mentions as opposed to doing pairwise classification like our LR model, and the mention ranking features may be optimized for newswire text.

5.4 Why Quiz Bowl Coreference is Challenging

While models trained on newswire falter on these data, is this simply a domain adaptation issue or something deeper? In the rest of this section, we examine specific examples to understand why quiz bowl coreference is so difficult. We begin with examples that *Final* gets wrong.

> *This writer* depicted a group of samurai's battle against an imperial. For ten points, name *this Japanese writer of A Personal Matter and The Silent Cry.*

While *Final* identifies most of pronouns associated with Kenzaburo Oe (the answer), it cannot recognize that the theme of the entire paragraph is building to the final reference, "this Japanese writer", despite the many Japanese-related ideas in the text of the question (e.g., Samurai and emperor). *Final* also cannot reason effectively about coreferences that are tied together by similar modifiers as in the below example:

> That *title character* plots to secure a "beautiful death" for Lovberg by burning his manuscript and giving him a pistol. For 10 points, name this play in which *the titular wife of George Tesman* commits suicide.

While a reader can connect "titular" and "title" to the same character, Hedda Gabler, the Berkeley system fails to make this inference. These data are a challenge for all systems, as they require extensive world knowledge. For example, in the following sentence, a model must know that the story referenced in the first sentence is about a dragon and that dragons can fly.

> The protagonist of *one of this man's works* erects a sign claiming that that story's title figure will fly to heaven from a pond. Identify this author of *Dragon: the Old Potter's Tale*

Humans solve cases like these using a vast amount of external knowledge, but existing models lack information about worlds (both real and imaginary) and thus cannot confidently mark these coreferences. We discuss coreference work that incorporates external resources such as Wikipedia in the next section; our aim is to provide a dataset that benefits more from this type of information than newswire does.

6 Related Work

We describe relevant data-driven coreference research in this section, all of which train and evaluate on only newswire text. Despite efforts to build better rule-based (Luo et al., 2004) or hybrid statistical systems (Haghighi and Klein, 2010), data-driven systems currently dominate the field. The 2012 CoNLL shared task led to improved data-driven systems for coreference resolution that finally outperformed both the Stanford system (Lee et al., 2011) and the IMS system (Björkelund and Farkas, 2012), the latter of which was the best available publicly-available English coreference system at the time. The recently-released Berkeley coreference system (Durrett and Klein, 2013) is especially striking: it performs well with only a sparse set of carefully-chosen features. Semantic knowledge sources—especially WordNet (Miller, 1995) and Wikipedia—have been used in coreference engines (Ponzetto and Strube, 2006). A system by Ratinov and Roth (2012) demonstrates good performance by using Wikipedia knowledge to strengthen a multi-pass rule based system. In a more recent work, Durrett and Klein (2014) outperform previous systems by building a joint model that matches mentions to Wikipedia entities while doing named entity resolution and coreference resolution simultaneously. We take a different approach by approximating semantic and world knowledge through our word embedding features. Our simple classifier yields a binary decision for each mention pair, a method that had been very popular before the last five years (Soon et al., 2001; Bengtson and Roth, 2008; Stoyanov et al., 2010). Recently, better results have been obtained with mention-ranking systems (Luo et al., 2004; Haghighi and Klein, 2010; Durrett and Klein, 2013; Björkelund and Kuhn, 2014). However, on quiz bowl data, our experiments show that binary classifiers can outperform mention-ranking approaches.

7 Embracing Harder Coreference

This paper introduces a new, naturally-occuring coreference dataset that is easy to annotate but difficult for computers to solve. We show that active learning allows us to create a dataset that is rich in different types of coreference. We develop an end-to-end coreference system using very simple mention detection and pairwise classification models that outperforms traditional systems on our dataset. The next challenge is to incorporate the necessary world knowledge to solve these harder coreference problems. Systems should be able to distinguish who is likely to marry whom, identify the titles of books from roundabout descriptions, and intuit family relationships from raw text. These are coreference challenges not found in newswire but that do exist in the real world. Unlike other AI-complete problems like machine translation, coreference in challenging datasets is easy to both annotate and evaluate. This paper provides the necessary building blocks to create and evaluate those systems.

Injecting Logical Background Knowledge into Embeddings for Relation Extraction

Abstract

Matrix factorization approaches to relation extraction provide several attractive features: they support distant supervision, handle open schemas, and leverage unlabeled data. Unfortunately, these methods share a shortcoming with all other distantly supervised approaches: they cannot learn to extract target relations without existing data in the knowledge base, and likewise, these models are inaccurate for relations with sparse data. Rule-based extractors, on the other hand, can be easily extended to novel relations and improved for existing but inaccurate relations, through first-order formulae that capture auxiliary domain knowledge. However, usually a large set of such formulae is necessary to achieve generalization.

In this paper, we introduce a paradigm for learning low-dimensional embeddings of entity-pairs and relations that combine the advantages of matrix factorization with first-order logic domain knowledge. We introduce simple approaches for estimating such embeddings, as well as a novel training algorithm to jointly optimize over factual and first-order logic information. Our results show that this method is able to learn accurate extractors with little or no distant supervision alignments, while at the same time generalizing to textual patterns that do not appear in the formulae.

1 Introduction

Relation extraction, the task of identifying relations between named entities, is a crucial component for information extraction. A recent successful approach (Riedel et al., 2013) relies on two ideas: (a) unifying traditional canonical relations, such as those of the Freebase schema, with OpenIE surface form patterns in a *universal schema*, and (b) completing a knowledge base of such a schema using matrix factorization. This approach has several attractive properties. First, for canonical relations it effectively performs distant supervision (Bunescu and Mooney, 2007; Mintz et al., 2009; Yao et al., 2011; Hoffmann et al., 2011; Surdeanu et al., 2012) and hence requires no textual annotations. Second, in the spirit of OpenIE, a universal schema can use textual patterns as novel relations and thus increases the coverage of traditional schemas (Riedel et al., 2013; Fan et al., 2014). Third, matrix factorization learns better embeddings for entity-pairs for which only surface form patterns are observed, and these can also lead to better extractions of canonical relations.

Unfortunately, populating a universal schema knowledge base using matrix factorization suffers from a problem all distantly-supervised techniques share: you can only reliably learn relations that appear frequently enough in the knowledge base. In particular, for relations that do not appear in the knowledge base or for which no facts are known we cannot learn a predictor at all. One way to overcome this problem is to incorporate additional domain knowledge, either specified manually or bootstrapped from auxiliary sources. In fact, domain knowledge encoded as simple logic formulae over patterns and relations has been used in practice to directly specify relation extractors (Reiss et al., 2008; Chiticariu et al., 2013; Akbik et al., 2014). However, these extractors can be brittle and obtain poor recall, since they are unable to generalize to textual patterns that are not

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1119–1129,
Denver, Colorado, May 31 – June 5, 2015.

found in given formulae. Hence, there is a need for learning extractors that are able to combine logical knowledge with benefits of factorization techniques to facilitate precise extractions and generalization to novel relations.

In this paper, we propose a paradigm for learning universal schema extractors by combining matrix factorization based relation extraction with additional information in the form of first-order logic knowledge. Our contributions are threefold: (i) We introduce simple baselines that enforce logic constraints through deterministic inference before and after matrix factorization (§3.1). (ii) We propose a novel joint training algorithm that learns vector embeddings of relations and entity-pairs using both distant supervision and first-order logic formulae such that the factorization captures these formulae (§3.2). (iii) We present an empirical evaluation using automatically mined rules that demonstrates the benefits of incorporating logical knowledge in relation extraction, in particular that joint factorization of distant and logic supervision is efficient, accurate, and robust to noise (§5).

2 Matrix Factorization and Logic

In this section we provide background on matrix factorization for universal schema relation extraction, and describe its connections to first-order logic.

2.1 Notation

In order to later unify observed facts and logical background knowledge, we first represent given factual data in terms of first-order logic. We have a set $\mathcal{E}$ of *constants* that refer to entities, and a set of *predicates* $\mathcal{R}$ that refer to relations between these entities. In the following we will focus on binary relations in a *universal schema* that contains both structured relations from one (or more) knowledge bases, and surface-form relations. Further, with $\mathcal{P} \subseteq \mathcal{E} \times \mathcal{E}$ we denote the domain over entity-pairs of interest.

In function-free first-order logic a *term* is defined as a constant or a variable, and the most basic form of a formula is an *atom* such as $\texttt{professorAt}(x, y)$ that applies a predicate to a pair of terms. More complex formulae such as $\forall x, y : \texttt{professorAt}(x, y) \Rightarrow \texttt{employeeAt}(x, y)$ can be constructed by combining atoms with logical connectives (such as $\neg$ and $\wedge$) and quantifiers ($\exists x$, $\forall x$).

The simplest form of first-order formulae are *ground atoms*: predicates applied to constants, such as $\texttt{directorOf}$(NOLAN,INTERSTELLAR). A *possible world* is a set of ground atoms. *Ground literals* are either ground atoms or negated ground atoms such as $\neg\,\texttt{bornIn}$(NOLAN,BERLIN), and correspond to positive or negative *facts*. Training data for distant supervision can now be viewed as a knowledge base of such ground literals. Our goal is to extend the class of formulae from such facts to rules such as the first-order formula above.

2.2 Matrix Factorization with Ground Atoms

Given the notation presented above, matrix factorization can now be seen as a learning task in which low-dimensional embeddings are estimated for all constant pairs in $\mathcal{P}$ and predicates (relations) in $\mathcal{R}$, given a collection of ground atoms (facts) as supervision. We represent constant-pairs as rows and predicates as columns of a $|\mathcal{P}| \times |\mathcal{R}|$ binary matrix, and each atom in the training data represents an observed cell in this matrix. As introduced in Riedel et al. (2013), we seek to find a low-rank factorization into a $|\mathcal{P}| \times k$ matrix of embeddings of constant-pairs and a $k \times |\mathcal{R}|$ matrix of predicate embeddings such that they approximate the observed matrix.

More precisely, let $\mathbf{v}_{(\cdot)}$ denote the mapping from constant-pairs and predicates to their corresponding embedding. That is, $\mathbf{v}_{r_m}$ is the embedding for predicate r_m, and $\mathbf{v}_{(e_i,e_j)}$ is the embedding for the pair of constants (e_i, e_j). Let $\mathbf{w}$ be a possible world (*i.e.* a set of ground atoms), and $\mathbf{V}$ be the set of all entity-pair and relation embeddings. Further, let $\pi_m^{e_i,e_j} = \sigma(\mathbf{v}_{r_m} \cdot \mathbf{v}_{e_i,e_j})$ where σ is the sigmoid function and $\mathbf{v}_{r_m} \cdot \mathbf{v}_{(e_i,e_j)}$ denotes the vector dot-product between the embeddings of relation r_m and entity-pair (e_i, e_j). We define the conditional probability of a possible world $\mathbf{w}$ given embeddings $\mathbf{V}$ as

$$p(\mathbf{w}|\mathbf{V}) = \prod_{r_m(e_i,e_j) \in w} \pi_m^{e_i,e_j} \prod_{r_m(e_i,e_j) \notin w} \left(1 - \pi_m^{e_i,e_j}\right).$$

The embeddings can be estimated by maximizing the likelihood of a set of observed ground atoms with ℓ_2 regularization (Collins et al., 2001), optimized using stochastic gradient descent. In summary, with atomic formulae (*i.e.* factual knowledge) we learn entity-pair and relation embeddings that reconstruct known facts and are able to generalize to unknown facts.

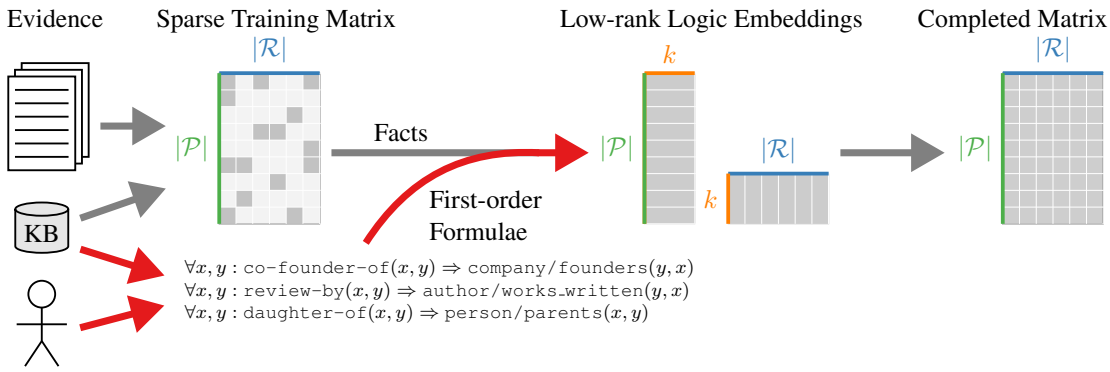

Figure 1: **Injecting Logic into Matrix Factorization:** Given a sparse binary matrix consisting of observed facts over entity-pairs $\mathcal{P}$ and predicates/relations $\mathcal{R}$, matrix factorization is used to learn k-dimensional relation and entity-pair embeddings that approximate the observed matrix. In this paper we use additional first-order logic formulae over entities and relations to learn the embeddings such that the predictions (completed matrix) also satisfy these formulae.

3 Injecting Logic Into Factorization

Matrix factorization is capable of learning complex dependencies between relations, but requires observed facts as training signal. However, often we either do not have this signal because the relations of interest do not have pre-existing facts, or this signal is noisy due to alignment errors or mismatches when linking knowledge base entities to mentions in text.

To overcome this problem we investigate the use of first-order logic background knowledge (*e.g.* implications) to aid relation extraction. One option is to rely on a fully symbolic approach that exclusively uses first-order logic (Bos and Markert, 2005; Baader et al., 2007; Bos, 2008). In this case incorporating additional background knowledge is trivial. However, it is difficult to generalize and deal with noise and uncertainty in language when relying only on manual rules. In contrast, matrix factorization methods can overcome these shortcomings, but it is not clear how they can be combined with logic formulae.

In this section, we propose to inject formulae into the embeddings of relations and entity-pairs, *i.e.*, estimate the embeddings such that predictions based on them conform to given logic formulae (see Figure 1 for an overview). We refer to such embeddings as *low-rank logic embeddings*. Akin to matrix factorization, inference of a fact at test time still amounts to an efficient dot product of the corresponding relation and entity-pair embeddings, and logical inference is not needed. We present two techniques for injecting logical background knowledge, *pre-factorization inference* (§3.1) and *joint optimization* (§3.2), and demonstrate in subsequent sections that they generalize better than direct logical inference, even if such inference is performed on the *predictions* of the matrix factorization model.

3.1 Pre-Factorization Inference

Background knowledge in form of first-order formulae can be seen as *hints* that can be used to generate additional training data (Abu-Mostafa, 1990). For *pre-factorization inference* we first perform logical inference on the training data and add inferred facts as additional training data. For example, for a formula $\mathcal{F} = \forall x, y : r_s(x, y) \Rightarrow r_t(x, y)$, we add an additional observed cell $r_t(x, y)$ for any (x, y) for which $r_s(x, y)$ is observed in the distant supervision training data. This is repeated until no further facts can be inferred. Subsequently, we run matrix factorization on the extended set of observed cells.

The intuition is that the additional training data generated by the formulae provide evidence of the logical dependencies between relations to the matrix factorization model, while at the same time allowing the factorization to generalize to unobserved facts and to deal with ambiguity and noise in the data. No further logical inference is performed during or after training of the factorization model as we expect that the learned embeddings encode the given formulae.

3.2 Joint Optimization

One drawback of pre-factorization inference is that the formulae are enforced only on observed atoms,

i.e., first-order dependencies on *predicted* facts are ignored. Instead we would like to include a loss term for the logical formulae directly in the matrix factorization objective, thus jointly optimizing embeddings to reconstruct factual training data as well as obeying to first-order logical background knowledge.

3.2.1 Training Objective

Here we first present a learning objective that unifies ground atoms (facts) and logical background knowledge by treating both as logic formulae (atomic or complex), and define a loss function over this general representation. We then define the loss function for ground atoms and simple implications, along with a brief sketch of how the loss can be defined for arbitrarily complex logic formulae.

As introduced in §2.1, let $\mathcal{R}$ be the set of all relations/predicates and $\mathcal{P}$ be the set of all entity-pairs/constants. Furthermore, let $\mathfrak{F}$ be a training set of logic formulae $\mathcal{F}$, and $\mathcal{L}$ a loss function. The training objective (omitting ℓ_2 regularization on $\mathbf{v}_{(\cdot)}$ for simplicity) is

$$\min_{\mathbf{V}} \sum_{\mathcal{F} \in \mathfrak{F}} \mathcal{L}([\mathcal{F}]) \tag{1}$$

where $\mathbf{V}$ is the set of all relation and entity-pair embeddings, and $[\mathcal{F}]$ is the marginal probability $p(w|\mathbf{V})$ that the formula $\mathcal{F}$ is true under the model. In this paper we use the logistic loss: $\mathcal{L}([\mathcal{F}]) := -\log([\mathcal{F}])$. The objective thus prefers embeddings that assign formulae a high marginal probability.

To optimize this function we need the marginal probabilities $[\mathcal{F}]$, and the gradients of the losses $\mathcal{L}([\mathcal{F}])$ for every $\mathcal{F} \in \mathfrak{F}$ with respect to entity-pair and relation embeddings, *i.e.*, $\partial\mathcal{L}([\mathcal{F}])/\partial\mathbf{v}_{r_m}$ and $\partial\mathcal{L}([\mathcal{F}])/\partial\mathbf{v}_{(e_i,e_j)}$. Below we discuss how these quantities can be computed or approximated for arbitrary first-order logic formulae, with details provided for ground atoms and implications.

Ground Atoms Due to the conditional independence of ground atoms in the distribution $p(\mathbf{w}|\mathbf{V})$, the marginal probability of a ground atom $\mathcal{F} = r_m(e_i, e_j)$ is $[\mathcal{F}] = \pi_m^{e_i,e_j} = \sigma(\mathbf{v}_{r_m} \cdot \mathbf{v}_{e_i,e_j})$. Hence when only ground atoms (or literals) are used, objective (1) reduces to the standard log-likelihood loss. The gradients of the loss for the entity-pair embedding $\mathbf{v}_{(e_i,e_j)}$ and relation embedding $\mathbf{v}_{r_m}$ are

$$\partial[\mathcal{F}]/\partial\mathbf{v}_{(e_i,e_j)} = [\mathcal{F}](1-[\mathcal{F}])\mathbf{v}_{r_m} \tag{2}$$

$$\partial[\mathcal{F}]/\partial\mathbf{v}_{r_m} = [\mathcal{F}](1-[\mathcal{F}])\mathbf{v}_{(e_i,e_j)} \tag{3}$$

$$\partial\mathcal{L}([\mathcal{F}])/\partial\mathbf{v}_{(e_i,e_j)} = -[\mathcal{F}]^{-1}\partial[\mathcal{F}]/\partial\mathbf{v}_{(e_i,e_j)} \tag{4}$$

$$\partial\mathcal{L}([\mathcal{F}])/\partial\mathbf{v}_{r_m} = -[\mathcal{F}]^{-1}\partial[\mathcal{F}]/\partial\mathbf{v}_{r_m}. \tag{5}$$

First-order Logic Crucially, and in contrast to the log-likelihood loss for matrix factorization, we can inject more expressive logic formulae than just ground atoms. We briefly outline how to recursively compute the probability of the formula $[\mathcal{F}]$ and the gradients of the loss $\mathcal{L}([\mathcal{F}])$ for any first-order formula $\mathcal{F}$. Again, note that the probabilities of ground atoms in our model are independent conditioned on embeddings. This means that for any two formulae $\mathcal{A}$ and $\mathcal{B}$, the marginal probability of $[\mathcal{A} \wedge \mathcal{B}]$ can be computed as $[\mathcal{A}][\mathcal{B}]$ (known as *product t-norm*), provided both formula concern non-overlapping sets of ground atoms. In combination with $[\neg\,\mathcal{A}] := 1 - [\mathcal{A}]$ and the $[\ ]$ operator as defined for ground atoms earlier, we can compute the probability of *any* propositional formula recursively, *e.g.*,

$$[\mathcal{A} \vee \mathcal{B}] = [\mathcal{A}] + [\mathcal{B}] - [\mathcal{A}][\mathcal{B}]$$
$$[\mathcal{A} \Rightarrow \mathcal{B}] = [\mathcal{A}]([\mathcal{B}] - 1) + 1$$
$$[\mathcal{A} \wedge \neg\,\mathcal{B} \Rightarrow \mathcal{C}] = ([\mathcal{A}](1 - [\mathcal{B}]))([\mathcal{C}] - 1) + 1.$$

Note that for statements $[\mathcal{F}] \in \{0, 1\}$, we directly recover logical semantics. First-order formulae in finite domains can be embedded through explicit grounding. For universal quantification we can get $[\forall x, y : \mathcal{F}(x, y)] = [\bigwedge_{x,y} \mathcal{F}(x, y)]$. If we again assume non-overlapping ground atoms in each of the arguments of the conjunction, we can simplify this to $\prod_{x,y}[\mathcal{F}(x, y)]$. When arguments do overlap we can think of this simplification as an approximation.

Since $[\mathcal{F}(x, y)]$ is defined recursively, we can back-propagate the training signal through the structure of $[\mathcal{F}]$ to compute $\partial[\mathcal{F}(x, y)]/\partial\mathbf{v}_{r_m}$ and $\partial[\mathcal{F}(x, y)]/\partial\mathbf{v}_{e_i,e_j}$ for any nested formula.

Implications A particularly useful family of formulae for relation extraction are universally quantified first-order formula over a knowledge base such as $\mathcal{F} = \forall x, y : r_s(x, y) \Rightarrow r_t(x, y)$. Assuming a finite domain, such a formula can be unrolled into a conjunction of propositional statements of the form $\mathcal{F}_{ij} = r_s(e_i, e_j) \Rightarrow r_t(e_i, e_j)$, one for

each entity-pair (e_i, e_j) in the domain. Specifically, $[\mathcal{F}] = \prod_{(e_i,e_j)\in\mathcal{P}} [\mathcal{F}_{ij}]$, and therefore $\mathcal{L}([\mathcal{F}]) = \sum_{(e_i,e_j)\in\mathcal{P}} \mathcal{L}([\mathcal{F}_{ij}])$. The gradients are derived as:

$$[\mathcal{F}_{ij}] = [r_s(e_i, e_j)]\,([r_t(e_i, e_j)] - 1) + 1 \quad (6)$$

$$\frac{\partial \mathcal{L}([\mathcal{F}_{ij}])}{\partial \mathbf{v}_{r_s}} = -[\mathcal{F}_{ij}]^{-1}\,([r_t(e_i, e_j)] - 1)\,\frac{\partial [r_s(e_i, e_j)]}{\partial \mathbf{v}_{r_s}}$$

$$\frac{\partial \mathcal{L}([\mathcal{F}_{ij}])}{\partial \mathbf{v}_{r_t}} = -[\mathcal{F}_{ij}]^{-1}[r_s(e_i, e_j)]\frac{\partial [r_t(e_i, e_j)]}{\partial \mathbf{v}_{r_t}} \quad (7)$$

$$\frac{\partial \mathcal{L}([\mathcal{F}_{ij}])}{\partial \mathbf{v}_{e_i,e_j}} = -[\mathcal{F}_{ij}]^{-1}\,([r_t(e_i, e_j)] - 1)\,\frac{\partial [r_s(e_i, e_j)]}{\partial \mathbf{v}_{e_i,e_j}} - [\mathcal{F}_{ij}]^{-1}[r_s(e_i, e_j)]\frac{\partial [r_t(e_i, e_j)]}{\partial \mathbf{v}_{e_i,e_j}}. \quad (8)$$

Following such a derivation, one can obtain gradients for other first-order logic formulae as well.

3.2.2 Learning

We learn the embeddings by minimizing Eq. 1 with ℓ_2-regularization using AdaGrad (Duchi et al., 2011). Since we have no negative training facts, we follow Riedel et al. (2013) by sampling unobserved facts that we assume to be false. Specifically, in every epoch and for every true training fact $r_m(e_i, e_j)$ we sample an (e_p, e_q) such that $r_m(e_p, e_q)$ is unobserved. Subsequently, we perform two kinds of updates: $\mathcal{F} = r_m(e_i, e_j)$ and $\mathcal{F} = \neg\, r_m(e_p, e_q)$. For every non-atomic first-order formula in $\mathfrak{F}$ we iterate over all entity-pairs for which at least one atom in the formula is observed (in addition to as many sampled entity-pairs for which *none* of the atoms have been observed) and add corresponding grounded propositional formulae to the training objective. At test time, predicting a score for any unobserved statement $r_m(e_i, e_j)$ is done efficiently by calculating $[r_m(e_i, e_j)]$. Note that this does not involve any explicit logical inference, instead we expect that the predictions from the learned embeddings already respect the provided formulae.

4 Experimental Setup

There are two orthogonal question when evaluating the effectiveness of low-rank logic embeddings: a) does injection of logic formulae into the embeddings of entity-pairs and relations provide any benefits, and b) where do the background formulae come from? The latter is a well-studied problem (Hipp et al., 2000; Schoenmackers et al., 2010; Völker and Niepert, 2011). In this paper we focus the evaluation on the ability of various approaches to benefit from formulae that we directly extract from the training data using a simple method.

Distant Supervision Evaluation We follow the procedure as used in Riedel et al. (2013) for evaluating knowledge base completion of Freebase (Bollacker et al., 2008) with textual data from the NYTimes corpus (Sandhaus, 2008). The training matrix consists of 4 111 columns, representing 151 Freebase relations and 3 960 textual patterns, 41 913 rows (entity-pairs) and 118 781 training facts of which 7 293 belong to Freebase relations. The entity-pairs are divided into train and test, and we hide all Freebase relations for the test pairs from training. Our primary evaluation measure is average and (weighted) mean average precision, **MAP** and **wMAP** respectively (see Riedel et al. (2013) for details).

Formulae Extraction and Annotation We use a simple technique for extracting formulae from the matrix factorization model. We first run matrix factorization over the complete training data to learn accurate relation and entity-pair embeddings. After training, we iterate over all pairs of relations (r_s, r_t) where r_t is a Freebase relation. For every relation-pair we iterate over all training atoms $r_s(e_i, e_j)$, evaluate the score $[r_s(e_i, e_j) \Rightarrow r_t(e_i, e_j)]$ as described in §3.2.1, and calculate the average to arrive at a score for the formula. Finally, we rank all formulae by their score and manually filter the top 100 formulae, which resulted in 36 annotated high-quality formulae (see Table 1 for examples). Note that our formula extraction approach does not observe the relations for test entity-pairs. All models used in our experiments have access to these formulae, except for the matrix factorization baseline.

Methods Our proposed methods for injecting logic into relation embeddings are *pre-factorization inference* (**Pre**; §3.1) which performs regular matrix factorization after propagating the logic formulae in a deterministic manner, and *joint optimization* (**Joint**; §3.2) which maximizes an objective that combines terms from factual and first-order logic knowledge. Additionally, we use the following three baselines. The *matrix factorization* (**MF**; §2.2) model uses only ground atoms to learn relation and entity-pair embed-

Formula	Score
$\forall x, y : \texttt{\#2-unit-of-\#1}(x, y) \Rightarrow \texttt{org/parent/child}(x, y)$	0.97
$\forall x, y : \texttt{\#2-city-of-\#1}(x, y) \Rightarrow \texttt{location/containedby}(x, y)$	0.97
$\forall x, y : \texttt{\#2-minister-\#1}(x, y) \Rightarrow \texttt{person/nationality}(x, y)$	0.97
$\forall x, y : \texttt{\#2-executive-\#1}(x, y) \Rightarrow \texttt{person/company}(x, y)$	0.96
$\forall x, y : \texttt{\#2-co-founder-of-\#1}(x, y) \Rightarrow \texttt{company/founders}(y, x)$	0.96

Table 1: **Sample Extracted Formulae:** Top implications of textual patterns to five different Freebase relations. These implications were extracted from the matrix factorization model and manually annotated. The premises of these implications are dependency paths, but we present a simplified version to make them more readable.

dings (*i.e.* it has no access to any formulae). Furthermore, we consider pure *logical inference* (**Inf**). Our final approach, *post-factorization inference* (**Post**), first runs matrix factorization and then performs logical inference on the known and predicted facts. Post-inference is computationally expensive, since for all premises of formulae we have to iterate over *all* rows (entity-pairs) in the matrix to assess whether the premise is true or not.

Parameters For every matrix factorization based method we use $k = 100$ as the dimension for the embeddings, $\lambda = 0.01$ as parameter of ℓ_2-regularization and $\alpha = 0.1$ as initial learning rate for AdaGrad, which we run for 200 epochs.

Complexity Each AdaGrad update is defined over a single cell of the matrix, and thus training data can be streamed one ground atom at a time. For matrix factorization, each AdaGrad epoch touches all the observed atoms once, and as many sampled negative atoms. With given formulae, it additionally revisits all the observed atoms that appear as an atom in the formula (and as many sampled negative atoms), and thus more general formulae will be more expensive. However the updates over atoms are performed independently and thus not all the data needs to be stored in memory. All presented models take less than 15 minutes to train on a 2.8 GHz Intel Core i7 machine.

5 Results and Discussion

To evaluate the utility of injecting logic formulae into embeddings, we present a comparison on a variety of benchmarks. First, in §5.1 we study the scenario of learning extractors for relations for which we do not have any Freebase alignments, evaluating how the approaches are able to generalize only from logic formulae and textual patterns. In §5.2 we then describe an experiment where the amount of Freebase alignments is varied in order to assess the effect of combining distant supervision and background knowledge on the accuracy of predictions. Although the methods presented in this paper target relations with insufficient alignments, we also provide a comparison on the complete distant supervision dataset in §5.3. We conclude in §5.4 with a brief analysis of the reasoning capacity of the learned embeddings.

Relation	#	MF	Inf	Post	Pre	Joint

Table 2: **Zero-shot Relation Learning:** Average and (weighted) mean average precisions with relations that do not appear in any of the annotated formulae omitted from the evaluation. The difference between "Pre" and "Joint" is significant according to the sign-test ($p < 0.05$).

5.1 Zero-shot Relation Learning

We start with the scenario of learning extractors for relations that do not appear in the knowledge base schema, *i.e.*, those that do not have any textual alignments. Such a scenario occurs in practice when a new relation needs to be added to a knowledge base for which there are no facts that connect the new relation to existing relations or surface patterns. For accurate extractions of such relations, the model needs to rely primarily on background domain knowledge to identify relevant textual alignments, but at the same time it also needs to utilize correlations between textual patterns for generalization. To simulate this setup, we remove all alignments between all entity-pairs and Freebase relations from the distant supervision data, use the extracted logic formulae (§4) as background knowledge, and evaluate on the ability of the different methods to recover the lost alignments.

Table 2 provides detailed results. Unsurprisingly,

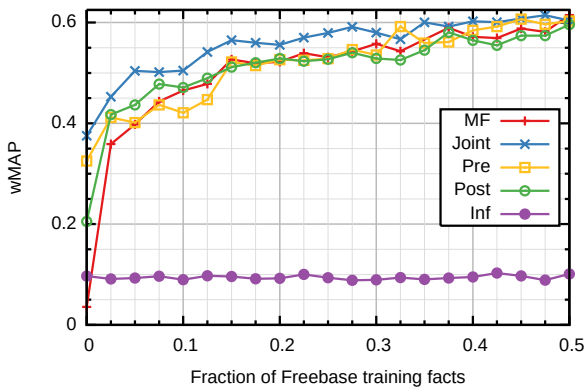

Figure 2: **Relations with Few Distant Labels:** Weighted mean average precisions of the various methods as the fraction of Freebase training facts is varied. For 0% Freebase training facts we get the zero-shot relation learning results presented in Table 2.

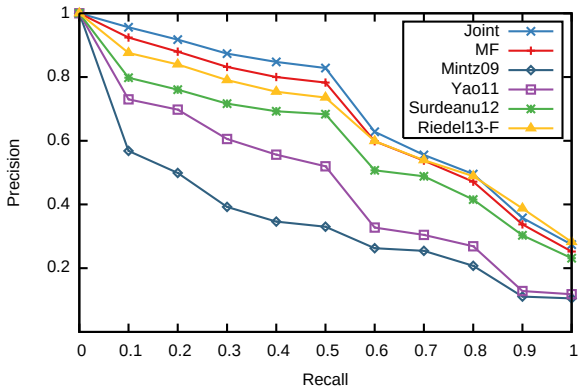

Figure 3: **Comparison on Complete Data:** Averaged precision/recall curve demonstrating that the "Joint" method outperforms existing factorization approaches ("MF" and "Riedel13-F"). The formulae used by our approach have been extracted only from the training data.

matrix factorization (**MF**) performs poorly since embeddings cannot be learned for the Freebase relations without any observed cells. Scores higher than zero for matrix factorization are caused by random predictions. Logical inference (**Inf**) is limited by the number of known facts that appear as premise in one of the implications. Although post-factorization inference (**Post**) is able to achieve a large improvement over logical inference, explicitly injecting logic formulae into the embeddings (*i.e.* learning low-rank logic embeddings) using pre-factorization inference (**Pre**) or joint optimization (**Joint**) gives superior results. Last, we observe that joint optimization is able to best combine logic formulae and textual patterns for accurate, zero-shot learning of relation extractors.

5.2 Relations with Few Distant Labels

In this section we study the scenario of learning relations that have only a few distant supervision alignments, in particular, we observe the behavior of the various methods as the amount of distant supervision is varied. We run all methods on training data that contains different fractions of Freebase training facts (and therefore different degrees of relation/text pattern alignment), but keep all textual patterns in addition to the set of extracted formulae.

Figure 2 summarizes the results. The performance of pure logical inference does not depend on the amount of distant supervision data, since it does not take advantage of the correlations in the data. Matrix factorization ignores logic formulae, and thus is the baseline performance when only using distant supervision. For the factorization based methods, only a small fraction (15%) of the training data is needed to achieve around 0.50 wMAP performance, thus demonstrating that they are efficiently exploiting correlations and generalizing to unobserved facts.

Pre-factorization inference, however, does not outperform post-factorization inference, and is on par with matrix factorization for most of the curve. This suggests that it is not an effective way of injecting logic into embeddings when ground facts are also available. In contrast, joint optimization leads to low-rank logic embeddings that outperform all other methods in the 0 to 30% Freebase training data interval. Beyond 30% there seem to be sufficient Freebase facts for matrix factorization to encode these formulae, thus yielding diminishing returns.

5.3 Comparison on Complete Data

Although the focus of this paper is injection of logical knowledge for relations without sufficient alignments to the knowledge base, we also present an evaluation on the complete distant supervision data as used by Riedel et al. (2013). Compared to the Riedel et al.'s "F" model, our matrix factorization implementation ("MF") achieves a lower wMAP (64% vs 68%) and a higher MAP (66% vs 64%). We attribute this difference to the different loss function (logistic loss in our case vs. ranking loss). We show the PR curve

in Figure 3, demonstrating that joint optimization provides benefits over the existing factorization and distant supervision techniques even on the complete dataset, and obtains 66% wMAP and 69% MAP. This improvement over the matrix factorization model can be explained by reinforcement of high-quality annotated formulae via the joint model.

5.4 Analysis of Asymmetry in the Predictions

Since the injected formulae are of the form $\forall x, y : r_s(x, y) \Rightarrow r_t(x, y)$, it is worthwhile to study the extent to which these rules are captured, and which approaches are in fact capturing the asymmetric nature of the implication. To this end, we compute the probabilities that the formulae and their inverse hold, averaged over all annotated formulae and cells. The degree to which $r_s \Rightarrow r_t$ is captured is quite high for all models (0.94, 0.96, and 0.97 for matrix factorization, pre-factorization inference, and joint optimization respectively). On the other hand, the probability of $r_t \Rightarrow r_s$ is also relatively high for matrix factorization and pre-factorization inference (0.81 and 0.83 respectively), suggesting that these methods are primarily capturing symmetric similarity between relations. Joint optimization, however, produces much more asymmetric predictions (probability of $r_t \Rightarrow r_s$ is 0.49), demonstrating that it is appropriate for encoding logic in the embeddings.

6 Related Work

Embeddings for Knowledge Base Completion Embedding predicates and constants (or pairs of constants) based on factual knowledge for knowledge base completion has for instance been investigated by Bordes et al. (2011), Nickel et al. (2012), Socher et al. (2013), Riedel et al. (2013) and Fan et al. (2014). Our work goes further in that we learn embeddings that follow not only factual but also first-order logic knowledge, and the ideas presented in this paper can be incorporated with any embedding-based method that uses a per-atom loss.

Logical Inference A common alternative that directly incorporates first-order logic knowledge is to perform logical inference (Bos and Markert, 2005; Baader et al., 2007; Bos, 2008), however such purely symbolic approaches cannot deal with the uncertainty inherent to natural language, and generalize poorly.

Probabilistic Inference To ameliorate some of the drawbacks of symbolic logical inference, probabilistic logic based approaches have been proposed (Schoenmackers et al., 2008; Garrette et al., 2011; Beltagy et al., 2013; Beltagy et al., 2014). Since logical connections between relations are modeled explicitly, such approaches are generally hard to scale. Specifically, approaches based on Markov Logic Networks (MLNs) (Richardson and Domingos, 2006) encode logical knowledge in dense, loopy graphical models, making structure learning, parameter estimation, and inference hard for the scale of our data. In contrast, in our model the logical knowledge is captured directly in the embeddings, leading to efficient inference. Furthermore, as our model is based on matrix factorization, we have a natural way to deal with linguistic ambiguities and label errors.

Weakly Supervised Learning Our work is also inspired by weakly supervised approaches (Ganchev et al., 2010) that use structural constraints as a source of indirect supervision, and have been used for several NLP tasks (Chang et al., 2007; Mann and McCallum, 2008; Druck et al., 2009; Singh et al., 2010). Carlson et al. (2010) in particular is similar since they use common sense constraints to jointly train multiple information extractors. In this work, however, we are training a matrix factorization model, and allowing for arbitrarily complex logic formulae.

Combining Symbolic and Distributed Representations There have been a number of recent approaches that combine distributed representations with symbolic knowledge. Grefenstette (2013) describes an isomorphism between first-order logic and tensor calculus, using full-rank matrices to exactly *memorize* facts. Based on this isomorphism, Rocktäschel et al. (2014) combine logic with matrix factorization for learning low-dimensional embeddings that approximately satisfy given formulae and generalize to unobserved facts on toy data. Our work extends this workshop paper by proposing a simpler formalism without tensor-based logical connectives, presenting results on a real-world task, and demonstrating the utility of this approach for learning relations with few textual alignments.

Chang et al. (2014) use Freebase entity types as hard constraints in a tensor factorization objective for universal schema relation extraction. In contrast, our

approach is imposing soft constraints that are formulated as universally quantified first-order formula.

de Lacalle and Lapata (2013) combine first-order logic knowledge with a topic model to improve surface pattern clustering for relation extraction. Since these formulae only specify which relations can be clustered and which not, they do not capture the variety of dependencies embeddings can model, such as asymmetry. Lewis and Steedman (2013) use distributed representations to cluster predicates before logical inference. Again, this approach is not as powerful as factorizing the relations, as it makes symmetry assumptions for the predicates.

Several studies have investigated the use of symbolic representations (such as dependency trees) to guide the composition of distributed representations (Clark and Pulman, 2007; Mitchell and Lapata, 2008; Coecke et al., 2010; Hermann and Blunsom, 2013). Instead we are using symbolic representations (first-order logic) as prior domain knowledge to directly learn better embeddings.

Combining symbolic information with neural networks has also been an active area of research. Towell and Shavlik (1994) introduce Knowledge-Based Artificial Neural Networks whose topology is isomorphic to a knowledge base of facts and inference formulae. There, facts are input units, intermediate conclusions hidden units, and final conclusions (inferred facts) output units. Unlike our work, there is no latent representation of predicates and constants. Hölldobler et al. (1999) and Hitzler et al. (2004) prove that for every logic program theoretically there exists a recurrent neural network that approximates the semantics of that program. Finally, Bowman (2014) recently demonstrated that a neural tensor network can accurately learn natural logic reasoning.

7 Conclusions

Inspired by the benefits of logical background knowledge that can lead to precise extractors, and of distant supervision based matrix factorization that can utilize dependencies between textual patterns to generalize, in this paper we introduced a novel training paradigm for learning embeddings that combine matrix factorization with logic formulae. Along with a deterministic approach to enforce the formulae a priori, we propose a joint objective that rewards predictions that satisfy given logical knowledge, thus learning embeddings that do not require logical inference at test time. Experiments show that the proposed approaches are able to learn extractors for relations with little to no observed textual alignments, while at the same time benefiting more common relations. The source code of the methods presented in this paper and the annotated formulae used for evaluation are available at `github.com/uclmr/low-rank-logic`.

This research has thrown up many questions in need of further investigation. As opposed to our approach that modifies both relation and entity-pair embeddings, further work needs to explore training methods that only modify relation embeddings in order to encode logical dependencies explicitly, and thus avoid *memorization*. Although we obtain significant gains by using implications, our approach facilitates the use of arbitrary formulae; it would be worthwhile to pursue this direction by following the steps outlined in §3.2.1. Furthermore, we are interested in combining relation extraction with models that learn *entity type* representations (*e.g.* tensor factorization or neural models) to allow for expressive logical statements such as $\forall x, y : \texttt{nationality}(x, y) \Rightarrow \texttt{country}(y)$. Since such common sense formulae are often not directly observed in distant supervision, they can go a long way in fixing common extraction errors. Finally, we will investigate methods to automatically mine commonsense knowledge for injection into embeddings from additional resources such as Probase (Wu et al., 2012) or directly from text using a semantic parser (Zettlemoyer and Collins, 2005).

Acknowledgments

The authors want to thank Mathias Niepert for proposing pre-factorization inference as alternative to joint optimization. We thank Edward Grefenstette, Luke Zettlemoyer, and Guillaume Bouchard for comments on the manuscript, and the reviewers for very helpful feedback. Abstract

Most successful Entity Linking (EL) methods aim to link mentions to their referent entities in a structured Knowledge Base (KB) by comparing their respective contexts, often using similarity measures. While the KB structure is given, current methods have suffered from impoverished information representations on the mention side. In this paper, we demonstrate the effectiveness of Abstract Meaning Representation (AMR) (Banarescu et al., 2013) to select high quality sets of entity "collaborators" to feed a simple similarity measure (Jaccard) to link entity mentions. Experimental results show that AMR captures contextual properties discriminative enough to make linking decisions, without the need for EL training data, and that system with AMR parsing output outperforms hand labeled traditional semantic roles as context representation for EL. Finally, we show promising preliminary results for using AMR to select sets of "coherent" entity mentions for collective entity linking [1].

1 Introduction

The Entity Linking (EL) task (Ji et al., 2010; Ji et al., 2011; Ji et al., 2014) aims at automatically linking each named entity mention appearing in a *source* text document to its unique referent in a *target* knowledge base (KB). For example, consider the following sentence posted to a discussion forum during the 2012 U.S. presidential election: "*Where would McCain be without Sarah?*". An Entity Linker should link the entity mentions "*McCain*" and "*Sarah*" to the entities `John McCain` and `Sarah Palin`, respectively, which serve as unique identifiers for the real people.

A typical EL system works as follows. Given a mention m (a string in a source document), the top N most likely entity referents from the KB are enumerated based on prior knowledge about which entities are most likely referred to using m. The candidate entities are re-ranked to ultimately link each mention to the top entity in its candidate list. Reranking consists of two key elements: *context representation* and *context comparison*. For a given mention, candidate entities are re-ranked based on a comparison of information obtained from the context of m with known structured and/or unstructured information associated with the top N KB entities, which can be considered the "context" of the KB entity[2]. The basic intuition is that the entity referents of m and related mentions should be similarly connected in the KB.

However, there might be many entity mentions in the context of a target entity mention that could potentially be leveraged for disambiguation. In this paper, we show that a deeper semantic knowledge representation - including the Abstract Meaning Representation (AMR) (Banarescu et al., 2013) - can capture contextual properties that are discriminative enough to disambiguate entity mentions that current state-of-the-art systems cannot handle, without the need for EL training data. Specifically, for a given

[1]The web service of this EL system is at: blender02.cs.rpi.edu:3300 and some related AMR tools are at: github.com/panx27/amr-reader

[2]Most work uses Wikipedia and related resources to derive the KB, prior link likelihood, and entity information (e.g., Wikipedia article text and infoboxes).

Denver, Colorado, May 31 – June 5, 2015.

entity mention, using AMR provides a rich context representation, facilitating the selection of an optimal set of *collaborator* entity mentions, i.e., those co-occurring mentions most useful for disambiguation. In previous approaches, collaborator sets have tended to be too narrow or too broad, introducing noise. We then use unsupervised graph inference for context comparison, achieving results comparable with state-of-the-art supervised methods and substantially outperforming context representation based on traditional Semantic Role Labeling.

In addition, most state-of-the-art EL approaches now rely on *collective inference*, where a set of *coherent mentions* are linked simultaneously by choosing an "optimal" or maximally "coherent" set of named entity targets - one target entity for each mention in the coherent set. We show preliminary results suggesting that AMR is effective for the partitioning of all mentions in a document into coherent sets for collective linking.

We evaluate our approach using both human and automatic AMR annotation, limiting target named entity types to person (PER), organization (ORG), and geo-political entities (GPE) [3].

2 Related Work

In most recent collective inference methods for EL (e.g., (Kulkarni et al., 2009; Pennacchiotti and Pantel, 2009; Fernandez et al., 2010; Radford et al., 2010; Cucerzan, 2011; Guo et al., 2011; Han and Sun, 2011; Ratinov et al., 2011; Chen and Ji, 2011; Kozareva et al., 2011; Dalton and Dietz, 2013)), the target entity mention's "collaborators" may simply include all mentions which co-occur in the same discourse (sentence, paragraph or document) (Ratinov et al., 2011; Nguyen et al., 2012). But this approach usually introduces many irrelevant mentions, and it's very difficult to automatically determine the scope of discourse. In contrast, some recent work exploited more restricted measures by only choosing those mentions which are topically related (Cassidy et al., 2012; Xu et al., 2012), bear a relation from a fixed set (Cheng and Roth, 2013), coreferential (Nguyen et al., 2012; Huang et al., 2014), socially related (Cassidy et al., 2012; Huang et al., 2014), dependent (Ling et al., 2014), or a combination of these through meta-paths (Huang et al., 2014). These measures can collect more precise collaborators but suffer from low coverage of predefined information templates and the unsatisfying quality of state-of-the-art coreference resolution, relation and event extraction.

In this paper, we demonstrate that AMR is an appropriate and elegant way to acquire, select, represent and organize deeper knowledge in text. Together with our novel utilization of the rich structures in merged KBs, the whole framework carries rich enough evidence for effective EL, without the need for any labeled data, collective inference, or sophisticated similarity.

3 Knowledge Network Construction from Source

Abstract Meaning Representation (AMR) (Banarescu et al., 2013) is a sembanking language that captures whole sentence meanings in a rooted, directed, labeled, and (predominantly) acyclic graph structure. AMR utilizes multi-layer linguistic analysis such as PropBank frames, non-core semantic roles, coreference, named entity annotation, modality and negation to represent the semantic structure of a sentence. AMR strives for a more logical, less syntactic representation. Compared to traditional dependency parsing and semantic role labeling, the nodes in AMR are entities instead of words, and the edge types are much more fine-grained[4]. AMR thus captures deeper meaning compared with other representations more commonly used to represent mention context in EL.

We use AMR to represent semantic information about entity mentions expressed in their textual context. Specifically, given an entity mention m, we use a rule based method to construct a Knowledge Network, which is a star-shaped graph with m at the hub, with leaf nodes obtained from entity mentions reachable by AMR graph traversal from m, as well as AMR node attributes such as entity type. A subset of the leaf nodes are selected as m's collaborators using rules presented in the following subsec-

[3]The mapping from AMR entity types to these three main types is at: amr.isi.edu/lib/ne-type-sc.txt

[4]AMR distinguishes between entities and concepts, the former being instances of the latter. We consider AMR concepts as entity mentions, and use AMR entity annotation for coreference resolution.

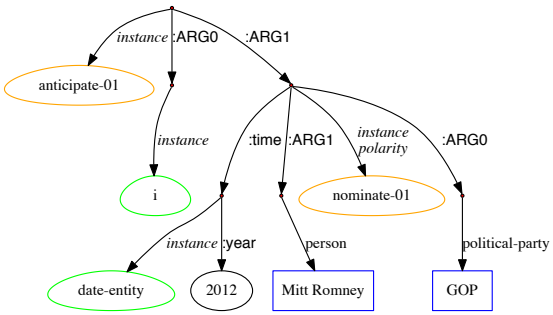
tions. Note that while we only evaluate linking of PER, ORG, and GPE entities, collaborators may be of any type. We also outline preliminary efforts to use AMR to create sets of coherent entity mentions.

In each of the following subsections we describe elements of AMR useful for context representation in EL. For each element we explain how our current system makes use of it (primarily, by using it to add entity mentions to a particular entity mention's set of collaborators). In doing so, we mainly refer to several examples from political discussion forums about "*Mitt Romney*", "*Ron Paul*" and "*Gary Johnson*". Their AMR graphs are depicted in Figure 1.

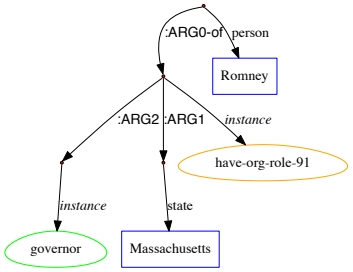
3.1 Entity Nodes

Each AMR node represents an entity mention, and contains its canonical name as inferred from sentential context. This property is called *name expansion*. Consider the following sentence: "*Indonesia lies in a zone where the **Eurasian**, **Philippine** and **Pacific** plates meet and occasionally shift, causing earthquakes and sometimes generating tsunamis.*". Here, the nodes representing the three plates will be labeled as "*Eurasian Plate*", "*Philippine Plate*" and "*Pacific Plate*" respectively, even though these strings do not occur in the sentence. Note that these labels may be recovered primarily by appealing to syntactic reasoning, without consulting a KB. In our implementation we consider these expanded names as mentions (these strings supersede raw mentions as input to the salience based candidate enumeration (Section 5.2)). Because the initial enumeration of entity candidates depends heavily on the mention's surface form, independent of context, name expansion will help us link "*Philippine*" to "`Philippine Sea Plate`" as opposed to the country.

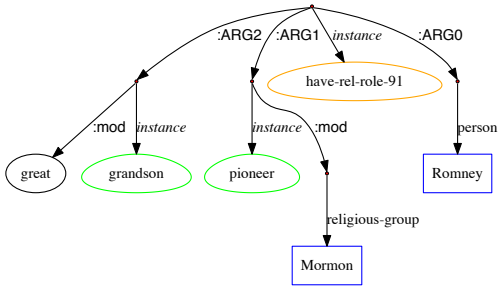
An AMR node also contains an entity type. AMR defines 8 main entity types (Person, Organization, Location, Facility, Event, Product, Publication, Natural object, Other) and over one hundred fine-grained subtypes. For example, company, government organization, military, criminal organization, political party, school, university, research institute, team and league are subtypes of organization. The fine-grained entity types defined in AMR help us restrict KB entity candidates for a given mention by encouraging entity type matching. For example, in "*The **Yuri dolgoruky** is the first in a series of new nuclear submarines to be commissioned this*



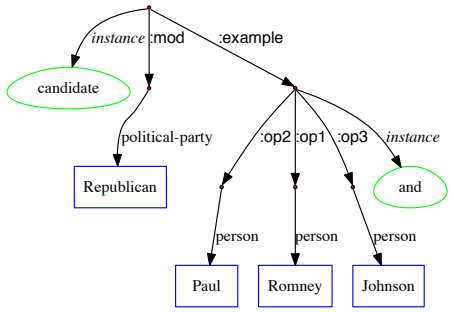
(a) *I am cautiously anticipating the GOP nominee in 2012 not to be **Mitt Romney**.*



(b) ***Romney** was the Governor of Massachusetts...*



(c) ***Romney** is the great-great-grandson of a Mormon pioneer...*



(d) *Republican candidates like **Romney**, **Paul**, and **Johnson**...*

Figure 1: AMR for the Walk-through Example

year but the bulava nuclear-armed missile developed to equip the submarine has failed tests and the deployment prospects are uncertain.", AMR labels "*Yuri dolgoruky*" as a product instead of a person. We manually mapped AMR entity types to equivalent DBpedia types to inform type matching restrictions [5]. However, to make our context comparison algorithm less dependent on the quality of this mapping, and on automatic AMR name type assignment, we add a mention's type to its collaborators [6]. In future work we plan to investigate the effects of different type matching techniques, varying degrees of strictness.

3.2 Semantic Roles

AMR defines core roles based on the OntoNotes (Hovy et al., 2006) semantic role layer. Each predicate is associated with a sense and frame description. If a target entity mention *m* and a context entity mention *n* are both playing core roles for the same predicate, we consider *n* as a collaborator of *m*. Consider the following post: "*Did **Palin** apologize to **Giffords**? He needs to conduct a beer summit between **Palin** and **NBC**.*". We add "*Giffords*" and "*NBC*" as collaborators of "*Palin*", because they play core roles in both the "*apologize-01*" and "*meet-03*" events.

AMR defines new core semantic roles which did not exist in PropBank (Palmer et al., 2005), NomBank (Meyers et al., 2004), or Ontonotes (Hovy et al., 2006). Intuitively, the following special roles should provide discriminative collaborators:

- The ARG2 role of the *have-org-role-91* frame indicates the title held by an entity (ARG0), such as President and Governor, within a particular organization (ARG1).
- ARG2 and ARG3 of *have-rel-role-91* are used to describe two related entities of the same type, such as family members.

AMR defines a rich set of general semantic relations through non-core semantic roles. We choose the following subset of non-core roles to provide collaborators for entity mentions: *domain*, *mod*, *cause*, *concession*, *condition*, *consist-of*, *extent*, *part*, *purpose*, *degree*, *manner*, *medium*, *instrument*, *ord*, *poss*, *quant*, *subevent*, *subset*, *topic*.

3.3 Background Time and Location

AMR provides rich temporal and spatial information about entities and events. Types instantiated in AMR include time, year, month, day, source, destination, path and location. We exploit time and location entities as collaborators for entity mentions when they each play a role in the same predicate. For example, in the following post, the time role of the "*die-01*" event is "*2008*": "*I just Read of Clark's death in 2008*". We can link "*Clark*" to `Arthur C Clark` in the KB, which contains the triple: <`Arthur C Clark`, *date-of-death*, 2008-03-19> (see Section 4). Similarly, it's very challenging to link the abbreviation "*BMKG*", in the following sentence, to the correct target entity `Indonesian Agency for Meteorology, Climatology and Geophysics`, whose headquarters are listed as `Jakarta` in the KB: "*It keeps on shaking. **Jakarta** BMKG spokesman Mujuhidin said*". Here, "*Jakarta*" is added as a collaborator of "*BMKG*" since AMR labels it as the location of the organization, which facilitates the correct link because in DBpedia `Jakarta` is listed as its headquarter.

Authors often assume that readers will infer implicit temporal information about events. In fact, half of the events extracted by information extraction (IE) systems lack time arguments (Ji et al., 2009). Therefore if an AMR parse includes no time information, we use the document creation time as an additional collaborator for mention in question. For example, knowing the document creation time "*2005-06-05*" can help us link "*Hsiung Feng*" in the following sentence "*The BBC reported that Taiwan has successfully test fired the **Hsiung Feng**, its first cruise missile.*" to `Hsiung Feng IIE`, which was deployed in 2005. Similarly, we include document creation location as a global collaborator.

3.4 Coreference

For linking purposes, we treat a coreferential chain of mentions as a single "mention". In doing so, the collaborator set for the entire chain is computed as the union over all of the chain's mentions' collabo-

[5] The mapping from three main types and AMR entity types to Dbpedia types is at: nlp.cs.rpi.edu/amrel/dbtype.txt

[6] A more strict approach might disallow type mismatches between entity mentions and their target KB entities outright.

rator sets. From here on we refer to a coreferential chain of mentions as simply a "mention".

AMR currently only represents sentence-level coreference resolution. In order to construct a knowledge network across sentences, we use the following heuristic rules. If two names have a substring match (on a token-wise basis with stop words removed), or one name consists of the initials of another in all capital letters, then we mark them as coreferential. We replace all names in a coreferential chain with their canonical name, which may have been derived via name expansion (Section 3.1): full names for people and abbreviations for organizations.

3.5 Knowledge Networks for Coherent Mentions

AMR defines a rich set of conjunction relations: "*and*", "*or*", "*contrast-01*", "*either*", "*compared to*", "*prep along with*", "*neither*", "*slash*", "*between*" and "*both*". These relations are often expressed between entities that have other relations in common. We therefore group mentions connected by conjunction relations into sets of coherent mentions. This representation is used only in preliminary experiments on collective entity linking.

Figure 2 shows the expanded knowledge network that includes results from individual networks for each of the coherent mentions from the walk-through example. For each coherent set, we merge the knowledge networks of all of its mentions [7].

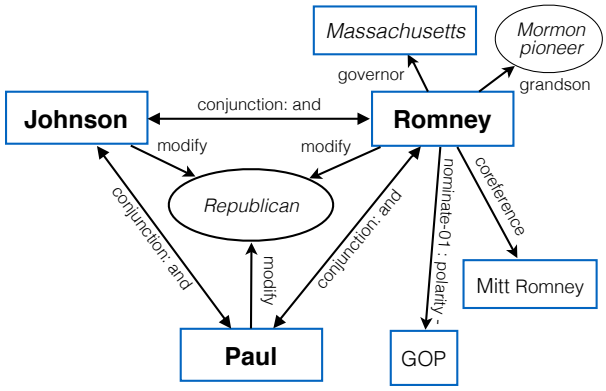


Figure 2: Knowledge Network for Mentions in Source

[7] recall that by mention, we mean a coreferential chain of mentions that may extend across sentences

4 Knowledge Network Construction from KB

We combine Wikipedia with derivative resources to create the KB. The KB is a single knowledge network in which nodes are entities (Wikipedia articles) or constant values (e.g. a dollar amount or date), and the edges represent relations. We use this structure for context representation for entities, which together with context representation for mentions (Section 3) feeds re-ranking based on context comparison.

The KB is formally represented by triples:

$$< Entity, EdgeLabel, Node >$$

where *Entity* is the entity's unique identifier, *EdgeLabel* is relation type, and *Node* is the corresponding relation value - either another Entity or a constant. These triples are derived from typed relations expressed within Wikipedia infoboxes, Templates, and Categories, untyped hyperlinks within Wikipedia article text, typed relations within DBpedia (dbpedia.org) and Freebase (www.freebase.com), and Google's "people also searched for" list [8]. Figure 3 shows a portion of the KB pertaining to the example in Figure 1.

In order to merge nodes from multiple KBs, we use the Wikipedia title as a primary key, and then use DBpedia *wikiPageID* and Freebase *Key* relations.

5 Linking Knowledge Networks

5.1 Overview

In this section we present our detailed algorithm to link each mention to a KB entity using a simple similarity measure over knowledge networks. Recall that a rule-based method has already been employed to construct star-shaped knowledge networks for individual mentions and entities (see sections 3 and 4; A KB knowledge network is the subnetwork of the entire KB centered at a candidate entity).

For each mention to be linked, an initial list of candidate entities are enumerated based on entity salience with respect to the mention, independent of mention context (Section 5.2)[9]. *Context collaborator* re-ranking proceeds in an unsupervised fashion

[8] In response to a query entity Google provides a list of entities that "people also search for" - we add them to the entity's network.

[9] Here, "mention" means coreferential chain of mentions.

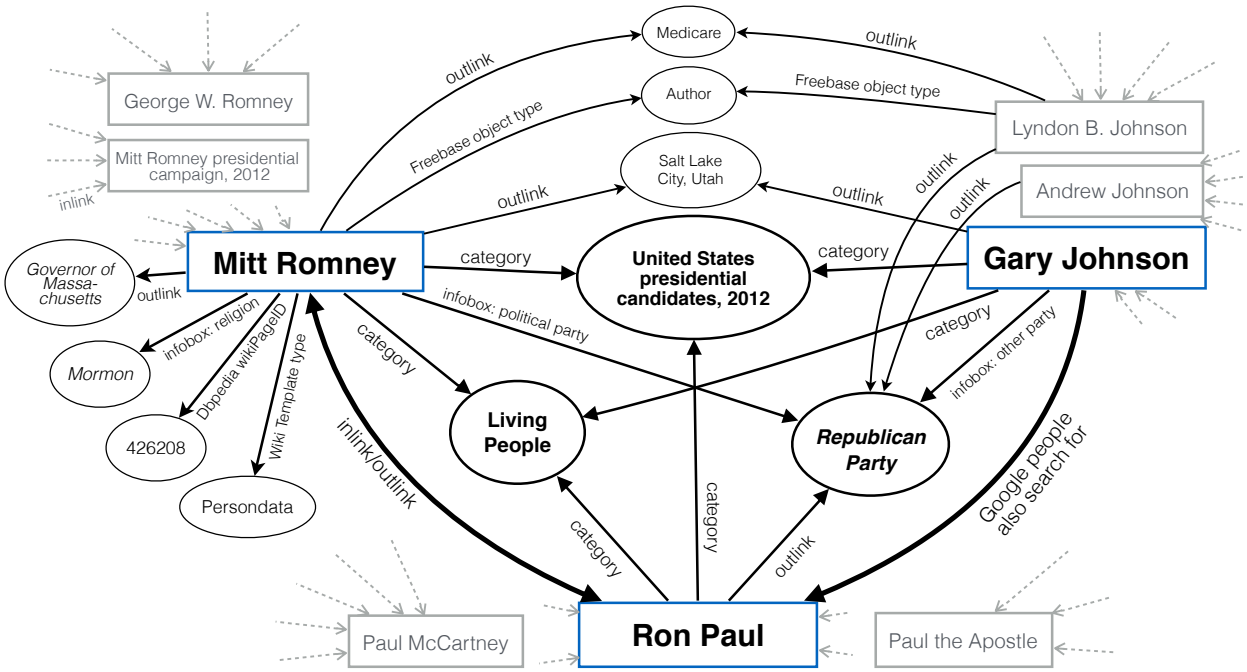

Figure 3: Knowledge Network for Entities in KB

agnostic to knowledge network edge labels using the Jaccard similarity measure computed between the mention and each entity, by taking their collaborator sets as inputs (Section 5.3).

We also describe *Context Coherence* re-ranking in terms of KB knowledge networks only, which constitutes preliminary steps toward unsupervised collective entity linking in section 5.4 based on the notion of coherence described in section 3.5. We leave a combination of the two re-ranking approaches to future work.

5.2 Salience

We use commonness (Medelyan and Legg, 2008) as a measure of context independent salience for each mention m, to generate an initial ranked list of candidate entities $E = (e_1, ..., e_N)$ where N is the cutoff for number of candidates. In all experiments, we used N = 15 which can give us an oracle accuracy score 97.58%.

$$Commonness(m, e) = \frac{count(m, e)}{\sum_{e'} count(m, e')}$$

Here, $count(m, e)$ is the number of hyperlinks with anchor text m and entity e within all of Wikipedia. As illustrated in Figure 3, using this salience measure "*Romney*" is successfully linked to `Mitt Romney`. For the mention "*Paul*", the politician `Ron Paul` is ranked at top 2 (less popular than the musician `Paul McCartney`). For the mention "*Johnson*", the correct entity `Gary Johnson` is ranked at top 9, after more popular entities such as `Lyndon B. Johnson` and `Andrew Johnson`.

5.3 Context Collaborator Based Re-ranking

Context collaborator based re-ranking is driven by the similarity between mention and entity knowledge networks. We construct knowledge network $g(m)$ for each mention m, and knowledge network $g(e_i)$ for each entity candidate e_i in m's entity candidate list E. We re-rank E according to Jaccard Similarity, which computes the similarity between $g(m)$ and $g(e_i)$:

$$J(g(m), g(e_i)) = \frac{|g(m) \cap g(e_i)|}{|g(m) \cup g(e_i)|}$$

Note that the edge labels (e.g., *nominate-01* for a mention, or *infobox: religion* for an entity) are ignored, as the similarity metric operates over sets of collaborators (leaf nodes in the knowledge networks). For set intersection and union computation, elements are treated as lists of lower-cased tokens with stop words removed, and two elements are considered equal if and only if they have one or

more token in common. Due to the support from their neighbor `Republican` in the KB (Figure 3) which matches the neighbor "*Republican*" of mentions "*Paul*" and "*Johnson*" (Figure 2), `Ron Paul` and `Gary Johnson` are promoted to top 1 and top 3 respectively. `Gary Johnson` is still behind two former U.S. presidents `Andrew Johnson` and `Lyndon B. Johnson` who also shares the neighbor `Republican` in the KB.

5.4 Context Coherence Based Re-ranking

Context coherence based re-ranking is driven by the similarity among KB entities. Let R_m be a set of coherent entity mentions, and R_E be the set of corresponding entity candidate lists, which are generated according to salience. Given R_E, we generate every combination of possible top candidate lists for the mentions in R_m, and denote the set of these combinations C_m. Formally, C_m is the Cartesian product of all candidate lists $E \in R_E$. In the walk-through example, R_m contains ["*Romney*", "*Paul*", "*Johnson*"], and C_m contains [`Mitt Romney, Ron Paul, Gary Johnson`], [`Mitt Romney, Paul McCartney, Lyndon Johnson`], etc. We compute coherence for each combination $c \in C_m$ as Jaccard Similarity, by applying a form of Equation 5.3 generalized to take any number of arguments to the set of knowledge networks for all entities in c, i.e., $\{g(e)|e \in c\}$. The highest similarity combination is selected, yielding a top candidate for each $m \in R_m$. For example, compared to `Andrew Johnson` and `Lyndon Johnson`, `Gary Johnson` is more coherently connected with `Mitt Romney` and `Ron Paul`, therefore it is promoted to top 1 with the coherence measure.

6 Experiments

6.1 Data And Scoring Metric

For our experiments we use a publicly available AMR R3 corpus (LDC2013E117) that includes manual EL annotations for all entity mentions (LDC2014E15) [10].

For evaluation we used all the discussion forum posts (DF), and news documents (News) that were sorted according to alphabetic order of document IDs and taken as a tenth. The detailed data statistics are presented in Table 1 [11].

	PER	ORG	GPE	All
News	159	187	679	1,025
DF	235	129	224	588
All	394	316	903	1,613

Table 1: Total # of Entity Mentions in Test Set

For each mention, we check whether the KB entity returned by an approach is correct or not. We compute accuracy for an approach as the proportion of mentions correctly linked.

6.2 Experiment Results

We focus primarily on context collaborator based reranking results. We compare our results with several baseline and state-of-the-art approaches in Table 2. In Table 3 we present preliminary results for collective linking.

Our Unsupervised Context Collaborator Approach substantially outperforms the popularity based methods. More importantly, we see that AMR provides the best context representation for collaborator selection. Even system AMR outperformed not only baseline co-occurrence based collaborator selection methods, but also outperforms the collaborator selection method based on human annotated core semantic roles. Figure 4 depicts accuracy increases as more AMR annotation is used in selecting collaborators. From the commonness baseline, additional knowledge about individual names leads to substantial gains followed by additional gains after incorporating links denoting semantic roles. Note that coreference here includes cross-sentence co-reference not based on AMR (Section 3.4). Furthermore, the results using human annotated AMR outperform the state-of-the-art supervised methods trained from a large scale EL training corpus, which rely on collective inference[12]. These results all verify the importance of incorporating a wider range of deep knowledge. Finally, Table 2 presents results in which our

[10] EL annotations are available to KBP shared task registrants (nlp.cs.rpi.edu/kbp/2014) via Linguistic Data Consortium (www.ldc.upenn.edu).

[11] The list of document IDs in the test set is at: nlp.cs.rpi.edu/amrel/testdoc.txt

[12] Note that the ground-truth EL annotation for the test set was created by correcting the output from supervised methods, so it may even favor these methods.

Approach		Definition	News	DF	Total
Popularity	Commonness	based on the popularity measure as described in section 5.2.	89.76	68.99	82.20
	Google Search	use the top Wikipedia page returned by Google search using the mention as a key word.	88.10	77.17	84.12
Supervised	State-of-the-art	supervised re-ranking using multi-level linguistic features for collaborators and collective inference, trained from 20,000 entity mentions from TAC-KBP2009-2014. We combined two systems (Chen and Ji, 2011; Cheng and Roth, 2013) using rules to highlight their strengths.	93.07	87.41	**91.01**
Unsupervised Context Collaborator Approach	Sen. Level Cooccurrence	sentence-level co-occurrence based collaborator selection	93.17	73.25	85.92
		(collaborators limited to human AMR-labeled named entities)	90.77	70.31	83.31
	Doc. Level Cooccurrence	document-level co-occurrence based collaborator selection	90.05	69.86	82.69
		(collaborators limited to human AMR-labeled named entities)	87.51	69.37	80.90
	Human AMR	using human annotated AMR nodes and edges.	93.56	86.88	**91.13**
	System AMR	using AMR nodes and edges automatically generated by an AMR parser (Flanigan et al., 2014).	90.15	85.69	**88.52**
	Human SRL	using human annotated core semantic roles defined in PropBank (Palmer et al., 2005) and NomBank (Meyers et al., 2004): ARG0, ARG1, ARG2, ARG4 and ARG5.	93.27	71.21	85.24
Unsupervised Combined Approach	Human AMR	coherence approach used where possible (215 mentions), collaborator approach elsewhere (remaining 1398 mentions), using human annotated AMR nodes and edges.	94.34	88.25	**92.12**

Table 2: Accuracy (%) on Test Set (1613 mentions)

context coherence method is used where possible (i.e., those 215 mentions that are members of coherent sets according to our criteria as described in Section 3.5), and the context collaborator approach based on human AMR annotation is applied elsewhere.

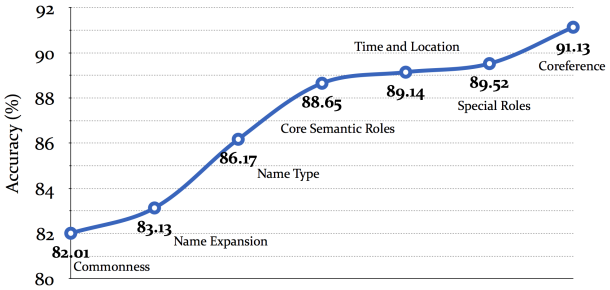

Figure 4: AMR Annotation Layers Effects on Accuracy

Table 3 focuses on the 215 mentions that met our narrow criteria for forming a coherent set of mentions. We applied the context coherence based reranking method (Section 5.4) to collectively link those mentions. This approach substantially outperforms the co-occurrence baseline, and even outperforms the context collaborator approach applied to those 215 mentions, especially for discussion forum data.

Approach Description	News	DF	All
Coherence: coherence set built from within-sentence collaborators limited to human AMR-labeled Named Entities.	72.64	76.85	75.47
Coherence: coherence set built from human AMR conjunctions (Sec. 3.5)	96.73	95.16	**96.28**
Collaborator: used coherent set based on human AMR as collaborators.	91.50	82.26	88.84

Table 3: Context Coherence Accuracy (%) on 215 Mentions which Can Form Coherent Sets

6.3 Remaining Error Analysis and Discussion

A challenging source of errors pertains to the *knowledge gap* between the source text and KB. News and social media are source text genres that tend to focus on new information, trending topics, breaking events, or even mundane details about the entity. In contrast, the KB usually provides a snapshot summarizing only the entity's most representative and important facts. A source-KB similarity driven approach alone will not suffice when a mention's context differs substantially from anything on the KB side. AMR annotation's synthesis of words and phrases from the surface texts into concepts only provides a first step toward bridging the knowledge gap. Successful linking may require (1) reasoning using general knowledge, or (2) retrieval of other sources that contain additional useful linking information. Table 4 illustrates two relevant examples

Type	Source	Knowledge Base
General Knowledge	**[Christies]$_{\mathbf{m}}$** denial of ***marriage*** privledges to ***gays*** will alienate independents and his "I wanted to have the people ***vote*** on it" will ring hollow.	**[Chris Christie]$_{\mathbf{e}}$** has said that he favoured New Jersey's law allowing ***same-sex*** couples to form civil unions, but would veto any bill legalizing ***same-sex marriage*** in New Jersey.
External Knowledge	Translation out of hype-speak: some kook made ***threatening*** noises at **[Brownback]$_{\mathbf{m}}$** and go ***arrested***.	**[Samuel Dale "Sam" Brownback]$_{\mathbf{e}}$** (born September 12, 1956) is an American politician, the 46th and current ***Governor*** of Kansas.

Table 4: Examples of Knowledge Gap

that our system does not correctly link. In the first example, if we don't already know that Christie is the topic of discussion, as humans we might use our general knowledge that "governors veto bills" to pick the correct entity. Using this type of knowledge presents interesting challenges (e.g., governors don't always veto bills, nor are they the only ones who can do so). In the second example, the rumor about this politician is not important enough to be reported in his Wikipedia page. We might first figure out, using cross-document coreference techniques, that a news article with the headline "*Man Accused Of Making Threatening Phone Call To Kansas Gov.* ***Sam Brownback*** *May Face Felony Charge...*" is talking about the same rumor. Then we might use biographical facts (e.g., Brownback is the governor of Kansas) from the article to enrich Brownback's knowledge network on the source side.

Sometimes helpful neighbor concepts are omitted because the current collaborator selection criteria are too restricted. For example, "*armed*" and "*conflicts*" are informative words for linking "*The Stockholm Institute*" to `Stockholm International Peace Research Institute` in the following sentence "***The Stockholm Institute*** *stated that 23 of 25 major armed conflicts in the world in 2000 occurred in impoverished nations.*", but they were not selected as context collaborators. In addition, our cross-sentence coreference resolution is currently limited to proper names. Expanding it to include nominals could further enrich context collaborators to overcome some remaining errors. For example, in the sentence, "*The first woman to serve on* ***SCOTUS***", if we know "*The first woman*" is coreferential with "*Sandra Day O'Connor*" in the previous sentence, we can link "*SCOTUS*" to `Supreme Court of the United States` instead of `Scotus College`.

7 Conclusions and Future Work

EL requires a representation of the relations among entities in text. We showed that the Abstract Meaning Representation (AMR) can better capture and represent the contexts of entity mentions for EL than previous approaches. We plan to improve AMR representation as well as automatic annotation. We showed that AMR enables EL performance comparable to the supervised state of the art using an unsupervised, non-collective approach. We plan to combine collaborator and coherence methods into a unified approach, and to use edge labels in knowledge networks for context comparison (note that the last of these is quite challenging due to normalization, polysemy, and semantic distance issues). We have only applied a subset of AMR representations to the EL task, but we aim to explore how more AMR knowledge can be used for other more challenging Information Extraction and Knowledge Base Population tasks.

Abstract

This paper describes IDEST, a new method for learning paraphrases of event patterns. It is based on a new neural network architecture that only relies on the weak supervision signal that comes from the news published on the same day and mention the same real-world entities. It can generalize across extractions from different dates to produce a robust paraphrase model for event patterns that can also capture meaningful representations for rare patterns. We compare it with two state-of-the-art systems and show that it can attain comparable quality when trained on a small dataset. Its generalization capabilities also allow it to leverage much more data, leading to substantial quality improvements.

1 Introduction

Most Open Information Extraction (Open-IE) systems (Banko et al., 2007) extract textual relational patterns between entities automatically (Fader et al., 2011; Mausam et al., 2012) and optionally organize them into paraphrase clusters. These pattern clusters have been found to be useful for Question Answering (Lin & Pantel, 2001; Fader et al., 2013) and relation extraction (Moro & Navigli, 2012; Grycner & Weikum, 2014), among other tasks.

A related Open-IE problem is that of automatically extracting and paraphrasing **event patterns**: those that describe changes in the state or attribute values of one or several entities. An existing approach lo learn paraphrases of event patterns is to build on the following weak supervision signal: news articles that were published on the same day and mention the same entities should contain good paraphrase candidates. Two state-of-the-art event paraphrasing systems that are based on this assumption are NEWSSPIKE (Zhang & Weld, 2013) and HEADY (Alfonseca et al., 2013; Pighin et al., 2014).

These two systems have a lot in common, yet they have never been compared with each other. They have specific weak and strong points, and there are many ways in which they are substantially different:

- *Scope of generalization.* In NEWSSPIKE the paraphrase clusters are learned separately for each publication day and entity set, and the system cannot generalize across events of the same type involving different entities occurring on the same or on different days. For example, if the event verbs *has married* and *wed* appear in news about two entities A and B marrying, and *has married* and *tied the knot with* appear in news involving two different entities C and D, NEWSSPIKE is not able to infer that *wed* and *tied the knot with* are also paraphrases, unless a post-processing is done.

  HEADY overcomes this limitation thanks to a global model that learns event representations across different days and sets of entities. However, the global nature of the learning problem can incur into other drawbacks. First, training a global model is more costly and more difficult to parallelize. Second, relatively frequent patterns that erroneously co-occur with other patterns may have a negative impact on the final models, potentially resulting in noisier clusters. Lastly, low-frequency patterns are likely to be

*Work performed during an internship at Google

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1140–1149,
Denver, Colorado, May 31 – June 5, 2015.

discarded as noisy in the final model. Overall, HEADY is better at capturing paraphrases from the head of the pattern distribution, and is likely to ignore most of the long tail where useful paraphrases can still be found.

- *Simplifying assumptions.* We already mentioned that the two systems share a common underlying assumption, i.e., that good paraphrase candidates can be found by looking at news published on the same day and mentioning the same entities. On top of this, NEWSSPIKE also assumes that better paraphrases are reported around spiky entities, verb tenses may not differ, there is one event mention per discourse, and others. These restrictions are not enforced by HEADY, where the common assumption is indeed even relaxed across days and entity sets.

- *Annotated data.* NEWSSPIKE requires hand-annotated data to train the parameters of a supervised model that combines the different heuristics, whereas HEADY does not need annotated data.

This paper describes IDEST, a new method for learning paraphrases of event patterns that is designed to combine the advantages of these two systems and compensate for their weaknesses. It is based on a new neural-network architecture that, like HEADY, only relies on the weak supervision signal that comes from the news published on the same day, requiring no additional heuristics or training data. Unlike NEWSSPIKE, it can generalize across different sets of extracted patterns, and each event pattern is mapped into a low-dimensional embedding space. This allows us to define a neighborhood around a pattern to find the ones that are closer in meaning.

IDEST produces a robust global model that can also capture meaningful representations for rare patterns, thus overcoming one of HEADY's main limitations. Our evaluation of the potential trade-off between local and global paraphrase models shows that comparably good results to NEWSSPIKE can be attained without relying on supervised training. At the same time, the ability of IDEST to produce a global model allows it to benefit from a much larger news corpus.

2 Related work

Relational Open-IE In an early attempt to move away from domain-specific, supervised IE systems, Riloff (1996) attempted to automatically find relational patterns on the web and other unstructured resources in an open domain setting. This idea has been further explored in more recent years by Brin (1999), Agichtein & Gravano (2000), Ravichandran & Hovy (2002) and Sekine (2006), among the others. Banko et al. (2007) introduced Open-IE and the TEXTRUNNER system, which extracted binary patterns using a few selection rules applied on the dependency tree. More recent systems such as REVERB (Fader et al., 2011) and OLLIE (Mausam et al., 2012) also define linguistically-motivated heuristics to find text fragments or dependency structures that can be used as relational patterns.

A natural extension to the previous work is to automatically identify which of the extracted patterns have the same meaning, by producing either a hard or a soft clustering. Lin & Pantel (2001) use the mutual information between the patterns and their observed slot fillers. Resolver (Yates & Etzioni, 2007) introduces a probabilistic model called the Extracted Shared Property (ESP) where the probability that two instances or patterns are paraphrases is based on how many properties or instances they share. USP (Poon & Domingos, 2009) produces a clustering by greedily merging the extracted relations. Yao et al. (2012) employ topic models to learn a probabilistic model that can capture also the ambiguity of polysemous patterns. More recent work also organizes patterns in clusters or taxonomies using distributional methods on the pattern contexts or entities extracted (Moro & Navigli, 2012; Nakashole et al., 2012), or implicitly clusters relational text patterns via the learning of latent feature vectors for entity tuples and relations, in a setting similar to knowledge-base completion (Riedel et al., 2013).

A shared difficulty for systems that cluster patterns based on the arguments they select is that it is very hard for them to distinguish between identity and entailment. If one pattern entails another, both are likely to be observed in the corpus involving the same entity sets. A typical example illustrating this problem is the two patterns e_1 *married* e_2 and e_1

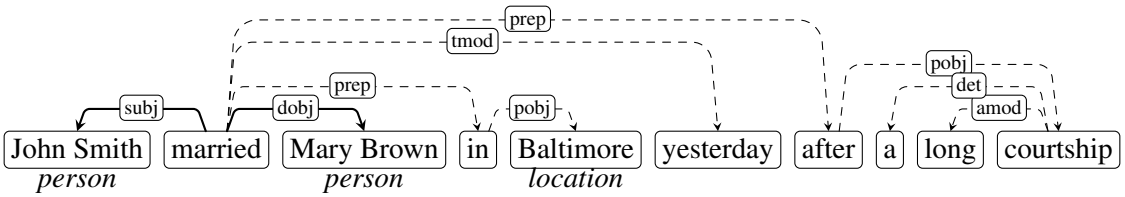

Figure 1: Example sentence, and extraction (the nodes connected through solid dependency edges).

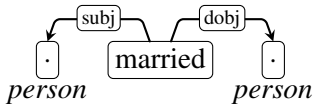

Figure 2: Example pattern that encodes a wedding event between two people.

dated e_2, which can be observed involving the same pairs of entities, but which carry a different meaning. As discussed below, relying on the temporal dimension (given by the publication date of the input documents) is one way to overcome this problem.

Event patterns and Open-IE Although some earlier work uses the temporal dimension of text as filters to improve precision of relational pattern clusters, NEWSSPIKE (Zhang & Weld, 2013) and HEADY (Alfonseca et al., 2013; Pighin et al., 2014) fully rely on it as its main supervision signal. In order to compare the two approaches, we will start by defining some terms:

- An **event pattern** encodes an expression that describes an event. It can be either a linear surface pattern or a lexico-syntactic pattern, and can possibly include entity-type restrictions on the arguments. For example, Figure 2 represents a binary pattern that corresponds to a wedding event between two people.

- An **extraction** is a pattern instance obtained from an input sentence, involving specific entities. For example, the subgraph represented with solid dependency edges in Figure 1 is an extraction corresponding to the pattern in Figure 2.

- An **Extracted Event Candidate Set** (EECSet (Zhang & Weld, 2013), or just EEC for brevity) is the set of extractions obtained from news articles published on the same day, and involving the same set of entities.

- Two extractions are **co-occurrent** if there is at least one EEC that contains both of them.

NEWSSPIKE produces extractions from the input documents using REVERB (Fader et al., 2011). The EECs are generated from the titles and all the sentences of the first paragraph of the documents published on the same day. From each EEC, potentially one paraphrase cluster may be generated. The model is a factor graph that captures several additional heuristics. Integer Lineal Programming (ILP) is then used to find the Maximum a Posteriori (MAP) solution for each set of patterns, and model parameters are trained using a labeled corpus that contains 500 of these sets.

Regarding HEADY, it only considers titles and first sentences for pattern extraction and trains a two-layer Noisy-OR Bayesian Network, in which the hidden nodes represent possible event types, and the observed nodes represent the textual patterns. A maximum-likelihood model is the one in which highly co-occurring patterns are generated by the same latent events. The output is a global soft clustering, in which two patterns may also be clustered together even if they never co-occur in any EEC, as long as there is a chain of co-occurring patterns generated by the same hidden node. HEADY was evaluated using three different extraction methods: a heuristic-based pattern extractor, a sentence compression algorithm and a memory-based method.

While this model produces a soft clustering of patterns, HEADY was evaluated only on a *headline generation* task and not intrinsically w.r.t. the quality of the clustering itself.

Neural networks and distributed representations Another related field aims to learn continuous vector representations for various abstraction levels of

natural language. In particular the creation of so-called word embeddings has attracted a lot of attention in the past years, often by implementing neural-network language models. Prominent examples include the works by Bengio et al. (2003) and Mikolov et al. (2013), with the skip-gram model of the latter providing a basis for the vector representations learned in our approach.

Also closely related to IDEST are approaches which employ neural networks capable of handling word sequences of variable length. For example, Le & Mikolov (2014) extend the architectures of Mikolov et al. (2013) with artificial paragraph tokens, which accumulate the meaning of words appearing in the respective paragraphs.

In contrast to these shallow methods, other approaches employ deep multi-layer networks for the processing of sentences. Examples include Kalchbrenner et al. (2014), who employ convolutional neural networks for analyzing the sentiment of sentences, and Socher et al. (2013), who present a special kind of recursive neural network utilizing tensors to model the semantics of a sentence in a compositional way, guided by the parse tree.

A frequent issue with the deeper methods described above is the high computational complexity coming with the large numbers of parameters in a multi-layer neural network or in the value propagation in unfolded recursive neural networks. To circumvent this problem, our model is inspired by Mikolov's simpler skip-gram model, as described below.

3 Proposed model

Similarly to HEADY and NEWSSPIKE, our model is also based on the underlying assumption that if sentences from two news articles were published on the same day and mention the same entity set, then they are good paraphrase candidates. The main novelty is in the way we train the paraphrase model from the source data. We propose a new neural-network architecture which is able to learn meaningful distributed representations of full patterns.

3.1 Skip-gram neural network

The original Skip-gram architecture (Mikolov et al., 2013) is a feed-forward neural network that is trained on distributional input examples, by assuming that each word should be able to predict to some extent the other words in its context. A skip-gram architecture consists of:

1. An input layer, usually represented as a *one-of-V* or *one-hot-spot* layer. This layer type has as many input nodes as the vocabulary size. Each training example will activate exactly one input node corresponding to the current word w_i, and all the other input nodes will be set to zero.

2. A first hidden layer, the embedding or projection layer, that will learn a distributed representation for each possible input word.

3. Zero or more additional hidden layers.

4. An output layer, expected to predict the words in the context of w_i: $w_{i-K}, ..., w_{i-1}, w_{i+1}, ..., w_{i+K}$.

In practice, when training based on this architecture, the network converges towards representing words that appear in similar contexts with vectors that are close to each other, as close vectors will produce a similar distribution of output labels in the network.

3.2 IDEST neural network

Figure 3 shows the network architecture we use for training our paraphrase model in IDEST. In our case, the input vocabulary is the set of N unique event patterns extracted from text, and our supervision signal is the co-occurrence of event patterns in EECs. We set the input to be a *one-hot-spot* layer with a dimensionality of N, and for each pair of patterns that belong to the same EECs, we will have these patterns predict each other respectively, in two separate training examples. The output layer is also a *one-of-V* layer, because for each training example only one output node will be set to 1, corresponding to a co-occurring pattern.

After training, if two patterns P_i and P_j have a large overlap in the set of entities they co-occur with, then they should be mapped onto similar internal representations. Note that the actual entities are only used for EEC construction, but they do not play a role in the training itself, thus allowing the network to generalize over specific entity instantiations. To exemplify, given the two EECs {"*[Alex] married [Leslie]*", "*[Leslie] tied the knot with*

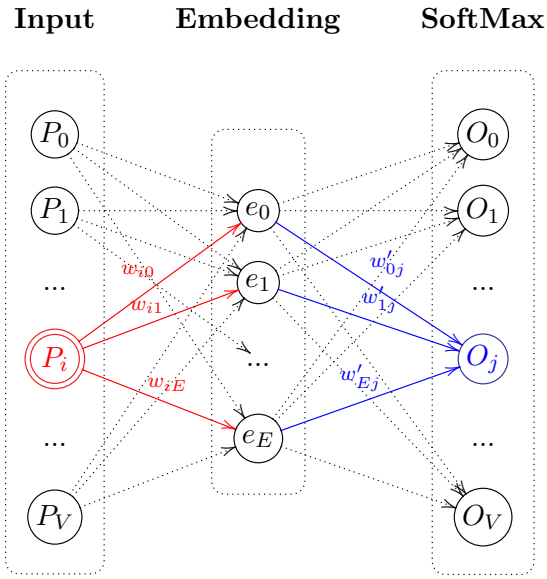

Figure 3: Model used for training. V is the total number of unique patterns, which are used both in the *one-of-V* input and output. E is the dimensionality of the embedding space.

[Alex]"} and {"*[Carl] and [Jane] wed*", "*[Carl] married [Jane]*"}, IDEST could learn an embedding space in which "*[Per] tied the know with [Per]*" and "*[Per] and [Per] wed*" are relatively close, even though the two patterns never co-occur in the same EEC. This is possible because both patterns have been trained to predict the same pattern {"*[Per] married [Per]*"}.

Reported representations of word embeddings typically use between 50 and 600 dimensions (Mikolov et al., 2013; Levy & Goldberg, 2014). For our pattern embeddings we have opted for an embedding layer size of 200 nodes. We also experimented with larger sizes and with adding more intermediate hidden layers, but while the added cost in terms of training time was substantial we did not observe a significant difference in the results.

4 Experimental settings

4.1 Pattern extraction methods used

In previous work we can find three different pattern extraction methods from a sentence:

- *Heuristic-based*, where a number of handwritten rules or regular expressions based on part-of-speech tags or dependency trees are used to select the most likely pattern from the source sentence (Fader et al., 2011; Mausam et al., 2012; Alfonseca et al., 2013).

- *Sentence compression*, which takes as input the original sentence and the entities of interest and produces a shorter version of the sentence that still includes the entities (Pighin et al., 2014).

- *Memory-based*, that tries to find the shortest reduction of the sentence that still includes the entities, with the constraint that its lexico-syntactic structure has been seen previously as a full sentence in a high-quality corpus (Pighin et al., 2014).

It is important to note that the final purpose of the system may impact the decision of which extraction method to choose. Pighin et al. (2014) use the event models to generate headlines, and using the memory-based method resulted in more grammatical headlines at the cost of coverage. If the purpose of the patterns is information extraction for knowledge base population, then the importance of having well-formed complete sentences as patterns becomes less obvious, and higher coverage methods become more attractive. For these reasons, in this paper we focus on the first two approaches, which are very well-established and can produce high-coverage output. More specifically, we use REVERB extractions and a statistical compression model trained on (sentence, compression) pairs implemented after Filippova & Altun (2013).

4.2 Generating clusters from the embedding vectors

IDEST does not produce a clustering like NEWSSPIKE and HEADY, so in order to be able to compare against them we have used the algorithm described in Figure 4 to build paraphrase clusters from the pattern embeddings. Given a similarity threshold on the cosine similarity of embedding vectors, we start by sorting the patterns by extraction frequency and proceed in order along the sorted vector by keeping the most similar pattern of each. Used patterns are removed from the original set to make sure that a pattern is not added to two clusters at the same time.

function COMPUTECLUSTERS(P, θ)
  $Result = \{\}$
  SORTBYFREQUENCY(P)
  while $|P| > 0$ **do**
    $p = \text{POP}(P)$ ▷ Take highest-frequency pattern
    $C_p = \{p\}$ ▷ Initialize cluster around p
    $N = \text{NEIGHBORS}(p, P, \theta)$ ▷ $n \in P, sim(n, p) > \theta$
    for all $n \in N$ **do**
      $C_p = C_p \cup \{n\}$
      REMOVE(P, n) ▷ Remember n has been used
    $Result = Result \cup \{C_p\}$
  return $Result$

Figure 4: Pseudocode of the algorithm for producing a clustering from the distributed representation of the extracted patterns. P is the set of extracted patterns, and θ is the similarity threshold to include two patterns in the same cluster.

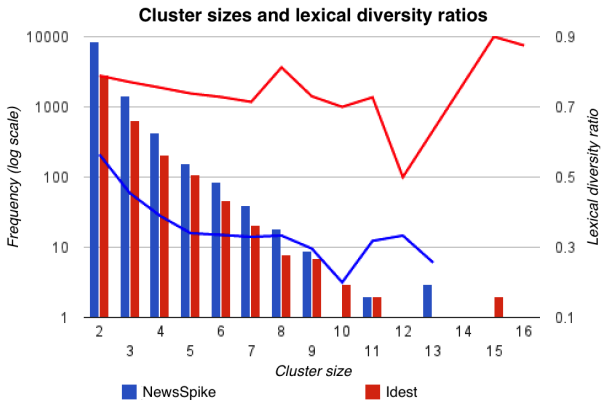

Figure 5: Cluster size (log-scale) and ratio of unique verb lemmas in the clusters generated from NEWSSPIKE and IDEST with the REVERB extractions as input.

5 Evaluation results

This section opens with a quantitative look at the clusterings obtained with the different methods to understand their implications with respect to the distribution of event clusters and their internal diversity. In 5.2, we will complement these figures with the results of a manual quality evaluation.

5.1 Quantitative analysis

5.1.1 NEWSSPIKE vs. IDEST-ReV-NS

This section compares the clustering models that were output by NEWSSPIKE and IDEST when using the same set of extractions, to evaluate the performance of the factor graph-based method and the neural-network method on exactly the same EECs. We have used as input the dataset released by Zhang & Weld (2013)[1], which contains 546,713 news articles, from which 2.6 million REVERB extractions were reportedly produced. 84,023 of these are grouped into the 23,078 distributed EECs, based on mentions of the same entities on the same day. We compare here the released output clusters from NEWSSPIKE and a clustering obtained from a IDEST-based distributed representation trained on the same EECs.

Figure 5 shows a comparative analysis of the two sets of clusters. As can be seen, IDEST generates somewhat fewer clusters for every cluster size than NEWSSPIKE. We have also computed a *lexical diversity ratio*, defined as the percentage of root-verb lemmas in a cluster that are unique. This metric captures whether a cluster mainly contains the same verb with different inflections or modifiers, or whether it contains different predicates. The figure shows that IDEST generates clusters with much more lexical diversity. These results make sense intuitively, as a global model should be able to produce more aggregated clusters by merging patterns originating from different EECs, resulting in fewer clusters with a higher lexical diversity. A higher lexical diversity may be a signal of richer paraphrases or noisier clusters. The manual evaluation in Section 5.2 will address this issue by comparing the quality of the clusterings.

5.1.2 NEWSSPIKE vs. IDEST-Comp-NS

Figure 6 compares NEWSSPIKE's clusters against IDEST clusters obtained using sentence compression instead of REVERB for extracting patterns. Both systems were trained on the same set of input news. Using sentence compression, the total number of extracted patterns was 321,130, organized in 41,740 EECs. We can observe that IDEST produced larger clusters than NEWSSPIKE. For cluster sizes larger or equal to 4, this configuration of IDEST produced more clusters than NEWSSPIKE. At the same time, lexical diversity remained consistently on much higher levels, well over 60%.

5.1.3 IDEST-Comp-NS vs. IDEST-Comp-All

In order to evaluate the impact of the size of training data, we produced a clustering from embedding vectors trained from a much larger dataset. We used

[1] http://www.cs.washington.edu/node/9473

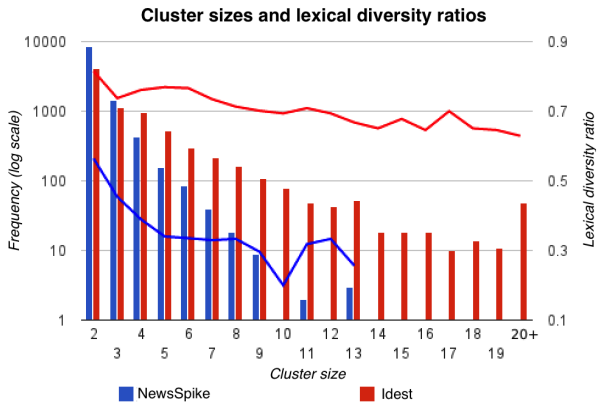

Figure 6: Cluster size (log-scale) and ratio of unique verb lemmas in the clusters generated from NEWSSPIKE and IDEST with compression-based pattern extraction.

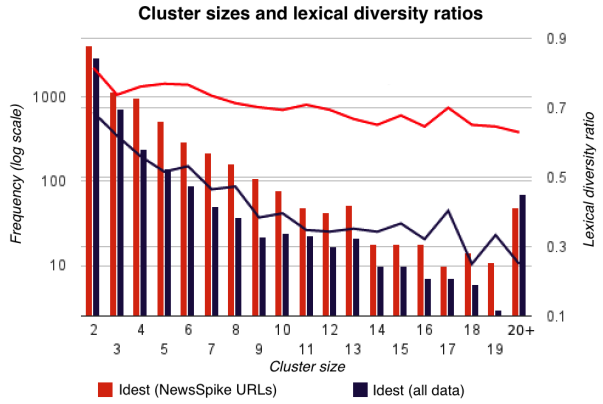

Figure 7: Cluster size (log-scale) and ratio of unique verb lemmas in the clusters generated from IDEST with compression-based pattern extraction, using only the 500,000 NEWSSPIKE articles, or the large dataset.

our own crawl of news collected between 2008 and 2014. Using sentence compression, hundreds of millions of extractions have been produced.

In order to keep the dataset at a reasonable size, and aiming at producing a model of comparable size to the other approaches, we applied a filtering step in which we removed all the event patterns that were not extracted at least five times from the dataset. After this filtering, 28,014,423 extractions remained, grouped in 8,340,162 non-singleton EECs.

Figure 7 compares the resulting clusterings. In the all-data setting, clusters were generally smaller and showed less lexical variability. We believe that this is due to the removal of the long tail of low-frequency and noisy patterns. Indeed, while high lexical variability is desirable it can also be a sign of noisy, unrelated patterns in the clusters. The cohesiveness of the clusters, which we will evaluate in Section 5.2, must also be considered to tell constructive and destructive lexical variability apart.

5.1.4 HEADY

HEADY produces a soft-clustering from a generative model, and expects the maximum number of clusters to be provided beforehand. The model then tries to approximate this number. In our experiments, 5,496 clusters were finally generated. One weak point of HEADY, mentioned above, is that low-frequency patterns do not have enough evidence and Noisy-OR Bayesian Networks tend to discard them; in our experiments, only 4.3% of the unique extracted patterns actually ended up in the final model.

5.2 Qualitative analysis

The clusters obtained with different systems and dataset have been evaluated by five expert raters with respect to three metrics, according to the following rating workflow:

1. The rater is shown the cluster, and is asked to annotate which patterns are meaningless or unreadable[2]. This provides us with a **Readability** score, which measures at the same time the quality of the extraction algorithm and the ability of the method to filter out noise.

2. The rater is asked whether there is a majority theme in the cluster, defined as having at least half of the readable patterns refer to the same real-world event happening. If the answer is *No*, the cluster is annotated as noise. We call this metric **Cohesiveness**.

3. If a cluster is cohesive, the rater is finally asked to indicate which patterns are expressing the main theme, and which ones are unrelated to it. The third metric, **Relatedness**, is defined as the percentage of patterns that are related to the main cluster theme. All the patterns in a non-cohesive cluster are automatically marked as unrelated.

[2]In the data released by NewsSpike, REVERB patterns are lemmatized, but the original inflected sentences are also provided. We have restored the original inflection of all the words to make those patterns more readable for the raters.

The inter-annotator agreement on the three metrics, measured as the intraclass correlation (ICC), was strong (Cicchetti, 1994; Hallgren, 2012). More precisely, the observed ICC scores (with 0.95 confidence intervals) were 0.71 [0.70, 0.72] for cohesiveness, 0.71 [0.70, 0.73] for relatedness and 0.66 [0.64, 0.67] for readability.

For the evaluation, from each model we selected enough clusters to achieve an overall size (number of distinct event patterns) comparable to NEWSSPIKE's. For HEADY and IDEST, the stopping condition in Figure 4 was modified accordingly.

Table 1 shows the outcome of the annotation. As expected, using a global model (that can merge patterns from different EECs into single clusters) and using the whole news dataset both led to larger clusters. At the same time, we observe that using REVERB extractions generally led to smaller clusters. This is probably because REVERB produced fewer extractions than sentence compression from the same input documents.

On REVERB extractions, NEWSSPIKE outperformed IDEST in terms of cohesiveness and relatedness, but NEWSSPIKE's lowest cluster size and lexical diversity makes it difficult to prefer any of the two models only w.r.t. the quality of the clusters. On the other hand, the patterns retained by IDEST-ReV-NS were generally more readable (65.16 vs. 56.66).

On the same original news data, using IDEST with sentence compression produced comparable results to IDEST-ReV-NS, Cohesiveness being the only metric that improved significantly.

More generally, in terms of readability all the models that rely on global optimization (i.e., all but NEWSSPIKE) showed better readability than NEWSSPIKE, supporting the intuition that global models are more effective in filtering out noisy extractions. Also, the more data was available to IDEST, the better the quality across all metrics. IDEST model using all data, i.e, IDEST-Comp-All, was significantly better (with 0.95 confidence) than all other configurations in terms of cluster size, cohesiveness and pattern readability. Pattern relatedness was higher, though not significantly better, than NEWSSPIKE, whose clusters were on average more than ten times smaller.

We did not evaluate NEWSSPIKE on the whole news dataset. Being a local model, extending the dataset to cover six years of news would only lead to many more EECs, but it would not affect the reported metrics as each final cluster would still be generated from one single EEC.

System	Ext	Data	Size	Coh(%)	Rel(%)	Read(%)
HEADY	Comp	All	12.66^{bcd}	$34.40^{!}$	$27.70^{!}$	60.70
NEWSSPIKE	ReV	NS	$3.40^{!}$	56.20^{ac}	66.42^{acd}	56.66
IDEST	ReV	NS	3.62^{b}	40.00	47.10^{a}	65.16^{b}
IDEST	Comp	NS	5.54^{bc}	50.31^{ac}	46.58^{a}	66.04^{b}
IDEST	Comp	All	44.09^{*}	87.93^{*}	68.28^{acd}	80.13^{*}

Table 1: Results of the manual evaluation, averaged over all the clusters produced by each configuration listed. **Extraction algorithms**: *ReV* = REVERB; *Comp* = Compression; **Data sets**: *NS* = NewsSpike URLs; *All* = news 2008-2014. **Quality metrics**: *Size*: average cluster size; *Coh*: cohesiveness; *Rel*: relatedness; *Read*: readability. **Statistical significance**: ^{a}: better than HEADY; ^{b}: better than NEWSSPIKE; ^{c}: better than IDEST-ReV-NS; ^{d}: better than IDEST-Comp-NS; *: better than all others; $^{!}$: worse than all others (0.95 confidence intervals, bootstrap resampling).

It is interesting to see that, even though they were trained on the same data, IDEST outperformed HEADY significantly across all metrics, sometimes by a very large margin. Given the improvements on cluster quality, it would be interesting to evaluate IDEST performance on the headline-generation task for which HEADY was initially designed, but we leave this as future work.

6 Conclusions

We described IDEST, a new approach based on neural networks to map event patterns into an embedding space. We show that it can be used to construct high quality pattern clusters based on neighborhood in the embedding space. On a small dataset, IDEST produces comparable results to NEWSSPIKE, but its main strength is in its ability to generalize extractions into a single global model. It scales to hundreds of millions of news, leading to larger clusters of event patterns with significantly better coherence and readability. When compared to HEADY, IDEST outperforms it significantly on all the metrics tried.

Abstract

This paper introduces a tensor-based approach to semantic role labeling (SRL). The motivation behind the approach is to automatically induce a compact feature representation for words and their relations, tailoring them to the task. In this sense, our dimensionality reduction method provides a clear alternative to the traditional feature engineering approach used in SRL. To capture meaningful interactions between the argument, predicate, their syntactic path and the corresponding role label, we compress each feature representation first to a lower dimensional space prior to assessing their interactions. This corresponds to using an overall cross-product feature representation and maintaining associated parameters as a four-way low-rank tensor. The tensor parameters are optimized for the SRL performance using standard online algorithms. Our tensor-based approach rivals the best performing system on the CoNLL-2009 shared task. In addition, we demonstrate that adding the representation tensor to a competitive tensor-free model yields 2% absolute increase in F-score.[1]

1 Introduction

The accuracy of Semantic Role Labeling (SRL) systems depends strongly on the features used by the underlying classifiers. For instance, the top performing system on the CoNLL–2009 shared task employs over 50 language-specific templates for feature generation (Che et al., 2009). The templates are manually created and thus offer specific means of incorporating prior knowledge into the method. However, finding compact, informative templates is difficult since the relevant signal may be spread over many correlated features. Moreover, the use of lexicalized features, which are inevitably sparse, leads to overfitting. In this case it is advantageous to try to automatically compress the feature set to use a small number of underlying co-varying dimensions. Dimensionality reduction of this kind can be incorporated into the classifier directly by utilizing tensor calculus. In this paper, we adopt this strategy.

We start by building high-dimensional feature vectors that are subsequently mapped into a low-dimensional representation. Since this high-dimensional representation has to reflect the interaction between different indicators of semantic relations, we construct it as a cross-product of smaller feature vectors that capture distinct facets of semantic dependence: *predicate*, *argument*, *syntactic path* and *role label*. By compressing this sparse representation into lower dimensions, we obtain dense representations for words (predicate, argument) and their connecting paths, uncovering meaningful interactions. The associated parameters are maintained as a four-way low-rank tensor, and optimized for SRL performance. Tensor modularity enables us to employ standard online algorithms for training.

Our approach to SRL is inspired by recent success of our tensor-based approaches in dependency parsing (Lei et al., 2014). Applying analogous techniques to SRL brings about new challenges, however. The scoring function needs to reflect the high-order interactions between the predicate, argument,

[1]Our code is available at https://github.com/taolei87/SRLParser.

Denver, Colorado, May 31 – June 5, 2015.

their syntactic path and the corresponding role label. Therefore, we parametrize the scoring function as a four-way tensor. Generalization to high-order tensors also requires new initialization and update procedures. For instance, the SVD initialization used in our dependency parsing work results in memory explosion when extending to our 4-way tensor. Instead, we employ the power method (De Lathauwer et al., 1995) to build the initial tensor from smaller pieces, one rank-1 component at a time. For learning, in order to optimize an overall non-convex objective function with respect to the tensor parameters, we modify the passive-aggressive algorithm to update all the low-rank components in one step. The update strategy readily generalizes to any high-order tensor.

We evaluate our tensor-based approach for SRL on the CoNLL–2009 shared task benchmark datasets of five languages: English, German, Chinese, Catalan and Spanish (Surdeanu et al., 2008). As a baseline, we use a simple SRL model that relies on a minimal set of standard features. Our results demonstrate that the tensor-based model outperforms the original SRL model by a significant margin, yielding absolute improvements of 2.1% F_1 score. We also compare our results against the best performing system on this task (Zhao et al., 2009a). On three out of five languages, the tensor-based model outperforms this system. These results are particularly notable because the system of Zhao et al. (2009a) employs a rich set of language-specific features carefully engineered for this task. Finally, we demonstrate that using four-way tensor yields better performance than its three-way counterpart, highlighting the importance of modeling the relation between role labels and properties of the path.

2 Related Work

A great deal of SRL research has been dedicated to designing rich, expressive features. The initial work by Gildea and Jurafsky (2002) already identified a compact core set of features, which were widely adopted by the SRL community. These features describe the predicate, the candidate argument, and the syntactic relation between them (*path*). Early systems primarily extended this core set by including local context lexicalized patterns (e.g., n-grams), several extended representations of the *path* features, and some linguistically motivated syntactic patterns, as the *syntactic frame* (Surdeanu et al., 2003; Xue and Palmer, 2004; Pradhan et al., 2005).

More recent approaches explored a broader range of features. Among others, Toutanova et al. (2008), Martins and Almeida (2014) and Yang and Zong (2014) have explored high-order features involving several arguments and even pairs of sentence predicates. Other approaches have focused on semantic generalizations of lexical features using selectional preferences, neural network embeddings or latent word language models (Zapirain et al., 2013; Collobert et al., 2011; Deschacht and Moens, 2009; Roth and Woodsend, 2014). To avoid the intensive feature engineering inherent in SRL, Moschitti et al. (2008) employ kernel learning. Although attractive from this perspective, the kernel-based approach comes with a high computational cost. In contrast to prior work, our approach effectively learns low-dimensional representation of words and their roles, eliminating the need for heavy manual feature engineering. Finally, system combination approaches such as reranking typically outperform individual systems (Björkelund et al., 2010). Our method can be easily integrated as a component in one of those systems.

In technical terms, our work builds on our recent tensor-based approach for dependency parsing (Lei et al., 2014). In that work, we use a three-way tensor to score candidate dependency relations within a first-order scoring function. The tensor captures the interaction between words and their syntactic (head-modifier) relations. In contrast, the scoring function in SRL involves higher-order interactions between the path, argument, predicate and their associated role label. Therefore, we parametrized the scoring function with a four-way low-rank tensor. To help with this extension, we developed a new initialization and update strategy. Our experimental results demonstrate that the new representation tailored to SRL outperforms previous approaches.

3 Problem Formulation

Our setup follows the CoNLL–2009 shared task (Hajič et al., 2009). Each token in sentence $\mathbf{x}$ is annotated with a predicted POS tag and predicted

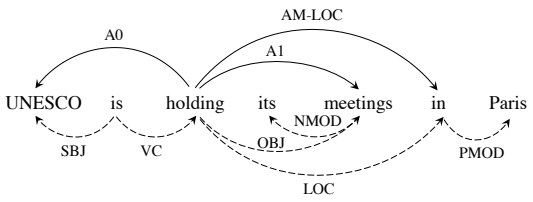

Figure 1: Example sentence from the CoNLL–2009 dataset annotated with syntactic and semantic dependencies. The lower graph is the syntactic dependency tree for the sentence. The upper part contains the semantic dependencies for the predicate "holding".

word lemma. Some tokens are also marked as predicates, i.e., argument-bearing tokens. The goal is to determine the semantic dependencies for each predicate p_i (cf. upper part of Figure 1). These dependencies identify the arguments of each predicate and their role labels. In this work, we focus only on the semantic side – that is, identification and classification of predicate arguments. To this end, our system takes as input a syntactic dependency tree $\mathbf{y}_{\text{syn}}$ derived from a state-of-the-art parser (bottom part of Figure 1).

More formally, let $\{p_i\} \subset \mathbf{x}$ be the set of verbal and nominal predicates in the sentence. For each predicate p_i (e.g., "holding"), our goal is to predict tuples (p_i, a_{ij}, r_{ij}) specifying the semantic dependency arcs, where $a_{ij} \in \mathbf{x}$ is one argument (e.g., "meetings"), and r_{ij} is the corresponding semantic role label (e.g., A1). The semantic parse is then the collection of predicted arcs $\mathbf{z}_{\text{sem}} = \{(p_i, a_{ij}, r_{ij})\}$.

We decouple syntactic and semantic inference problems into two separate steps. We first run our syntactic dependency parser RBGParser[2] to obtain the syntactic dependency tree $\mathbf{y}_{\text{syn}}$. The semantic parse $\mathbf{z}_{\text{sem}}$ is then found conditionally on the syntactic part:

$$\mathbf{z}^*_{\text{sem}} = \arg\max_{\mathbf{z}_{\text{sem}}} \; S_{\text{sem}}(\mathbf{x}, \mathbf{y}_{\text{syn}}, \mathbf{z}_{\text{sem}}), \qquad (1)$$

Here $S_{\text{sem}}(\cdot)$ is the parametrized scoring function to be learned. We build our scoring function by combining a traditional feature scoring function with a tensor-based scoring function.

Predicate word	Path
Predicate POS	Path + arg. POS
Argument word	Path + pred. POS
Argument POS	Path + arg. word
Pred. + arg. words	Path + pred. word
Pred. + arg. POS	Voice + pred. + arg. POS
Voice + pred. word	Voice + pred. POS

Table 1: Templates for first-order semantic features. These features are also (optionally) combined with role labels.

3.1 Traditional Scoring Using Manually-designed Features

In a typical feature-based approach (Johansson, 2009; Che et al., 2009), feature templates give rise to rich feature descriptions of the semantic structure. The score $S_{\text{sem}}(\mathbf{x}, \mathbf{y}_{\text{syn}}, \mathbf{z}_{\text{sem}})$ is then defined as the inner product between the parameter vector and the feature vector. In the first-order arc-factored case,

$$\begin{aligned} S_{\text{sem}}(\mathbf{x}, \mathbf{y}_{\text{syn}}, \mathbf{z}_{\text{sem}}) &= \mathbf{w} \cdot \boldsymbol{\phi}(\mathbf{x}, \mathbf{y}_{\text{syn}}, \mathbf{z}_{\text{sem}}) \\ &= \sum_{(p,a,r) \in \mathbf{z}_{\text{sem}}} \mathbf{w} \cdot \boldsymbol{\phi}(p, a, r), \end{aligned}$$

where $\mathbf{w}$ are the model parameters and $\boldsymbol{\phi}(p, a, r)$ is the feature vector representing a single semantic arc (p, a, r) (we suppress its dependence on $\mathbf{x}$ and $\mathbf{y}_{\text{syn}}$). We also experiment with second order features, i.e., considering two arguments associated with the same predicate, or two predicates sharing the same token as argument.

For the arc-factored model, there are mainly four types of atomic information that define the arc features in $\boldsymbol{\phi}(p, a, r)$:

(a) the predicate token p (and its local context);
(b) the argument token a (and its local context);
(c) the dependency label path that connects p and a in the syntactic tree;
(d) the semantic role label r of the arc.

These pieces of atomic information are either used directly or combined as unigram up to 4-gram features into traditional models. To avoid heavy feature engineering and overfitting, we use a light and compact feature set derived from the information in (a)–(d). Table 1 shows the complete list of feature

templates, used as our first-order semantic baseline in the experiments.

3.2 Low-rank Scoring via Projected Representations

Now, we describe the tensor-based scoring function. We characterize each semantic arc (p, a, r) using the cross-product of atomic feature vectors associated with the four types of information described above: the predicate vector $\boldsymbol{\phi}(p)$, the argument vector $\boldsymbol{\phi}(a)$, the dependency path vector $\boldsymbol{\phi}(path)$ and the semantic role label vector $\boldsymbol{\phi}(r)$. For example, in the simplest case $\boldsymbol{\phi}(p), \boldsymbol{\phi}(a) \in [0,1]^n$ are one-hot indicator vectors, where n is the size of the vocabulary. Similarly, $\boldsymbol{\phi}(path) \in [0,1]^m$ and $\boldsymbol{\phi}(r) \in [0,1]^l$ are indicator vectors where m is the number of unique paths (seen in the training set) and l is the number of semantic role labels. Of course, we can add other atomic information into these atomic vectors. For example, $\boldsymbol{\phi}(p)$ will not only indicate the word form of the current predicate p, but also the word lemma, POS tag and surrounding tokens as well. The cross-product of these four vectors is an extremely high-dimensional rank-1 tensor,

$$\boldsymbol{\phi}(p) \otimes \boldsymbol{\phi}(a) \otimes \boldsymbol{\phi}(path) \otimes \boldsymbol{\phi}(r) \in \mathbb{R}^{n \times n \times m \times l}$$

in which each entry indicates the combination of four atomic features appearing in the semantic arc (p, a, r)[3]. The rank-1 tensor (cross-product) captures all possible combinations over atomic units, and therefore it is a full feature expansion over the manually selected feature set in Table 1. Similar to the traditional scoring, the semantic arc score is the inner product between a 4-way parameter tensor A and this feature tensor:

$$\begin{aligned} &A \in \mathbb{R}^{n \times n \times m \times l}: \\ &vec(A) \cdot vec\left(\boldsymbol{\phi}(p) \otimes \boldsymbol{\phi}(a) \otimes \boldsymbol{\phi}(path) \otimes \boldsymbol{\phi}(r)\right), \end{aligned} \tag{2}$$

where $vec(\cdot)$ denotes the vector representation of a matrix / tensor.

Instead of reducing and pruning possible feature concatenations (e.g., by manual feature template construction as in the traditional approach), this tensor scoring method avoids parameter explosion and overfitting by assuming a low-rank factorization of the parameters A. Specifically, A is decomposed into the sum of k simple rank-1 components,

$$A = \sum_{i=1}^{k} P(i) \otimes Q(i) \otimes R(i) \otimes S(i). \tag{3}$$

Here k is a small constant, $P, Q \in \mathbb{R}^{k \times n}$, $R \in \mathbb{R}^{k \times m}$ and $S \in \mathbb{R}^{k \times l}$ are parameter matrices, and $P(i)$ (and similarly $Q(i)$, $R(i)$ and $S(i)$) represents the i-th row vector of matrix P.

The advantages of this low-rank assumption are as follows. First, computing the score no longer requires maintaining and constructing extremely large tensors. Instead, we can project atomic vectors via P, Q, R and S obtaining small dense vectors, and subsequently calculating the arc score by

$$\sum_{i=1}^{k} \left[P\boldsymbol{\phi}(p)\right]_i \left[Q\boldsymbol{\phi}(a)\right]_i \left[R\boldsymbol{\phi}(path)\right]_i \left[S\boldsymbol{\phi}(r)\right]_i.$$

Second, projecting atomic units such as words, POS tags and labels into dense, low-dimensional vectors can effectively alleviate the sparsity problem, and it enables the model to capture high-order feature interactions between atomic units, while avoiding the parameter explosion problem.

3.3 Combined System

Similar to our low-rank syntactic dependency parsing model (Lei et al., 2014), our final scoring function $S_{\text{sem}}(\mathbf{x}, \mathbf{y}_{\text{syn}}, \mathbf{z}_{\text{sem}})$ is the combination of the traditional scoring and the low-rank scoring,

$$\begin{aligned} &S_{\text{sem}}(\mathbf{x}, \mathbf{y}_{\text{syn}}, \mathbf{z}_{\text{sem}}) \quad = \\ &\gamma\ \mathbf{w} \cdot \boldsymbol{\phi}(\mathbf{x}, \mathbf{y}_{\text{syn}}, \mathbf{z}_{\text{sem}}) + (1-\gamma) \sum_{(p,a,r) \in \mathbf{z}_{\text{sem}}} \sum_{i=1}^{k} \\ &\left[P\boldsymbol{\phi}(p)\right]_i \left[Q\boldsymbol{\phi}(a)\right]_i \left[R\boldsymbol{\phi}(path)\right]_i \left[S\boldsymbol{\phi}(r)\right]_i. \end{aligned}$$

where $\gamma \in [0,1]$ is a hyper-parameter balancing the two scoring terms. We tune this value on the development set. Finally, the set of parameters of our model is denoted as $\boldsymbol{\theta} = \{\mathbf{w}, P, Q, R, S\}$. Our goal is to optimize the weight vector $\mathbf{w}$ as well as the four projection matrices given the training set.

[3] We always add a bias term into these atomic vectors (e.g., a fixed "1" attached to the beginning of every vector). Therefore, their cross-product will contain all unigram to 4-gram concatenations, not just 4-gram concatenations.

4 Learning

We now describe the learning method for our SRL model. Let $D = \{(\hat{\mathbf{x}}^{(i)}, \hat{\mathbf{y}_{\text{syn}}}^{(i)}, \hat{\mathbf{z}_{\text{sem}}}^{(i)})\}_{i=1}^{N}$ be the collection of N training samples. The values of the set of parameters $\boldsymbol{\theta} = \{\mathbf{w}, P, Q, R, S\}$ are estimated on the basis of this training set. Following standard practice, we optimize the parameter values in a maximum soft-margin framework. That is, for the given sentence $\hat{\mathbf{x}}$ and the corresponding syntactic tree $\hat{\mathbf{y}_{\text{syn}}}$, we adjust parameter values to separate gold semantic parse and other incorrect alternatives:

$$\begin{aligned}&\forall \mathbf{z}_{\text{sem}} \in \mathcal{Z}(\hat{\mathbf{x}}, \hat{\mathbf{y}_{\text{syn}}}) : \\ &\quad S_{sem}(\hat{\mathbf{x}}, \hat{\mathbf{y}_{\text{syn}}}, \hat{\mathbf{z}_{\text{sem}}}) \geq S_{sem}(\hat{\mathbf{x}}, \hat{\mathbf{y}_{\text{syn}}}, \mathbf{z}_{\text{sem}}) \\ &\quad + cost(\hat{\mathbf{z}_{\text{sem}}}, \mathbf{z}_{\text{sem}}) \end{aligned} \quad (4)$$

where $\mathcal{Z}(\hat{\mathbf{x}}, \hat{\mathbf{y}_{\text{syn}}})$ represent the set of all possible semantic parses, and $cost(\hat{\mathbf{z}_{\text{sem}}}, \mathbf{z}_{\text{sem}})$ is a non-negative function representing the structural difference between $\hat{\mathbf{z}_{\text{sem}}}$ and $\mathbf{z}_{\text{sem}}$. The cost is zero when $\mathbf{z}_{\text{sem}} = \hat{\mathbf{z}_{\text{sem}}}$, otherwise it becomes positive and therefore is the "margin" to separate the two parses. Following previous work (Johansson, 2009; Martins and Almeida, 2014), this cost function is defined as the sum of arc errors – we add 1.0 for each false-positive arc, 2.0 for each false-negative arc (a missing arc) and 0.5 if the predicate-argument pair (p, a) is in both parses but the semantic role label r is incorrect.

4.1 Online Update

The parameters are updated successively after each training sentence. Each update first checks whether the constraint (4) is violated. This requires "cost-augmented decoding" to find the maximum violation with respect to the gold semantic parse:

$$\begin{aligned}\tilde{\mathbf{z}_{\text{sem}}} = \arg\max_{\mathbf{z}_{\text{sem}}} \; & S_{\text{sem}}(\hat{\mathbf{x}}, \hat{\mathbf{y}_{\text{syn}}}, \mathbf{z}_{\text{sem}}) \\ & + cost(\hat{\mathbf{z}_{\text{sem}}}, \mathbf{z}_{\text{sem}})\end{aligned}$$

When the constraint (4) is violated (i.e. $\tilde{\mathbf{z}_{\text{sem}}} \neq \hat{\mathbf{z}_{\text{sem}}}$), we seek a parameter update $\Delta\boldsymbol{\theta}$ to fix this violation. In other words, we define the hinge loss for this example as follows,

$$\begin{aligned}loss(\boldsymbol{\theta}) \quad = \quad & \max\{\, 0, \; S_{\text{sem}}(\hat{\mathbf{x}}, \hat{\mathbf{y}_{\text{syn}}}, \tilde{\mathbf{z}_{\text{sem}}}) \\ & + cost(\hat{\mathbf{z}_{\text{sem}}}, \tilde{\mathbf{z}_{\text{sem}}}) - S_{\text{sem}}(\hat{\mathbf{x}}, \hat{\mathbf{y}_{\text{syn}}}, \hat{\mathbf{z}_{\text{sem}}}) \,\}\end{aligned}$$

and we revise the parameter values to minimize this loss function.

Since this loss function is neither linear nor convex with respect to the parameters $\boldsymbol{\theta}$ (more precisely the low-rank component matrices P, Q, R and S), we can use the same alternating passive-aggressive (PA) update strategy in our previous work (Lei et al., 2014) to update one parameter matrix at one time while fixing the other matrices. However, as we demonstrated later, modifying the passive-aggressive algorithm slightly can give us a **joint** update over all components in $\boldsymbol{\theta}$. Our preliminary experiment shows this modified version achieves better results compared to the alternating PA.

4.2 Joint PA Update for Tensor

The original passive-aggressive parameter update $\Delta\theta$ is derived for a linear, convex loss function by solving a quadatic optimization problem. Although our scoring function $S_{\text{sem}}(\cdot)$ is not linear, we can simply approximate it with its first-order Taylor expansion:

$$S(\mathbf{x}, \mathbf{y}, \mathbf{z}; \boldsymbol{\theta} + \Delta\boldsymbol{\theta}) \approx S(\mathbf{x}, \mathbf{y}, \mathbf{z}; \boldsymbol{\theta}) + \frac{dS}{d\boldsymbol{\theta}} \cdot \Delta\boldsymbol{\theta}$$

In fact, by plugging this into the hinge loss function and the quadratic optimization problem, we get a joint closed-form update which can be simply described as,

$$\Delta\boldsymbol{\theta} = \max\left\{C, \; \frac{loss(\boldsymbol{\theta})}{\|g\boldsymbol{\theta}\|^2}\right\} g\boldsymbol{\theta}$$

where

$$g\boldsymbol{\theta} = \frac{dS}{d\boldsymbol{\theta}}(\hat{\mathbf{x}}, \hat{\mathbf{y}_{\text{syn}}}, \hat{\mathbf{z}_{\text{sem}}}) - \frac{dS}{d\boldsymbol{\theta}}(\hat{\mathbf{x}}, \hat{\mathbf{y}_{\text{syn}}}, \tilde{\mathbf{z}_{\text{sem}}}),$$

and C is a regularization hyper-parameter controlling the maximum step size of each update. Note that $\boldsymbol{\theta}$ is the set of all parameters, the update jointly adjusts all low-rank matrices and the traditional weight vector. The PA update is "adaptive" in the sense that its step size is propotional to the $loss(\boldsymbol{\theta})$ of the current training sample. Therefore the step size is adaptively decreased as the model fits the training data.

4.3 Tensor Initialization

Since the scoring and loss function with high-order tensor components is highly non-convex, our model

performance can be impacted by the initialization of the matrices P, Q, R and S. In addition to intializing these low-rank components randomly, we also experiment with a strategy to provide a good guess of the low-rank tensor.

First, note that the traditional manually-selected feature set (i.e., $\phi(p, a, r)$ in our notation) is an expressive and informative subset of the huge feature expansion covered in the feature tensor. We can train our model using only the manual feature set and then use the corresponding feature weights $\mathbf{w}$ to intialize the tensor. Specifically, we create a sparse tensor $T \in \mathbb{R}^{n \times n \times m \times l}$ by putting each parameter weight in $\mathbf{w}$ into its corresponding entry in T. We then try to find a low-rank approximation of sparse tensor T by approximately minimizing the squared error:

$$\min_{P,Q,R,S} \|T - \sum_i P(i) \otimes Q(i) \otimes R(i) \otimes S(i)\|_2^2$$

In the low-rank dependency parsing work (Lei et al., 2014), this is achieved by unfolding the sparse tensor T into a $n \times nml$ matrix and taking the SVD to get the top low-rank components. Unfortunately this strategy does not apply in our case (and other high-order tensor cases) because even the number of columns in the unfolded matrix is huge, $nml > 10^{11}$, and simply taking the SVD would fail because of memory limits.

Instead, we adopt the generalized high-order power method, a.k.a. power iteration (De Lathauwer et al., 1995), to incrementally obtain the most important rank-1 component one-by-one – $P(i)$, $Q(i)$, $R(i)$ and $S(i)$ for each $i = 1..k$. This method is a very simple iterative algorithm and is used to find the largest eigenvalues and eigenvectors (or singular values and vectors in SVD case) of a matrix. Its generalization directly applies to our high-order tensor case.

5 Implementation Details

Decoding Following Lluís et al. (2013), the decoding of SRL is formulated as a bipartite maximum assignment problem, where we assign arguments to semantic roles for each predicate. We use the maximum weighted assignment algorithm (Kuhn, 1955). For syntactic dependency parsing, we employ the randomized hill-climbing algorithm from our previous work (Zhang et al., 2014).

Input: sparse tensor T, rank number i and fixed rank-1 components $P(j)$, $Q(j)$, $R(j)$ and $S(j)$ for $j = 1..(i-1)$
Output: new component $P(i)$, $Q(i)$, $R(i)$ and $S(i)$.

Randomly initialize four unit vectors p, q, r and s
$T' = T - \sum_j P(j) \otimes Q(j) \otimes R(j) \otimes S(j)$
repeat
  $p = \langle T', -, q, r, s \rangle$ and normalize it
  $q = \langle T', p, -, r, s \rangle$ and normalize it
  $r = \langle T', p, q, -, s \rangle$ and normalize it
  $s = \langle T', p, q, r, - \rangle$
  $norm = \|s\|_2^2$
until $norm$ converges
$P(i) = p$ and $Q(i) = q$
$R(i) = r$ and $S(i) = s$

Figure 2: The iterative power method for high-order tensor initialization. The operator $p = \langle T', -, q, r, s \rangle$ is the multiplication between the tensor and three vectors, defined as $p_i = \sum_{jkl} T_{ijkl} q_j r_k s_l$. Similarly, $q_j = \sum_{ikl} T_{ijkl} p_i r_k s_l$ etc.

Features Table 1 summarizes the first-order feature templates. These features are mainly drawn from previous work (Johansson, 2009). In addition, we extend each template with the argument label.

Table 2 summarizes the atomic features used in $\phi(p)$ and $\phi(a)$ for the tensor component. For each predicate or argument, the feature vector includes its word form and POS tag, as well as the POS tags of the context words. We also add unsupervised word embeddings learned on raw corpus.[4] For atomic vectors $\phi(path)$ and $\phi(r)$ representing the path and the semantic role label, we use the indicator feature and a bias term.

6 Experimental Setup

Dataset We evaluate our model on the English dataset and other 4 datasets in the CoNLL-2009 shared task (Surdeanu et al., 2008). We use the

[4] https://github.com/wolet/sprml13-word-embeddings

word	word-l	word-r
pos	pos-l	pos-r
pos-l + pos	pos + pos-r	pos + word
pos-l + pos + pos-r	voice	embeddings

Table 2: Predicate/argument atomic features used by our tensor for SRL. `word` stands for the word form (and also lemma), `pos` stands for the predicted POS tag and `voice` stands for the voice of the predicate. The suffixes `-l` and `-r` refer to the left and right of the current token respectively. For example, `pos-l` means the POS tag to the left of the current word in the sentence.

official split for training, development and testing. For English, the data is mainly drawn from the Wall Street Journal. In addition, a subset of the Brown corpus is used as the secondary out-of-domain test set, in order to evaluate how well the model generalizes to a different domain. Following the official practice, we use predicted POS tags, lemmas and morphological analysis provided in the dataset across all our experiments. The predicates in each sentence are also given during both training and testing. However, we neither predict nor use the sense for each predicate.

Systems for Comparisons We compare against three systems that achieve the top average performance in the joint syntactic and semantic parsing track of the CoNLL-2009 shared task (Che et al., 2009; Zhao et al., 2009a; Gesmundo et al., 2009). All approaches extensively explored rich features for the SRL task. We also compare with the state-of-the-art parser (Björkelund et al., 2010) for English, an improved version of systems participated in CoNLL-2009. This system combines the pipeline of dependency parser and semantic role labeler with a global reranker. Finally, we compare with the recent approach which employs distributional word representations for SRL (Roth and Woodsend, 2014). We directly obtain the outputs of all these systems from the CoNLL-2009 website[5] or the authors.

Model Variants Our full model utilizes 4-way tensor component and a standard feature set from (Johansson, 2009). We also compare against our model without the tensor component, as well as a variant with a 3-way tensor by combining the path and semantic role label parts into a single mode (dimension).

Evaluation Measures Following standard practice in the SRL evaluation, we measure the performance using labeled F-score. To this end, we apply the evaluation script provided on the official website.[6] The standard evaluation script considers the predicate sense prediction as a special kind of semantic label.[7] Since we are neither predicting nor using the predicate sense information, we exclude this information in most of the evaluation. In addition, we combine the predicate sense classification output of (Björkelund et al., 2010) with our semantic role labeling output, to provide results directly comparable to previous reported numbers.

Experimental Details Across all experiments, we fix the rank of the tensor to 50 and train our model for a maximum of 20 epochs. Following common practice, we average parameters over all iterations. For each experimental setting, we tune the hyper-parameter $\gamma \in \{0.3, 0.5, 0.7, 0.9\}$ and $C \in \{0.01, 0.1, 1\}$ on the development set and apply the best model on the test set. Each model is evaluated on the development set after every epoch to pick the the best number of training epoch. For the experiments with random initialization on the tensor component, the vectors are initialized as random unit vectors. We combine our SRL model with our syntactic dependency parser, RBGParser v1.1 (Lei et al., 2014), for joint syntactic and semantic parsing. The labeled attachment score (LAS) of RBGParser is 90.4 on English, when we train the "standard" model type using the unsupervised word vectors.

7 Results

We first report the performance of our methods and other state-of-the-art SRL systems on English datasets (See Table 3). We single out performance

(Roth and Woodsend, 2014) + reranking	–	82.10	**71.12**	86.34	**75.88**
(Björkelund et al., 2010) + reranking	80.50	**82.87**	70.91	**86.86**	75.71

Table 3: SRL labeled F-score of our model variants, and state-of-the-art systems on the CoNLL shared task. We consider a tensor-free variant of our model, and tensor-based variants that include first-order SRL features. For the latter, we consider implementations with 3-way and 4-way tensors. Winning systems (with and without a reranker) are marked in bold. Statistical significance with $p < 0.05$ is marked with $*$.

on English corpora because these datasets are most commonly used for system evalutation. As a single system without reranking, our model outperforms the five top performing systems (second block in Table 3) on both in-domain and out-of-domain datasets. The improvement from the F-score of 82.08% to our result 82.51% on the WSJ in-domain test set is significant with $p < 0.05$, which is computed using a randomized test tool[8] based on Yeh (2000). For comparison purposes, we also report F-score performance when predicate senses are included in evaluation. The relative performance between the systems is consistent independent of whether the predicate senses are included or excluded.

Table 4 shows the results of our system on other languages in the CoNLL-2009 shared task. Out of five languages, our model rivals the best performing system on three languages, achieving statistically significant gains on English and Chinese. Note that our model uses the same feature configuration for all the languages. In contrast, Zhao et al. (2009b) rely on language-specific configurations obtained via "huge feature engineering" (as noted by the authors).

Results in Table 3 and 4 also highlight the contribution of the tensor to the model performance, which is consistent across languages. Without the tensor component, our system trails the top two performing systems. However, adding the tensor component provides on average 2.1% absolute gain, resulting in competitive performance. The mode of the tensor also contributes to the performance – the 4-way tensor model performs better than the 3-way counterpart, demonstrating the importance of modeling the interactions between dependency paths and semantic role labels.

		WSJ-test	Brown-test
1st-order w/o tensor		80.84	69.38
+ 3-way tensor	Rnd. Init.	81.87	69.82

Language	Test set			
	Ours (4-way tensor)	Ours (no tensor)	CoNLL 1st	CoNLL 2nd
English	**82.51***	80.84	82.08	81.20
Catalan	74.67	71.86	**76.78***	74.02
Chinese	**69.16***	68.43	68.52	68.71
German	**76.94**	74.03	74.65	76.27
Spanish	75.58	72.85	**77.33***	74.01
Average	75.77	73.60	75.87	74.84

Table 4: Semantic labeled F-score excluding predicate senses on 5 languages in the CoNLL-2009 shared task. Statistical significance with $p < 0.05$ is marked with $*$. Adding the tensor leads to more than 2% absolute gain on average F-score. Our method with the same feature configuration (a standard set + 4-way tensor) rivals the best CoNLL-2009 system which explores much richer feature sets, language-specific feature engineering, and n-best parse combination (Zhao et al., 2009a).

Our method	**WSJ-test**	**Gain**
1st order w/o tensor	80.84	–
+ 4-way tensor	82.51	+1.67
+ 3-way tensor	82.19	+1.35

(Roth and Woodsend)	**WSJ-test**	**Gain**
original baseline	80.38	–
+ pred & arg	80.23	-0.15
+ deppath	80.63	+0.25
+ span	80.87	+0.49

Table 6: Comparision between our low-rank tensor method and (Roth and Woodsend, 2014) for leveraing word compositions.

3-way and 4-way tensors. However, random initialization still delivers reasonable performance, outperforming the tensor-free model by more than 1% in F-score.

Finally, we compare our tensor-based approach against a simpler model that captures interactions between predicate, argument and syntactic path using word embeddings (Roth and Woodsend, 2014). Table 6 demonstrates that modeling feature interactions using tensor yields higher gains than using word embeddings alone. For instance, the highest gain achieved by Roth and Woodsend (2014) when the embeddings of the arguments are averaged is 0.5%, compared to 1.6% obtained by our model.

8 Conclusions

In this paper we introduce a tensor-based approach to SRL that induces a compact feature representation for words and their relations. In this sense, our dimensionality reduction method provides a clear alternative to a traditional feature engineering approach used in SRL. Augmenting a simple, yet competitive SRL model with the tensor component yields significant performance gains. We demonstrate that our full model outperforms the best performing systems on the CoNLL-2009 shared task.

Lexical Event Ordering with an Edge-Factored Model

Omri Abend, Shay B. Cohen and Mark Steedman

Abstract

Extensive lexical knowledge is necessary for temporal analysis and planning tasks. We address in this paper a lexical setting that allows for the straightforward incorporation of rich features and structural constraints. We explore a *lexical event ordering* task, namely determining the likely temporal order of events based solely on the identity of their predicates and arguments. We propose an "edge-factored" model for the task that decomposes over the edges of the event graph. We learn it using the structured perceptron. As lexical tasks require large amounts of text, we do not attempt manual annotation and instead use the textual order of events in a domain where this order is aligned with their temporal order, namely cooking recipes.

1 Introduction

Temporal relations between events are often implicit, and inferring them relies on lexical and world knowledge about the likely order of events. For instance, to execute the instruction "fry the onion," the hearer should probably obtain oil beforehand, even if not instructed so explicitly. Lexical knowledge about the likely order of events is therefore necessary for any semantic task that requires temporal reasoning or planning, such as classifying temporal relations (Mani et al., 2006; Lapata and Lascarides, 2006; Yoshikawa et al., 2009; D'Souza and Ng, 2013; Mirza and Tonelli, 2014, *inter alia*), textual entailment (Dagan et al., 2013) or temporal information extraction (Ling and Weld, 2010). Lexical temporal knowledge is further important for modeling grammatical phenomena such as tense and aspect (Steedman, 2002).

In this paper we address the task of lexical event ordering, namely predicting the ordering of events based only on the identity of the words comprising their predicates and arguments. Concretely, the task is to predict the order of an unordered set of predicate-argument structures. Predicting the likely order of event types is a step towards more intricate planning and reasoning scenarios (see §3), and is useful in itself for tasks such as concept-to-text generation (Reiter et al., 2000), or in validating the correctness of instruction sets. A related idea can be found in modeling sentence coherence (Lapata, 2003; Barzilay and Lapata, 2008, *inter alia*), although here we focus on lexical relations between events, rather than coherence relations between complete sentences.

Compiling a resource of temporal tendencies between events can hardly be done manually, given the number and wealth of phenomena that have to be accounted for. Temporally annotated corpora, often annotated according to TimeML principles (Pustejovsky et al., 2003), are a useful resource for studying temporal relations. However, due to incurred costs, annotated corpora are too small for most lexical tasks. For instance, the TimeML annotated data used in the latest TempEval shared task contains only 100K words or so (UzZaman et al., 2013).

Previous work that does not rely on manually annotated data has had some success in discovering temporal lexical relations between predicates (Chklovski and Pantel, 2004; Chambers and Jurafsky, 2008b; Talukdar et al., 2012). However, despite their appeal, these methods have mostly fo-

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1161–1171,
Denver, Colorado, May 31 – June 5, 2015.

cused on inducing simple event types, consisting of single words (e.g., "buy-own") or fixed expressions, and are hard to extend to include rich features (e.g., order-based and pattern-based features). Furthermore, measuring recall without annotated data is notoriously difficult, and evaluation is often precision-based or extrinsic.

We take a graph-based structured prediction approach to the task, motivated by the flexibility it allows in incorporating various feature sets and constraints. We use an edge-factored model, which decomposes over the edges in the graph of events comprising the recipe (§4). We estimate the model using the structured perceptron algorithm. We compare the structured perceptron approach to an approximate greedy baseline and to a locally normalized model reminiscent of common approaches for order learning, obtaining superior results (§8). The learning algorithm is of potential use in other ordering tasks such as machine translation reordering (Tromble and Eisner, 2009).

We focus on domains in which the order of events in the text is aligned with their temporal order. By doing so we avoid the costly and error-prone manual annotation of temporal relations by using the textual order of recipes to approximate their temporal order.[1] Specifically, we address the cooking recipes domain, which we motivate in §2.

In summary, the contribution of this paper is three-fold: (1) we explore the task of lexical event ordering and means for its evaluation; (2) we present an edge-factored model for the task, and show it can be used to predict the order of events well (77.7% according to standard measures for ordering evaluation); (3) we present a method for extracting events and create a dataset of ordered events using recipes extracted from the web.

2 Related Work

Temporal semantics is receiving increasing attention in recent years. Lexical features are in frequent use and rely in most part on external resources which are either manually compiled or automatically induced. The line of work most closely related to ours focuses on inducing lexical relations between event types. Most work has been unsupervised, often using pattern-based approaches relying on manually crafted (Chklovski and Pantel, 2004) or induced patterns (Davidov et al., 2007), that correlate with temporal relations (e.g., temporal discourse connectives). Talukdar et al. (2012) uses the textual order of events in Wikipedia biographical articles to induce lexical information. We use both textual order and discourse connectives to define our feature set, and explore a setting which allows for the straightforward incorporation of additional features.

Chambers and Jurafsky (2008b; 2009) addressed the unsupervised induction of partially ordered event chains (or schema) in the news domain, centered around a common protagonist. One of their evaluation scenarios tackles a binary classification related to event ordering, and seeks to distinguish ordered sets of events from randomly permuted ones, yielding an accuracy of 75%. Manshadi et al. (2008) used language models to learn event sequences and conducted a similar evaluation on weblogs with about 65% accuracy. The classification task we explore here is considerably more complex (see §8).

The task of script knowledge induction has been frequently addressed in recent years. Balasubramanian et al. (2013) and Pichotta and Mooney (2014) extended Chambers and Jurafsky's model to include events that have multiple arguments. Jans et al. (2012) use skip-grams to capture event-event relations between not necessarily consecutive events.

Regneri et al. (2010) constructed a temporal lexical knowledge base through crowd-sourcing. Their approach is appealing as it greatly reduces the costs incurred by manual annotation and can potentially be used in conjunction with lexical information obtained from raw text. Modi and Titov (2014) jointly learns the stereotypical order of events and their distributional representation, in order to capture paraphrased instances of the same event type. Frermann et al. (2014) models the joint task of inducing event paraphrases and their order using a Bayesian framework. All latter three works evaluated their induced temporal ordering knowledge on a binary prediction of whether a temporal relation between a pair of (not necessarily related) events holds, and not on the prediction of a complete permutation given an unordered event set as in this work. Their evaluation was conducted on 30 event pairs manually an-

[1] See Cassidy et al. (2014) for a discussion of inter-annotator agreement in TimeML-based schemes.

notated through crowd-sourcing, where Modi and Titov (2014) further included an evaluation on a large set of pairs automatically extracted from the Gigaword corpus.

The appeal of the cooking domain for studying various semantic phenomena has been recognized by several studies in NLP and AI (Tasse and Smith, 2008; Bollini et al., 2013; Cimiano et al., 2013; Regneri et al., 2013; Malmaud et al., 2014). The domain is here motivated by several considerations. First, recipes mostly describe concrete actions, rather than abstract relations, which are less relevant to temporal ordering. Second, from a practical point of view, many recipes are available online in computer-readable format. Third, the restrictiveness of the cooking domain can also be seen as an advantage, as it can reveal major conceptual challenges raised by the task, without introducing additional confounds.

3 Temporally Ordering Lexical Events

We formalize our task as follows. Let U be a set of event types, namely actions or states (represented as predicates) and objects which these actions operate on (represented as arguments to the predicates; mostly ingredients or kitchenware). Formally, each $e \in U$ is a tuple $\langle a, c_1, \ldots, c_n \rangle$ where a is the main verb or predicate describing the event (such as "stir" or "mix") and $c_1, \ldots, c_n$ is a list of arguments that the predicate takes (e.g., "salt" or "spoon"). Two additional marked events, s and f, correspond to "start" and "finish" events. A recipe is a sequence of events in U, starting at s and ending at f.

Given a recipe $R = \langle e_1, ..., e_m \rangle$, we wish to predict the order of the events just from the (multi)set $\{e_i\}_{i=1}^{m}$. In this work we use the textual order of events to approximate their temporal order (see, e.g., Talukdar et al. (2012) for a similar assumption). The validity of this assumption for cooking recipes is supported in §6.

Figure 1 gives an example of a set of events extracted from our dataset for the dish "Apple Crisp Ala [sic] Brigitte." Lexical information places quite a few limitations on the order of this recipe. For instance, in most cases serving is carried out at the end while putting the ingredients in is done prior to baking them. However, lexical knowledge in itself is unlikely to predict the exact ordering of the events as given in the recipe (e.g., spreading butter might be done before or after baking).

One of the major obstacles in tackling planning problems in AI is the knowledge bottleneck. Lexical event ordering is therefore a step towards more ambitious goals in planning. For instance, temporal relations may be used to induce planning operators (Mourão et al., 2012), which can in turn be used to generate a plan (recipe) given a specified goal and an initial set of ingredients.

4 Model, Inference and Learning

In this section we describe the main learning components that compose our approach to event ordering.

4.1 Edge-Factored Model for Event Ordering

We hereby detail the linear model we use for ordering events. Let $S = \{e_1, \ldots, e_m\} \subseteq U$ be a set of events as mentioned in §3. Let $G(S) = (S \cup \{s, f\}, E(S))$ be an almost-complete directed graph with $E(S) = (S \cup \{s\}) \times (S \cup \{f\}) \subseteq U \times U$. Every Hamiltonian path[2] in $G(S)$ that starts in s and ends in f defines an ordering of the events in S. The edge (e_i, e_j) in such a path denotes that e_i is the event that comes before e_j.

The modeling problem is to score Hamiltonian paths in a given directed graph $G(S)$. Here, we use an edge-factored model. Let $\phi\colon (U \times U) \rightarrow \mathbb{R}^d$ be a feature function for pairs of events, represented as directed edges. In addition, let $\theta \in \mathbb{R}^d$ be a weight vector. We define the score of a Hamiltonian path $h = (h_1, \ldots, h_{m+1})$ ($h_i \in E(S)$) as:

$$\text{score}(h|S) = \sum_{i=1}^{m+1} \theta^\top \phi(h_i) \qquad (1)$$

Given a weight vector θ and a set of events S, inference is carried out by computing the highest scoring Hamiltonian path in $G(S)$:

$$h^* = \arg \max_{h \in H(S)} \text{score}(h|S) \qquad (2)$$

where $H(S)$ is the set of Hamiltonian paths in $G(S)$ that start with s and end with f. The path h^* is the best temporal ordering of the set of events S according to the model in Eq. 1 with weight vector θ.

[2] A path in a graph that visits all nodes exactly once.

(a)
$e_1 = \langle butter, dish \rangle$
$e_2 = \langle put, apples, water, ... \; flour, cinnamon, it \rangle$
$e_3 = \langle mix, with\ spoon, \rangle$
$e_4 = \langle spread, butter, salt, ... \; over\ mix \rangle$
$e_5 = \langle bake, F \rangle$
$e_6 = \langle serve, cream, cream \rangle$

(b) Butter a deep baking dish, put apples, water, flour, sugar and cinnamon in it. Mix with spoon and spread butter and salt over the apple mix. Bake at 350 degrees F until the apples are tender and the crust brown, about 30 minutes. Serve with cream or whipped cream.

(c)

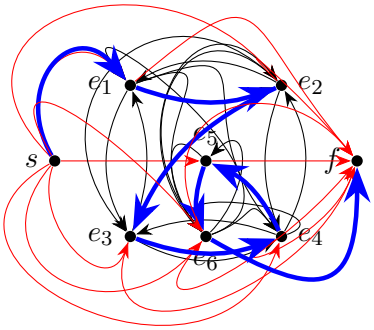

Figure 1: (a) The sequence of events representing the recipe for the dish "Apple Crisp Ala [sic] Brigitte." (b) The actual recipe for this dish. (c) A complete graph over the set of events with start and finish states. Each internal node in the graph is one of the events e_i for $i \in \{1, \ldots, 6\}$. The path in blue bold denotes the correct Hamiltonian path describing the set of actions as ordered in the recipe. Red edges denote edges from the start state and to the end state. The edges, in practice, are weighted.

4.2 Inference

As mentioned above, inference with the edge-factored model requires solving the maximization problem in Eq. 2. This corresponds to finding a Hamiltonian path in a complete graph, which is generally an NP-hard problem. Reasonable approximations for this problem are also NP-hard. Still techniques are developed for specialized cases, due to the problem's importance in discrete optimization.

Despite its theoretical NP-hardness, this maximization problem can be represented as an Integer Linear Program (ILP), and then solved using generic techniques for ILP optimization. Due to the relatively short length of recipes (13.8 events on average in our corpus), the problem can be effectively solved in most cases.

The proposed algorithmic setting is appealing for its flexibility. The linear score formulation allows us to use rich features, while using ILP allows to easily incorporate structural constraints. Indeed, ILP has been proven valuable in various NLP tasks (Roth and Yih, 2007; Talukdar et al., 2012; Scaria et al., 2013). See Appendix A for our ILP formulation.

As a baseline, we experiment with an additional greedy inference algorithm, similar to the one described by Lapata (2003) for sentence ordering. The algorithm iteratively selects an outgoing edge (starting from the node s) that has the largest weight to a node that has not been visited so far, until all vertices are covered, at which point the path terminates by traveling to f.

4.3 Learning

The learning problem takes as input a dataset consisting of unordered sets of events, paired with a target ordering. We consider two types of learning algorithms for the edge-factored model in the previous section. The first learns in a global training setting using the averaged structured perceptron (Collins, 2002), with the decoding algorithm being either the one based on ILP (henceforth, GLOBAL-PRC), or the greedy one (GREEDY-PRC). Given a training instance S and its correct label h^c, the structured perceptron calls the inference procedure as a subroutine and updates the weight vector θ according to the difference between the value of the feature function on the predicted path ($\sum_{h^*} \phi(h_i)$) and on the correct path ($\sum_{h^c} \phi(h_i)$).

The second learning algorithm we try is based on *factored* training. This algorithm maximizes the likelihood of a conditional log-linear model p:

$$p(e_2|e_1, \theta, S) = \frac{\exp\left(\theta^\top \phi(e_1, e_2)\right)}{Z(\theta, S, e_1)}$$

$$Z(\theta, S, e_1) = \sum_{e:\ (e_1,e) \in E(S)} \exp\left(\theta^\top \phi(e_1, e)\right)$$

where $e_1, e_2 \in S \cup \{s, f\}$. This is a locally normalized log-linear model that gives the probability of transitioning to node e_2 from node e_1. Maximizing the score in Eq. 1 has an interpretation of finding the highest scoring path according to an edge-factored Markovian model, such that:

$$p(h|\theta, S) = \prod_{i=1}^{m+1} p(e_i|e_{i-1}, \theta, S),$$

where $h = (h_1, \ldots, h_{m+1})$ is a Hamiltonian path with $h_i = (e_{i-1}, e_i)$ being a directed edge in the path. Initial experimentation suggested that greedy inference (henceforth, GREEDY-LOGLIN) works better in practice than the ILP formulation for the locally-normalized model. We therefore do not report results on global inference with this log-linear model. We suspect that greedy inference works better with the log-linear model because it is trained locally, while the perceptron algorithm includes a global inference step in its training, and therefore better matches global decoding.

GREEDY-LOGLIN closely resembles the learning model of Lapata (2003), as both are first-order Markovian and use the same (greedy) inference procedure. Lapata's model differs from GREEDY-LOGLIN in being a generative model, where each event is a tuple of features, and the transition probability between events is defined as the product of transition probabilities between feature pairs. GREEDY-LOGLIN is discriminative, so to be maximally comparable to the presented model.

5 The Feature Set

Table 1 presents the complete set of features. We consider three sets of features: Lexical encodes the written forms of the event pair predicates and objects; Brown uses Brown clusters (Brown et al., 1992) to encode similar information, but allows generalization between distributionally similar words; and Frequency encodes the empirical distribution of temporally-related phenomena.

The feature definitions make use of several functions. For brevity, we sometimes say that an event e is (a, c_1) if e's predicate is a and its first argument is c_1, disregarding its other arguments. Let C be a reference corpus of recipes for collecting statistics. The function $B(w)$ gives the Brown cluster of a word w, as determined by clustering C into 50 clusters $\{1, \ldots, 50\}$. The function $\mathrm{ORD}(a, c)$ returns the mean ordinal number of an (a, c) event in C. The ordinal number of the event e_i in a recipe $(e_1, ..., e_m)$ is defined as $i - \frac{m}{2}$.

	Template	Example
Lexical	(a^1, a^2)	(*fry*, *add*)
	(a^1, c_1^2)	(*fry*, *oil*)
	(a^2, c_1^1)	(*onions*, *add*)
	(c_1^1, c_1^2)	(*onions*, *oil*)
Brown	$(B(a^1), B(a^2))$	(1,3)
	$\forall (k, k') \in K.$ $\lvert\{(c_i^1, c_j^2) \colon B(c_i^1) = k, B(c_j^2) = k'\}\rvert$	(5,4) : 2
	$\forall k \in K.\ \lvert\{c_i^2 \colon B(c_i^2) = k\}\rvert$	12 : 1
	$B(a^2)$	5
Frequency	$\forall \ell \in L.\ \log(\epsilon + P_\ell[(a^2, c_1^2) \lvert (a^1, c_1^1)])$	-2.3
	$\forall \ell \in L.\ \mathrm{PMI}_\ell((a^1, c_1^1), (a^2, c_1^2))$	3.1
	$\forall \ell \in L.\ \mathrm{PMI}_\ell((a^2, c_1^2), (a^1, c_1^1))$	-2.0
	$\mathrm{ORD}(a^2, c_1^2)$	3.2

Table 1: Feature templates used for computing ϕ. The templates operate on two events $\langle a^1, c_1^1, \ldots, c_{m_1}^1 \rangle$ and $\langle a^2, c_1^2, \ldots, c_{m_2}^2 \rangle$. $B(w)$ maps a word w to its Brown cluster in $K = \{1, \ldots, 50\}$. $\mathrm{ORD}(e)$ returns the mean ordinal value of e. Feature templates which start with $\forall$ stand for multiple features, one for each element in the set quantified over. Non-numerical feature templates correspond to binary features. E.g., (*fry*, *add*) as an instance of (a^1, a^2) is a binary feature indicating the appearance of an event with $a^1 =$ *fry* on one end of the edge and an event with $a^2 =$ *add* on the other end of it. $\epsilon = 10^{-3}$ in our experiments. See text for elaboration.

We further encode the tendency of two events to appear with temporal discourse connectives, such as "before" or "until." We define a linkage between two events as a triplet $(e_1, e_2, \ell) \in (U \times U \times L)$, where L is the set of linkage types, defined according to their marker's written form. §6 details the extraction process of linkages from recipes. We further include a special linkage type *linear* based on the order of events in the text, and consider every pair of events e_1 and e_2 that follow one another in a recipe as linked under this linkage type.

For each linkage type $\ell \in L$, we define an empirical probability distribution $P_\ell((a, c_1), (a', c_1')) = P((a, c_1), (a', c_1')|\ell)$, based on simple counting. The function PMI gives the point-wise mutual information of two events and is defined as:

$$\mathrm{PMI}_\ell((a, c), (a', c')) = \log\left(\frac{P_\ell((a, c_1), (a', c_1'))}{P_\ell(a, c_1) \cdot P_\ell(a', c_1')}\right)$$

Frequency-based features encode the empirical estimate of the probabilities that various pairs of features would occur one after the other or linked with a discourse marker. They are equivalent to using probabilities extracted from maximum likelihood estima-

tion according to a bigram model in the discriminative learning. While some of this information is implicitly found in the lexical features, collecting frequency counts from a large training set is much quicker than running costly structured optimization. Rather the discriminative training can weigh the different empirical probabilities according to their discriminative power. Indeed we find that these features are important in practice and can result in high accuracy even after training on a small training set.

6 The Recipe Dataset

Data and Preprocessing. The data is extracted from a recipe repository found on the web.[3] The recipes are given as free text. To extract event types we run the Stanford CoreNLP[4] pipeline of a tokenizer, POS tagger, a lexical constituency parser (the *englishPCFG* parsing model) and extract typed Stanford dependencies (de Marneffe and Manning, 2008). As is common with web extractions, the recipes contain occasional spelling, grammatical and formatting errors. The corpus consists of 139 files, 73484 recipes, 1.02M events (13.8 events per recipe on average) and 11.05M words.[5]

Event Extraction. We focus on verbal events and do not extract nominal and adjectival argument structures, which are not as well supported by current parsing technology. Any verb is taken to define an event, aside from modal verbs, auxiliaries and secondary verbs. A secondary verb (e.g., "let," "begin") does not describe an action in its own right, but rather modifies an event introduced by another verb. We identify these verbs heuristically using a list given in Dixon (2005, p. 490–491) and a few simple rules defined over parse trees. E.g., from the sentence "you should begin to chop the onion," we extract a single event with a predicate "chop." Arguments are taken to be the immediate dependents of the predicate that have an argument dependency type (such as direct or indirect objects) according to the extracted Stanford dependencies. For prepositional phrases, we include the preposition as part of the argument. Argument indices are determined by their order in the text. The order of events is taken to be the order of their verbs in the text.

Linkage Extraction. We focus on a subset of linkage relations, which are relevant for temporal relations. We use Pitler and Nenkova's (2009) explicit discourse connectives classifier to identify temporal discourse linkers, discarding all other discourse linkers. Once a discourse linker has been detected, we heuristically extract its arguments (namely the pair of verbs it links) according to a deterministic extraction rule defined over the parse tree. We find 28 distinct connectives in our training set, where the 5 most common linkers "until," "then," "before," "when" and "as" cover over 95% of the instances. We extract 36756 such linkages from the corpus, 0.5 linkages per recipe on average.

Temporal and Textual Ordering. In order to confirm that temporal and textual order of recipes are generally in agreement, we manually examine the first 20 recipes in our development set. One recipe was excluded as noise[6], resulting in 19 recipes and 353 events. We identify the sources of misalignment between the linear order and the temporal order of the events.[7] 13 events (3.7%) did not have any clear temporal orderings. These consisted of mostly negations and modalities (e.g., "do not overbrown!"), sub-section headings (e.g., "Preparation") or other general statements that do not constitute actions or states. For the remaining 340 events, we compare their linear and the temporal orderings.

We estimate the frequency of sub-sequences that contradict the temporal order and confirm that they occur only infrequently. We find that most disagreements fall into these two categories: (1) disjunctions between several events, only one of which will actually take place (e.g., "roll Springerle pin over dough, or press mold into top"); (2) a pair, or less commonly a triplet, of events are expressed in reverse order. For instance, "*place* on *greased* and *floured* cookie sheet," where greasing and flouring should occur before the placing action. We note that assuming the alignment of the temporal and textual order

[3] http://www.ffts.com/recipes.htm

[4] http://nlp.stanford.edu/software/corenlp.shtml

[5] Links to the original recipes, the preprocessed recipes and all extracted events can be found in http://homepages.inf.ed.ac.uk/oabend/event_order.html.

[6] This did not result from an extraction problem, but rather from the recipe text itself being too noisy to interpret.

[7] Events are parsed manually so to avoid confounding the results with the parser's performance.

of recipes does not suggest that the textual order is the only order of events that would yield the same outcome.

We compute the Kendall's Tau correlation, a standard measure for information ordering (Lapata, 2006), between the temporal and linear orderings for each recipe. In cases of several events that happen simultaneously (including disjunctions), we take their ordinals to be equal. For instance, for three events where the last two happen at the same time, we take their ordering to be (1,2,2) in our analysis. We find that indeed temporal and textual orderings are in very high agreement, with 6 recipes of the 19 perfectly aligned. The average Kendall's Tau between the temporal ordering and the linear one is 0.924.

7 Experimental Setup

Evaluation. We compute the accuracy of our algorithms by comparing the predicted order to the one in which the events are written. We first compute the number of exact matches, denoted with EXACT, namely the percentage of recipes in which the predicted and the textual orders are the same.

For a more detailed analysis of imperfect predictions, we compute the agreement between subsequences of the orderings. We borrow the notion of a "concordant pair" from the definition of Kendall's Tau and generalize it to capture agreement of longer sub-sequences. Two k-tuples of integers $(x_1, ..., x_k)$ and $(y_1, ..., y_k)$ are said to "agree in order" if for every $1 \leq i < j \leq k$, $x_i < x_j$ iff $y_i < y_j$. Given two orderings of the same recipe $O_1 = (e_{\tau(1)}, ..., e_{\tau(m)})$ and $O_2 = (e_{\sigma(1)}, ..., e_{\sigma(m)})$ (where τ and σ are permutations over $[m] = \{1, \ldots, m\}$) and given a sequence of k monotonically increasing indices $t = (i_1, ..., i_k)$, t is said to be a "concordant k-tuple" of O_1 and O_2 if $(\tau(i_1), ..., \tau(i_k))$ and $(\sigma(i_1), ..., \sigma(i_k))$ agree in order, as defined above.

Denote the unordered recipes of the test data as $\{R_i\}_{i=1}^N$, where $R_i = \{e_1^i, ..., e_{m_i}^i\} \subset U$ for all i, and their target orderings $\Sigma = \{\sigma_i\}_{i=1}^N$, where σ_i is a permutation over $[m_i]$. Assume we wish to evaluate a set of predicted orderings for this test data $\mathrm{T} = \{\tau_i\}_{i=1}^N$, where again τ_i is a permutation over $[m_i]$. Denote the number of concordant k-tuples of σ_i and τ_i as $\mathrm{conc}(\sigma_i, \tau_i)$. The total number of of monotonically increasing k-tuples of indices is $\binom{m_i}{k}$. The k-wise (micro-averaged) accuracy of T with respect to Σ is:

$$\mathrm{acc}_k(\Sigma, \mathrm{T}) = \frac{\sum_{i=1}^N \mathrm{conc}(\sigma_i, \tau_i)}{\sum_{i=1}^N \binom{m_i}{k}}$$

Any k-tuples containing the start node s or the end node f are excluded, as their ordering is trivial. Recipes of length less than k are discarded when computing acc_k. A micro-averaged accuracy measure is used so as not to disproportionately weigh short recipes. However, in order to allow comparison to mean Kendall's Tau, commonly used in works on order learning, we further report a macro-averaged acc_2 by computing acc_2 for each recipe separately, and taking the average of resulting accuracy levels. Average Kendall's Tau can now be computed by $2\mathrm{acc}_2 - 1$ for the macro-averaged acc_2 score.

Data. We randomly partition the text into training, test and development sets, taking an 80-10-10 percent split. We do not partition the individual files so as to avoid statistical artifacts introduced by recipe duplications or near-duplications. The training, development and test sets contain 58038, 7667 and 7779 recipes respectively. The total number of feature template instantiations in the training data is 8.94M.

Baselines and Algorithms. We compare three learning algorithms. GLOBAL-PRC is the structured perceptron algorithm that uses ILP inference. GREEDY-PRC is a structured perceptron in which inference is done greedily. GREEDY-LOGLIN is the locally normalized log-linear model with greedy inference. RANDOM randomly (uniformly) selects a permutation of the recipe's events.

Experimental Settings. The structured perceptron algorithms, GLOBAL-PRC and GREEDY-PRC, are run with a learning rate of 0.1 for 3 iterations. To avoid exceedingly long runs, we set a time limit in seconds β on the running time of each ILP inference stage used in GLOBAL-PRC. We consider two training scenarios: *4K*, which trains on the first 4K recipes of the training set, and *58K*, which trains on the full training data of 58K recipes. In GLOBAL-PRC we set β to be 30 seconds for the 4K

	Alg.	acc_2		acc_3	acc_4	EXACT
		MI	MA			
4K	GLOBAL-PRC	**71.2**	**77.7**	**44.7**	**27.9**	**35.1**
4K	GREEDY-PRC	60.8	68.0	30.6	15.0	20.4
4K	GREEDY-LOGLIN	65.6	71.5	35.8	18.7	21.0
58K	GLOBAL-PRC	68.9	76.4	41.3	24.8	34.4
58K	GREEDY-PRC	60.7	67.8	30.6	15.2	20.5
58K	GREEDY-LOGLIN	66.3	72.4	36.6	19.4	21.3
	RANDOM	50.0	51.2	16.7	4.2	0.5

Table 2: Accuracy of the different models on the test data in percents. Columns correspond to evaluation measures, namely accuracy of sub-sequences of lengths 2 (micro and macro averages), 3 and 4, and exact match. The upper (lower) part presents results for a training set of 4K (58K) samples. GLOBAL-PRC is run with $\beta = 30$ for 4K and with $\beta = 5$ for 58K. In 58K, all models are run with the Full feature set. In 4K, following prior experimentation on the development set, we select the best performing feature sets (Full for GREEDY-LOGLIN and GREEDY-PRC; Fr + Lex for GLOBAL-PRC).

β	Set	acc_2		acc_3	acc_4	EXACT
		MI	MA			
30	FrLim	55.9	61.5	21.6	6.9	8.2
30	Fr	68.7	75.9	40.6	**23.9**	31.7
30	Fr + Le	**68.9**	**76.2**	**40.7**	23.8	**32.1**
30	Full	68.4	76.0	39.9	23.1	31.8
5	FrLim	55.1	60.9	20.9	6.5	8.2
5	Fr	65.9	74.2	36.0	19.3	30.4
5	Fr + Le	66.2	74.3	36.8	20.4	30.7
5	Full	66.3	74.5	36.9	20.4	30.4

Table 3: The performance of GLOBAL-PRC on the development set in various settings (4K scenario). Columns correspond to evaluation measures, namely accuracy of sub-sequences of lengths 2 (micro and macro averages), 3 and 4, and exact match. The upper (lower) part of the table presents results for a time limit of β=30 (5). Fr includes the Frequency features estimated on 58K recipes. Fr + Le further includes Lexical features. Full includes all features. FrLim includes all features, where Frequency features are estimated only on 4K recipes.

scenario, and 5 seconds in the 58K scenario. The number of threads was limited to 3. Where the time limit is reached before an optimal solution is found, the highest scoring Hamiltonian path found up to that point is returned by the ILP solver. In the infrequent samples where no feasible solution is found during training, the sample is skipped over, while at test time, we perform greedy inference instead.

We define the following feature sets. Fr includes only features of class Frequency, while Fr + Lex includes features from both the Frequency and Lexical categories. Full includes all feature sets. All above feature sets take C, the reference corpus for computing FREQUENCY features, to be the entire 58K training samples in both scenarios. In the 4K scenario, we also experiment with FrLim, which includes all features, but takes C to contain only the 4K samples of the training data.

We use the Gurobi package for ILP.[8] Brown clusters are extracted from the 58K samples of the training data using Liang's implementation.[9] The convex log-likelihood function of GREEDY-LOGLIN is optimized using LBFGS. All features are selected and all parameters are tuned using the development set.

8 Results

Table 2 presents the results of the three major algorithms in the two main scenarios *58K* and *4K*. We find that the structured perceptron algorithm, GLOBAL-PRC, obtains the best results in both cases and under all evaluation measures. The importance of global optimization was also stressed in other works on event ordering (Chambers and Jurafsky, 2008a; Talukdar et al., 2012).

In order to assess the contribution of the different components of the model of the best scoring model, GLOBAL-PRC, we compare the performance of the different feature sets and settings of β on the development set in 4K (Table 3). Results reveal the strong impact of the Frequency feature set on the results. Using this category set alone (Fr) yields slightly lower results than using the full feature set, while estimating the Frequency features on a small corpus (FrLim) lowers results dramatically. Adding Lexical and Brown features yields a small improvement over using Frequency alone.

While Table 3 demonstrates the importance of β in the performance of GLOBAL-PRC, it also shows that on a limited time budget, a small training set and few features (4K, Fr) and a reasonably small β (5) can yield competitive results. Increasing β from 5 to 30 generally improves results by 2 to 3 percent absolute. The importance of β is further demonstrated in Table 2, where performance with 4K training instances and $\beta = 30$ is better than with 58K training instances and $\beta = 5$. Preliminary experiments conducted on the development data with higher values of β of 60 and 120 suggest that further increasing β

[8] http://www.gurobi.com

[9] https://github.com/percyliang/brown-cluster

yields no further improvement.

Previous studies evaluated their models on the related problem of distinguishing randomly permuted and correctly ordered chains of events (§2). In this paper we generalize this task to complete event ordering. In order to demonstrate the relative difficulty of the tasks, we apply our highest scoring model (4K, Fr + Le) to the binary task (without re-training it). We do so by computing the percentage of cases in which the correct ordering obtains a higher score than an average ordering. The high resulting accuracy of 93%, as opposed to considerably lower accuracies obtained under ordering evaluation measures, reflects the relative difficulty of the tasks.

The proposed edge-factored model can easily capture pair-wise ordering relations between events, but is more limited in accounting for relations between larger sets of events. A simple way of doing so is by adding the feature $\sum_e P(e_i|e)P(e|e_j)$ between events e_i and e_j (in addition to the regular transition probabilities $P(e_i|e_j)$). However, preliminary experimentation with this technique did not yield improved performance. Future work will address higher-order models that straightforwardly account for such long-distance dependencies.

To qualitatively assess what generalizations are learned by the model, we apply GLOBAL-PRC to the development data and look at what event pairs obtained either particularly high or particularly low results. For each pair of predicates and their first arguments (a^1,c_1^1), (a^2,c_1^2), we compute the average weight of an edge connecting events of these types, discarding pairs of frequency less than 20.

The 20 highest scoring edges contain pairs such as ("add," "mixing after addition"), ("beat whites," "fold into mixture") and ("cover for minutes," "cook"), in addition to a few noisy pairs resulting from parser errors. The 20 lowest scoring edges contain event pairs that are likely to appear in the opposite order. 11 of the cases include as a first argument the predicates "serve," "cool" or "chill," which are likely to occur at the end of a recipe. 3 other edges linked duplications (e.g., ("reduce heat," "reduce heat")), which are indeed unlikely to immediately follow one another. These findings suggest the importance of detecting both lexical pairs that are unlikely to follow one another, in addition to those that are likely to.

9 Conclusion

We addressed the problem of lexical event ordering, and developed an edge-factored model for tackling it. We rely on temporally aligned texts, using a new dataset of cooking recipes as a test case, thereby avoiding the need for costly and error-prone manual annotation. We present results of a pair-wise accuracy of over 70% using a basic set of features, and show the utility of the structured perceptron algorithm over simpler greedy and local approaches. The setup we explore, which uses a discriminative model and an ILP formulation, is easy to extend both in terms of features and in terms of more complex formal constraints and edge dependencies, as was done in graph-based dependency parsing (McDonald et al., 2005). Future work will address the extension of the feature set and model, and the application of this model to temporal semantics and planning tasks. We will further address the application of semi-supervised variants of the proposed techniques (e.g., self-training) to other domains, where no sizable corpora of temporally aligned data can be found.

Appendix A: Maximal Hamiltonian Path

Let $G(S) = (S \cup \{s, f\}, E(S))$ be an almost-complete directed graph with $E = E(S) = (S \cup \{s\}) \times (S \cup \{f\})$. Let $c_{ij} \in \mathbb{R}$ be weights for its edges ($(i,j) \in E$). A Hamiltonian path between $s, f \in V$ can be found by solving the following program, returning $P = \{(i,j)|x_{ij} = 1\}$.

$$\max_{\substack{x_{ij}\in\{0,1\}:\ (i,j)\in E \\ u_i\in\mathbb{Z}:\ i\in V}} \sum_{i\neq j}^{n} c_{ij}x_{ij}$$

$$\text{s.t.} \sum_{i=0,i\neq j}^{n} x_{ij} = 1\ \forall j \neq s; \quad \sum_{j=0,j\neq i}^{n} x_{ij} = 1\ \ \forall i \neq e;$$

$$u_i - u_j + |V|x_{ij} \leq |V| - 1\ \ \forall (i,j) \in E$$

Abstract

Current approaches to cross-lingual information retrieval (CLIR) rely on standard retrieval models into which query translations by statistical machine translation (SMT) are integrated at varying degree. In this paper, we present an attempt to turn this situation on its head: Instead of the retrieval aspect, we emphasize the translation component in CLIR. We perform search by using an SMT decoder in forced decoding mode to produce a bag-of-words representation of the target documents to be ranked. The SMT model is extended by retrieval-specific features that are optimized jointly with standard translation features for a ranking objective. We find significant gains over the state-of-the-art in a large-scale evaluation on cross-lingual search in the domains patents and Wikipedia.

1 Introduction

Approaches to CLIR have been plentiful and diverse. While simple word translation probabilities are easily integrated into term-based retrieval models (Berger and Lafferty, 1999; Xu et al., 2001), state-of-the-art SMT systems (Koehn, 2010; Chiang, 2007) are complex statistical models on their own. The use of established translation models for context-aware translation of query strings, effectively reducing the problem of CLIR to a pipeline of translation and monolingual retrieval, has been shown to work well in the past (Chin et al., 2008). Only recently, approaches have been presented to include (weighted) translation alternatives into the query structure to allow a more generalized term matching (Ture et al., 2012a; Ture et al., 2012b). However, this integration of SMT remains agnostic about its use for CLIR and is instead optimized to match fluent, human reference translations. In contrast, retrieval systems often use bag-of-word representations, stopword filtering, and stemming techniques during document scoring, and queries are rarely fluent, grammatical natural language queries (Downey et al., 2008). Thus, most of a translation's structural information is lost during retrieval, and lexical choices may not be optimal for the retrieval task. Furthermore, the nature of modeling translation and retrieval separately requires that a single query translation is selected, which is usually done by choosing the most probable SMT output.

Attempts to inform the SMT system about its use for retrieval by optimizing its parameters towards a retrieval objective have been presented in the form or re-ranking (Nikoulina et al., 2012) or ranking (Sokolov et al., 2014). In this paper, we take this idea a step further and directly integrate the task of scoring documents with respect to the query into the process of *translation decoding*. We make the full expressiveness of the translation search space available to the retrieval model, without enumerating all possible translation alternatives. This is done by augmenting the linear model of the SMT system with features that relate partial translation hypotheses to documents in the retrieval collection. These retrieval-specific features decompose over partial translation hypotheses and thus allow efficient decoding using standard dynamic programming techniques. Furthermore, we apply learning-to-rank to jointly optimize translation and retrieval for the ob-

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1172–1182,
Denver, Colorado, May 31 – June 5, 2015.

jective of retrieving relevant documents, and use decoding over the weighted translation hypergraph directly to perform cross-lingual search. Since high weights on retrieval features for words in the bag-of-words (BOW) representation of documents *force* the decoder to prefer relevant documents with high probability, by a slight abuse of terminology, we call our approach *BOW Forced Decoding*.

One of the key features of our approach is the use of context-sensitive information such as the language model and reordering information. We show that the use of such a translation-benign search space is crucial to outperform state-of-the-art CLIR approaches. Our experimental evaluation of retrieval performance is done on Wikipedia cross-lingual article retrieval (Bai et al., 2010; Schamoni et al., 2014) and patent prior art search (Fujii et al., 2009; Guo and Gomes, 2009; Sokolov et al., 2013; Schamoni et al., 2014). On both datasets, we show substantial improvements over the CLIR baselines of direct translation (Chin et al., 2008) or Probabilistic Structured Queries (Ture et al., 2012b), with and without further parameter tuning using learning-to-rank techniques and extended feature sets. From our results we conclude, that, in spite of algorithmic complexity, it is central to model translation and retrieval jointly to create more powerful CLIR models.

2 Related Work

The framework of translation-model based retrieval has been introduced by Berger and Lafferty (1999). An extension to the cross-lingual case using context-free lexical translation tables has been given by Xu et al. (2001). While the industry standard to CLIR is a pipeline of SMT-based query translation feeding into monolingual retrieval (Chin et al., 2008), recent approaches include (weighted) SMT translation alternatives into the query structure to allow a more generalized term matching (Ture et al., 2012a; Ture et al., 2012b). Less work has been devoted to optimizing SMT towards a retrieval objective, for example in a re-ranking framework (Nikoulina et al., 2012) or by integrating a decomposable proxy for retrieval quality of query translations into discriminative ranking (Sokolov et al., 2014).

The idea of forced decoding has been employed recently to select better perceptron updates from the full SMT search space for discriminative parameter tuning of SMT systems (Yu et al., 2013; Zhao et al., 2014).

Most similar to our approach is the recent work of Dong et al. (2014) who use the `Moses` translation option lattices for translation retrieval, i.e., for mining comparable data. Their query lattices given by the translation options encode exponentially many queries and are used to retrieve the most probable translation candidate from a set of candidates. The approach is evaluated in the context of a parallel corpus mining system. We present a model that not only uses the full search space, including the language model and reordering information, but also evaluate the model specifically for the task of retrieval, rather than mate-finding only. We show that a forced decoding model using bag-of-word representations for documents and retrieval features that are decomposable over query terms significantly outperforms state-of-the-art CLIR baselines such as direct translation (Chin et al., 2008) or Probabilistic Structured Queries obtained from n-best list query translations (Darwish and Oard, 2003; Ture et al., 2012b). Additionally we find that the use of context-sensitive translation information such as language models or reordering information, greatly improves retrieval quality in these types of models. We furthermore show how to directly optimize the retrieval objective using large-scale retrieval data sets with automatically induced relevance judgments.

3 A Bag-of-Words Forced Decoding Model

Model Definition. SMT systems use a Viterbi approximation to find the output hypothesis q_e^*

$$q_e^* = \arg\max_{q_e} \max_{h \in \mathcal{E}_{q_f}} P(h, q_e | q_f). \qquad (1)$$

over the search space of hypotheses or derivations $h \in \mathcal{E}_{q_f}$ for a given input q_f. The probability of a translation output q_e under derivation h given q_f is usually modeled in a log-linear model

$$P(h, q_e | q_f; \mathbf{w}_{smt}) = \frac{e^{F_{smt}(h, q_e, q_f)}}{\sum_{q_e, h} e^{F_{smt}(h, q_e, q_f)}},$$

where $F(h, q_e, q_f)$ is a learned linear combination of input-output features, that is, the dot product between parameter column vector $\mathbf{w}_{smt}$ and feature

column vector given by feature map $\mathbf{\Phi}_{smt}$,

$$F_{smt}(h, q_e, q_f) = \mathbf{w}_{smt}^T \mathbf{\Phi}_{smt}(h, q_e, q_f). \quad (2)$$

In CLIR, we seek to choose a derivation that is *both* an accurate translation of the input according to the translation model, and a well-formed discriminative query that matches relevant documents with high probability. We combine both objectives by directly modeling the probability of a document d_e in target language e given a query q_f in source language f, factorized as follows:

$$P(d_e|q_f) = \sum_{h \in \mathcal{E}_{q_f}} \underbrace{P(h|q_f)}_{\text{translation}} \times \underbrace{P(d_e|h, q_f)}_{\text{retrieval}}.$$

Applying the same Viterbi approximation during inference as in (1), we choose the retrieval score of d_e to be the score of the highest scoring hypothesis h,

$$score(q_f, d_e) = \max_{h \in \mathcal{E}_{q_f}} P(h|q_f) \times P(d_e|h, q_f), \quad (3)$$

where the product between both models can be interpreted as a conjunctive operation similar to a product of experts (Hinton, 2002): A high score is achieved if both experts, namely translation and retrieval models, assign high scores to a hypothesis. That is, the model attempts to produce a well-formed translation, but at the same time chooses lexical items present in the bag-of-words representation of the document. Similarly, we can interpret the inclusion of the retrieval component as a constraint to *force* the decoder to retrieve d_e with high probability. By a slight abuse of terminology, we will henceforth call our approach Bag-of-Words Forced Decoding (BOW-FD).[1]

The translation term $P(h|q_f)$ is modeled as in (2) for standard hierarchical phrase-based SMT (Chiang, 2007) and left unchanged in our joint model. The retrieval term $P(d_e|h, q_f)$ is modeled in a similar form

$$F_{ir}(h, d_e) = \mathbf{w}_{ir}^T \mathbf{\Phi}_{ir}(h, d_e),$$

where IR features do not depend on q_f (thus allowing us to drop this term) and decompose over derivation terms. This allows a bag-of-word vector representation of documents, and retrieval features are local to single edges in the search space for efficient Viterbi inference. The joint scoring model is defined as follows:

$$score(q_f, d_e; \mathbf{w}) = \max_{h \in \mathcal{E}_{q_f}} e^{F_{smt}(h, q_e, q_f) + F_{ir}(h, d_e)},$$

where the weight vector is defined by the vector concatenation $\mathbf{w} = \mathbf{w}_{smt} \| \mathbf{w}_{ir}$, and q_e refers to the yield that is determined uniquely by derivation h.

Following the interpretation of our joint model as forced or constrained decoding, we can view pipeline approaches such as the direct translation baseline as instances of *unconstrained* decoding. That is, the SMT decoder yields a single translation output for every document and the assignment of document scores is deferred to a (monolingual) retrieval model given this single output structure. Other CLIR approaches such as probabilistic structured queries (Darwish and Oard, 2003; Ture et al., 2012b) try to mitigate this early disambiguation by keeping enumerated translation alternatives at retrieval time. However, they either use context-free word-based translation tables or select only terms from a small n-best fraction of the full search space.

Dynamic Programming on Hypergraphs. Decoding in a hierarchical phrase-based SMT (Chiang, 2007) is usually understood as a two-step process: Initially, an input sentence is parsed using a Weighted Synchronous Context-Free Grammar (WSCFG) in a bottom-up manner to construct an initial hypergraph $\mathcal{H}$ that compactly encodes the full search space ("translation forest") (Gallo et al., 1993; Klein and Manning, 2001; Huang and Chiang, 2005; Dyer et al., 2010). An ordered, directed hypergraph $\mathcal{H}$ is a tuple $\langle V, E, g, \mathcal{W} \rangle$, consisting of a finite set of nodes V, a finite set of hyperedges E, and weight function $\mathcal{W} : E \mapsto \mathbb{R}$ assigning real-valued weights to $e \in E$. Language models are typically added in a second rescoring phase that is carried out by approximate solutions, such as cube-pruning (Chiang, 2007; Huang and Chiang, 2007), limiting the number of derivations created at each node. A translation hypothesis $h \in \mathcal{E}$ corresponds

[1] Standardly, the term forced decoding is used to describe the search for only those derivations that exactly produce the reference translation. Our use of this terminology deviates from the standard in two respects: First, we do not require exact reachability of the reference, but only a BOW match. Second, our constraint on the decoder is not strict, but only applies with high probability.

to a sequence of nodes $S \subseteq V$ connected via hyperedges e ending in goal node g. Each edge e is associated with a synchronous grammar rule $r(e)$, and corresponding feature values $\mathbf{\Phi}(r(e))$. The weight of hyperedge e is defined as $\mathcal{W}(e; \mathbf{w}) = \mathbf{w}^T \mathbf{\Phi}(r(e))$.

The quantity in (1) is efficiently computed using dynamic programming under the proper semiring. A commutative semiring K is a tuple $\langle \mathbb{K}, \bigoplus, \bigotimes, \bar{0}, \bar{1} \rangle$, of a set $\mathbb{K}$, an associative and commutative addition operator $\bigoplus$, an associative multiplication operator $\bigotimes$, and their "neutral" elements $\bar{0}$ and $\bar{1}$, respectively (Dyer, 2010). The Inside algorithm over the topologically sorted, acyclic hypergraph $\mathcal{H}$ under the tropical $\langle \mathbb{R}, \max, \times, -\infty, 0 \rangle$ semiring (Goodman, 1999; Mohri, 2009) computes the inside score α of the Viterbi hypothesis, i.e. the weight of its sequence of nodes ending in goal node g:

$$\begin{aligned} \arg\max_{h \in \mathcal{E}_q} & P(h|q) \equiv \alpha(g) \\ & = \bigoplus_{h \in \mathcal{H}_q} \bigotimes_{e \in h} \mathcal{W}(e; \mathbf{w}_{smt}), \end{aligned}$$

where $\mathcal{W}(e; \mathbf{w}_{smt}) = \mathbf{w}_{smt}^T \mathbf{\Phi}_{smt}(r(e))$ assigns weights given parameters and features of the translation model.

For Bag-of-Words Forced Decoding, we extend $\mathcal{W}$ with another set of parameters $\mathbf{w}_{ir}$ for local IR features $\mathbf{\Phi}_{ir}$:

$$\begin{aligned} \arg\max_{h \in \mathcal{E}_q} & P(h|q, d) \equiv \alpha(g) \\ & = \bigoplus_{h \in \mathcal{H}_q} \bigotimes_{e \in h} \mathcal{W}'(e, d; \mathbf{w}_{smt}, \mathbf{w}_{ir}), \end{aligned} \quad (4)$$

with $\mathcal{W}'(e, d; \mathbf{w}_{smt}, \mathbf{w}_{ir}) = \mathbf{w}_{smt}^T \mathbf{\Phi}_{smt}(r(e)) + \mathbf{w}_{ir}^T \mathbf{\Phi}_{ir}(r(e), d)$. Note that $\mathbf{\Phi}_{ir}$ depends on both translation rule $r(e)$ and document d, while $\mathbf{\Phi}_{smt}$ solely depends on source and target side of $r(e)$.

Decomposable Retrieval Features. We use sparse, lexicalized, real-valuead IR features that relate derivations h to document d using *Okapi bm25 term weights* (Robertson and Zaragoza, 2009):

$$bm25(t, d) = rsj(t, \mathcal{C}) \cdot tf_{bm25}(t, d),$$

where $rsj(t, \mathcal{C}) = log\Big(\frac{|\mathcal{C}| - df(t,\mathcal{C}) + 0.5}{df(t,\mathcal{C}) + 0.5}\Big)$ is a constant term weight approximated on document frequencies for collection $\mathcal{C}$, and $tf_{bm25}(t, d) = tf(t, d)/(k_1((1-b) + b\frac{dl}{avdl}) + tf(t, d))$ a saturated term frequency weight of term t in document d, taking into account (average) document lengths dl and $avdl$[2]. We fire the Okapi $bm25$ term weight for each derivation term $t \in h$ w.r.t. document d in collection $\mathcal{C}$. The sum of feature values for all derivation terms $t_i \in h$ equals the regular $BM25$ score $BM25(h, d) = \sum_{t \in h} bm25(t, d)$. Weights $\mathbf{w}_{ir}$ for this type of features are interpretable as additional, general term weights.

Additionally, we report experiments using sparse alignment features that fire an indicator for each alignment, insertion, or deletion of words in source and target. They allow the model to adapt lexical choice and dropping of function words for retrieval.

Default Retrieval Weights & Self-Translation. To enforce a ranking over documents, we define an *IR default weight* v, $\mathbf{w}_{ir} = \mathbf{1}v$. Intuitively, v controls the model's disposition to diverge from the SMT Viterbi path. If IR features fire in other regions of the search space than the SMT Viterbi path, this weight compensates for the loss incurred for not producing the Viterbi hypothesis. Furthermore, the default weight allows the model to generalize to unseen data: If an unknown query word, for example a named entity, causes an IR feature to fire at test time, the decoder will simply *pass through* the source word to any derivation, and the IR feature can contribute to the retrieval score with $v > 0$.

Multi-Sentence Queries. Specialized retrieval tasks such as patent prior art search may exhibit long, coherent search queries that contain multiple sentences. If multiple sentences of query $q = (s_1, \ldots, s_m)$ are processed independently, we need to combine the sentence-wise rankings to obtain a final ranking. We model this task from a product of experts perspective (Hinton, 2002) and multiply scores $score(\cdot, d)$ of document d in all m sentence rankings, re-sorting the final output. If d is not in the top-k ranking of a sentence, we take the minimum score of that top-k ranking as a smoothing value to prevent the product to become zero.

[2] bm25 parameters were fixed at $k_1 = 1.2$ and $b = 0.75$

Implementation and Complexity Analysis.[3] We implemented the above model on top of the hierarchical phrase-based decoder `cdec` (Dyer et al., 2010), but there are no limitations for applying this approach to phrase-based systems (Koehn et al., 2007). Procedurally, after `cdec` yields the translation forest, we compute the overlap of IR feature activations between edges in the forest and the document candidates. The Inside algorithm is only carried out for documents that activate at least one IR feature in the search space. For documents with no activation we can skip the computation of scores and assign the SMT Viterbi score, which constitutes a lower bound on the model score.

For a single query q, forced decoding requires a single pass over the topologically sorted search space to find IR feature activations along hyperedges, yielding a complexity of $O(|V| + |E|)$. The dynamic programming procedure that computes a score for a document requires another pass over the forest evaluating the extended edge weight (4) for every edge $e \in E$, where the dot product for translation features is already precomputed by `cdec` , and the retrieval part depends on the number of active IR features, $\omega := |\mathbf{\Phi}_{ir}(r(e), d)|$. Overall complexity for a single query and all documents $d \in \mathcal{C}$ is thus

$$O\Big(|V| + |E| + \big(|V| + |E| \cdot \omega\big) \cdot |\mathcal{C}|\Big).$$

As noted above, we can reduce the quantity $|\mathcal{C}|$ by checking if a document candidate shares any IR features with the search space and avoid superfluous executions of the Inside algorithm. In our experiments on Wikipedia data, we found that this check reduces $|\mathcal{C}|$ to about 64% of its original size. This pre-filtering is similar to the coarse query approach of Dong et al. (2014), who score only documents that contain at least one term in the query lattice. We further reduce runtime of the inference procedure by using approximate decoding. We experimented with using a beam search approach to limit the number of weight evaluations in (4) for incoming edges at each node. The $\max$ operation of the tropical semiring is discontinued once the number of considered incoming edges at a node exceeds the size of the beam.

[3]The complexity of the construction of the translation forest including the language model is common to BOW-FD and the other baselines and thus not included in the following analysis.

4 Learning to Decode for Retrieval

We now turn to the problem of learning parameter weights for the BOW-FD model. The objective is to prefer a relevant document d^+ over an irrelevant one d^- by assigning a higher score to d^+ than to d^-,

$$score(q, d^+; \mathbf{w}) > score(q, d^-; \mathbf{w}).$$

We sample a set of preference pairs

$$\mathcal{P} = \{(d^+, d^-) | rl(d^+, q) > rl(d^-, q)\}$$

from relevance-annotated data where $rl(d, q)$ indicates the relevance level of a document given query. Furthermore, we require the difference of scores to satisfy a certain margin:

$$score(q, d^+; \mathbf{w}) > score(q, d^-; \mathbf{w}) + \Delta,$$

where the margin is defined as

$$\Delta = rl(d^+, q) - rl(d^-, q).$$

Our final objective is a margin-rescaled hinge-loss

$$L(\mathcal{P}) = \sum_{d^+, d^- \in \mathcal{P}} \big[score(q, d^-; \mathbf{w}) - score(q, d^+; \mathbf{w}) + \Delta\big]_+$$

where $[\cdot]_+ = max(0, \cdot)$.

We use stochastic (sub)gradient descent optimization using the *Adadelta* (Zeiler, 2012) update rule. Adadelta does not require manual tuning of a global learning rate and requires only two hyperparameters that have shown to be quite robust to changes: the sliding window decay rate $\rho = 0.95$ and a constant $\epsilon = 10^{-6}$ were set to the default parameters given in the original paper. We furthermore use the distributed learning technique of *Iterative Parameter Mixing* (McDonald et al., 2010), where multiple models on several shards of the training data are trained in parallel and parameters are averaged after each epoch. We perform incremental optimization using a *cyclic order* of the data sequence (Bertsekas, 2011), that is, the learner steps through a fixed sequence of pairs, query by query, and relevant document by relevant document, without randomization after epochs. This allows us to cache consecutive query search spaces and feature vectors for relevant documents. Regularization is done by early stopping where the best iteration is found on a held-out development set.

Table 2: SMT-based CLIR models without a language model. Numbers in superscripts denote the absolute loss with respect to equivalent systems in Table 1.

5 Evaluation

Data and Systems. We conducted experiments on two large-scale CLIR tasks, namely German-English Wikipedia cross-lingual article retrieval[4] (Bai et al., 2010; Schamoni et al., 2014), and patent prior art search with Japanese-English patent abstracts[5] (Fujii et al., 2009; Guo and Gomes, 2009; Sokolov et al., 2013; Schamoni et al., 2014), comparing retrieval performance of BOW-FD against the state-of-the-art SMT-based CLIR baselines of *Direct Translation* (DT) and cross-lingual *Probabilistic Structured Queries* (PSQ) (Ture et al., 2012a; Ture et al., 2012b). The SMT models, as well as baseline evaluation scores were taken from (Schamoni et al., 2014).

We present results for BOW-FD using a default weight v optimized on the development sets, and for models with parameters trained using pairwise learning-to-rank. We compute MAP, NDCG (Manning et al., 2008) and PRES (Magdy and Jones, 2010) scores on the top 1,000 returned documents to provide an extensive evaluation across precision-, and recall-oriented measures. Differences in evaluation scores between two systems were tested for statistical significance using paired randomization tests (Smucker et al., 2007). Significance levels are either indicated as superscripts, or provided in the captions of the respective tables.

Baseline SMT systems and BOW-FD share the hierarchical phrase-based SMT systems built with `cdec` (Dyer et al., 2010). For German-English cross-lingual article retrieval on Wikipedia, we built a system analogously to Schamoni et al. (2014) from parallel training data (over 104M words) consisting of the Europarl corpus (Koehn, 2005) in version 7, the News Commentary corpus, and the Common Crawl corpus (Smith et al., 2013). Word alignments were created with `fast_align` (Dyer et al., 2013). The 4-gram language model was trained with the KenLM toolkit (Heafield, 2011) on the English side of the training data and the English Wikipedia articles. Language model scores are added to the search spaces using the cube pruning algorithm (Huang and Chiang, 2007) with $poplimit = 200$. SMT Model parameters were optimized using MIRA (Chiang et al., 2008) on the WMT2011 news test set (3003

[4] `http://www.cl.uni-heidelberg.de/statnlpgroup/wikiclir/`

[5] `http://www.cl.uni-heidelberg.de/statnlpgroup/boostclir/`

sentences). The parameters for the baseline PSQ model were found on a development set consisting of 10,000 German queries using 1,000-best lists: interpolation parameter $\lambda = 0.4$, lower threshold $L = 0$, and cumulative threshold $C = 1$.

For the task of Japanese-English patent prior-art search, we use a system analog to Sokolov et al. (2013) and Schamoni et al. (2014). Its SMT features are trained on 1.8M parallel sentences of NTCIR-7 data (Fujii et al., 2008) and weights were tuned on the NTCIR-8 test collection (2,000 sentences) using MIRA (Chiang et al., 2008). A 5-gram language model on the English side of the training data was trained with the KenLM toolkit (Heafield, 2011). The system uses a cube pruning poplimit of 30. Parameters for the baseline PSQ model were found on a development set of 2,000 patent abstract queries and set to n-best list size = 1000, $\lambda = 1.0$, $L = 0.005$, $C = 0.95$

Experimental Results. We first find a default weight v using grid search within $v = [0, 3]$ and $v = [0, 2]$ on the development sets for Wikipedia and patents, respectively. v controls the balance between the retrieval and translation features and with larger v, the model is more likely to produce query derivations diverging from the SMT 1-best translation. For Wikipedia, we sample 1,000 out of 10,000 queries to reduce the time of the grid search. For patents we use the full development set of 2,000 queries with 8,381 sentences. We combine rankings for single-sentence queries from multi-sentence patent abstracts using the product method as previously described. Well performing values were found at $v = 1.6$ for Wikipedia, and $v = 0.8$ for patents, respectively.

Table 1 shows test set performance of DT and PSQ baselines versus BOW-FD. Scores for DT and PSQ are as reported in Schamoni et al. (2014). We observe that BOW-FD significantly outperforms both baselines by over 2 points on Wikipedia and patents under all three evaluation measures. While the cube pruning poplimit was set to 200 for the Wikipedia experiments, it is set to 30 for patents. This may reduce the diversity of the search space considerably. Increasing the poplimit from 30 to 200 yielded another significant gain (MAP=0.2893, NDCG=0.5807, PRES=0.6172) on this dataset.

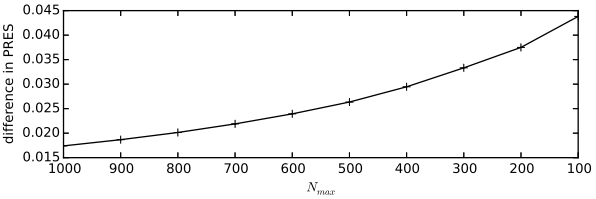

Figure 1: Difference in PRES scores on the Wikipedia development set as a function of PRES's N_{max} parameter between BOW-FD +LM and -LM systems.

Learning-to-rank results. We learned the weights of the BOW-FD model starting from IR default weights optimized by grid search, and from SMT feature weights "pre-trained" on parallel data. We furthermore found improvements over BOW-FD in precision-oriented metrics (MAP and NDCG) by freezing SMT weights. Table 1 shows that BOW-FD+(LEX+)LTR models significantly outperform BOW-FD on both data sets, with the largest improvement for PRES. Differences between models with and without lexical alignment features are not statistically significant. We conjecture that LTR models mostly optimize recall rather than precision, i.e. placing more relevant document in the ranking. This is supported by the fact that BOW-FD+LTR retrieves 70.1% of the relevant documents in the test set, compared to 68.0% by BOW-FD, while Mean Reciprocal Rank (MRR) hardly differs (0.7344 vs. 0.7332). An experiment with no pre-trained SMT or default IR weights, performed worse, indicating the importance of translation-benign search spaces and IR default weights for generalization to unseen terms.

Importance of Language Model for Retrieval. Liu et al. (2012) and Dong et al. (2014) claim that computationally expensive SMT feature functions such as language models have only minor impact on CLIR performance of SMT-based models. We found that such context-sensitive information present in single 1-best query translations (DT), weighted translation alternatives from the n-best list (PSQ), and forced decoding in a "translation-benign" search space (BOW- FD) is crucial for retrieval performance in the experiments reported this paper. In order to investigate the question of the importance of context-sensitive information such as

language model scores for retrieval we conducted an experiment in which the language model information is removed from all three SMT-based models. For the PSQ models, we also set the parameter λ to 1.0 to disable interpolation with the context-free lexical translation table (Ture et al., 2012a). Table 2 shows that retrieval performance drops significantly for all models. The drop in performance for the two baseline models is comparable on both data sets. Removing the language model for BOW-FD hurts performance the most (with an average drop of 6 points in MAP and NDCG scores for Wikipedia, and over 11 points in all measures for patents). However, scores for recall-oriented PRES on Wikipedia remains relatively stable for BOW-FD with and without a language model. A closer analysis on the rankings for BOW-FD on Wikipedia shows that the -LM model returns 1,589 (out of 86,994) relevant documents less than the +LM model. However, only 2 documents with relevance level 3, i.e., directly linked cross-lingual "mates", were no longer retrieved, suggesting that excluding the language model from the system mostly affects the retrieval of "non-mates", i.e. documents that are linked by, or link to the cross-lingual mate. We explain this behavior as follows: Cross-lingual mates are likely to contain words that are close to an adequate query translation, since they constitute the beginning of a Wikipedia article with the same topic as the query. Derivations generated for these documents are such that both translation model features (with or without the LM) *and* retrieval features agree on a path close to the SMT Viterbi translation. In contrast, other relevant documents require more non-standard lexical choices that are harder to achieve in a +LM search space, since the strong weight on the language model, plus a language model-driven pruning technique, strongly favor lexical choices that agree with the language model's concept of fluency. In a -LM search space, disfluent derivations are easily reached by IR feature activations whose default weight is much larger in relation to the remaining SMT features. The use of "glue rules" allowing left-to-right concatenation of partial translations along with loosely extracted synchronous grammar rules give hierarchical MT models large degrees of freedom in producing very disfluent translations in the -LM space. If a language model is not ensuring a more or less "translation-benign" search space, the "reachability" of terms in irrelevant documents is increased causing them to interfere with the ranking of relevant documents that may be closer translations of the query. This behavior immediately affects precision-oriented scores such as MAP and NDCG, while PRES is only affected if its recall cutoff parameter, N_{max}, is lowered, as shown in Figure 1.

The major drop in performance for patent data may be explained with the way multiple sentence queries are evaluated: A language model limits diversity of translation options for multiple sentences. Without a language model, the sets of documents retrieved by each sentence are almost disjoint, i.e. the sentences do not agree on a common set of documents.

6 Conclusion

In this paper, we presented an approach to CLIR that shifts the focus from retrieval to translation by forcing a standard SMT decoder to produce a bag-of-words representation of the document repository. This is done by joint optimization of a linear model including both translation and retrieval features under a ranking objective. Highly weighted term-match features are then used to find a decoding path that gives highest score to the document that is optimal with respect to both relevance and translational adequacy. We showed in a large-scale evaluation on cross-lingual retrieval tasks in the domains of patents and Wikipedia pages that our approach significantly outperforms direct translation and Probabilistic Structured Query approaches under a variety of evaluation metrics. Furthermore, we investigated the role of context-sensitive information such as language model scores in retrieval. In contrast to previous claims about the minor impact of language models in retrieval performance in SMT-based CLIR, we found significant drops in MAP and NDCG across all models when removing language model information. This confirms the dual role of the language model to ensure fluency and to select the proper translation terms in the context of the neighboring target terms. The latter role of the language model makes it an indispensable ingredient of any SMT-based CLIR approach.

Open questions in our work regard further im-

provements in efficiency of retrieval. So far we could achieve substantial reductions in retrieval complexity by pre-filtering based on coarse term matches. The inherent complexity of SMT decoding is less of a problem in offline applications such as translation retrieval (Dong et al., 2014), but it becomes prohibitive in online applications such as cross-lingual web search. In future work, we would like to address efficiency, e.g. by investigating the possibility of incorporating an inverted index into online applications of forced decoding.

Accurate Evaluation of Segment-level Machine Translation Metrics

Yvette Graham[†‡] **Nitika Mathur**[†] **Timothy Baldwin**[†]

Abstract

Evaluation of segment-level machine translation metrics is currently hampered by: (1) low inter-annotator agreement levels in human assessments; (2) lack of an effective mechanism for evaluation of translations of equal quality; and (3) lack of methods of significance testing improvements over a baseline. In this paper, we provide solutions to each of these challenges and outline a new human evaluation methodology aimed specifically at assessment of segment-level metrics. We replicate the human evaluation component of WMT-13 and reveal that the current state-of-the-art performance of segment-level metrics is better than previously believed. Three segment-level metrics — METEOR, NLEPOR and SENTBLEU-MOSES — are found to correlate with human assessment at a level not significantly outperformed by any other metric in both the individual language pair assessment for Spanish-to-English and the aggregated set of 9 language pairs.

1 Introduction

Automatic segment-level machine translation (MT) metrics have the potential to greatly advance MT by providing more fine-grained error analysis, increasing efficiency of system tuning methods and leveraging techniques for system hybridization. However, a major obstacle currently hindering the development of segment-level metrics is their evaluation. Human assessment is the gold standard against which metrics must be evaluated, but when it comes to the task of evaluating translation quality, human annotators are notoriously inconsistent. For example, the main venue for evaluation of metrics, the annual Workshop on Statistical Machine Translation (WMT), reports disturbingly low inter-annotator agreement levels and highlights the need for better human assessment of MT. WMT-13, for example, report Kappa coefficients ranging from 0.075 to 0.324 for assessors from crowd-sourcing services, only increasing to between 0.315 and 0.457 for MT researchers (Bojar et al., 2013a). For evaluation of metrics that operate at the system or document-level such as BLEU, inconsistency in individual human judgments can, to some degree, be overcome by aggregation of individual human assessments over the segments within a document. However, for evaluation of segment-level metrics, there is no escaping the need to boost the consistency of human annotation of individual segments.

This motivates our analysis of current methods of human evaluation of segment-level metrics, and proposal of an alternative annotation mechanism. We examine the accuracy of segment scores collected with our proposed method by replicating components of the WMT-13 human evaluation (Bojar et al., 2013b), with the sole aim of optimizing agreement in segment scores to provide an effective gold standard for evaluating segment-level metrics. Our method also supports the use of significance testing of segment-level metrics, and tests applied to the WMT-13 metrics over nine language pairs reveal for the first time which segment-level metrics outperform others. We have made available code for acquiring accurate segment-level MT human evaluations from the crowd, in addition to significance

2 WMT-style Evaluation of Segment-level MT Metrics

Since 2008, the WMT workshop series has included a shared task for automatic metrics, and as with the translation shared task, human evaluation remains the official gold standard for evaluation. In order to minimize the amount of annotation work and enforce consistency between the primary shared tasks in WMT, the same evaluations are used to evaluate MT systems in the shared translation task, as well as MT evaluation metrics in the document-level metrics and segment-level metrics tasks. Although WMT have trialled several methods of human evaluation over the years, the prevailing method takes the form of ranking a set of five competing translations for a single source language (SL) input segment from best to worst. A total of ten pairwise human relative preference judgments can be extracted from each set of five translations. Performance of a segment-level metric is assessed by the degree to which it corresponds with human judgment, measured by the number of metric scores for pairs of translations that are either concordant (Con) or discordant (Dis) with those of a human assessor, which the organizers describe as "Kendall's τ":

$$\tau = \frac{|Con| - |Dis|}{|Con| + |Dis|}$$

Pairs of translations deemed equally good by a human assessor are omitted from evaluation of segment-level metrics (Bojar et al., 2014).

There is a mismatch between the human judgments data used to evaluate segment-level metrics and the standard conditions under which Kendall's τ is applied, however: Kendall's τ is used to measure the association between a set of observations of a single pair of joint random variables, X (e.g. the human rank of a translation) and Y (e.g. the metric score for the same translation). A conventional application of Kendall's τ would be comparison of all pairs of values within X with each corresponding pair within Y. Since the human assessment data is, however, a large number of separately ranked sets of five competing translations and not a single ranking of all translations, it is not possible to compute a single Kendall's τ correlation.[1] The formula used to assess the performance of a metric in the task, therefore, is not what is ordinarily understood to be a Kendall's τ coefficient, but, in fact, equivalent to a weighted average of all Kendall's τ for each human-ranked set of five translations.

A more significant problem, however, lies in the inconsistency of human relative preference judgments within data sets. Since overall scores for metrics are described as correlations, possible values achievable by any metric could be expected to lie in the range $[-1, 1]$ (or "± 1"). This is not the case, and achievements of metrics are obscured by contradictory human judgments. Before any metric has provided scores for segments, for example, the maximum and minimum correlation achievable by a participating metric can be computed as, in the case of WMT-13:

- Russian-to-English: ± 0.92
- Spanish-to-English: ± 0.90
- French-to-English: ± 0.90
- German-to-English: ± 0.92
- Czech-to-English: ± 0.89
- English-to-Russian: ± 0.90
- English-to-Spanish: ± 0.90
- English-to-French: ± 0.91
- English-to-German: ± 0.90
- English-to-Czech: ± 0.87

If we are interested in the relative performance of metrics and take a closer look at the formula used to contribute a score to metrics, we can effectively ignore the denominator ($|Con| + |Dis|$), as it is constant for all metrics. The numerator ($|Con| - |Dis|$) is what determines our evaluation of the relative performance of metrics, and although the formula appears to be a straightforward subtraction of counts of concordant and discordant pairs, due to the large numbers of contradictory human relative preference judgments in data sets, what this number actually represents is not immediately obvious. If, for example, translations A and B were scored by a metric such that metric_score(A) $>$ metric_score(B), one

[1] This would in fact require all (|MT systems| $\times$ |distinct segments|) translations included in the evaluation to be placed in a single rank order.

might expect an addition or subtraction of 1 depending on whether or not the metric's scores agreed with those of a human. Instead, however, the following is added:

$$(\max(|A > B|, |A < B|) - \min(|A > B|, |A < B|)) \times d$$

where:

$$\begin{aligned} |A > B| &= \text{\# human judgments where A was preferred over B} \\ |A < B| &= \text{\# human judgments where B was preferred over A} \\ d &= \begin{cases} 1 & \text{if } |A < B| > |A > B| \\ -1 & \text{if } |A < B| < |A > B| \end{cases} \end{aligned}$$

For example, translations of segment 971 for Czech-to-English systems *uedin-heafield* and *uedin-wmt13* were compared by human assessors a total of 12 times: the first system was judged to be best 4 times, the second system was judged to be best 2 times, and the two systems were judged to be equal 6 times. This results in a score of $4-2$ for a system-level metric that scores the *uedin-heafield* translation higher than *uedin-wmt13* (tied judgments are omitted), or score of $2 - 4$ in the converse case.

Another challenge is how to deal with relative preference judgments where two translations are deemed equal quality (as opposed to strictly better or worse). In the current setup, tied translation pairs are excluded from the data, meaning that the ability for evaluation metrics to evaluate similar translations is not directly evaluated, and a metric that manages to score two equal quality translations closer, does not receive credit. A segment-level metric that can accurately predict not just disparities between translations but also similarities is likely to have high utility for MT system optimization, and is possibly the strongest motivation for developing segment-level metrics in the first place. In WMT-13, however, 24% of all relative preference judgments were omitted on the basis of ties, broken down as follows:

- Spanish-to-English: 28%
- French-to-English: 26%
- German-to-English: 27%
- Czech-to-English: 25%
- Russian-to-English: 24%
- English-to-Spanish: 23%
- English-to-French: 23%
- English-to-German: 20%
- English-to-Czech: 16%
- English-to-Russian: 27%

Although significance tests for evaluation of MT systems and document-level metrics have been identified (Koehn, 2004; Graham and Baldwin, 2014; Graham et al., 2014b), no such test has been proposed for segment-level metrics, and it is unfortunately common to conclude success without taking into account the fact that an increase in correlation can occur simply by chance. In the rare cases where significance tests have been applied, tests or confidence intervals for *individual* correlations form the basis for drawing conclusions (Aziz et al., 2012; Machacek and Bojar, 2014). However, such tests do not provide insight into whether or not a metric outperforms another, as all that's required for rejection of the null hypothesis with such a test is a likelihood that an individual metric's correlation with human judgment is not equal to zero. In addition, data sets for evaluation in both document and segment-level metrics are not independent and the correlation that exists between pairs of metrics should also be taken into account by significance tests.

3 Segment-Level Human Evaluation

Many human evaluation methodologies attempt to elicit precisely the same quality judgment for individual translations from all assessors, and inevitably produce large numbers of conflicting assessments in the process, including from the same individual human judge (Callison-Burch et al., 2007; Callison-Burch et al., 2008; Callison-Burch et al., 2009). An alternative approach is to take into account the fact that different judges may genuinely disagree, and allow assessments provided by individuals to each contribute to an overall estimate of the quality of a given translation.

In an ideal world in which we had access to assessments provided by the entire population of qualified human assessors, for example, the mean of those assessments would provide a statistic that, in theory at least, would provide a meaningful segment-level human score for translations. If it were possible to collect assessments from the entire

population we could directly compute the *true mean score* for a translation segment. This is of course not possible, but thanks to the law of large numbers we can make the following assumption:

> Given a sufficiently large assessment sample for a given translation, the mean of assessments will provide a very good estimate of the true mean score of the translation sourced from the entire assessor population.

What the law of large numbers does not tell us, however, is, for our particular case of translation quality assessment, precisely how large the sample of assessments needs to be, so that the mean of scores provides a close enough estimate to the true mean score for any translation. For a sample mean for which the variance is known, the required sample size can be computed for a specified standard error. However, due to the large number of distinct translations we deal with, the variance in sample score distributions may change considerably from one translation to the next. In addition, the choice as to what exactly is an acceptable standard error in sample means would be somewhat arbitrary. On the one hand, if we specify a standard error that's lower than is required, and subsequently collect more repeat assessments than is needed, we would be wasting resources that could, for example, be targeted at the annotation of additional translation segments.

Our solution is to empirically investigate the impact on sample size of repeat assessments on the mean score for a given segment, and base our determination of sample size on the findings. Since we later motivate the use of Pearson's correlation to measure the linear association between human and metric scores (see Section 4), we base our investigation on Pearson's correlation.

We collect multiple assessments per segment to create score distributions for segments for a fixed set per language pair. This is repeated twice over the same set of segments to generate two distinct sets of annotations: one set is used to estimate the true mean score, and the second set is randomly downsampled to simulate a set of assessments of fixed sample size. We measure the Pearson correlation between the true mean score and different numbers of assessments for a given assessment, to ask the question: how many assessments must be collected for a given segment to obtain mean segment scores that truly reflects translation quality? Scores are sampled according to annotation time to simulate a realistic setting.

Language pair	# translations	# assessments per translation
es-en	280	40
en-es	140	19
en-ru	140	15
en-de	140	14

Table 1: Datasets used to assess translation assessment sample size

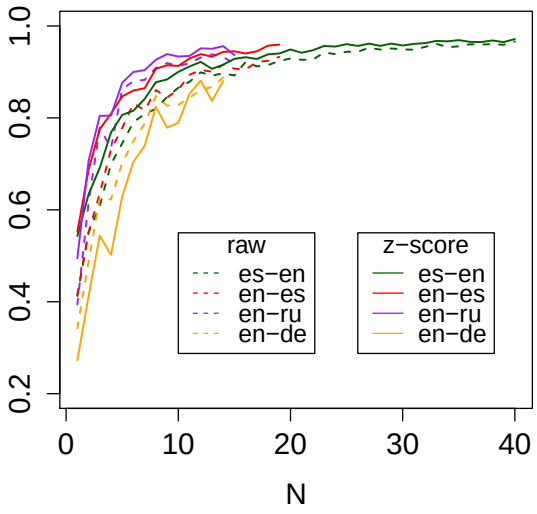

Figure 1: Correlation (r) of translation quality estimates between the initial and repeat experiment runs for each of the four language pairs from WMT-13, for sample size N and based on raw and standardized (z) scores.

3.1 Translation Assessment Sample Size

MTurk was used to collect large numbers of translation assessments, in sets of 100 translations per assessment task (or "HIT" in MTurk parlance). The HITS were structured to include degraded translations and repeat translations, and rated on a continuous Likert scale with a single translation assessment displayed to the assessor at one time (Graham et al., 2014a; Graham et al., 2013). This supports accurate quality-control as well as normalisation of translation scores for each assessor. The assessment

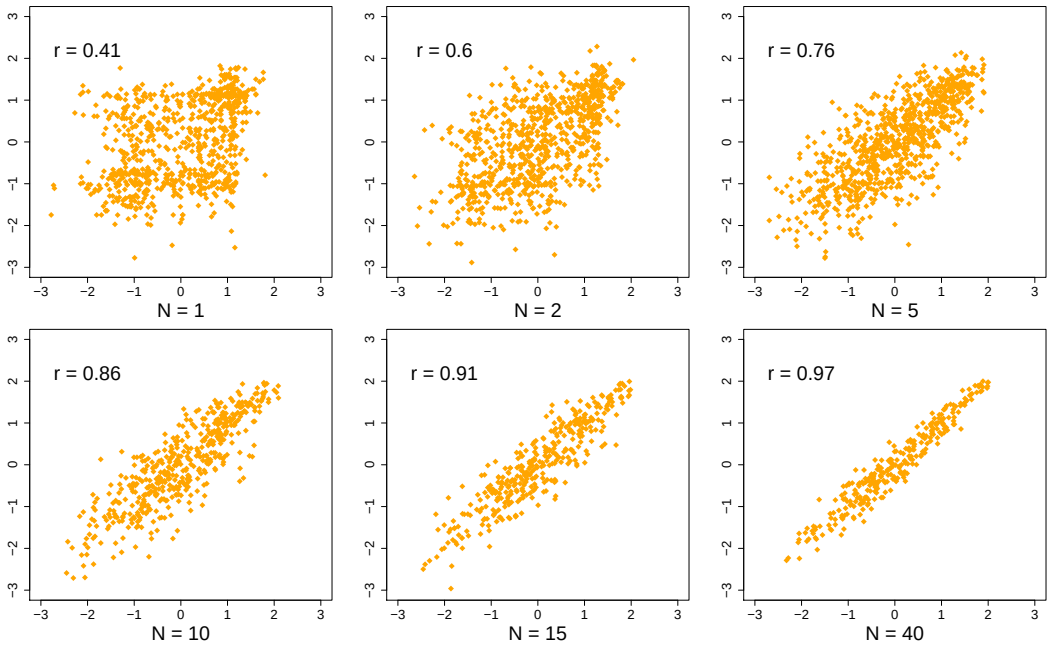

Figure 2: Plots and correlation (r) of translation quality assessments in the initial (x-axis) and replicate experiments (y-axis) for Spanish-to-English over WMT-13, where each point represents a standardized segment-level score computed as the mean of the N individual assessments for that plot.

task was posed as a monolingual task, where assessors were asked to rate the degree to which the MT system output adequately expressed the meaning of the corresponding reference translation. Translations were sampled at random from the WMT-13 data sets for the four language pairs, as detailed in Table 1. Due to low-quality assessors on MTurk and the need for assessments solely for quality assurance purposes, the exercise required a substantial number of individual assessments. For Spanish-to-English, for example, a total of (280 translations + 120 translations for quality-control purposes) $\times$ 40 assessments per translation $\times$ 2 separate data collections $\times$ $\sim$2 to allow for filtering of low-quality assessors = $\sim$64k assessments were collected; after quality control filtering and removing the quality-control translations, around 22k assessments were used for the actual experiment.

Figure 1 shows the Pearson correlation between mean segment-level scores calculated for varying numbers of assessments (N), and the full set of assessments for the second set of assessments. For each language pair, we calculate the correlation first over the raw segment scores and second over standardized scores, based on the method of Graham et al. (2014a).[2] For all language pairs, although the correlation is relatively low for single assessments, as the sample size increases, it increases, and by approximately $N = 15$ assessments, for all four language pairs, the correlation reaches $r = 0.9$. For Spanish-to-English, for which most assessments were collected, when we increase the number of assessments to $N = 40$ per translation, the correlation reaches $r = 0.97$. Figure 2 is a set of scatter plots for mean segment-level scores for Spanish-to-English rising, for varying sample sizes N.

As expected, the larger the sample size of assessments, the greater the agreement with the true mean score, but what is more surprising is that with as few as 15 assessments, the scores collected in the two separate experiments correlate extremely well, and provide what we believe to be a sufficient stability to evaluate segment-level metrics.

[2]Standardized segment scores are computed by standardizing individual raw scores according to the mean and standard deviation of individual assessors, and then combined into mean segment scores.

4 Segment-level Metric Evaluation

Since the scores generated by our method are continuous and segment-level metrics are also required to output continuous-valued scores, we can now compare the scores directly using Pearson's correlation. Pearson's correlation has three main advantages for this purpose. Firstly, the measure is unit-free, so metrics do not have to produce scores on the same scale as the human assessments. Secondly, scores are absolute as opposed to relative and therefore more intuitive and ultimately more powerful; for example, we are able to evaluate metrics over the 20% of translations of highest or lowest quality in the test set. Finally, the use of Pearson's correlation facilitates the measurement of statistical significance in correlation differences.

It is important to point out, however, that moving from Kendall's τ over relative preference judgments to Pearson's r over absolute scores does, in fact, change the task required of metrics in one respect: previously, there was no direct evaluation of the scores generated by a metric, nor indeed did the evaluation ever directly compare translations for different source language inputs (as relative preference judgments were always relative to other translations for the same input). Pearson's correlation, on the other hand, compares scores across the entire test set.

4.1 Significance Testing of Segment-level Metrics

With the move to Pearson's correlation, we can also test statistical significance in differences between metrics, based on the Williams test (Williams, 1959),[3] which evaluates significance in a difference in dependent correlations (Steiger, 1980). As suggested by Graham and Baldwin (2014), the test is appropriate for evaluation of document-level MT metrics since the data is not independent, and for similar reasons, the test can also be used for evaluation of segment-level metrics.

4.2 Spanish-to-English Segment-level Metrics

We first carry out tests for Spanish-to-English segment-level metrics from WMT-13. In our experiments in Section 3.1, we used only a sub-sample of segments, so the first thing is to collect assessments for the remaining Spanish-to-English translation segments using MTurk, based on a sample of at least 15 assessments. A total of 24 HITs of 100 translations each were posted on MTurk; after removal of low quality workers (∼50%) and quality control items (a further 30%), this resulted in 840 translation segments with 15 or more assessments each. The scores were standardized and combined into mean segment scores.

Metric	r	τ
METEOR	0.484	0.324
NLEPOR	0.483	0.281
SENTBLEU-MOSES	0.465	0.266
DEP-REF-EX	0.453	0.307
DEP-REF-A	0.453	0.312
SIMPBLEUP	0.450	0.287
SIMPBLEUR	0.444	0.388
LEPOR	0.408	0.236
UMEANT	0.353	0.202
MEANT	0.342	0.202
TERRORCAT	0.313	0.313

Table 2: Pearson's correlation and Kendall's τ between WMT-13 segment-level metrics and human assessment for Spanish-to-English (ES-EN). Note that Kendall's τ is based on the WMT-13 formulation, and the preference judgments from WMT-13.

Table 2 shows the Pearson's correlation for each metric that participated in the WMT-13 Spanish-to-English evaluation task, along with the Kendall's τ based on the original WMT-13 methodology and relative preference assessments. Overall, when we compare correlations using the new evaluation methodology to those from the original evaluation, even though we have raised the bar by assessing the raw numeric outputs rather than translating them into preference judgments relative to other translations for the same SL input, all metrics achieve higher correlation with human judgment than reported in the original evaluation. This indicates that the new evaluation setup is by no means unrealistically difficult, and that even though it was not required of the metrics in the original task setup, the metrics are doing a relatively good job of absolute scoring of translation adequacy. In addition,

[3] Also sometimes referred to as the Hotelling–Williams test.

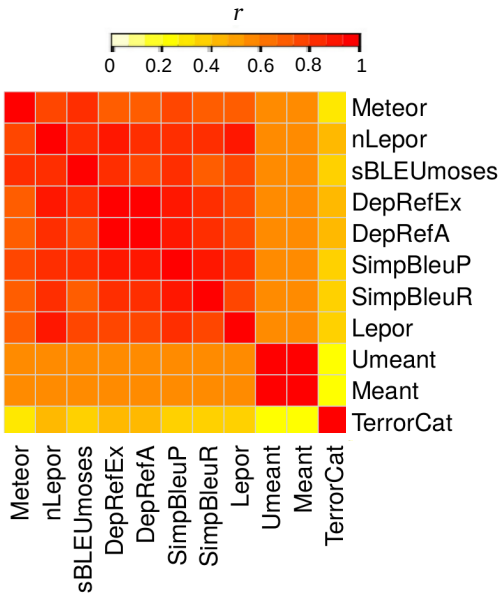

Figure 3: Pearson's correlation between every pair of segment-level metric competing in the WMT-13 Spanish-to-English task.

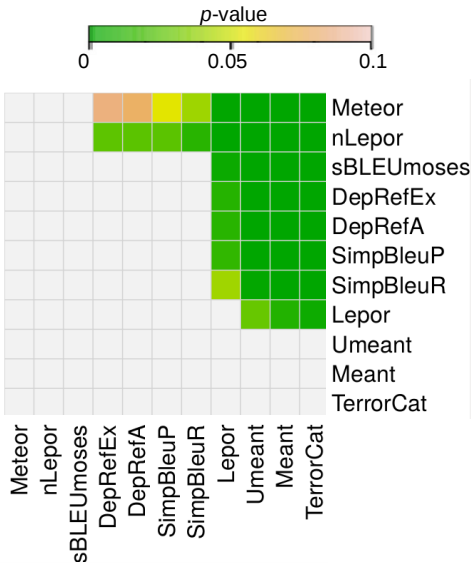

Figure 5: Evaluation of significance of increase in correlation with human judgment between every pair of segment-level metrics competing in the Spanish-to-English WMT-13 metrics task. A colored cell (i,j) indicates that system named in row i significantly outperforms system named in column j at $p < 0.1$, and green cells at $p < 0.05$.

the new assessment reflects how well metrics score translations of very close or equal quality, and, as described in Section 2, ameliorates the issue of low inter-annotator agreement as well as resolving the original mismatch between discrete human relative preference judgments and continuous metric scores.

Figure 3 is a heat map of the Pearson's correlation between each pair of segment-level metrics for Spanish-to-English from WMT-13, and Figure 4 shows correspondence between scores of three segment-level metrics with our human evaluation data. Figure 5 displays the outcome of the Williams significance test as applied to each pairing of competing metrics. Since the power of Williams test increases with the strength of correlation between a pair of metrics, it is important *not* to conclude the best system by the number of other metrics it outperforms. Instead, the best choice of metric for that language pair is any metric that is *not significantly outperformed by any other metric*. Three metrics prove not to be significantly outperformed by any other metric for Spanish-to-English, and tie for best performance: METEOR (Denkowski and Lavie, 2011), NLEPOR (Han et al., 2013) and SENTBLEU-MOSES (sBLEU-moses).

Metric	r
METEOR	0.441
NLEPOR	0.416
SENTBLEU-MOSES	0.422
SIMPBLEUP	0.418
SIMPBLEUR	0.404
LEPOR	0.326

Table 3: Pearson's correlation between each WMT-13 segment-level metric and human assessment for the combined set of nine language pairs.

4.3 9 Language Pairs

Since human assessments are now absolute, scores effectively have the same meaning across language pairs, facilitating the combination of data across multiple language pairs. Since many approaches to MT are language-pair independent, the ability to know what segment-level metric works best across all language pairs is useful for choosing an appropriate default metric or simply avoiding having to swap and change metrics across different language

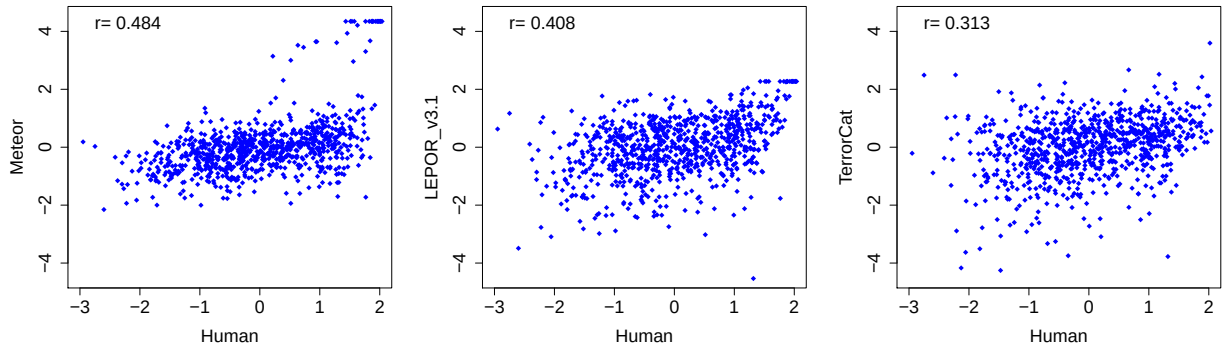

Figure 4: Standardized segment-level scores for human vs. metric over the WMT-13 Spanish-to-English segment-level metric task, for a metric achieving highest, mid-range and lowest Pearson's correlation with human judgment.

pairs.

Assessments of translations were crowd-sourced for nine language pairs used in the WMT-13 shared metrics task: Russian-to-English, Spanish-to-English, French-to-English, German-to-English, Czech-to-English, English-to-Russian, English-to-Spanish, English-to-French and English-to-German.[4] Again, we obtain a minimum of 15 assessments per translation, and collect scores for 100 translations per language pair. After removal of quality control items, this leaves 70 distinct translations per language pair, combined into a cross-lingual test set of 630 distinct translations spanning nine language pairs.

Table 3 shows Pearson's correlation with human assessment for the six segment-level metrics that competed across all language pairs in WMT-13, and Figure 6 shows the outcomes of Williams test for statistical significance between different pairings of metrics. Results reveal that the same three metrics as before (METEOR, SENTBLEU-MOSES and NLEPOR), in addition to SIMPBLEUP and SIMPBLEUR are not significantly outperformed by any other metric at $p<0.05$. However, since the latter two were shown to be outperformed for Spanish-to-English, all else being equal, METEOR, SENTBLEU-MOSES and NLEPOR are still a superior choice of default metric.

[4]We were regrettably unable to include English-to-Czech, due to a lack of Czech-speaking MTurk workers.

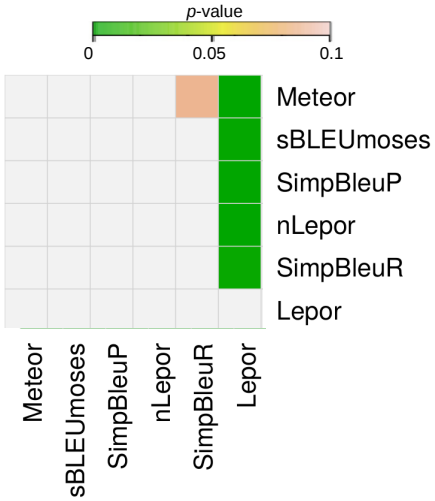

Figure 6: Evaluation of significance of increase in correlation with human judgment between every pair of segment-level metrics competing in all nine in WMT-13 metrics task. A colored cell (i,j) indicates that system named in row i significantly outperforms system named in column j at $p < 0.1$ and green cells specifically $p < 0.05$.

5 Conclusion

We presented a new evaluation methodology for segment-level metrics that overcomes the issue of low inter-annotator agreement levels in human assessments, includes evaluation of very close and equal quality translations, and provides a significance test that supports system comparison with confidence. Our large-scale human evaluation reveals three metrics to not be significantly outperformed by any other metric in both Spanish-to-

English and a combined evaluation across nine language pairs, namely: METEOR, NLEPOR and SENTBLEU-MOSES.

Abstract

We present our work on leveraging multilingual parallel corpora of small sizes for Statistical Machine Translation between Japanese and Hindi using multiple pivot languages. In our setting, the source and target part of the corpus remains the same, but we show that using several different pivot to extract phrase pairs from these source and target parts lead to large BLEU improvements. We focus on a variety of ways to exploit phrase tables generated using multiple pivots to support a direct source-target phrase table. Our main method uses the Multiple Decoding Paths (MDP) feature of Moses, which we empirically verify as the best compared to the other methods we used. We compare and contrast our various results to show that one can overcome the limitations of small corpora by using as many pivot languages as possible in a multilingual setting. Most importantly, we show that such pivoting aids in learning of additional phrase pairs which are not learned when the direct source-target corpus is small. We obtained improvements of up to 3 BLEU points using multiple pivots for Japanese to Hindi translation compared to when only one pivot is used. To the best of our knowledge, this work is also the first of its kind to attempt the simultaneous utilization of 7 pivot languages at decoding time.

1 Introduction

With the increasing size of parallel corpora it has become possible to achieve very high quality translation. However, not all language pairs are blessed with the availability of large parallel corpora in the sizes of millions of lines. With the exception of the major European languages and a few Asian languages like Chinese and Japanese, other languages have parallel corpora in the sizes of a few thousands of lines. Since translation quality is related to the size of the parallel corpus, it is impossible to achieve the same level of translation quality as that in the case of resource rich languages. To remedy this scenario, an intermediate resource rich language can be exploited. Although, finding a direct parallel corpus between source and target languages might be difficult, there are higher odds of finding a pair of parallel corpora: one between the source language and an intermediate resource rich language (henceforth called pivot[1]) and one between that pivot and the target language.

Using the methods developed for Pivot Based SMT (Wu and Wang, 2007) (Utiyama and Isahara, 2007) one can use the source-pivot and pivot-target parallel corpora to develop a source-target translation system (henceforth called as pivot based system [2]) . Moreover, if there exists a small source-target parallel corpus then the resulting system (henceforth called as direct system[3]) can be supported by the pivot based source-target system to significantly improve the translation quality. Note that in this paper we use the terms "translation system" and "phrase table" interchangeably since the phrase table is the

[1] In most cases this is English.

[2] The phrase table will be known as the pivot phrase table.

[3] The phrase table will be called as direct phrase table and the corpus will be the direct parallel corpus.

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1192–1202,
Denver, Colorado, May 31 – June 5, 2015.

main component of the translation system. Reordering tables are supplementary and can usually be replaced by a simple distortion model.

Major problems arise when source-pivot and pivot-target corpora belong to different domains leading to rather poor quality translations. Even if the individual corpora are large, one will run into domain adaptation problems. In such a scenario the availability of a small size multilingual corpus of a few thousand lines belonging to a single domain can be beneficial. The setting of this paper is:

1. We suppose the existence of a multilingual corpus with sentences aligned across N[4] different languages.

2. We show using the other languages as additional pivots leads to the construction of better phrase tables and better translation results.

Note that this setting is realistic and differs from the majority of existing work on pivot languages, in which the source-pivot and pivot-target corpora are unrelated (or at least do not have equivalent sentences). In addition to the well-known Europarl corpus, many other similar multilingual corpora exist. For example, a multilingual parallel corpus for 9 major Indian Languages belonging to the Health and Tourism domain of approximately 50000 lines was used to develop basic SMT systems (Kunchukuttan et al., 2014). For our experiments we will use a recently released Bible domain multilingual parallel corpus (Resnik et al., 1999) for a large number (over 25) of languages (other than Indian) including Japanese and Hindi (Japanese to Hindi translation being our focus) of approximately 30000 lines. We chose this setting because we feel that this multilingual approach is especially important for low-resource language pairs.

Typically system combination methods like linear interpolation are used to combine the direct and pivot phrase tables by modifying the probabilities of phrase pairs leading to the modification of the underlying distribution which affects the resultant translation quality. The Multiple Decoding Paths (Birch and Osborne, 2007) (MDP) feature has been used to combine two source-target phrase tables of different domains for domain adaptation (Koehn and Schroeder, 2007) but not so extensively in a pivot language scenario, especially when multiple pivots are involved (7 in our case). Our work is different from other previous works in the following ways:

- We work on a realistic low resource setting for translation between Japanese and Hindi in which we use small sized multilingual corpora containing translations of a sentence in multiple languages.

- We focus on the impact of using a relatively large number of pivot languages (7 to be precise) to improve the translation quality and compare this to when only one pivot language is used.

- Most works focus on obtaining pivot based phrase tables on relatively larger corpora than the ones used for the direct phrase table. We use the same corpora sizes for the pivot as well as direct tables.

- We verify that Multiple Decoding Paths (MDP) feature of Moses is much more effective than plain linear interpolation, especially when more pivot languages are used together.

- We show that simply varying the pivot language leads to additional phrase pairs being acquired that impact translation quality.

Section 2 contains the related work. Section 3 begins with a basic description about the languages involved, followed by the corpora details and the experimental methodology. Section 4 consists of results, observations and discussions. The paper ends with conclusions and future work.

2 Related Work

Utiyama and Isahara (2007) developed a method (sentence translation strategy) for cascading a source-pivot and a pivot-target system to translate from source to target using a pivot language. Since this results in multiplicative error propagation Wu and Wang (2009) developed a method (triangulation) in which they combined the source-pivot and pivot-target phrase tables to get a source-target

[4]The construction of a multilingual corpus has already the benefit that each new language added to it will allow direct translation with a SMT system for N new language pairs.

phrase table. They then combine the pivoted and direct tables by linear interpolation whose weights were manually specified. There is a method to automatically learn the weights (Sennrich, 2012) but it requires reference phrase pairs not easily available in resource constrained scenarios like ours. Work on translation from Indonesian to English using Malay and Spanish to English using Portuguese (Nakov and Ng, 2009) as pivot languages worked well since the pivots had substantial similarity to the source languages. This is one of the first works to use MDP in the pivot based SMT scenario.

(Paul et al., 2013) and (Paul et al., 2009) showed that English is not the best pivot language for many language pairs, including Japanese and Hindi. This was reason enough for us to not consider English as a pivot in our experiments. None of the above works focus on the utilization and impact of more than 2 pivots in their experiments which was one of our main objectives. Related to multilingual translation are works by Habash and Hu (2009), El Kholy et al. (2013), Salloum et al. (2014) and Koehn et al. (2009). Work on multi source translation (Och and Ney, 2001) which is complementary to our work must also be noted.

In the related field of information retrieval, pivot languages were employed to translate queries in cross-language information retrieval (CLIR) (Gollins and Sanderson, 2001) (Kishida and Kando, 2003). Chinnakotla et al. (2010) retrieved feedback terms from documents written in the pivot languages (after translating back from the pivot), and augmented source queries leading to improvements in information retrieval. We now talk about the languages, corpora and experiments conducted.

3 Description of Languages, Corpora and Experiments

We first describe the pivot languages and the corpora we use. We follow this with a description of the triangulation method which we use to construct phrase tables using the pivot languages, the methods used to combine the constructed tables and then the experiments that use them.

3.1 Languages involved

We performed experiments on translation between Japanese and Hindi which do not belong to the same language group but exhibit many similarities: Japanese (J) and Hindi (H) both have SOV order and are morphologically rich. For pivots we considered languages like Chinese, Korean (East-Asian languages of which Korean is closer to source), Marathi, Kannada, Telugu (Indian languages closer to target), Paite (Sino-Tibetian) and Esperanto (relatively distant from both source and target). Increasing the number of languages reduced the size of multilingual parallel translations available[5]. Our choice of languages was initially random but led to interesting observations as will be seen later.

3.2 Corpora Details

The corpora used comes from the freely available multilingual Bible corpus[6] stored in XML files. After sentence aligning all 9 languages we got 29780 sentence tuples. A tuple contains 9 sentences: 1 for each language. This we divided into 29000 training tuples, 280 tuning tuples and 500 testing tuples. The Japanese sentences were segmented using JUMAN (Kurohashi et al., 1994). The Chinese and Korean (Hangul blocks were space separated) sentences were directly available in their character segmented form. The corpora of the other languages were left morphologically and syntactically unprocessed.

3.3 Phrase Table Triangulation

We implemented the phrase table triangulation method (Wu and Wang, 2007) using JAVA as the programming language. The phrase table has 4 main scores: forward and inverse phrase translation probabilities (equations 1 and 2) accompanied by forward and inverse lexical translation probabilities (equations 3 and 4). The formulae for generating them using pivots are:

$$\Theta(f|e) = \sum_{p_i} \Theta(f|p_i) * \Theta(p_i|e) \qquad (1)$$

[5]It must be noted that Hebrew and Greek are most likely the languages from which the Bible sentences were translated into the other languages.

[6]http://homepages.inf.ed.ac.uk/s0787820/bible/

$$\Theta(e|f) = \sum_{p_i} \Theta(e|p_i) * \Theta(p_i|f) \quad (2)$$

$$P_w(f|e,a) = \sum_{p_i} P_w(f|p_i,a_1) * P_w(p_i|e,a_2) \quad (3)$$

$$P_w(e|f,a) = \sum_{p_i} P_w(e|p_i,a_2) * P_w(p_i|f,a_1) \quad (4)$$

Here a_1 is the alignment between phrases f (source) and p_i (pivot), a_2, the alignment between p_i and *e* (target) and *a* the alignment between *e* and *f*. Note that the lexical translation probabilities are calculated in the same way as the phrase probabilities. Our results might improve even more if we used more sophisticated approaches like crosslanguage similarity method or the method which uses pivot induced alignments (Wu and Wang, 2007).

3.4 Phrase Table Combination

There are 3 ways to combine phrase tables: linear interpolation, fillup interpolation and multiple decoding paths. Linear interpolation is performed by merging the tables and computing a weighted sum of phrase pair probabilities from each phrase table giving a final single table. Typically, the direct phrase table is given a significantly higher weight than the pivot based table.

$$\Theta(f|e) = \alpha_0 * \Theta_{direct}(f|e) + \sum_{l_i} \alpha_{l_i} * \Theta_{l_i}(f|e)$$
$$subject\ to\ \alpha_0 + \sum_{l_i} \alpha_{l_i} = 1 \quad (5)$$

Typically α_0 is 0.9 (Wu and Wang, 2009) and the pivot languages are collectively given a weight of 0.1. $\Theta_{l_i}(f|e)$ is the inverse translation probability for language l_i. In our experiments we set the α's according to the ratio of the BLEU scores, on the test set, of the translations using the individual phrase tables. It is possible to learn optimal weights but this requires a collection of reference phrase pairs which would not be readily available in a resource constrained scenario.

Fillup interpolation does not modify phrase probabilities but selects phrase pair entries from the next table if they are not present in the current table. The priority of the phrase tables should be specified which we do by ranking them according to the BLEU scores on a test set.

Multiple Decoding Paths (MDP) method of Moses which uses all the tables simultaneously while decoding ensures that each pivot table is kept separate and translation options are collected from all the tables. Increasing the number of pivot languages slows the decoding process drastically but the existence of powerful machines negates this limitation. For the sake of completeness we also experimented with a combination of both, linear and MDP, methods by: Firstly, combining the pivot based phrase tables into a single table using equation 5 (using the ratio of BLEU scores as interpolation weights) followed by using this table to support the direct phrase table by MDP. Note that the right way would be to use the BLEU scores on the tuning set but our objective was to show that even in the best case scenario (also called Oracle[7] scenario) this method is still inferior compared to only using the MDP method.

3.5 Descriptions of Experiments

Our experiments were centered around Phrase Based SMT (PBSMT). We used the open source Moses decoder (Hoang et al., 2007) package (including Giza++) for word alignment, phrase table extraction and decoding for sentence translation. We also used the Moses scripts for linear and fillup interpolation along with the multiple decoding paths (MDP) setting (by modifying the moses.ini files). We performed MERT (Och, 2003) based tuning using the MIRA algorithm. We used BLEU (Papineni et al., 2002) as our evaluation criteria and the bootstrapping method (Koehn, 2004) for significance testing. For the sake of comparison with previous methods, we experimented with sentence translation strategy (Utiyama and Isahara, 2007) using 10 as the n-best list size for intermediate and target language translations. The experiments we performed are given below. Each experiment involves either the creation of a phrase tables or combination of phrase tables. We tune, test and evaluate these tables or combinations.

1. A src (source) to tgt (target) direct phrase table.
2. For piv in Pivot_Languages_Set; the set of pivot languages to be used (Tables 1 and 2):

[7] By Oracle scenario we mean that we already know the performance on the test sets and exploit this information to "unfairly" boost the translation scores.

(a) src to piv and piv to tgt phrase tables. Translate the src test sentences to tgt using the sentence translation strategy and evaluate. (Column 2)

(b) Triangulate the src-piv and piv-tgt phrase tables to get the src-piv-tgt phrase table. (Column 3)

(c) Perform linear interpolation of the src-tgt and src-piv-tgt table using 9:1 weight ratio in equation 5 to get a combined table. (Column 4)

(d) Perform linear interpolation of the src-tgt and src-piv-tgt table using the ratio of their BLEU scores as weights in equation 5 to get a combined table. (Column 5)

(e) Perform fillup interpolation of the src-tgt (main) and src-piv-tgt table (secondary) to get a combined table. (Column 6)

(f) Combine the src-tgt and src-piv-tgt phrase table using MDP (2 paths, 1 for direct and 1 for pivot). (Column 7)

3. Combine **all** the src-piv-tgt tables into a single table using linear (weights are ratios of BLEU scores) and fillup interpolation independently, giving the phrase tables: linear_interp_all and fill_interp_all respectively. Table 3, rows 4 and 5.

4. Perform linear interpolation of the src-tgt and linear_interp_all tables using 9:1 weight ratio in equation 5 to get a combined table. Table 3, row 6.

5. Perform linear interpolation of the src-tgt and **all** src-piv-tgt phrase tables using the ratio of their BLEU scores as weights in equation 5 to get a combined table. Table 3, row 7.

6. Perform fillup interpolation of the src-tgt and **all** src-piv-tgt phrase tables. The priority of the tables is given by the descending order of BLEU scores. Table 3, row 8.

7. Combine the linear_interp_all with the src-tgt phrase table using MDP. Repeat this for fill_interp_all. Table 3, rows 9 and 10.

8. Combine **all** the src-piv-tgt phrase tables with the src-tgt phrase table using MDP (8 paths, 1 for direct and 1 for each of the 7 pivots). Table 3, row 11.

9. Combine the **top 3** pivot phrase tables with the src-piv-tgt phrase tables with the src-tgt phrase table using MDP (4 paths, 1 for direct and 1 for each of the 3 pivots). The pivot tables with the 3 highest[8] standalone BLEU scores are selected. Table 3, row 12.

4 Results and Discussions

BLEU scores obtained after testing the tuned tables are reported. Scores in bold are statistically significant ($p<0.05$) over the baseline which is the system trained using a direct src-tgt parallel corpus.

4.1 Results

The Japanese-Hindi direct translation system gave a BLEU of 33.86 whereas the Hindi-Japanese one gave 37.47. For the rest of the paper these will be the baselines, unless mentioned otherwise.

The evaluation scores are split into 3 tables. Table 1 contains the scores for Japanese to Hindi (Table 2 for Hindi to Japanese) translation using each pivot separately and has 7 columns whose details are given in section 3.5 from 2.a to 2.f. Table 3 contains the scores for Japanese to Hindi (and vice versa) translation using all 7 pivots together in various ways. Each row is self explanatory. In row 6, we mean that the direct phrase table has a weight of 0.9 and the remainder 0.1 is distributed amongst the pivot phrase tables in the ratio of their standalone BLEU scores which can be seen in column 3 of tables 1 and 2. It is quite clear that sentence translation strategy is the most inferior technique.

4.2 Observations

Below, we give an explanation of the observed scores from various points of views.

4.2.1 On the Pivots Used

It is logical to consider that the closeness of a pivot language to the source or target is an important factor in the improvement of translation quality, since Korean helps Japanese-Hindi translation.

[8] We chose 3 since our evaluation showed that the BLEU scores for the 3 pivot languages were much larger than the remaining ones.

Pivot Language	Sentence Strategy	Standalone	Linear Interpolate (1) With Direct	Linear Interpolate (2) With Direct	Fill Interpolate With Direct	MDP With Direct
1. Direct	**33.86**					
2. Chinese	23.53	28.89	34.03	**34.61**	34.31	**35.66**
3. Korean	26.30	28.92	**34.65**	34.18	34.64	**35.60**
4. Esperanto	22.43	28.73	**34.63**	**34.55**	35.32	**35.74**
5. Paite	19.40	26.64	34.17	34.40	**34.66**	**35.22**
6. Marathi	15.68	21.80	33.88	33.80	33.83	34.03
7. Kannada	16.94	24.15	33.74	34.13	**34.87**	**35.52**
8. Telugu	14.15	21.31	33.81	33.85	34.04	**34.57**

Table 1: Japanese-Hindi Results Using Single Pivots

Pivot Language	Sentence Strategy	Standalone	Linear Interpolate (1) With Direct	Linear Interpolate (2) With Direct	Fill Interpolate With Direct	MDP With Direct
1. Direct	**37.47**					
2. Chinese	27.93	30.97	35.90	**38.47**	**38.41**	**39.49**
3. Korean	30.68	32.67	35.99	**38.72**	**38.55**	**39.49**
4. Esperanto	26.67	30.80	36.07	37.82	37.85	**39.14**
5. Paite	23.37	29.17	35.89	37.73	37.39	**38.19**
6. Marathi	20.59	26.21	35.89	37.57	37.72	**38.30**
7. Kannada	23.21	26.96	35.84	38.05	37.79	**38.05**
8. Telugu	19.01	25.22	37.25	36.98	37.11	37.04

Table 2: Hindi-Japanese Results Using Single Pivots

Of all the scores, the ones obtained using Korean and Chinese as pivots stand out as the best and it is known that Korean and Japanese share many similarities. Although this gives reason to believe that languages belonging to the same language group should act as good choices of pivots, the languages Kannada, Telugu and (especially) Marathi should have helped improve Hindi to Japanese translation. Moreover, languages like Paite and Esperanto which are relatively distant from both Hindi and Japanese gave better performance than the Indian Languages. Remember that the Chinese and Korean corpora were character segmented[9] and that Esperanto and Paite are not so morphologically rich. The Indian pivot languages have agglutinative features which is one of the main causes of poor quality SMT. This clearly indicates that morphological similarity to source and target is another equally important aspect that affects the translation quality. Had this not been the case, the Indian Languages would have acted as good pivots. This shows that experiments involving forcing the morpheme to morpheme ratio, of the source to pivot to target sentences, to be the same, must be conducted. Henceforth, it is to be expected that the most significant improvements will be obtained when Chinese, Korean and Esperanto (in a number of cases) are used as pivots.

[9]Hangul blocks were space separated in the Korean case.

4.2.2 On the Linear and Fill Interpolation Methods

Single pivots: All the interpolation methods (columns 4, 5 and 6 of Tables 1 and 2) gave small improvements in BLEU in most cases compared to the baselines for both language pairs. The results do not show drastic improvements, which is expected since the baseline and pivots based phrase tables are constructed from the same multilingual

Combination Type	Jap-Hin	Hin-Jap
1. Direct phrase table (baseline)	33.86	37.47
2. Best result using single pivot	35.74 (Esp.)	39.49 (Kor.)
3. Combine All Pivots using MDP	34.49	37.02
4. A - Linear Interpolate All Pivot tables (BLEU score ratio)	32.50	35.65
5. B - Fill Interpolate All Pivot tables (Priority according to BLEU score)	32.12	34.44
6. Linear Interpolate (9:1 ratio) Direct with All Pivot tables	**34.56**	**38.60**
7. Linear Interpolate (BLEU score ratio) Direct with All Pivots	**35.24**	**39.08**
8. Fill Interpolate Direct with All Pivots (Priority according to BLEU score)	**35.28**	**38.70**
9. Combine Direct and A using MDP	**36.40**	**39.85**
10. Combine Direct and B using MDP	**36.67**	**40.07**
11. Combine Direct and All Pivots tables using MDP	**38.42**	**40.19**
12. Combine Direct and Top 3 (BLEU) pivot tables using MDP (Oracle)	**38.22**	**41.09**

Table 3: Results Using Multiple Pivots With Different Combination Methods

training instances (29000 tuples - see section 3.2). Typically the interpolation methods are shown to give substantial performance boosts when the direct source-target phrase table is obtained using relatively smaller corpora sizes compared to those used for the source-pivot and pivot-target tables. In case of linear interpolation with a 9:1 weight ratio, the scores improve slightly in some cases for Japanese-Hindi but degrade in case of Hindi-Japanese. However, in the case of linear interpolation where the BLEU score ratio is used as the weight ratio, the improvements are much better[10].

Fill based interpolation also gives improvements in some cases, mostly when Chinese and Korean are used as pivots. An overall comparison shows that there is no consistency when a single pivot language is used and no conclusive comment can be made on the efficacy of these interpolation methods.

Multiple Pivots: However in Table 3, rows 6 to 8 show that using all the pivots together, result in a significant improvement over the direct phrase tables. Linear interpolation with BLEU score ratio gives 35.24 BLEU (33.86 for direct phrase table) for Japanese-Hindi and 39.08 BLEU (37.47 for direct phrase table). Rows 4 and 5 show the scores of the linear and fill interpolation of only the pivot based phrase tables. It is interesting to see that in case of Japanese-Hindi the BLEU scores rival that of the direct phrase table (32.50/32.12 v.s. 33.86). This is similar in the case of Hindi-Japanese: 35.65/34.44 v.s. 37.47. The following points must be noted:

a. Since the setting is multilingual and improvements, however slight, are observed in some cases it must be the case that, through pivoting, additional (and possibly improved) phrase pairs are induced which are not extracted using the direct source-target parallel corpus. This also gives reason to believe that every pivot induces a different set of phrase pairs thereby overcoming the limitations of poor alignment (and effectively phrase extraction) on small corpora. Even if there is no alignment error, pivoting still introduces new phrase pairs which improves MT performance.

b. The pivot based phrase tables already have an incomplete probability space with respect to the phrase pair distribution. Linear interpolation tends to violate the overall probability mass since the phrase pair distribution gets changed. Fill interpolation just adds additional phrase pairs from the next phrase table when not available in the current one which leads to poor mixing of different probability models giving poorer performance in-spite of additional phrase pairs being available.

c. Since some pivot languages are obviously bad, their probability scores would drastically affect the overall probability mass. They should be excluded or given low weights, which we do by considering the BLEU score ratio. However, this is not a good idea because the scores for Telugu, a bad pivot for Hindi-Japanese translation, degraded to a lesser ex-

[10]Expected as we use test set evaluation information.

tent when the Telugu based phrase table was linearly combined with the direct phrase table. Sennrich (2012) gave a method to learn these weights, but in a resource constrained scenario such a method is difficult to apply.

This motivated us to try the Multiple Decoding Paths (MDP) feature of Moses.

4.2.3 On using MDP

Single pivots: Since log linear combination does not modify the probability space it should lead to definitive increase in translation scores. This claim is validated by the last columns of Tables 1 and 2. For Japanese-Hindi: barring Marathi, the combination of the direct and pivot phrase table leads to significant improvement over the direct phrase tables. A similar situation occurs for Hindi-Japanese except that Telugu behaves as a bad pivot.

Multiple pivots: Row 3 of Table 3 indicates that the log linear combination of all the pivot tables using MDP for Japanese-Hindi gives a BLEU of 34.49, an improvement ($p<0.05$) over the direct table (BLEU 33.86). For Hindi-Japanese, although the equivalent BLEU score (37.02) is not an improvement over that of the direct table (37.47), it does show that multiple pivots can be used to achieve translation quality similar to the quality obtained by a direct table.

Since it was observed that the interpolation of all the pivot tables into a single one gave scores close to the direct tables we decided to try the combination of the all pivots interpolated table with the direct table using MDP. Rows 9 and 10 show that there is a significant improvement compared to the scores of the direct tables alone. But this method of linear + log linear combination would still suffer from the limitation of linear interpolation which led to the final 2 experiments which use only log linear combination.

Row 11 shows that the method of combining the direct and all the pivot tables using MDP (one for each table) outperforms all the methods so far. The reason is simple: Only good translation options are collected from all tables during hypothesis expansion, the bad ones are automatically pruned. For Japanese-Hindi the BLEU is 38.42 which is an improvement of 4.56 (13% relative) over the BLEU of the direct phrase table (33.86). For Hindi-Japanese the BLEU of 40.19 is an improvement of 2.72 (7.25% relative) over that of the direct table (37.47). The increment is lesser because of the premise we established in section 4.2.1. This points to an interesting observation that pivot languages induce better phrase pairs in a multilingual setting which are not present in the direct phrase table. This is quite beneficial when the corpora sizes are small which lead to poor quality phrase tables.

To test whether exclusion of bad performing pivots leads to improvements in BLEU we performed another oracle experiment in which we only included the pivot phrase tables having significant standalone BLEU difference compared to the others. Korean, Chinese and Esperanto were the ones that stood out. The last row shows that for Japanese-Hindi the BLEU (38.22) does not significantly increase over the situation when all pivots are used together (38.42). However for Hindi-Japanese the BLEU is 41.09 which is a significant ($p<0.05$) increase compared to when all the pivots are used together (40.19 - 2.2% relative). Note that this leads to an absolute BLEU difference of 3.62 (9.66% relative) compared to the BLEU of the direct phrase table. The improvements for Japanese-Hindi were already so large (13%) that more significant improvements would need deeper inspection and improved methods. We believe that further significant improvements are possible and advanced methods to effectively select multiple pivots need to be studied and implemented.

4.2.4 On the number of new phrase pairs induced

Based on the cutoff of 0.001 for the inverse translation probability, Table 4 contains the statistics of the unique phrase pairs in each pivot table (Columns 4 to 10) and the direct table (Column 3) along with the number of phrase pairs common (Column 2) to all. It is quite obvious that each pivot[11] induces its own set of unique phrase pairs.

4.2.5 On the improvement in translations

Table 5 gives the count of improved translations, out of 500 tested sentences, over the direct using sentence level BLEU difference at various cutoffs. On an average 50% of the sentences showed increase

[11] For each language we use their first 3 characters of their names as the shortened versions.

Direction	Common	Direct	Chi	Kor	Esp	Pai	Kan	Mar	Tel
1. Jap-Hin	0.032	1.404	20.74	18.65	16.06	23.85	26.56	30.92	26.84
2. Hin-Jap	0.034	1.528	26.20	20.26	18.06	28.83	29.90	36.98	31.23

Table 4: Unique phrase pairs in each table (in millions of pairs)

Direction	>0	>0.1	>0.2	>0.3	>0.4	>0.5	>0.6	>0.7
1. Jap-Hin	267	108	36	12	6	4	2	0
2. Hin-Jap	275	124	60	24	12	4	1	1

Table 5: Number of improved translations (out of 500) using sentence level BLEU difference at various cutoffs

in BLEU and the number of improved sentences decreases with increasing cutoff. We manually verified a random sample and found that the improvements were commensurate with the reported differences. Finally, consider an example of improvement in Japanese to Hindi translation.

Input: それから、ヨハネの弟子たちがきる、死体を引き取る葬る。そして、イエスのところに行く報告する。 (Sore kara, Yohane no deshi-tachi ga kiru, shitai o hikitoru homuru. Soshite, iesu no tokoro ni iku hokoku suru.)

English equivalent: After that, John's disciples came and took his corpse away, buried it and then went to Jesus to give him the news.

Direct translation: तब यूहन्ना के चेलों ने आकर उस की लोथ ले गया और उसके पास जाकर बता दिया (Tab yohanna ke chelo ne aakar uss ki lotha le gaya; aura uske paas jaakar bata diya)

Best translation using MDP: तब यूहन्ना के चेलों ने आकर उस की लोथ को ले जाकर गाढ दिया और जाकर यीशु को समाचार दिया (Tab yohanna ke chelo ne aakar usa ki lotha ko le jaakar gaad diya aura jakar yesu ko samachara diya)

Analysis: Note that in the direct translation the part about "burying the corpse" (gaad diya) and "Jesus" (yesu) is missing which is present in the MDP translation. Also the verb forms indicating the sequence of actions like "came and" (aakar) and "took his corpse away" (usa ki lotha ko le jaakar) are much better in the MDP translation. Instead of "samachara diya" (gave news) the preferred translation is "samachara di".

5 Conclusions and Future Work

We have presented our work on leveraging a small sized multilingual parallel corpus using 7 pivot languages for SMT between Japanese and Hindi. Our main objective was to augment a phrase table on direct parallel corpus using many pivot language based phrase tables constructed from the same multilingual corpus. We confirm that this induces additional and improved phrase pairs which, under the Multiple Decoding Paths setting (MDP), leads to substantial improvements over the direct phrase tables. More importantly, we show that using multiple pivot languages simultaneously lead to large improvements in BLEU compared to the when a single pivot is used; which is the novel aspect of our work. This opens up many further research directions like **a.** How can one choose a set of good pivot languages amongst available choices? **b.** Does this multilingual leveraging help in a situation where we have large size corpora like Europarl corpora? **c.** How much of an impact can treatment (morphological or syntactic) of the pivot language help in improving translation quality? **d.** Can good reordering information be extracted by pivoting? **e.** Can multi source and multi pivot setting further enhance quality? **f.** How can the noise induced by pivoting be controlled by methods other than probability cutoffs? and finally **g.** Can simpler but more effective methods compared to triangulation be exploited in a multilingual scenario? The last 4 questions have long been ignored and deserve to be answered. We will pursue these directions in the future and attempt to provide satisfactory answers.

Abstract

The rapid growth of information sources brings a unique challenge to biographical information extraction: how to find specific facts without having to read all the words. An effective solution is to follow the human scanning strategy which keeps a specific keyword in mind and searches within a specific scope. In this paper, we mimic a scanning process to extract biographical facts. We use event and relation *triggers* as keywords, identify their scopes and apply type constraints to extract answers within the scope of a trigger. Experiments demonstrate that our approach outperforms state-of-the-art methods up to 26% absolute gain in F-score without using any syntactic analysis or external knowledge bases.

1 Introduction

Extracting biographical information is an important task because it can help readers understand an ongoing event more easily by providing the background biographical information of participants in this event. In fact, this task has been part of the Text Analysis Conference (TAC) - Knowledge Base Population (KBP) Slot Filling (SF) Track (Ji et al., 2010; Ji et al., 2011; Surdeanu, 2013; Surdeanu and Ji, 2014) for years.

Overall, state-of-the-art research still needs improvement. A typical approach is based on patterns which include triggers (*e.g.*, (Sun et al., 2011; Li et al., 2012)). Here *trigger* is defined as the smallest extent of a text which most clearly expresses an event occurrence or indicates a relation type. High-quality patterns yield quite high precision but relatively low recall. In addition, it's relatively expensive to maintain and update a set of extraction patterns.

Furthermore, we carefully investigated the TAC-KBP SF 2012 ground truth corpus and find that 94.36% of the biographical facts are mentioned in a sentence containing indicative fact-specific triggers. For example, *born* is a trigger for extracting birth-related facts. Triggers are crucial in predicting the type of facts (Aguilar et al., 2014). However, most previous studies only focused on using triggers to create more patterns (*e.g.*, (Li et al., 2013)). Therefore the critical problem is how to make the most of triggers in biographical fact extraction?

We observe that people tend to scan a document when they want to quickly find a biographical fact within limited time. According to Douglas and Frazier (2001), *scanning* is a strategy for quickly finding specific information (keywords or ideas) in a text while ignoring its broader meaning. Scanning involves skipping words, but the emphasis is that the reader knows what to look for and rapidly scans until words are found and closer reading can occur (Phipps, 1983).

There are five steps in implementing scanning strategy according to Arnold (1999):

1. Keep in mind what you are searching for.
2. Anticipate in what form the information is likely to appear – number, proper nouns, etc.
3. Analyze the organization of the content before starting to scan.

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1203–1208,
Denver, Colorado, May 31 – June 5, 2015.

4. Let your eyes run rapidly over several lines of print at a time.

5. When you find the sentence that has the information you seek, read the entire sentence.

Educators have verified that scanning is an effective strategy in enhancing reading comprehension (Motallebzadeh and Mamdoohi, 2011). There are two important aspects in the scanning strategy: keywords and their corresponding scopes. For biographical fact extraction, triggers can easily act as the keywords used by human during scanning and thus we focus on identifying the scopes of triggers.

Given a sentence that contains one or more triggers, we define *trigger scope* as the shortest fragment that is related to a trigger. Based on our observation, each fact-specific trigger has its own scope and its corresponding facts seldom appear outside of its scope. In the following sentence, if we can identify the scope of *graduated*, a trigger for education-related facts, we can skip the rest of the sentence after *1965* even though *Chesterbrook Academy* is an educational organization.

*She [<**graduated**> from **Barnard** in 1965] and soon began teaching English at **Chesterbrook Academy** in Pennsylvania.*[1]

In this paper, we study the effect of triggers by learning their linguistic scopes at the sentence level and apply this strategy to extract 11 types of biographical facts, namely, *birth date, death date, birth place, death place, residence place, education, parents, spouse, children, siblings* and *other family* as described in the KBP SF task.

We design our extraction process following the scanning steps corresponding to Arnold's scanning theory.

1. Let the computer know the query and the fact type to be extracted.

2. Let the computer know what form or entity type the candidate answer is likely to appear – person, organization, phrase, time, etc.

3. Locate all the triggers of the given fact type and recognize their respective scopes.

4. Within each scope, extract candidate answers which satisfy the entity type constraint in 2.

The contributions of our paper are as follows.

- We are the first to study the application of trigger scoping in biographical fact extraction.

- Our approach does not rely on any external knowledge bases for training or manually created fact-specific rules, and yet dramatically advances state-of-the-art.

2 Approach

In this section, we present the detailed approach of applying trigger scoping to biographical fact extraction. In Section 2.1, we first introduce the annotation methods of constructing the gold-standard dataset for evaluating scope identification. We use the sentence in Figure 1 as our illustrative example.

> *Paul Francis Conrad* and his [twin <**brother**>, James], were [<**born**> in Cedar Rapids, Iowa, on June 27, 1924], [<**sons**> of Robert H. Conrad and Florence Lawler Conrad].

Figure 1: Trigger and scope annotation example.

2.1 Trigger and Scope Annotation

2.1.1 Basic issues

In a text, the sentences containing biographical facts (*e.g.*, birth, death, family, residence or education) are considered for annotation. We discard a sentence if it expresses a biographical fact without surface cues.

During annotation, triggers are marked by angle brackets (*e.g.*, <*resident*>), and the scope boundaries of a trigger are denoted by square brackets as shown in Figure 1.

2.1.2 Trigger Tagging

We mined fact-specific trigger lists from existing patterns (Chen et al., 2010; Min et al., 2012; Li et al., 2012) and ground truth sentences from KBP 2012

[1] The scope is marked with [] and the trigger is marked with <>.

SF corpus. In our experiment, we use 343 triggers and 38 triggers on average for each fact type[2].

We examine all the sentences containing any possible triggers. The presence of a word in one trigger list does not necessarily mean that the sentence contains an event or a relation. For instance, the second *child* in the following sentence is part of an organization's name.

*He and his wife, Ann McGarry Buchwald moved to Washington in 1963 with their [<**child**>], who was adopted from orphanages and [<**child**> welfare agencies] in Ireland, Spain and France.*

We also keep such sentences and annotate their trigger scopes without distinction.

Note that we only mark the syntactic head of a trigger phrase. For example, we mark *child* for the noun phrase *the second child*.

2.1.3 Scope Tagging

During the scope annotation, we first include the trigger within its own scope and then mark its left and right boundaries. Usually the left boundary is the trigger itself.

When there are multiple triggers in the same sentence, we annotate each trigger's scope separately since it is possible that the scopes of different triggers are overlapped or nested as shown in the following instance (the scope of *daughters* covers the scope of *wife*):

*Pavarotti had three [<**daughters**> with his first wife, Lorenza, Cristina and Giuliana; and one, Alice, with his second wife].*

*Pavarotti had three daughters with his first [<**wife**>], Lorenza, Cristina and Giuliana; and one, Alice, with his second [<**wife**>].*

The scope of a word is not transitive. In the phrase *"his [<**son**>'s home] in Washington"*, *home* is within *son*'s scope and *in Washington* is within *home*'s scope, however, the last prepositional phrase is outside of *son*'s scope.

2.2 Scope Identification

We will introduce two methods for identifying trigger scopes.

[2]The trigger lists are publicly available for research purposes at: http://nlp.cs.rpi.edu/data/triggers.zip

2.2.1 Rule-based Method

This method is used to investigate the performance of trigger scoping strategy when we do not have any labeled data. We use trigger as the left scope boundary. A verb or trigger with other fact types is regarded as the right boundary.

The rule-based scoping result of the walk-through example is as follows:

> *Paul Francis Conrad* and his twin [<**brother**>, James, were] [<**born**> in Cedar Rapids, Iowa, on June 27, 1924,] [<**sons**> of Robert H. Conrad and Florence Lawler Conrad.]

2.2.2 Supervised Classification

Alternatively we regard scope identification as a classification task. For each detected trigger, scope identification is performed as a binary classification of each token in the sentence as to whether it is within or outside of a trigger's scope.

We apply the Stanford CoreNLP toolkit (Manning et al., 2014) to annotate part-of-speech tags and names in each document. We design the following features to train a classifier.

- Position: The feature takes value 1 if the word appears before the trigger, and 0 otherwise.
- Distance: The distance (in words) between the word and the trigger.
- POS: POS tags of the word and the trigger.
- Name Entity: The name entity type of the word.
- Interrupt: The feature takes value 1 if there is a verb or a trigger with other fact type between the trigger and the word, and 0 otherwise. Verbs and triggers with other fact types can effectively change the current topic or continue in another way.

Note that the trained classifier can make predictions that result in nonconsecutive blocks of scope tokens. In this case, we aggregate the labels of all the words of an entity to assign a global label, which means that we assign the entity the majority label of the words it contains.

Fact Type	Recall (%)			Precision (%)			F-score (%)		
	1	2	3	1	2	3	1	2	3
per:place_of_birth	59.4	88.2	88.2	76.0	87.0	88.2	66.7	87.6	**88.2**
per:date_of_birth	59.1	94.4	100.0	100.0	94.4	100.0	74.3	94.4	**100.0**
per:place_of_death	55.4	92.4	86.1	86.1	58.9	63.6	67.4	71.9	**73.1**
per:date_of_death	46.4	98.2	96.5	81.3	48.3	53.4	59.1	64.7	**68.8**
per:place_of_residence	60.0	68.9	68.9	40.4	64.2	61.3	48.3	**66.5**	64.9
per:school_attended	54.3	65.8	68.4	86.4	67.6	76.5	66.7	66.7	**72.2**
per:parents	41.9	75.7	73.0	68.4	31.8	50.0	52.0	44.8	**59.3**
per:sibling	50.0	76.2	76.2	61.5	59.3	55.2	55.2	**66.7**	64.0
per:spouse	36.0	63.3	81.7	78.3	54.3	49.5	49.3	58.5	**61.6**
per:children	39.5	61.8	76.4	73.2	58.5	71.6	51.3	60.1	**73.9**
per:other_family	23.1	66.7	71.4	75.0	53.9	53.6	35.3	59.6	**61.2**
overall	47.7	77.4	80.6	75.1	61.7	65.7	56.9	67.4	**71.6**

Table 1: performance on KBP 2013 (1:state-of-the-art; 2:rule-based; 3: SVMs).

2.3 Biographical Fact Extraction

For each relevant document of a given query, we use Stanford CoreNLP to find the coreferential mentions of the query and then return all the sentences which contain at least one query entity mention. For each trigger in a sentence, we extract the entities which satisfy fact-specific constraints within its scope. As shown in Figure 1, *brother* is the trigger for *per:siblings* and the candidate fact should be a person name. Thus we return all the person names (*e.g.*, *James*) within *brother*'s scope as the query *Paul*'s siblings.

3 Experiments and Discussion

3.1 Data

We use the KBP 2012 and 2013 SF corpora as the development and testing data sets respectively. There are 50 person queries each year.

From the KBP 2012 SF corpus, we annotated 2,806 sentences in formal writing from news reports as the gold-standard trigger scoping data set. We randomly partitioned the labeled data and performed ten-fold cross-validation using LIBSVM toolkit (Chang and Lin, 2011). We employ the classification model trained from all the labeled sentences to classify tokens in the unlabeled sentences.

3.2 Results

3.2.1 Scope Identification

The scope identification evaluation results of the rule-based method and the SVMs with the RBF kernel are presented in Table 2. We can see that the supervised classification method performs better since it incorporates the weights of different features rather than simply applying hard constraints. In addition, it allows the answers to appear before a trigger as shown in the following sentence. Our rule-based method fails to extract *Fred* since it appears before the trigger *married*:

*She was a part of a group of black intellectuals who included philosopher and poet [**Fred Clifton**, whom she <**married**> in 1958].*

Fact Group	Accuracy (%)		F-score (%)	
	Rule	SVMs	Rule	SVMs
Birth	85.97	**96.66**	80.01	**94.21**
Death	92.31	**94.56**	82.16	**89.01**
Residence	90.67	**95.67**	76.11	**83.25**
Family	92.49	**94.11**	75.30	**77.31**
Education	91.51	**93.87**	88.46	**90.65**

Table 2: Scope identification results.

3.2.2 Biographical Fact Extraction

The fact extraction results in Table 1 demonstrate our trigger scoping strategy can outperform state-of-the-art methods. For a certain fact type, we choose the SF system which has the best performance for comparison. Specifically, we compare with two successful approaches: (1) the combination of distant supervision and rules (*e.g.*, (Grishman, 2013; Roth et al., 2013)); (2) patterns based on dependency paths (*e.g.*, (Li et al., 2013; Yu et al., 2013)).

The advantage of our method lies in trigger-driven

exploration. The positions of facts in the sentence can be very flexible and therefore difficult to be captured using a limited number of patterns. For example, the patterns in table 2[3] fail to extract *James* in Figure 1. However, the ways in which we express the trigger and words it dominated tend to be relatively fixed. For example, all the following patterns contain a fact-specific trigger and also facts usually appear within its scope.

PER:SIBLING
[Q] poss^{-1} **brother** appos **[A]**
[Q] appos^{-1} **brother** appos **[A]**
[Q] appos **brother** appos-1 **[A]**
[Q] nsubjpass^{-1} survived agent **brother** appos **[A]**
[Q] poss^{-1} **sister** appos **[A]**
[Q] appos^{-1} **sister** appos **[A]**
[Q] appos **sister** appos^{-1} **[A]**
[Q] nsubjpass^{-1} survived agent **sister** appos **[A]**

Table 3: Patterns used for extracting sibling facts (Li et al., 2013). Q: Query, A: Answer.

The limitation of our method is that we assume a sentence centers around only one person thus every biographical fact mentioned should be related to the centroid person. For example, our method mistakenly extracted *February* as the death-date fact for both *Reina* and *Orlando* in the following case.

*Also at the mass was **Reina Tamayo**, the mother of **Orlando Zapata**, who [<**died**> in February] after an 85-day hunger strike to protest the fate of political prisoners here.*

In order to solve this problem, we need to further analyze the relation between the query entity mention and the trigger so that we can identify *Orlando Zapata* is irrelevant to the death-related fact.

4 Related Work

Previous successful approaches to construct the biographical knowledge base are relatively expensive: Distant Supervision (Surdeanu et al., 2010) relies upon external knowledge bases and it is time-consuming to manually write or edit patterns (Sun et al., 2011; Li et al., 2012). The main impact of our trigger scoping strategy is to narrow down the text span of searching for facts, from sentence-level to fragment-level. We only focus on analyzing the content which is likely to contain an answer.

Our trigger scoping method is also partially inspired from the negation scope detection work (*e.g.*, (Szarvas et al., 2008; Elkin et al., 2005; Chapman et al., 2001; Morante and Daelemans, 2009; Agarwal and Yu, 2010)) and reference scope identification in citing sentences (Abu-Jbara and Radev, 2011; Abu-Jbara and Radev, 2012).

5 Conclusions and Future Work

In this paper we explore the role of triggers and their scopes in biographical fact extraction. We implement the trigger scoping strategy using two simple but effective methods. Experiments demonstrate that our approach outperforms state-of-the-art without any syntactic analysis and external knowledge bases.

In the future, we will aim to explore how to generate a trigger list for a "surprise" new fact type within limited time.

Lachmannian Archetype Reconstruction for Ancient Manuscript Corpora

Armin Hoenen
Goethe University
Robert- Mayer Strasse 10

hoenen@em.uni-frankfurt.de

Abstract

Two goals are targeted by computer philology for ancient manuscript corpora: firstly, making an edition, that is roughly speaking one text version representing the whole corpus, which contains variety induced through copy errors and other processes and secondly, producing a stemma. A stemma is a graph-based visualization of the copy history with manuscripts as nodes and copy events as edges. Its root, the so-called archetype, is the supposed original text or *urtext* from which all subsequent copies are made. Our main contribution is to present one of the first computational approaches to automatic archetype reconstruction and to introduce the first text-based evaluation for automatically produced archetypes. We compare a philologically generated archetype with one generated by bio-informatic software.

1 Introduction

In philology, oftentimes more than one single manuscript of the same *tradition* (that is, the same text) has survived. These manuscripts often differ in their wording in various places since copy errors, corrections, and other processes have led to deviation from the original text. This causes two problems: uncertainty about the original wording and uncertainty about which manuscript has been copied from which other.

The reconstruction of the copy history of manuscript texts is largely similar to that of DNA, which is why phylogenetic approaches have been adopted (Robinson and O'Hara, 1996; Robinson et al., 1998; van Reenen et al., 1996; van Reenen et al., 2004; Spencer et al., 2004; Roos and Heikkilä, 2009; Roelli and Bachmann, 2010; Andrews and Macé, 2013). However, the main goal of the philological work on ancient manuscripts is not the reconstruction of the copy history but compiling an edition of a historical text. This entails reducing the variation encountered so that one single main text as the prototypical representation of the manuscript corpus emerges. Ideally, this text is believed to be the author's original or closest possible to it. Two model approaches to making an edition are most widespread. The earlier one by Lachmann (see for instance Lachmann (1853)) opts for reconstructing an urtext actively, that is if needed by means of *emendation*, which refers to inferring the original (authorial) wording from the extant variants even if the so-inferred form is not itself extant and thus not attested in any of the manuscripts. The later approach after Bédier (see for instance Bédier (1928)) bases the edition directly on the text of the best available manuscript.

In this paper, we will present a first automatic implementation of the earlier approach. Additionally, an algorithm for evaluation of a so-reconstructed text will be presented and applied to artificial benchmark data sets (gold standard). First, we will introduce the data sets. Then, two methods, rule-based (using philological principles) and statistical (likelihood-based using bio-informatic software) will be explained in detail before the results are being presented, followed by a general discussion, a field specific discussion, and a conclusion and outlook.

Text	Lang	MS	Tok
Parzival	English	21	957
Notre Besoin	French	13	1029

Table 1: The artificial traditions. MS = number of manuscripts, Tok = number of tokens, Lang = language

2 Artificial Traditions

An *artificial tradition* is a fully digitized set of manuscripts which have been produced through manual copying in recent times whilst recording the true copy history/genealogical relationships. Three of these corpora have been published to date, *Parzival* by (Spencer et al., 2004), *Notre Besoin* by (Baret et al., 2004), and *Heinrichi* by (Roos and Heikkilä, 2009). They are provided in a fully word-aligned tabular version by the authors, so that collation must not be performed anymore. We excluded the Heinrichi tradition from computation as Old Finnish data could not be interpreted by us. Table 1 displays the composition of the artificial traditions we used.

3 Method

Contrasting a rule-based and a statistical approach, we automatically reconstruct the archetype text for the two aforementioned traditions. To the best of our knowledge, this paper treats automatic archetype reconstruction in connection with evaluation for the first time and applies suitable bio-informatic programs for the first time. While the transfer of biological software to philology, especially in stemmatics, is done since the 1990ies, (O'Hara, 1996), purely philological automatic reconstructions are a recent development. As input for both reconstruction methods, we use the same tree, generated by bio-informatic software. Corresponding to this tree, we reconstruct the archetype using a) a philological rule-based majority-vote bottom-up algorithm and b) statistical bio-informatic software.

3.1 Philological Reconstruction

A lost manuscript text can be reconstructed in different ways given a precomputed stemma. The key question is how to resolve variation. Depending on a concrete decision rule for disambiguation of variation among the direct descendents of a lost manuscript node, there are several possible reconstructions, which means one stemma can correspond to several possible archetype texts (depending on the decision rule). We implement the majority-vote decision rule as referred to frequently in philological discourse, see for instance (West, 1973). The algorithm simply assigns the most frequent variant of all direct descendents. If more than one variant is most frequent, our reconstruction retains all for later disambiguation either through majority-vote in subsequent recursion steps or for manual disambiguation through the expert if more than one variants end undisambiguated in the reconstructed archetype. Lost text of leaf nodes should be pruned since their texts are more corrupt than the one of their ancestors, thus unnecessarily corrupting the tradition. This pruning roughly parallels the philological practice of *recensio*, the prior exclusion of uninformative manuscripts.

In mathematical terms, let S be a rooted stemmatic tree (directed acyclic) consisting of a set of vertices V, a set of edges E, and one root node v_0; Each vertex has an indegree of 1, only v_0 has no incoming edges. Let each vertex v_i be associated with a text $T_i \in T_{all}$, which is its textual content, $|V| = |T_{all}|$. While T_{all} is the set of all texts that really existed in the tradition, T' initially is the set of surviving texts, $T' \subseteq T_{all}$. The texts in T_{all} are aligned, that is each text consists of a sequence of tokens or reconstructed tokens $\{T_{i_i}, .., T_{i_n}\}$ and all T_i have the same length. A recontructed token can be a set of to be disambiguated tokens. For each $T_j \in T_{all} \setminus T'$, we reconstruct the lost text in the following way:

1. Collect all texts $\{T_k, .., T_m\}, 1 \leq (k, m) \leq |T_{all}| - 1; k, m \neq j$ associated with the vertices $\{v_k, .., v_m\}$ which are direct descendents of vertex v_j, which is associated with T_j. If one of the texts in $\{T_k, .., T_m\}$ is itself not in T', delay the actual reconstruction and start a new reconstruction for the next unreconstructed text until all texts $\{T_k, .., T_m\}$ are reconstructed

2. Text reconstruction for each token T_{j_i}: $T_{j_i} = majority(\{T_{k_i}, .., T_{m_i}\})$; in case $|majority(\{T_{k_i}, .., T_{m_i}\})| > 1$ assign all variants to T_j (using a separator), if one of $\{T_{k_i}, .., T_{m_i}\}$ does already carry multiple variants, treat each one as one variant

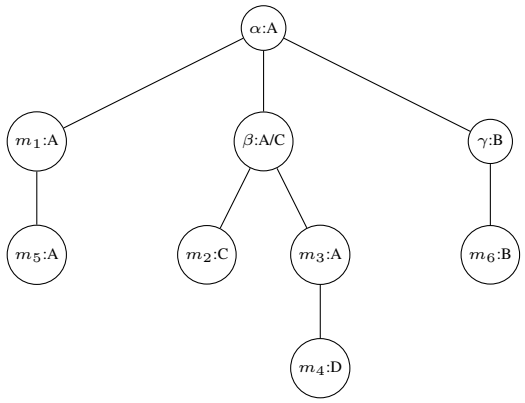

Figure 1: A simple stemma of a one word tradition, Greek letters denoting lost (hype)archetype(s). The Roman upper case letters refer to the observed variant (manuscripts m_i) or to the reconstructed variant ((hype)archetype(s)) inferred bottom-up.

m_1	m_2	m_3	m_4	**Variants**
this	t'	it	dis	A-D
is	is	is	is	A
a	an	a		A-C
text	text	text	text	A

and compute the majority variant (example: $\{T_{2_i}, T_{5_i}\} = \{this/tis, tis\}$ then $majority(\{T_{2_i}, T_{5_i}\}) = tis$)

3. $T' = T' \cup T_j$; if $T' = T_{all}$ end else start next reconstruction

For an example see Figure 1.

3.2 Bio-informatic Reconstruction

In bio-informatics, reconstruction of ancestral genomes has been undertaken. The most famous case is presumably that of the mammoths, (Miller et al., 2008). However, bacterial asexual reproduction is generally more similar to manuscript copying than mammalian sexual reproduction. Therefore and for other methodological reasons, it is more appropriate to transfer bacteriological reconstruction to philology. Bacteriologists sucessfully reconstructed the predecessors of yeast, (Voordeckers et al., 2012). Given a pregenerated tree, they used Bayesian marginal and joint probabilities to generate the sequences best explaining the tree. A program performing this is PAML, (Yang, 2007).

We converted the already word-aligned traditions into sequences of letters for each manuscript, see Table 2. Each letter encodes the variant the current manuscript carries at the current position. For the so-produced pseudo-DNA sequences, the PAML software generates a stemmatic tree using the maximum likelihood (ML) criterion without resolving variation at inferred internodes. This ML tree or any other can be used as input to generate ancestral sequences at the internodes and the root node using an optimization with a) marginal probabilities, for details see (Yang et al., 1995) and b) an optimization with joint probabilities, for details see (Pupko et al., 2000). Yang (2007) states that the results of a) and b) differ only in borderline cases. Indeed we found, that the respectively produced archetypes were identical in our case.

The ML tree is usually bifurcating, generating many internodes and an extra-corporal root. Although in our context, it challenges performance of automatic reconstruction, bifurcations are not a circumstance necessarily paralleling philology closely, (Howe et al., 2012).

4 Evaluation

For each position of the alignment, a produced archetype (PA) is compared to the original archetype present in the benchmark data sets. Whenever the PA has at least one variant at the current position corresponding to the archetype, an agreement score is incremented by one divided through the number of current variants in the PA. This assumes implicitly that manual disambiguation is at random and represents therefore a baseline evaluation. The agreement score is divided by the number of positions in the alignment to give the total precision of the PA text. This evaluation is called whole text evaluation (WTE). It serves as an orientation point towards the overall reliability of the reconstructed text as a whole. A second evaluation concerns the proportion of correctly disambiguated positions of variation. That agreement score is produced in the same way as described above, but only for positions where the corpus had variation. This evaluation is called po-

Tradition	WTE	PVE	ASD
Parzival(PAML)	0.91	0.73	51.38
Parzival(MV)	0.96	0.88	
Notre Besoin(PAML)	0.95	0.9	54.95
Notre Besoin(MV)	0.97	0.94	

Table 3: Evaluation of the archetypes by PAML and majority-vote (MV). ML trees evaluated with ASD.

sition of variation evaluation (PVE). Formally, both WTE and PVE can be represented by

$$\frac{\sum_{i=0}^{n} \frac{\mathbb{1}_{C_i}(a_i)}{|C_i|}}{n}, \mathbb{1}_{C_i}(a_i) = \begin{cases} 1 & \text{if } a_i \in C_i \\ 0 & \text{if } a_i \notin C_i \end{cases} \quad (1)$$

where n is either the number of words in the alignment (WTE) or the number of positions of variation (PVE), a is the archetype, a_i the i-th token in the archetype, and C_i the set of variants of the PA at the i-th position.

5 Results

We evaluated the PAs (rule-based and statistical) with WTE and PVE and additionally evaluated the initial ML trees against the true stemma by means of the graph-based Average Sign Distance (ASD),[1] a measure of distance of genealogical trees using vertex triple distances as described in (Roos and Heikkilä, 2009). In order to achieve this, we converted the stemmas automatically from the Newick output format by PAML into the required format of the ASD. Results are displayed in Table 3. The philological reconstruction outperformed the PAML one in both cases.

In order to assess the quality of these results, we produced the majority archetype (MA), which at each position carried the majority variant. Additionally, we produced a random archetype (RA), where a randomizer as implemented in the Java programming language chose one variant at random for every place of variation. The RA was then evaluated. This procedure was repeated 1000 times and then we averaged over the RA evaluation results. As a point of orientation, we additionally provide the evaluation score of the maximally wrong archetype (MW), which is the one archetype that has a non-archetypical variant at each position where variation occurred. Note that none of these automatically produced archetypes requires a stemma beforehand. The results are displayed in Table 4. The RAs are considerably better than the MWs, but are clearly outperformed by both reconstructions and the MAs.

[1] For details, data sets and evaluation scripts, browse `http://www.cs.helsinki.fi/u/ttonteri/casc`.

α(P/NB)	WTE	PVE
MW(P)	0.68	0
RA(P)	0.8	0.38
MA(P)	0.96	0.87
MW(NB)	0.52	0
RA(NB)	0.76	0.49
MA(NB)	0.98	0.95

Table 4: Evaluation of archetypes. α as used in philology denotes the archetype. We evaluated the majority archetypes (MA), the averaged random archetypes (RA) and the maximally wrong archetypes (MW) for the Parzival (P) and Notre Besoin (NB) traditions.

6 Discussion

The MA and MV archetypes are the most accurate ones. Hence, the true distribution of variants considering all manuscripts is such that the majority variant in the majority of cases is the archetypical one. Whether this conclusion holds for historical corpora remains to be shown. The PAML-generated archetypes performed well and were considerably better than the random condition. Note that the ML tree's ASD score was relatively low as compared to other algorithms evaluated in (Roos and Heikkilä, 2009). The limitation of the current reconstruction is that at each position the reconstructed text can only carry one of the variants of the extant manuscripts. This makes any reconstruction with many reconstructed internodes, such as the MVs or the PAML reconstructions by definition quite similar to the MAs.

6.1 Comparing Stemma and Archetype Production

From a bad stemma, disambiguation rules can nevertheless produce an accurate archetype and vice versa. One stemma can correspond to several possible archetypes and one archetype can be consistent with several different stemmas. The two tasks

and evaluations should therefore be considered separately. This is of utter importance as it points to an imbalance of computational effort in the field.

6.2 Implications for Computer Philology

In biology the establishment of genealogical relations is in its own rights a primary goal, reconstruction of ancestral sequences being rather secondary. On the contrary in philology, compiling an edition is not only historically preceeding stemmatology, but can be considered the main target of dealing with manuscript corpora. Stemma construction is rather a secondary goal.[2] Despite this imbalance between the fields, the technological emphasis is on genealogical trees in both. This may be seen as a computer philological co-loan from bio-informatics. On the other hand it might correspond to a more Bédierian edition practise, where stemmatology is emphasized because it can point to the most important manuscript, which is however implicit and unlikely. Another reason for a benefit resulting from a shifting focus onto automatic archetype reconstruction is the problem of having two vorlages for one copy called *contamination*. Whilst especially excessive contamination is a bad problem for stemmatology, (Maas, 1960), considering automatic archetype reconstruction, on a word level it doesn't increase diversity and should therefore be a less severe problem.

For both traditions, the produced archetype was reasonably accurate. The automatisation of this process could thus accelerate the production of editions, making them most dependent on the indispensable digitization of corpora.

6.3 Implications for Bio-Informatics

In biology, reconstructive algorithms such as the one by Yang (2007) have been developed alongside biological benchmark data sets enumerated by Linder et al. (2010). However, in stemmatology, the probability to have a manuscript and its copy in the corpus at the same time is disproportionately higher than in the biological case making archetype production more transparent here. The resulting algorithmic conclusions from philology could therefore enrich the field of ancestral sequence reconstruction.

[2]For more details, consider for instance Pasquali (1988), Timpanaro (2005), and Reynolds & Wilson (2013).

7 Conclusion and Outlook

We have presented an automated reconstruction of an archetypical text through philological rules and phylogenetic software. Additionally, we invented an evaluation for the produced archetypes, where we found the reconstruction to produce results considerably above chance level.

The inversion of the process is implicit. From a (manually or automatically) constructed archetype, all possible corresponding stemmas on the given set of manuscript digitizations can be computed and evaluated, which would be a new approach to stemmatology. Both tasks could thus profit from each other provided they are understood as separate and developed each in its own right.

Many issues remain unaddressed. The phenomena encountered in manuscripts are much more varied than word substitutions as modelled in this paper; an enumeration of some of the phenomena will corroborate this: word deletions, word separation errors, whole passages missing, text on the margins, unreadable or destructed text, crossing out of sections, oral variation, contamination. Trovato (2009) claims that manuscript loss of far more than 90% is realistic. In linguistics, historical-comparative studies have engaged in using bio-informatic software for instance in connection with the recontruction of language family trees. For automatic emendation these studies as well as the reconstruction of unattested word forms are a valuable source. Stemmatology itself offers ever new algorithms, artificial traditions and tools for electronic editing.

In the light of these manifold possibilities for elaboration and cooperation, the current study presents but one entry point into automatic archetype reconstruction.

Acknowledgments

We greatfully acknowledge the financial support of the Goethe University, the Federal State of Hesse and the Federal Ministry of Education and Research BMBF. We express our gratitude to our colleagues of the Texttechnology Lab for valuable comments, help and advice.

Distributed Representations of Words to Guide Bootstrapped Entity Classifiers

manning@stanford.edu

Abstract

Bootstrapped classifiers iteratively generalize from a few seed examples or prototypes to other examples of target labels. However, sparseness of language and limited supervision make the task difficult. We address this problem by using distributed vector representations of words to aid the generalization. We use the word vectors to expand entity sets used for training classifiers in a bootstrapped pattern-based entity extraction system. Our experiments show that the classifiers trained with the expanded sets perform better on entity extraction from four online forums, with 30% F_1 improvement on one forum. The results suggest that distributed representations can provide good directions for generalization in a bootstrapping system.

1 Introduction

Bootstrapped or distantly-supervised learning is a form of semi-supervised learning, in which supervision is provided by seed examples. Supervised machine learning systems, on the other hand, require hand-labeling sufficient data to train a model, which can be costly and time consuming. Bootstrapped information extraction (IE) has become even more pertinent with the ever-growing amount of data coupled with the emergence of open IE systems (Carlson et al., 2010; Fader et al., 2011) and shared tasks like TAC-KBP.[1]

Limited supervision provided in bootstrapped systems, though an attractive quality, is also one of its main challenges. When seed sets are small, noisy, or do not cover the label space, the bootstrapped classifiers do not generalize well.

We use a major guiding inspiration of deep learning: we can learn a lot about syntactic and semantic similarities between words in an unsupervised fashion and capture this information in word vectors. This distributed representation can inform an inductive bias to generalize in a bootstrapping system.

In this paper, we present a simple approach of using the distributed vector representations of words to expand training data for entity classifiers in a bootstrapped system (see Algorithm 1). To improve the step of learning an entity classifier, we first learn vector representation of entities using the continuous bag of words model (Mikolov et al., 2013a). We then use kNN to expand the training set of the classifier by adding unlabeled entities close to seed entities in the training set. The key insight is to use the word vector similarity indirectly by enhancing training data for the entity classifier. We do not directly label the unlabeled entities using the similarity between word vectors, which we show extracts many noisy entities. We show that classifiers trained with expanded sets of entities perform better on extracting drug-and-treatment entities from four online health forums from MedHelp.[2]

2 Related Work

Bootstrapping has many variants, such as self-training, co-training, and label propagation. Yarowsky's style of self-training algo-

rithms (Yarowsky, 1995) have been shown to be successful at bootstrapping (Collins and Singer, 1999). Co-training (Blum and Mitchell, 1998) and its boostrapped adaptation (Collins and Singer, 1999) require disjoint views of the features of the data. Whitney and Sarkar (2012) proposed a modified Yarowsky algorithm that used label propagation on graphs, inspired by Subramanya et al. (2010) algorithm that used a large labeled data for domain adaptation.

In this paper, we use the setting of bootstrapped pattern-based entity extraction (Riloff, 1996; Thelen and Riloff, 2002). This can be viewed as a form of the Yarowsky algorithm, with pattern learning as an additional step. Pattern based approaches have been widely used for IE (Chiticariu et al., 2013; Fader et al., 2011; Etzioni et al., 2005). Patterns are useful in two ways: they are good features, and they identify promising candidate entities. Recently, Gupta and Manning (2014) improved pattern scoring (Step 2 in Algorithm 1) using predicted labels of unlabeled entities. For entity scoring (Step 3), they used an average of feature values to predict the scores. We use the same framework but focus on improving the entity classifiers.

In most IE systems, including ours, word classes or word vectors are used as features in a classifier (Haghighi and Klein, 2006; Ratinov and Roth, 2009).

To the best of our knowledge, our work is the first to use distributed representations of words to improve a bootstrapped system by expanding the training set.

3 Background

In a bootstrapped pattern-based entity learning system, seed dictionaries and/or patterns provide weak supervision to label data. The system iteratively learns new entities belonging to a specific label from unlabeled text (Riloff, 1996; Collins and Singer, 1999) using patterns, such as lexico-syntactic surface word patterns (Hearst, 1992) and dependency tree patterns (Yangarber et al., 2000). We use lexico-syntactic surface word patterns to extract entities from unlabeled text starting with seed dictionaries for multiple classes. Algorithm 1 gives an overview. In this paper, we focus on improving the entity classifier (Step 3) by expanding its training data using distributed vector representations of words.

Algorithm 1 Bootstrapped Pattern-based Entity Extraction

Given: Text D, labels L, seed entities $E_l \; \forall l \in$ L
while not-terminating-condition (e.g. precision is high) **do**
 for $l \in L$ **do**
  1. Label D with E_l
  2. Create patterns around labeled entities. Learn good patterns and use them to extract candidate entities C_l.
  3. Learn an entity classifier and classify C_l. Add new classified entities to E_l.

Labeling known entities: The text is labeled using the label dictionaries, starting with the seed dictionaries in the first iteration.

Creating and Learning Patterns: Patterns are then created using the context around the labeled entities to create candidate patterns for label l. Candidate patterns are scored using a pattern scoring measure and the top ones are added to the list of learned patterns for label l. In our experiments, we use a widely used pattern scoring measure, RlogF (Riloff, 1996; Thelen and Riloff, 2002). Top ranked patterns with scores above a certain threshold are used to extract candidate entities C_l from text.

Learning entities: An entity classifier predicts the labels of C_l and adds the newly classified entities to label l's dictionary, E_l. We discard common words, negative entities, and those containing non-alphanumeric characters from the set.

Entity Classifier We build a one-vs-all entity classifier using logistic regression. In each iteration, for label l, the entity classifier is trained by treating l's dictionary entities (seed and learned in previous iterations) as positive and entities belonging to all other labels as negative. To improve generalization, we also sample the unlabeled entities that are not function words as negative. To train with a balanced dataset, we randomly sub-sample the negatives such that the number of negative instances is equal to the number of positive instances. The features for the entities are similar to Gupta and Manning (2014): edit distances from positive and negative entities, relative frequency of the entity words

in the seed dictionaries, word classes computed using the Brown clustering algorithm (Brown et al., 1992; Liang, 2005), and pattern TF-IDF score. The last feature gives higher scores to entities that are extracted by many learned patterns and have low frequency in the dataset. In our experiments, we call this classifier as *NotExpanded*.

4 Approach

The lack of labeled data to train a good entity classifier is one of the challenges in bootstrapped learning. We use distributed representations of words, in the form of word vectors, to guide the entity classifier by expanding its training set. As explained in the previous section, we train a one-vs-all entity classifier in each iteration of the bootstrapped entity extraction for each label. We use unlabeled entities that are similar to the seed entities of the label as positive examples, and use unlabeled entities that are similar to seed entities of other labels as negative examples.[3]

To compute similarity of an unlabeled entity to the positive entities, we find k most similar positive entities, measured by cosine similarity between the word vectors, and average the scores. Similarly, we compute similarity of the unlabeled entity to the negative entities. If the entity's positive similarity score is above a given threshold θ and is higher than its negative similarity score, it is added to the training set with positive label. We expand the negative entities similarly.[4]

An alternative to our approach is to directly label the entities using the vector similarities. Our experimental results suggest that even though exploiting similarities between word vectors is useful for guiding the classifier by expanding the training set, it is not robust enough to use for labeling entities directly. For example, for our development dataset, when θ was set as 0.4, 16 out of 41 unlabeled entities that were expanded into the training set as positive entities were false positives.[5] Thus, labeling entities solely based on similarity scores resulted in lower performance. A classifier, on the other hand, can use other sources of information as features to predict an entity's label.

We compute the distributed vector representations using the continuous bag-of-words model (Mikolov et al., 2013a; Mikolov et al., 2013b) implemented in the word2vec toolkit.[6] We train 200-dimensional vector representations on a combined dataset of a 2014 Wikipedia dump (1.6 billion tokens), a sample of 50 million tweets from Twitter (200 million tokens), and an in-domain dataset of all MedHelp forums (400 million tokens). We removed words that occurred less than 20 times, resulting in a vocabulary of 89k words. We call this dataset Wiki+Twit+MedHelp. We used the parameters suggested in Pennington et al. (2014): negative sampling with 10 samples and a window size of 10. We ran the model for 3 iterations.

5 Experimental Setup

We present results on the same experimental setup, dataset, and seed lists as used in Gupta and Manning (2014). The task is to extract drug-and-treatment (DT) entities in sentences from four forums on the MedHelp user health discussion website: 1. Asthma, 2. Acne, 3. Adult Type II Diabetes (called Diabetes), and 4. Ear Nose & Throat (called ENT). A DT entity is defined as a pharmaceutical drug, or any treatment or intervention mentioned that may help a symptom or a condition. The output of all systems were judged by the authors, following the guidelines in (Gupta and Manning, 2014). We used Asthma as the development forum for parameter and threshold tuning. We used threshold θ as 0.4 and use k (number of nearest neighbors) as 2 when expanding the seed sets.

We evaluate systems by their precision and recall. Precision is defined as the fraction of correct entities among the entities extracted. Similar to (Gupta and Manning, 2014), we present the precision and recall curves for precision above 75% to compare systems when they extract entities with reasonably

[3] We take the cautious approach of finding similar entities only to the seed entities and not the learned entities. The algorithm can be modified to find similar entities to learned entities as well. Cautious approaches have been shown to be better for bootstrapped learning (Abney, 2004).

[4] We tried expanding just the positive entities and just the negative entities. Their relative performance, though higher than the baselines, varied between the datasets. Thus, for conciseness, we present results only for expanding both positives and negatives.

[5] Increasing θ extracted far fewer entities. $\theta = 0.5$ extracted only 5 entities, all true positives, and $\theta = 0.6$ extracted none.

Forum	Expanded	Expanded-M	NotExpanded	Average
Asthma	**77.01**	75.68	74.48	65.42
Acne	73.84	**75.41**	71.65	65.05
Diabetes	**82.37**	44.25	48.75	21.82
ENT	**80.66**	80.04	77.02	59.50

Table 1: Area under Precision-Recall curve for all the systems. Expanded is our system when word vectors are learned using the Wiki+Twit+MedHelp data and Expanded-M is when word vectors are learning using the MedHelp data.

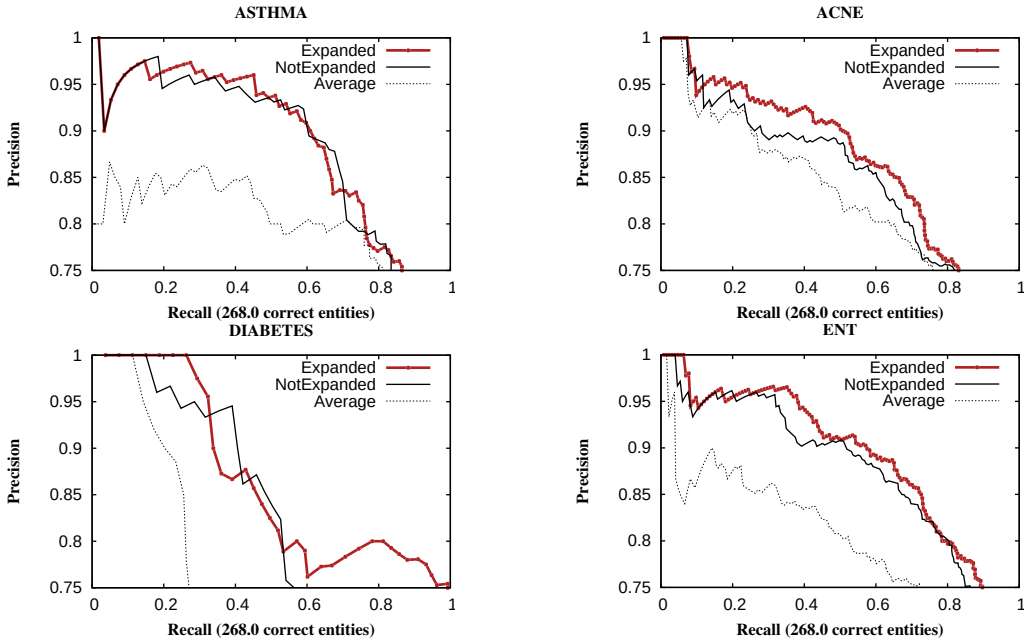

Figure 1: Precision vs. Recall curves of our system and the baselines for the four forums.

high precision. Recall is defined as the fraction of correct entities among the total unique correct entities pooled from all systems.[7] We calculate the area under the precision-recall curves (AUC-PR) to compare the systems.

We call our system *Expanded* in the experiments. To compare the effects of word vectors learned using different types of datasets, we also study our system when the word vectors are learned using just the in-domain MedHelp data, called *Expanded-M*. We compare against two baselines: *NotExpanded* as explained in Section 3, and *Average*, in which we average the feature values, similar to (Gupta and Manning, 2014).

6 Results and Discussion

Table 1 shows AUC-PR of various systems and Figure 1 shows the precision-recall curves. Our systems *Expanded* and *Expanded-M*, which used similar entities for training, improved the scores for all four forums. We believe the improvement for the Diabetes forum was much higher than other forums because the baseline's performance on the forum degraded quickly in later iterations (see the figure), and improving the classifier helped in adding more correct entities. Additionally, Diabetes DT entities are more lifestyle-based and hence occur frequently in web text, making the word vectors trained using the Wiki+Twit+MedHelp dataset better suited.

In three out of four forums, word vectors trained

[7]Note that calculating lower precisions or true recall is very hard to compute. Our dataset is unlabeled and manually labeling all entities is expensive. Pooling is a common evaluation strategy in such situations (such as, TAC-KBP shared task).

Positives	Negatives
Asthma

Diabetes	
quinoa, vinegars, vegatables, threadmill, possilbe, asanas, omegas	nicely, chiropracter, exhales, paralytic, metabolize, fluffy

Table 2: Examples of unlabeled entities that were expanded into the training sets. Gray colored entities were judged by the authors as falsely labeled.

using a large corpus perform better than those trained using the smaller in-domain corpus. For the Acne forum, where brand name DT entities are more frequent, the entities expanded by MedHelp vectors had fewer false positives than those expanded by Wiki+Twit+MedHelp.

Table 2 shows some examples of unlabeled entities that were included as positive/negative entities in the entity classifiers. Even though some entities were included in the training data with wrong labels, overall the classifiers benefited from the expansion.

7 Conclusion

We improve entity classifiers in bootstrapped entity extraction systems by enhancing the training set using unsupervised distributed representations of words. The classifiers learned using the expanded seed sets extract entities with better F_1 score. This supports our hypothesis that generalizing labels to entities that are similar according to unsupervised methods of word vector learning is effective in improving entity classifiers, notwithstanding that the label generalization is quite noisy.

Multi-Task Word Alignment Triangulation for Low-Resource Languages

Tomer Levinboim and **David Chiang**

University of Notre Dame
{levinboim.1,dchiang}@nd.edu

Abstract

We present a multi-task learning approach that jointly trains three word alignment models over disjoint bitexts of three languages: source, target and pivot. Our approach builds upon model triangulation, following Wang et al., which approximates a source-target model by combining source-pivot and pivot-target models. We develop a MAP-EM algorithm that uses triangulation as a prior, and show how to extend it to a multi-task setting. On a low-resource Czech-English corpus, using French as the pivot, our multi-task learning approach more than doubles the gains in both F- and B scores compared to the interpolation approach of Wang et al. Further experiments reveal that the choice of pivot language does not significantly affect performance.

1 Introduction

Word alignment (Brown et al., 1993; Vogel et al., 1996) is a fundamental task in the machine translation (MT) pipeline. To train good word alignment models, we require access to a large parallel corpus. However, collection of parallel corpora has mostly focused on a small number of widely-spoken languages. As such, resources for almost any other pair are either limited or non-existent.

To improve word alignment and MT in a low-resource setting, we design a multitask learning approach that utilizes parallel data of a third language, called the *pivot* language (§3). Specifically, we derive an efficient and easy-to-implement MAP-EM-like algorithm that jointly trains source-target, source-pivot and pivot-target alignment models, each on its own bitext, such that each model benefits from observations made by the other two.

Our method subsumes the model interpolation approach of Wang et al. (2006), who independently train these three models and then interpolate the source-target model with an approximate source-target model, constructed by combining the source-pivot and pivot-target models.

Pretending that Czech-English is low-resource, we conduct word alignment and MT experiments (§4). With French as the pivot, our approach significantly outperforms the interpolation method of Wang et al. (2006) on both alignment F- and B scores. Somewhat surprisingly, we find that our approach is insensitive to the choice of pivot language.

2 Triangulation and Interpolation

Wang et al. (2006) focus on learning a word alignment model without a source-target corpus. To do so, they assume access to both source-pivot and pivot-target bitexts on which they independently train a source-pivot word alignment model $\Theta_{\mathtt{sp}}$ and a pivot-target model $\Theta_{\mathtt{pt}}$. They then combine the two models by marginalizing over the pivot language, resulting in an approximate source-target model $\Theta_{\widetilde{\mathtt{st}}}$. This combination process is referred to as *triangulation* (see §5).

In particular, they construct the triangulated source-target t-table $\mathtt{t}_{\widetilde{\mathtt{st}}}$ from the source-pivot and pivot-target t-tables $\mathtt{t}_{\mathtt{sp}}, \mathtt{t}_{\mathtt{pt}}$ using the following approximation:

$$\begin{aligned} \mathtt{t}_{\widetilde{\mathtt{st}}}(t \mid s) &= \sum_p \mathtt{t}(t \mid p, s) \cdot \mathtt{t}(p \mid s) \\ &\approx \sum_p \mathtt{t}_{\mathtt{pt}}(t \mid p) \cdot \mathtt{t}_{\mathtt{sp}}(p \mid s) \end{aligned} \quad (1)$$

Subsequently, if a source-target corpus is available, they train a standard source-target model $\Theta_{\mathtt{st}}$, and tune the interpolation

$$\hat{\mathtt{t}}_{\mathtt{st}} = \lambda_{\text{interp}} \mathtt{t}_{\mathtt{st}} + (1 - \lambda_{\text{interp}}) \mathtt{t}_{\widetilde{\mathtt{st}}}$$

with respect to λ_{interp} to reduce alignment error rate (Koehn, 2005) over a hand-aligned development set.

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1221–1226,
Denver, Colorado, May 31 – June 5, 2015.

Wang et al. (2006) propose triangulation heuristics for other model parameters; however, in this paper, we consider only t-table triangulation.

3 Our Method

We now discuss two approaches that better exploit model triangulation. In the first, we use the triangulated t-table to construct a prior on the source-target t-table. In the second, we place a prior on each of the three models and train them jointly.

3.1 Triangulation as a Fixed Prior

We first propose to better utilize the triangulated t-table $\mathtt{t}_{\widetilde{\mathtt{st}}}$ (Eq. 1) by using it to construct an informative prior for the source-target t-table $\mathtt{t}_{\mathtt{st}} \in \Theta_{\mathtt{st}}$.

Specifically, we modify the word alignment generative story by placing Dirichlet priors on each of the multinomial t-table distributions $\mathtt{t}_{\mathtt{st}}(\cdot \mid s)$:

$$\mathtt{t}_{\mathtt{st}}(\cdot \mid s) \sim \text{Dirichlet}(\alpha_s) \qquad \text{for all } s. \tag{2}$$

Here, each $\alpha_s = (\ldots, \alpha_{st}, \ldots)$ denotes a hyperparameter vector which will be defined shortly.

Fixing this prior, we optimize the model posterior likelihood $P(\Theta_{\mathtt{st}} \mid \mathtt{bitext}_{\mathtt{st}})$ to find a maximum-*a-posteriori* (MAP) estimate. This is done according the MAP-EM framework (Dempster et al., 1977), which differs slightly from standard EM. The E-step remains as is: fixing the model $\Theta_{\mathtt{st}}$, we collect expected counts $E[\mathtt{c}(s,t)]$ for each decision in the generative story. The M-step is modified to maximize the *regularized* expected complete-data log-likelihood with respect to the model parameters $\Theta_{\mathtt{st}}$, where the regularizer corresponds to the prior.

Due to the conjugacy of the Dirichlet priors with the multinomial t-table distributions, the sole modification to the regular EM implementation is in the M-step update rule of the t-table parameters:

$$\mathtt{t}_{\mathtt{st}}(t \mid s) = \frac{E[\mathtt{c}(s,t)] + \alpha_{st} - 1}{\sum_t (E[\mathtt{c}(s,t)] + \alpha_{st} - 1)} \tag{3}$$

where $E[\mathtt{c}(s,t)]$ is the expected number of times source word s aligns with target word t in the source-target bitext. Moreover, through Eq. 3, we can view $\alpha_{st} - 1$ as a pseudo-count for such an alignment.

To define the hyperparameter vector α_s we decompose it as follows:

$$\alpha_s = C_s \cdot m_s + 1 \tag{4}$$

where $C_s > 0$ is a scalar parameter, m_s is a probability vector, encoding the mode of the Dirichlet and 1 denotes an all-one vector. Roughly, when C_s is high, samples drawn from the Dirichlet are likely to concentrate near the mode m_s. Using this decomposition, we set for all s:

$$m_s = \mathtt{t}_{\widetilde{\mathtt{st}}}(\cdot \mid s) \tag{5}$$

$$C_s = \lambda \cdot \mathtt{c}(s)^{\gamma} \cdot \frac{\sum_{s'} \mathtt{c}(s')}{\sum_{s'} \mathtt{c}(s')^{\gamma}} \tag{6}$$

where $\mathtt{c}(s)$ is the count of source word s in the source-target bitext, and the scalar hyperparameters $\lambda, \gamma > 0$ are to be tuned (We experimented with completely eliminating the hyperparameters γ, λ by directly learning the parameters C_s. To do so, we implemented the algorithm of Minka (2000) for learning the Dirichlet prior, but only learned the parameters C_s while keeping the means m_s fixed to the triangulation. However, preliminary experiments showed performance degradation compared to simple hyperparameter tuning). Thus, the distribution $\mathtt{t}_{\mathtt{st}}(\cdot \mid s)$ arises from a Dirichlet with mode $\mathtt{t}_{\widetilde{\mathtt{st}}}(\cdot \mid s)$ and will tend to concentrate around this mode as a function of the frequency of s.

The hyperparameter λ linearly controls the strength of all priors. The last term in Eq. 6 keeps the sum of C_s insensitive to γ, such that $\sum_s C_s = \lambda \sum_s \mathtt{c}(s)$. In all our experiments we fixed $\gamma = 0.5$. Setting $\gamma < 1$ down-weights the parameter C_s of frequent words s compared to rare ones. This makes the Dirichlet prior relatively weaker for frequent words, where we can let the data speak for itself, and relatively stronger for rare ones, where a good prior is needed.

Finally, note that this EM procedure reduces to an interpolation method similar to that of Wang et al. by applying Eq. 3 only at the very last M-step, with α_s, m_s as above and $C_s = \lambda \sum_t E[\mathtt{c}(s,t)]$.

3.2 Joint Training

Next, we further exploit the triangulation idea in designing a multi-task learning approach that jointly trains the three word alignment models $\Theta_{\mathtt{st}}$, $\Theta_{\mathtt{sp}}$, and $\Theta_{\mathtt{pt}}$.

To do so, we view each model's t-table as originating from Dirichlet distributions defined by the triangulation of the other two t-tables. We then train

Algorithm 1 Joint training of $\Theta_{\mathtt{st}}, \Theta_{\mathtt{sp}}, \Theta_{\mathtt{pt}}$

Parameters: $\lambda, \gamma > 0$

- Initialize $\left\{\Theta_{\mathtt{st}}^{(0)}, \Theta_{\mathtt{sp}}^{(0)}, \Theta_{\mathtt{pt}}^{(0)}\right\}$
- Initialize $\{C_{\mathtt{s}}\}, \{C_{\mathtt{p}}\}, \{C_{\mathtt{t}}\}$ as in Eq. 6
- For each EM iteration i:

  Estimate hyperparameters α:

  1. Compute $\mathtt{t}_{\widetilde{\mathtt{st}}}^{(i)}$ from $\mathtt{t}_{\mathtt{sp}}^{(i-1)}$ and $\mathtt{t}_{\mathtt{pt}}^{(i-1)}$ (Eq. 1)
  2. Set $\alpha_{st}^{(i)} := C_s \cdot \mathtt{t}_{\widetilde{\mathtt{st}}}^{(i)}(t \mid s) + 1$

  E: collect expected counts $E[\mathtt{c}(\cdot)]^{(i)}$ from $\Theta_{\mathtt{st}}^{(i-1)}$

  M: Update $\Theta_{\mathtt{st}}^{(i)}$ using $E[\mathtt{c}(\cdot)]^{(i)}$ and $\alpha_{\mathtt{st}}^{(i)}$ (Eq. 3)

  Repeat for $\Theta_{\mathtt{sp}}^{(i)}, \Theta_{\mathtt{pt}}^{(i)}$ using Eq. 7 as required

the models in a MAP-EM like manner, updating both the model parameters and their prior hyperparameters at each iteration. Roughly, this approach aims at maximizing the posterior likelihood of the three models with respect to both model parameters and their hyperparameters (see Appendix).

Procedurally, the idea is simple: In the E-step, expected counts $E[\mathtt{c}(\cdot)]$ are collected from each model as usual. In the M-step, each t-table is updated according to Eq. 3 using the current expected counts $E[\mathtt{c}(\cdot)]$ and an estimate of α from the triangulation of the *most recent* version of the other two models. See Algorithm 1.

Note, however, that we cannot obtain the triangulated t-tables $\mathtt{t}_{\widetilde{\mathtt{sp}}}, \mathtt{t}_{\widetilde{\mathtt{pt}}}$ by simply applying the triangulation equation (Eq. 1). For example, to construct $\mathtt{t}_{\widetilde{\mathtt{sp}}}$ we need both source-to-target and target-to-pivot distributions. While we have the former in $\mathtt{t}_{\mathtt{st}}$, we do not have $\mathtt{t}_{\mathtt{tp}}$. To resolve this issue, we simply approximate $\mathtt{t}_{\mathtt{tp}}$ from the reverse t-table $\mathtt{t}_{\mathtt{pt}} \in \Theta_{\mathtt{pt}}$ as follows:

$$\mathtt{t}_{\mathtt{tp}}(p \mid t) := \frac{\mathtt{c}(p)\mathtt{t}_{\mathtt{pt}}(t \mid p)}{\sum_p \mathtt{c}(p)\mathtt{t}_{\mathtt{pt}}(t \mid p)} \tag{7}$$

where $\mathtt{c}(p)$ denotes the unigram frequency of the word $\mathtt{p}$. A similar transformation is done on $\mathtt{t}_{\mathtt{sp}}$ to obtain $\mathtt{t}_{\mathtt{ps}}$, which is then used in computing $\mathtt{t}_{\widetilde{\mathtt{pt}}}$.

3.3 Adjustment of the t-table

Note that a t-table resulting from the triangulation equation (Eq. 1) is both noisy and dense. To see why, consider that $\mathtt{t}_{\widetilde{\mathtt{st}}}(t \mid s)$ is non-zero whenever there is a pivot word p that co-occurs with both s and t. This is very likely to occur, for example, if p is a function word.

To adjust for both density and noise, we propose a simple product-of-experts re-estimation that relies on the available source-target parallel data. The two experts are the triangulated t-table as defined by Eq. 1 and the exponentiated pointwise mutual information (PMI), derived from simple token co-occurrence statistics of the source-target bitext. That is, we adjust:

$$\mathtt{t}_{\widetilde{\mathtt{st}}}(t \mid s) \quad := \quad \mathtt{t}_{\widetilde{\mathtt{st}}}(t \mid s) \cdot \frac{p(s,t)}{p(s)p(t)}$$

and normalize the result to form valid conditional distributions.

Note that the sparsity pattern of the adjusted t-table matches that of a co-occurrence t-table. We applied this adjustment in all of our experiments.

4 Experimental Results

Pretending that Czech-English is a low-resource pair, we conduct two experiments. In the first, we set French as the pivot language and compare our fixed-prior (Sec. §3.1) and joint training (Sec. §3.2) approaches against the interpolation method of Wang et al. and a baseline HMM word alignment model (Vogel et al., 1996).

In the second, we examine the effect of the pivot language identity on our joint training approach, varying the pivot language over French, German, Greek, Hungarian, Lithuanian and Slovak.

4.1 Data

For word alignment, we use the Czech-English News Commentary corpus, along with a development set of 460 hand aligned sentence pairs. For the MT experiments, we use the WMT10 tuning set (2051 parallel sentences), and both WMT09/10 shared task test sets. See Table 1.

For each of the 6 pivot languages, we created Czech-pivot and pivot-English bitexts of roughly the same size (ranging from 196k sentences for English-Greek to 223k sentences for Czech-Lithuanian). Each bitext was created by forming a Czech-pivot-English tritext, consisting of about 500k sentences

from the Europarl corpus (Koehn, 2005) which was then split into two disjoint Czech-pivot and pivot-English bitexts of equal size. Sentences of length greater than 40 were filtered out from all training corpora.

4.2 Experiment 1: Method Comparison

We trained word alignment models in both source-to-target and target-to-source directions. We used 5 iterations of IBM Model 1 followed by 5 iterations of HMM. We tuned hyperparameters to maximize alignment F-score of the hand-aligned development set. Both interpolation parameters λ_{interp} and λ were tuned over the range $[0, 1]$. For our methods, we fixed $\gamma = 0.5$, which we found effective during preliminary experiments. Alignment F-scores using grow-diag-final-and (gdfa) symmetrization (Koehn, 2010) are reported in Table 2, column 2.

We conducted MT experiments using the Moses translation system (Koehn, 2005). We used a 5-gram LM trained on the Xinhua portion of English Gigaword (LDC2007T07). To tune the decoder, we used the WMT10 tune set. MT B scores are reported in Table 2, columns 3–4.

Both our methods outperform the baseline and the interpolation approach. In particular, the joint training approach more than doubles the gains obtained by the interpolation approach, on both F- and B .

We also evaluated the Czech-French and French-English alignments produced as a by-product of our joint method. While our French-to-English MT experiments showed no improvement in B , we saw a +0.6 (25.6 to 26.2) gain in B on the Czech-to-French translation task. This shows that joint training may lead to some improvements even on high-resource bitexts.

4.3 Other Pivot Languages

We examined how the choice of pivot language affects the joint training approach by varying it over 6 languages (French, German, Greek, Hungarian, Lithuanian and Slovak), while keeping the size of the pivot language resources roughly the same.

	train	dev	WMT09	WMT10
sentences	85k	460	2525	2489
cz tokens	1.63M	9.7k	55k	53k
en tokens	1.78M	10k	66k	62k

Table 1: Czech-English sentence and token statistics.

	F	B	
method/dataset	**dev**	**WMT09**	**WMT10**
baseline	63.8	16.2	16.6
interpolation (Wang)	66.2	16.6	17.1
fixed-prior (§3.1)	67.3	16.9	17.3
joint (§3.2)	**70.1**	**17.2**	**17.7**

Table 2: F- and B scores for Czech-English via French. The joint training method outperforms all other methods tested.

	fr	fr, sk	fr, el	fr, sk, el	all 6
Tune	16.1	16.4	16.4	16.4	16.4
WMT09	17.2	17.2	17.2	17.3	17.4
WMT10	17.7	17.8	17.8	17.8	17.8

Table 3: Czech-English B scores over pivot language combinations. Key: fr=French, sk=Slovak, el=Greek.

Somewhat surprisingly, all models achieved an F-score of about 70%, which resulted in B scores comparable to those reported with French (Table 2). Subsequently, we combined all pivot languages by simply concatenating the aligned parallel texts across pairs, triples and all pivot languages. Combining all pivots yielded modest B score improvements of +0.2 and +0.1 on the test datasets (Table 3).

Considering the low variance in F- and B scores across pivot languages, we computed the pairwise F-scores between the predicted alignments: All scores ranged around 97–98%, indicating that the choice of pivot language had little effect on the joint training procedure.

To further verify, we repeated this experiment over Greek-English and Lithuanian-English as the source-target task (85k parallel sentences), using the same pivot languages as above, and with comparable amounts of parallel data (~200k sentences). We obtained similar results: In all cases, pairwise F-scores were above 97%.

5 Related Work

The term "triangulation" comes from the *phrase-table* triangulation literature (Cohn and Lapata, 2007; Razmara and Sarkar, 2013; Dholakia and

Sarkar, 2014), in which source-pivot and pivot-target phrase tables are triangulated according to Eq. 1 (with words replaced by phrases). The resulting triangulated phrase table can then be combined with an existing source-target phrase table, and is especially useful in increasing the source language vocabulary coverage, reducing OOVs. In our case, since word alignment is a closed vocabulary task, OOVs are never an issue.

In word alignment, Kumar et al. (2007) uses *multilingual* parallel data to compute better source-target alignment posteriors. Filali and Bilmes (2005) tag each source token and target token with their most likely translation in a pivot language, and then proceed to align (source word, source tag) tuple sequences to (target word, target tag) tuple sequences. In contrast, our word alignment method can be applied without multilingual parallel data, and does not commit to hard decisions.

6 Conclusion and Future Work

We presented a simple multi-task learning algorithm that jointly trains three word alignment models over disjoint bitexts. Our approach is a natural extension of a mathematically sound MAP-EM algorithm we originally developed to better utilize the model triangulation idea. Both algorithms are easy to implement (with closed-form solutions for each step) and require minimal effort to integrate into an EM-based word alignment system.

We evaluated our methods on a low-resource Czech-English word alignment task using additional Czech-French and French-English corpora. Our multi-task learning approach significantly improves F- and B scores compared to both baseline and the interpolation method of Wang et al. (2006). Further experiments showed our approach is insensitive to the choice of pivot language, producing roughly the same alignments over six different pivot language choices.

For future work, we plan to improve word alignment and translation quality in a more data restricted case where there are very weak source-pivot resources: for example, word alignment of Malagasy-English via French, using only a Malagasy-French dictionary, or Pashto-English via Persian.

Appendix: Joint Training Generative Story

We argue that our joint training procedure can be seen as optimizing the posterior likelihood of the three models. Specifically, suppose we place Dirichlet priors on each of the t-tables $\mathtt{t_{st}}, \mathtt{t_{sp}}, \mathtt{t_{pt}}$ as before, but define the prior parameterization using a single hyperparameter $\alpha = \{\alpha_{spt}\}$ and its marginals such that:

$$\begin{aligned}
\mathtt{t_{st}}(\cdot \mid s) &\sim D(\ldots, \alpha_{s\cdot t}, \ldots) & \alpha_{s\cdot t} &= \textstyle\sum_p \alpha_{spt} \\
\mathtt{t_{sp}}(\cdot \mid s) &\sim D(\ldots, \alpha_{sp\cdot}, \ldots) & \alpha_{sp\cdot} &= \textstyle\sum_t \alpha_{spt} \\
\mathtt{t_{pt}}(\cdot \mid p) &\sim D(\ldots, \alpha_{\cdot pt}, \ldots) & \alpha_{\cdot pt} &= \textstyle\sum_s \alpha_{spt}
\end{aligned}$$

Intuitively, α_{spt} represents the number of times a source-pivot-target triplet (s, p, t) was observed.

With this prior, we can maximize the posterior likelihood of the three models given the three bitexts (denoted $\mathtt{data} = \{\mathtt{bitext_{st}}, \mathtt{bitext_{sp}}, \mathtt{bitext_{pt}}\}$) with respect to all parameters and hyperparameters:

$$\begin{aligned}
&\arg\max_{\Theta,\alpha} P(\Theta \mid \alpha, \mathtt{data}) = \\
&\quad \arg\max_{\Theta,\alpha} \textstyle\prod_{d\in\{\mathtt{st},\mathtt{sp},\mathtt{pt}\}} P(\mathtt{bitext}_d \mid \Theta_d) P(\Theta_d \mid \alpha)
\end{aligned}$$

Under the generative story, we need only observe the marginals $\alpha_{s\cdot t}, \alpha_{sp\cdot}, \alpha_{\cdot pt}$ of α. Therefore, instead of explicitly optimizing over α, we can optimize over the marginals while keeping them consistent (via constraints such as $\sum_t \alpha_{s\cdot t} = \sum_p \alpha_{sp\cdot}$ for all s).

In our joint training algorithm (Algorithm 1) we abandon these consistency constraints in favor of closed form estimates of the marginals $\alpha_{s\cdot t}, \alpha_{sp\cdot}, \alpha_{\cdot pt}$.

Abstract

In this paper, we describe the problem of cognate identification in NLP. We introduce the idea of gap-weighted subsequences for discriminating cognates from non-cognates. We also propose a scheme to integrate phonetic features into the feature vectors for cognate identification. We show that subsequence based features perform better than state-of-the-art classifier for the purpose of cognate identification. The contribution of this paper is the use of subsequence features for cognate identification.

1 Introduction

Cognates are words across languages whose origin can be traced back to a common ancestral language. For example, English $\sim$ German *night* $\sim$ *Nacht* 'night' and English *hound* $\sim$ German *Hund* 'dog' are cognates whose origin can be traced back to Proto-Germanic. Sometimes, cognates are not revealingly similar but have changed substantially over time such that they do not share form similarity. An example of such a cognate pair is the English *wheel* and Sanskrit *chakra* 'wheel', which can be traced back to Proto-Indo-European (PIE) $*k^wek^welo$.

Automatic cognate identification, in NLP, refers to the application of string similarity or phonetic similarity algorithms either independently, or in tandem with machine learning algorithms for determining if a given word pair is cognate or not (Inkpen et al., 2005). In NLP, even borrowed words (*loanwords*) are referred to as cognates. In contrast, historical linguistics makes a stark distinction between loanwords and cognates. For example, English *beef* is a loanword from Norman French.

In this paper, we use cognates to refer to those words whose origin can be traced back to a common ancestor. We use string subsequence based features (motivated from string kernels) for automatic cognate identification. We show that subsequence-based features outperform word similarity measures at the task of automatic cognate identification. We motivate the use of subsequence based features in terms of linguistic examples and then proceed to formulate the subsequence based features that can be derived from string kernels (Shawe-Taylor and Cristianini, 2004). In information retrieval literature, string subsequences go under the name of skip-grams (Järvelin et al., 2007).

2 Related work

The approaches developed by Kondrak and Sherif (2006) and Inkpen et al. (2005) supply different string distances between a pair of words as features to a linear classifier. Usually, a linear classifier such as SVM is trained on labeled positive ("cognates") and negative ("non-cognates") examples and tested on a held-out dataset. Basic vocabulary lists such as the ones devised by Morris Swadesh (Swadesh, 1952), provide a suitable testing ground for applying machine learning algorithms to automatically identify cognates. Some standardized word lists come with cognate information and, subsequently, can used to infer the relationship between the languages (Dyen et al., 1992).

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1227–1231,
Denver, Colorado, May 31 – June 5, 2015.

Ellison and Kirby (2006) use scaled edit distance (normalized by average length) to measure the intra-lexical divergence in a language. The inter-language distance matrix is supplied to a clustering algorithm to infer a tree for the Indo-European language family. The authors only perform a qualitative evaluation of the inferred tree. The authors mention string kernels but do not pursue this line of research further.

Bouchard-Côté et al. (2013) employ a graphical model to reconstruct the proto-word forms from the synchronic word-forms for the Austronesian language family. They compare their automated reconstructions with the ones reconstructed by historical linguists and find that their model beats an edit-distance baseline. However, their model has a requirement that the tree structure between the languages under study has to be known beforehand.

Hauer and Kondrak (2011) – referred to as HK – supply different string similarity scores as features to a SVM classifier for determining if a given word pair is a cognate or not. The authors also employ an additional binary language-pair feature – that is used to weigh the language distance – and find that the additional feature assists the task of semantic clustering of cognates. In this task, the cognacy judgments given by a linear classifier is used to flat cluster the lexical items belonging to a single concept. The clustering quality is evaluated against the gold standard cognacy judgments. Unfortunately, the experiments of these scholars cannot be replicated since the partitioning details of their training and test datasets is not available.

In our experiments, we compare our system's performance with the performance of the classifiers trained from HK-based features. In the next section, we will describe string similarity measures, subsequences features, dataset, and results.

3 Cognate identification

3.1 String similarity features and issues

Edit distance counts the minimum number of insertions, deletions, and substitutions required to transform one word into another word. Identical words have 0 edit distance. For example, the edit distance between two cognates English *hound* and German *hund* is 1. Similarly, the edit distance between Swedish *i* and Russian *v* 'in', which are cognates, is 1. The edit distance treats both of the cognates at the same level and does not reflect the amount of change which has occurred in the Swedish and Russian words from the PIE word.

Dice is another string similarity measure that defines similarity between two strings as the ratio between the number of common bigrams to the total number of bigrams. The similarity between Lusatian *dolhi* and Czech *dluhe* 'long' is 0 since they do not share any common bigrams and the edit distance between the two strings is 3. Although the two words share all the consonants, the Dice score is 0 due to the intervening vowels.

Another string similarity measure, Longest Common Subsequence (LCS) measures the length of the longest common subsequence between the two words. The LCS is 4 (*hund*), 0 (*i* and *v*), and 3 (*dlh*) for the above examples. One can put forth a number of examples which are problematical for the commonly-used string similarity measures. Alternatively, string kernels in machine learning research offer a way to exploit the similarities between two words without any restrictions on the length and character similarity.

3.2 Subsequence features

Subsequences as formulated below weigh the similarity between two words based on the number of dropped characters and combine phoneme classes seamlessly. Having motivated why subsequences seems to be a good idea, we formulate subsequences below.

We follow the notation given in Shawe-Taylor and Cristianini (2004) to formulate our representation of a string (word). Let Σ denote the set of phonetic alphabet. Given a string s over Σ, the subsequence vector $\mathbf{\Phi(s)}$ is defined as follows. The string s can be decomposed as $s_1, \ldots, s_{|s|}$ where $|s|$ denotes the length of the string. Let $\overrightarrow{I}$ denote a sequence of indices $(i_1, \ldots, i_{|u|})$ where, $1 \leq i_1 < \ldots < i_{|u|} \leq |s|$. Then, a subsequence u is a sequence of characters $s[\overrightarrow{I}]$. Note that a subsequence can occur multiple times in a string. Then, the weight of u, $\phi_u(s)$ is defined as $\sum_{\overrightarrow{I}:u=s[\overrightarrow{I}]} \lambda^{l(\overrightarrow{I})}$ where, $l(\overrightarrow{I}) = i_{|u|} - i_1 + 1$ and $\lambda \in (0, 1)$ is a decay factor.

The subsequence vector $\Phi(s)$ is composed of

$\phi_u(s)\ \forall u \in \bigcup_{n=1}^{p} \Sigma^n$, where $1 \leq n \leq p$ is the length of u and p is the maximum length of the subsequences. As $\lambda \to 0$, a subsequence is constrained to a substring. As $\lambda \to 1$, $\phi_u(s)$ counts the frequency of u in s. We also experiment with different values of λ in this paper.

The λ factor is exponential and penalizes u over long gaps in a string. Due to the above formulation, the frequency of a subsequence u in a single string is also taken into account. The subsequence formulation also allows for the incorporation of a class-based features easily. For instance, each σ in u can be mapped to its **C**onsonant/**V**owel class: $\sigma \mapsto \{C, V\}$. The subsequence formulation also allows us to map each phonetic symbol (for example, from International Phonetic Alphabet [IPA]) to an intermediary phonetic alphabet also. Unfortunately, the current dataset is not transcribed in IPA to convert it into an intermediary broader format. In this paper, we map each string s into its C, V sequence s_{cv} and then compute the subsequence weights.[1]

A combined subsequence vector $\Phi(s+s_{cv})$ is further normalized by its norm, $\|\Phi(s + s_{cv})\|$, to transform into a unit vector. The common subsequence vector $\Phi(s_1, s_2)$ is composed of all the common subsequences between s_1 and s_2. The weight of a common subsequence is $\phi_u(s_1) + \phi_u(s_2)$.

Moschitti et al. (2012) list the features of the above weighting scheme.

- Longer subsequences receive lower weights.
- Characters can be omitted (called *gaps*).
- The exponent of λ penalizes recurring subsequences with longer gaps.

For a string of length m and subsequence length n, the computational complexity is in the order of $\mathcal{O}(mn)$.

On a linguistic note, gaps are consistent with the prevalent sound changes such as sound loss, sound gain, and assimilation,[2] processes which alter word forms in an ancestral language causing the daughter languages to have different surface forms. The λ factor weighs the number of gaps found in a subsequence. For instance, the Sardinian word form for 'fish' *pissi* has the subsequence *ps* occurring twice but with different weights: λ^3, λ^4. Hence, *ps*'s weight is $\lambda^3 + \lambda^4$. On another note, the idea of gap subsequences subsumes the definitions of different n-gram similarities introduced by Kondrak (2005).

The combined feature vector, for a word pair, is used to train a SVM classifier. In our experiments, we use the LIBLINEAR package (Fan et al., 2008) to solve the primal problem with L_2-regularization and L_2-loss. The next subsection describes the makeup of the dataset. We use the default SVM parameters since we did not observe any difference in our development experiments.

3.3 Dataset and results

In this section, we will present the dataset, HK features, and results of our experiments.

Dataset. We used the publicly available[3] Indo-European dataset (Dyen et al., 1992) for our experiments. The dataset has $16,520$ lexical items for 200 concepts and 84 language varieties. Each word form is assigned to a unique CCN (Cognate Class Number). There are more than 200 identical non-cognate pairs in the dataset. For the first experiment, we extracted all word pairs for a concept and assigned a positive label if the word pair has an identical CCN; a negative label, if the word pair has different CCNs. We extracted a total of $619,635$ word pairs out of which $145,145$ are cognates. The dataset is transcribed in a broad romanized phonetic alphabet.

We explored if we could use two other word list databases: ASJP (Brown et al., 2008) and Ringe et al. (2002) for our experiments. Although the ASJP database has word lists for more than half of the world's languages, it has cognacy judgments for few selected languages and is limited to 40 concepts. Moreover, the ASJP database does not have cognacy judgments for Indo-European family. The other dataset of Ringe et al. (2002) has items for 24 Indo-European languages which are transcribed in an orthographic format and not in a uniform phonetic alphabet.[4] Moreover, there are a number of missing items for some of the languages. Hence, we did not use Ringe et al.'s dataset in our experiments. In contrast, Dyen's dataset is much larger and transcribed in an uniform format. Now, we proceed to

[1] $V = \{a, e, i, o, u, y\}$, $C = \Sigma \setminus V$.

[2] A sound can assimilate to a neighboring sound. Sanskrit *agni* > Prakrit *aggi* 'fire'. Compare the Latin form *ignis* with the Sanskrit form.

[3] http://www.wordgumbo.com/ie/cmp/iedata.txt

[4] http://www.cs.rice.edu/ nakhleh/CPHL/ie-wordlist-07.pdf

describe the previous best-performing system.

HK's system. We compare the performance of subsequence features against the SVM classifier system trained on the following word-similarity features from Hauer and Kondrak (2011):

- Edit distance.
- Length of longest common prefix.
- Number of common bigrams.
- Lengths of individual words.
- Absolute difference between the lengths of the words.

Cross-Validation experiment. As a first step, we perform a random ten-fold cross-validation of the dataset and report the accuracies for various values of λ and p. The results of this experiment are

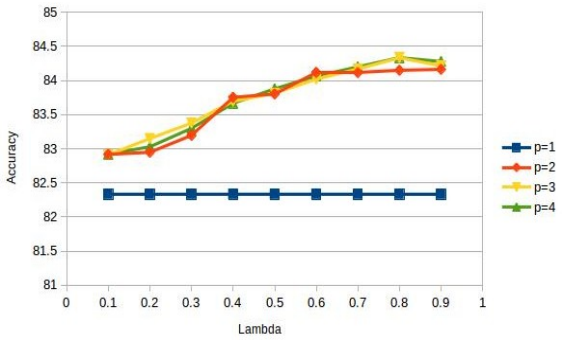

Figure 1: Ten-fold cross-validation accuracy for incremental λ and p. The accuracy of the system of HK is 82.61%.

shown in figure 1. The best results are obtained at $\lambda = 0.8, p = 3$. The accuracies increase with an increment in the value of λ until 0.8 for all $p > 1$ (non-unigram models). This experiment is mainly designed to test the robustness of subsequence features against random splits in the dataset which turns out to be robust. The subsequence features outperform HK-based classifier in this experiment.

	positive	negative
training	$111,918$	$353,957$
test	$33,227$	$120,533$

Table 1: Number of positive and negative examples in the training and test sets. The ratio of positive to negative examples is $1 : 3.62$.

Concepts experiment. In this experiment, we split our dataset into two sets by concepts; and train on one set and test on the other. To replicate our dataset, we performed an alphabetical sort of the concepts and split the concepts into training and testing datasets with a ratio of $3 : 1$. Now, we extract positive and negative examples from each subset of concepts; and train and test on each concepts' subset. We also performed a 3-fold cross-validation on the training set to tune c (SVM hyperparameter). We observed that the value of c did not effect the cross-validation accuracy on the training dataset. Hence we fixed c at 1. We also experimented with radial-basis function kernel and polynomial kernels but did not find any improvement over the linear kernel classifier. The composition of the training and test sets is given in table 1.

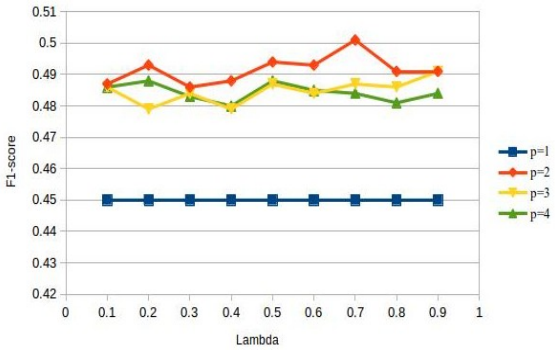

Figure 2: F_1-score for different values of p and λ. The F_1-score of the system of HK is 0.46.

In this experiment, we report the F_1-score, defined as $\frac{2PR}{P+R}$ (**P**recision and **R**ecall), for different values of λ and p. The results of this experiment are shown in figure 2. The F_1-score of the system of HK is 0.46 whereas the best performing subsequence system ($\lambda = 0.7, p = 2$) has a score of 0.5. Our system performs better than the system of HK in terms of cross-validation accuracy as well as F_1-score. Overall, all non-unigram models perform better than the system of HK at cross-validation and concepts experiments.

4 Conclusion

In this paper, we proposed a string kernel based approach for the purpose of cognate identification. We formulated an approach to integrate phonetic features of a phonetic symbol into the feature vector and showed that it beats the system of HK at cog-

nate identification at cross-validation and concepts subsets experiments.

In future, we plan to make a larger dataset of cognacy judgments for other language families in a richer phonetic transcription and integrate articulatory phonetic features into the feature vectors for the purpose of cognate identification. We also plan on testing with different feature vector combinations.

Short Text Understanding by Leveraging Knowledge into Topic Model

Abstract

In this paper, we investigate the challenging task of understanding short text (*STU* task) by jointly considering topic modeling and knowledge incorporation. Knowledge incorporation can solve the content sparsity problem effectively for topic modeling. Specifically, the phrase topic model is proposed to leverage the auto-mined knowledge, i.e., the phrases, to guide the generative process of short text. Experimental results illustrate the effectiveness of the mechanism that utilizes knowledge to improve topic modeling's performance.

1 Introduction

The explosion of online text content, such as twitter messages, text advertisements, QA community messages and product reviews has given rise to the necessity of understanding these prevalent short texts.

Conventional topic modeling, like PLSA (Hofmann, 1999) and LDA (Blei et al., 2003) are widely used for uncovering the hidden topics from text corpus. However, the sparsity of content in short texts brings new challenges to topic modeling.

In fact, short texts usually do not contain sufficient statistical signals to support many state-of-the-art approaches for text processing such as topic modeling (Hua et al., 2015). Knowledge is indispensable to *STU* task, where knowledge-based topic model (Andrzejewski et al., 2009; Hu et al., 2011; Jagarlamudi et al., 2012; Mukherjee and Liu, 2012; Chen et al., 2013; Yan et al., 2013) has attracted more attention recently.

*Corresponding author

We consider, in the *STU* task, the available knowledge can be divided into two classes: self-contained knowledge and external knowledge. Self-contained knowledge, which is focused in this paper, is extracted from the short text itself, such as key-phrase. External knowledge is constructed without special purpose, such as WordNet (Miller, 1995), KnowItAll (Etzioni et al., 2005), Wikipedia (Gabrilovich and Markovitch, 2007), Yago (Suchanek et al., 2007), NELL (Carlson et al., 2010) and Probase (Wu et al., 2012).

PLSA and LDA are the typical unsupervised topic models, that is non-knowledgeable model. In contrast, Biterm topic model (BTM) (Yan et al., 2013) leverages self-contained knowledge into semantic analysis. BTM learns topics over short texts by modeling the generation of biterms in the whole corpus. A biterm is an unordered word-pair co-occurring in short contexts. BTM posits that the two words in a biterm share the same topic drawn from a mixture of topics over the whole corpus. The major advantage of BTM is that BTM explicitly model the word co-occurrences in the local context, which well captures the short-range dependencies between words.

External knowledge-based models incorporate expert domain knowledge to help guide the models. DF-LDA (Andrzejewski et al., 2009) model incorporates domain knowledge in the form of *must-link* and *cannot-link*. *Must-link* states that two words should belong to the same topic, while *cannot-link* states that two words should not be in the same topic. GK-LDA (Chen et al., 2013) leverages lexical semantic relations of words such as synonyms, antonyms and adjective attributes in topic models. A

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1232–1237,
Denver, Colorado, May 31 – June 5, 2015.

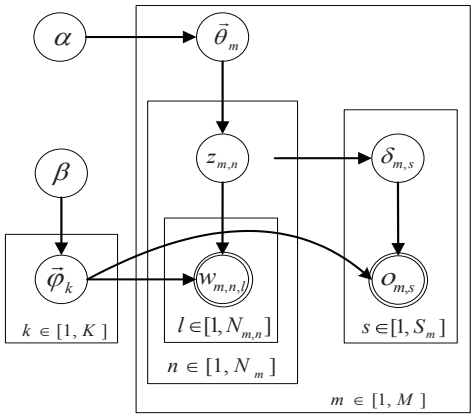

Figure 1: The phrase topic model proposed in this paper.

vast amount of lexical knowledge about words and their relationships, denoted as *LR-sets*, available in online dictionaries or other resources can be exploited by this model to generate more coherent topics.

However, for external knowledge-based models, the incorporated knowledge is too general to be consistent with the short text in the semantic space. On the other hand, BTM, as a typical self-contained knowledge-based model, makes rough assumption on the generated biterms. The generated biterms are inundated with noise, for not any two terms in short text share same topic. Based on the above analysis, we first identify key-phrases from short text, which can be deemed as self-contained knowledge, then propose phrase topic model (PTM), which constrains same topic for terms in key-phrase and sample topics for non-phrase terms from mixture of key-phrase's topic.

2 Phrase Topic Model

2.1 Model

A phrase is defined as a consecutive sequence of terms, or unigrams. In this paper, we focus on self-contained knowledge in short text, i.e., the key-phrases. Key-phrase extraction is a fundamental component in our work. We use CRF++[1] to identify key-phrases in a short text. The training data is built manually, and the features contain the word itself, the part of speech tagged by Stanford Log-linear Part-Of-Speech Tagger (Toutanova et al., 2003). Sample identified key-phrases are shown in Table 2.

In this paper, our phrase topic model is proposed based on three assumptions:

- Key-phrases are the key points of interest in the short text, which should be the focus.
- Terms consisting of the same key-phrase will share common topic.
- Non-phrase term's topic assignment should depend on that of key-phrases in the same text.

Our assumptions is indeed similar to other models (Gruber et al., 2007), for example each sentence is assumed to be assigned to one topic, however this assumption is too general, in many cases, different words should be assigned different topics even in short text. Our model is more refined to distinguish key-phrase and non-phrase. In addition, if two or more key-phrases exist in the same short text, they are probably assigned different topics.

The graphical representation of PTM is illustrated in Figure 1. α and β are hyper-parameters, which are experienced tuned. φ is corpus-level parameter, while θ is document-level parameter. The hidden variables consist of $z_{m,n}$ and $\delta_{m,s}$. The generative process of phrase topic model is presented as follows.

- For each topic $k \in [1, K]$
  - draw a topic-specific word distribution $\varphi_k \sim Dir(\beta)$
- For each document $m \in [1, M]$
  - draw a topic distribution $\theta_m \sim Dir(\alpha)$
  - For each key-phrase $n \in [1, N_m]$
    - draw topic assignment $z_{m,n} \sim Multi(\theta_m)$
    - For each word $l \in [1, N_{m,n}]$
      - draw $w_{m,n,l} \sim Multi(\varphi_{z_{m,n}})$
  - For each non-phrase word $s \in [1, S_m]$
    - draw a topic assignment $\delta_{m,s} \sim Uniform(z_{m,1}, \ldots, z_{m,N_m})$
    - draw word $o_{m,s} \sim Multi(\varphi_{\delta_{m,s}})$

From this process, we can see the generation of key-phrases and non-phrases are distinguished and non-phrase's generation is based on the topic assignment of key-phrases in the same document.

[1] http://crfpp.googlecode.com/svn/trunk/doc/index.html

2.2 Inference By Gibbs Sampling

Similarly with LDA, collapsed Gibbs sampling (Griffiths and Steyvers, 2004) can be utilized to perform approximate inference. In our model, the hidden variables are key-phrase's topic assignment $\boldsymbol{z}$ and non-phrase word's topic assignment $\boldsymbol{\delta}$. To perform Gibbs sampling, we first randomly initialize the hidden variables. Then we sample the topic assignment based on the conditional distribution $p(z_{m,n} = k|\mathbf{z}_{\neg(m,n)}, \mathbf{w}, \mathbf{o}, \delta)$ and $p(\delta_{m,s} = k|\mathbf{z}, \mathbf{w}, \mathbf{o}, \delta_{\neg(m,s)})$.

We can derive the conditional probability for $z_{m,n}$ following Equation 1, where $n^{k}_{m,\neg(m,n)}$ denotes the number of key-phrases whose topic assignment are k in document m without consideration of key-phrase $\{m, n\}$, which is similar to $n^{k'}_{m,\neg(m,n)}$. $n^{w_{m,n,l}}_{k,\neg(m,n)}$ denotes the number of times key-phrase term $w_{m,n,l}$ assigned to topic k without consideration of key-phrase $\{m, n\}$, which is similar to $n^{w}_{k,\neg(m,n)}$. $n^{o_{m,s}}_{k,\neg m}$ denotes the number of times non-phrase term $o_{m,s}$ assigned to topic k without consideration of document m, which is similar to $n^{w}_{k,\neg m}$.

Similarly, we can derive the conditional probability for $\delta_{m,s}$ following Equation 2, where $n^{o_{m,s}}_{k,\neg(m,s)}$ denotes the number of times non-phrase term $o_{m,s}$ assigned to topic k without consideration of non-phrase term $\{m, s\}$, which is similar to $n^{w}_{k,\neg(m,s)}$. L_m denotes the number of topics assigned to key-phrases in document m.

Finally, we can easily estimate the topic distribution $\theta_{m,k}$ and topic-word distribution $\varphi_{k,w}$ following Equation 3 and 4.

$$\theta_{m,k} = \frac{n^{k}_{m} + \alpha}{\sum_{k'=1}^{K} n^{k'}_{m} + K\alpha} \tag{3}$$

$$\varphi_{k,w} = \frac{n^{w}_{k} + \beta}{\sum_{w'=1}^{V} n^{w'}_{k} + V\beta} \tag{4}$$

3 Experiments and Results

Online reviews dataset (Chen et al., 2013), which consists of four domains, is utilized to evaluate our model, where each domain collection contains 500 reviews. Each review's average length is 20.42. The statistics of each domain are presented in Table 1. It's worth noting that the ***Phrase*** is auto-identified by the key-phrase extraction method. And the ***Word*** represents the whole distinct words for those identified key-phrases.

In our paper, we assumed each domain has a single topic model. For different domain, we think the semantic space is quite different. So we performed the proposed topic model with respect to different domain. The number of topics is usually determined by experience, in our experiment, each domain collection contains 500 reviews, we think the number of topics ranging from 2 to 20 is appropriate, and these reviews are sufficient to train a topic model.

Table 1: Statistic information of the dataset.

Dataset	***Phrase***	***Word***	Vocabulary
Computer	1439	1423	5109
Cellphone	1110	1109	4184
Camera	2962	2620	8366
Food	1235	1350	4488

Recent research (Chang et al., 2009; Newman et al., 2010) shows that the models which achieve better predictive perplexity often have less interpretable latent spaces. So the *Topic Coherence Metric* (Mimno et al., 2011) is utilized to assess topic quality, which is consistent with human labeling.

We compare our model with four baseline models: non-knowledgeable model LDA, self-contained knowledgeable model BTM, external knowledge-based model GK-LDA (Chen et al., 2013) and DF-LDA (Andrzejewski et al., 2009). Those identified key-phrases are used as *must-links* in DF-LDA and *LR-sets* in GK-LDA. This can ensure the incorporated knowledge upon different models are equal.

Table 2 illustrates the auto-identified phrases from cellphone dataset. From this result, we can see key-phrase extraction method can efficiently identify mostly phrases. More than one phrase, for example *warranty service* and *android phone*, may appear in a single sentence, and their topic assignments are probably different. Our proposed phrase topic model(PTM) can well handle this case, which is more well-defined than the assumption of all words within a sentence share one topic. Our phrase topic model assumes non-phrase term's topic assignment should depend on that of key-phrases in the same text. This assumption can be clearly confirmed by Table 2, for example, *Nokia N97 mini* is semantic dependent *US-*

$$p(z_{m,n}=k|\mathbf{z}_{\neg(m,n)},\mathbf{w},\mathbf{o},\delta) = \frac{n^{k}_{m,\neg(m,n)}+\alpha}{\sum_{k'=1}^{K} n^{k'}_{m,\neg(m,n)}+K\alpha} \cdot \frac{\prod_{l=1}^{N_{m,n}}(n^{w_{m,n,l}}_{k,\neg(m,n)}+\beta)}{\prod_{l=1}^{N_{m,n}}(\sum_{w=1}^{V} n^{w}_{k,\neg(m,n)}+V\beta)} \cdot \frac{\prod_{s=1}^{S_m}(n^{o_{m,s}}_{k,\neg m}+\beta)}{\prod_{s=1}^{S_m}(\sum_{w=1}^{V} n^{w}_{k,\neg m}+V\beta)} \tag{1}$$

$$p(\delta_{m,s}=k|\mathbf{z},\mathbf{w},\mathbf{o},\delta_{\neg(m,s)}) = \frac{n^{o_{m,s}}_{k,\neg(m,s)}+\beta}{\sum_{w=1}^{V} n^{w}_{k,\neg(m,s)}+V\beta} \cdot \frac{1}{L_m} \tag{2}$$

B charge cable, the same as *company* and *warranty service*.

For all models, posterior inference was drawn after 1000 Gibbs iterations with an initial burn-in of 800 iterations. For all models, we set the hyperparameters $\alpha = 2$ and $\beta = 0.5$.

The evaluation results over *Topic Coherence Metric* are presented in Figure 2 and Figure 3. This figure indicates our model and BTM can get higher topic coherence score than GK-LDA and DF-LDA, which means the self-defined knowledge and the mechanism of knowledge incorporation are effective to topic model. LDA's performance is acceptable but not stable. Our model performs better than BTM, which is probably because the rough assumption of BTM on generated biterms. From the above analysis, we can see our proposed model can get the best performance.

T-test results show that the performance improvement of our model over baselines is statistically significant on *Topic Coherence Metric*. All p-values for t-test are less than 0.00001.

Figure 4 presents the fluctuation of topic coherence when tuning the hyper-parameter α and β. We can see that the performance fluctuates within a limited range as we vary α and β. The topic coherence fluctuates between -550 and -950 other than food dataset, which gets less fluctuation range.

Table 3 shows example topics for each domain, where inconsistent words are highlighted in red. From this results, we can see the number of errors in phrase topic model(PTM) is significantly less than LDA, which indicates our proposed topic model is more suitable than LDA for short text.

4 Conclusions and Future Work

In this paper, we present a topic model to achieve *STU* task starting from key-phrases. The terms in key-phrases identified from the short texts are supposed to share a common topic respectively. And those key-phrases are assumed to be the central focus in the generative process of documents. In the future work, the self-contained knowledge, such as those identified key-phrases, and the external knowledge-base should be integrated to guide topic modeling.

Abstract

An acid test for any new Word Sense Disambiguation (WSD) algorithm is its performance against the Most Frequent Sense (MFS). The field of WSD has found the MFS baseline very hard to beat. Clearly, if WSD researchers had access to MFS values, their striving to better this heuristic will push the WSD frontier. However, getting MFS values requires sense annotated corpus in enormous amounts, which is out of bounds for most languages, even if their WordNets are available. In this paper, we propose an unsupervised method for MFS detection from the untagged corpora, which exploits word embeddings. *We compare the word embedding of a word with all its sense embeddings and obtain the predominant sense with the highest similarity.* We observe significant performance gain for Hindi WSD over the WordNet First Sense (WFS) baseline. As for English, the SemCor baseline is bettered for those words whose frequency is greater than 2. Our approach is language and domain independent.

1 Introduction

The MFS baseline is often hard to beat for any WSD system and it is considered as the strongest baseline in WSD (Agirre and Edmonds, 2007). It has been observed that supervised WSD approaches generally outperform the MFS baseline, whereas unsupervised WSD approaches fail to beat this baseline. The MFS baseline can be easily created if we have a large amount of sense annotated corpora. The frequencies of word senses are obtained from the available sense annotated corpora. Creating such a costly resource for all languages is infeasible, looking at the amount of time and money required. Hence, unsupervised approaches have received widespread attention as they do not use any sense annotated corpora.

In this paper, we propose an unsupervised method for MFS detection. We explore the use of word embeddings for finding the most frequent sense. We have restricted our approach only to nouns. Our approach can be easily ported to various domains and across languages.

The roadmap of the paper is as follows. Section 2 describes our approach - 'UMFS-WE'. Experiments are given in Section 3. Results and Discussions are given in Section 4. Section 5 mentions the related work. Finally, Section 6 concludes the paper and points to future work.

2 Our Approach: UMFS-WE

Word Embeddings have recently gained popularity among Natural Language Processing community (Bengio et al., 2003; Collobert et al., 2011). They are based on Distributional Hypothesis which works under the assumption that similar words occur in similar contexts (Harris, 1954). Word Embeddings represent each word with a low-dimensional real valued vector with similar words occurring closer in that space.

In our approach, we use the word embedding of a given word and compare it with all its sense embeddings to find the most frequent sense of that word. Sense embeddings are created using the WordNet based features in the light of the extended Lesk algorithm (Banerjee and Pedersen, 2003) as described

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1238–1243,
Denver, Colorado, May 31 – June 5, 2015.

later in this paper.

2.1 Training of Word Embeddings

Word embeddings for English and Hindi have been trained using *word2vec*[1] tool (Mikolov et al., 2013). This tool provides two broad techniques for creating word embeddings: Continuous Bag of Words (CBOW) and Skip-gram model. The CBOW model predicts the current word based on the surrounding context, whereas, the Skip-gram model tries to maximize the probability of a word based on other words in the same sentence (Mikolov et al., 2013).

Word Embeddings for English

We have used publicly available pre-trained word embeddings for English which were trained on Google News dataset[2] (about 100 billion words). These word embeddings are available for around 3 million words and phrases. Each of these word embeddings have 300-dimensions.

Word Embeddings for Hindi

Word embeddings for Hindi have been trained on Bojar's (2014) corpus. This corpus contains 44 million sentences. Here, the Skip-gram model is used for obtaining word embeddings. The dimensions are set as 200 and the window size as 7 (i.e. $w = 7$).

We used the test of similarity to establish the correctness of these word embeddings. We observed that given a word and its embedding, the list of words ranked by similarity score had at the top of the list those words which were actually similar to the given word.

2.2 Sense Embeddings

Sense embeddings are similar to word embeddings which are low dimensional real valued vectors. Sense embeddings are obtained by taking the average of word embeddings of each word in the sense-bag. The sense-bag for each sense of a word is obtained by extracting the context words from the WordNet such as synset members (S), content words in the gloss (G), content words in the example sentence (E), synset members of the hypernymy-hyponymy synsets (HS), content words in the gloss of the hypernymy-hyponymy synsets (HG) and content words in the example sentence of the hypernymy-hyponymy synsets (HE).

We consider word embeddings of all words in the sense-bag as a cluster of points and choose the sense embedding as the centroid of this cluster.

Consider a word w with k senses $w_{S_1}, w_{S_2}, ...w_{S_k}$ taken from the WordNet. Sense embeddings are created using the following formula,

$$\texttt{vec}(w_{S_i}) = \frac{\sum_{x \in \texttt{SB}(w_{S_i})} \texttt{vec}(x)}{N} \quad (1)$$

where, N is the number of words present in the sense-bag $\texttt{SB}(w_{S_i})$ and $\texttt{SB}(w_{S_i})$ is the sense-bag for the sense w_{S_i} which is given as,

$$\texttt{SB}(w_{S_i}) = \{x | x \in \texttt{Features}(w_{S_i})\}$$

where, $\texttt{Features}(w_{S_i})$ includes the WordNet based features for w_{S_i} which are mentioned earlier in this section.

As we can see in Figure 1, consider the sense-bag created for the senses of a word *table*. Here, the word *table* has three senses, S_1 {*a set of data arranged in rows and columns*}, S_2 {*a piece of furniture having a smooth flat top that is usually supported by one or more vertical legs*} and S_3 {*a company of people assembled at a table for a meal or game*}. The corresponding word embeddings of all words in the sense-bag will act as a cluster as shown in the Figure. Here, there are three clusters with centroids C_1, C_2, C_3 which corresponds to the three sense embeddings of the word *table*.

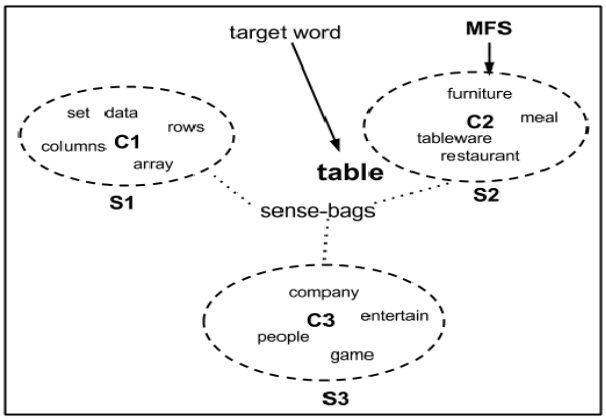

Figure 1: Most Frequent Sense (MFS) detection using Word Embeddings and Sense Embeddings

[1] https://code.google.com/p/word2vec/

[2] Downloaded from https://code.google.com/p/word2vec/

2.3 Most Frequent Sense Identification

For a given word w, we obtain its word embedding and sense embeddings as discussed earlier. We treat the most frequent sense identification problem as finding the closest cluster centroid (i.e. sense embedding) with respect to a given word. We use the cosine similarity as the similarity measure. The most frequent sense is obtained by using the following formulation,

$$\texttt{MFS}_w = \arg\max_{w_{S_i}} \cos(\texttt{vec}(w), \texttt{vec}(w_{S_i}))$$

where, $\texttt{vec}(w)$ is the word embedding for word w, w_{S_i} is the i^{th} sense of word w and $\texttt{vec}(w_{S_i})$ is the sense embedding for w_{S_i}.

As seen in Figure 1, the word embedding of the word *table* is more closer to the centroid C_2 as compared to the centroids C_1 and C_3. Therefore, the MFS of the word *table* is chosen as S_2 {*a piece of furniture having a smooth flat top that is usually supported by one or more vertical legs*}.

3 Experiments

We have performed several experiments to compare the accuracy of UMFS-WE for Hindi and English WSD. The experiments are restricted to only polysemous nouns. For Hindi, a newspaper sense-tagged dataset of around 80,000 polysemous noun entries was used. This is an in-house data. For English, SENSEVAL-2 and SENSEVAL-3 datasets[3] were used. The accuracy of WSD experiments was measured in terms of precision (P), recall (R) and F-Score (F-1).

To compare the performance of UMFS-WE approach, we have used the WFS baseline for Hindi, while the SemCor[4] baseline is used for English. In the WFS baseline, the first sense in the WordNet is used for WSD. For Hindi, the WFS is manually determined by a lexicographer based on his/her intuition. In SemCor baseline, the most frequent sense obtained from the SemCor sense tagged corpus is used for WSD. For English, the SemCor is considered as the most powerful baseline for WSD.

[3]SENSEVAL-2 and SENSEVAL-3 datasets are downloaded from http://web.eecs.umich.edu/ mihalcea/downloads.html

[4]http://web.eecs.umich.edu/~mihalcea/downloads.html#semcor

4 Results and Discussions

In this section, we present and discuss results of the experiments performed on Hindi and English WSD. Results of Hindi WSD on the newspaper dataset are given in Table 1, while English WSD results on SENSEVAL-2 and SENSEVAL-3 datasets are given in Table 2 and Table 3 respectively. The UMFS-WE approach achieves F-1 of 62% for the Hindi dataset and 52.34%, 43.28% for English SENSEVAL-2, SENSEVAL-3 datasets respectively.

System	P	R	F-1
UMFS-WE	62.43	61.58	62.00
WFS	61.73	59.31	60.49

Table 1: Results of Hindi WSD on the newspaper dataset

System	P	R	F-1
UMFS-WE	52.39	52.27	52.34
SemCor	61.72	58.16	59.88

Table 2: Results of English WSD on the SENSEVAL-2 dataset

System	P	R	F-1
UMFS-WE	43.34	43.22	43.28
SemCor	66.57	64.89	65.72

Table 3: Results of English WSD on the SENSEVAL-3 dataset

We have performed several tests using various combinations of WordNet based features (refer Section 2.2) for Hindi and English WSD, as shown in Table 4 and Table 5 respectively. We study its impact on the performance of the system for Hindi and English WSD and present a detailed analysis below.

4.1 Hindi

Our approach, UMFS-WE achieves better performance for Hindi WSD as compared to the WFS baseline. We have used various WordNet based features for comparing results. It is observed that synset members alone are not sufficient for identifying the most frequent sense. This is because some of synsets have a very small number of synset members. Synset members along with gloss members improve results as gloss members are more direct in

WordNet Features	P	R	F-1
S	51.73	38.13	43.89
S+G	53.31	52.39	52.85
S+G+E	56.61	55.84	56.22
S+G+E+HS	59.53	58.72	59.12
S+G+E+HG	60.57	59.75	60.16
S+G+E+HE	60.12	59.3	59.71
S+G+E+HS+HG	57.59	56.81	57.19
S+G+E+HS+HE	58.93	58.13	58.52
S+G+E+HG+HE	**62.43**	**61.58**	**62.00**
S+G+E+HS+HG+HE	58.56	57.76	58.16

Table 4: UMFS-WE accuracy on Hindi WSD with various WordNet features

defining the sense. The other reason is to bring down the impact of topic drift which may have occurred because of polysemous synset members. Similarly, it is observed that adding hypernym/hyponym gloss members gives better performance compared to hypernym/hyponym synset members. Example sentence members also provide additional information in determining the MFS of a word, which further improves the results.

On the whole, we achieve the best performance when S, G, E, HG and HE features are used together. This is shown in Table 4.

WordNet Features	P	R	F-1
S	22.89	22.82	22.85
S+G	32.72	32.64	32.68
S+G+E	30.87	30.79	30.84
S+G+E+HS	33.46	33.37	33.42
S+G+E+HG	39.36	39.26	39.31
S+G+E+HE	29.77	29.69	29.73
S+G+E+HS+HG	46.00	45.89	45.95
S+G+E+HS+HE	39.11	39.02	39.06
S+G+E+HG+HE	41.82	41.72	41.77
S+G+E+HS+HG+HE	**52.39**	**52.27**	**52.34**
S+G+HS+HG	51.17	51.04	51.11

Table 5: UMFS-WE accuracy on English WSD with various WordNet features

4.2 English

We achieve good performance for English WSD on the SENSEVAL-2 dataset, whereas the performance on the SENSEVAL-3 dataset is comparatively poor. Here also, synset members alone perform badly. However, adding gloss members improves results. The same is observed for hypernym/hyponym gloss members. Using example sentence members of either synsets or their hypernymy/hyponymy synsets bring down the performance of the system. This is also justified when we consider only synset members, gloss members, hypernym/hyponym synset members, hypernym/hyponym gloss members which give a score close to the best obtained score. All the features (S, G, E, HS, HG & HE), when used together, give the best performance as shown in Table 5.

Also, we have calculated the F-1 score for Hindi and English WSD for increasing thresholds on the frequency of nouns appearing in the corpus. This is depicted in Figure 2 and Figure 3 for Hindi and English WSD respectively. Here, in both plots, it is clearly shown that, as the frequency of nouns in the corpus increases our approach outperforms baselines for both Hindi and English WSD. On the other hand, SemCor baseline accuracy decreases for those words which occur more than 8 times in the test corpus. This is depicted in Figure 3. There are 15 such frequent word types. The main reason for low SemCor accuracy is that these words occur very few times with their MFS as listed by the SemCor baseline. For example, the word *cell* never appears with its MFS (as listed by SemCor baseline) in the SENSEVAL-2 dataset.

As opposed to baselines, our approach gives a feasible way to extract predominant senses in an unsupervised setup. Our approach is domain independent sothat it can be very easily adapted to a domain specific corpus. To get the domain specific word embeddings, we simply have to run the *word2vec* program on the domain specific corpus. The domain specific word embeddings can be used to get the MFS for the domain of interest. Our approach is language independent. However, due to time and space constraints we have performed our experiments on only Hindi and English languages.

5 Related Work

McCarthy et al. (2007) proposed an unsupervised approach for finding the predominant sense using an automatic thesaurus. They used WordNet similarity for identifying the predominant sense. Their approach outperforms the SemCor baseline for words

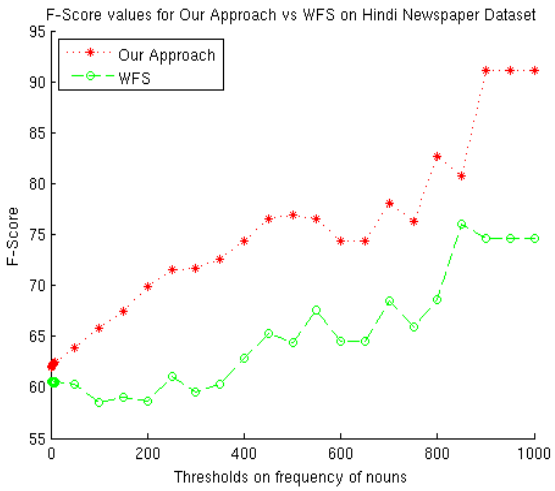

Figure 2: UMFS-WE accuracy on Hindi WSD for words with various frequency thresholds in Newspaper dataset

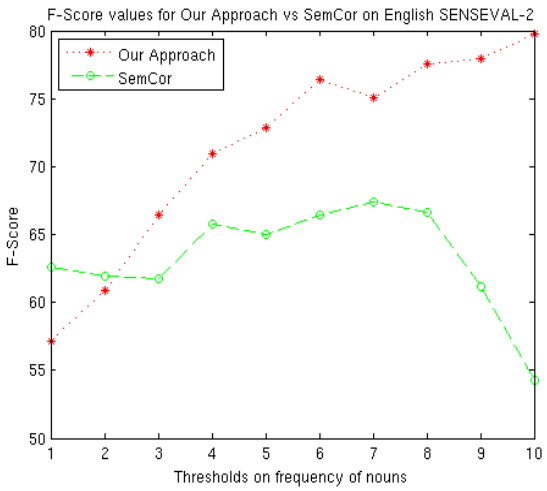

Figure 3: UMFS-WE accuracy on English WSD for words with various frequency thresholds in SENSEVAL-2 dataset

with SemCor frequency below five. Buitelaar et al. (2001) presented the knowledge based approach for ranking GermaNet synsets on specific domains. Lapata et al. (2004) worked on detecting the predominant sense of verbs where verb senses are taken from the Levin classes. Our approach is similar to that of McCarthy et al. (2007) as we are also learning predominant senses from the untagged text.

6 Conclusion and Future Work

In our paper, we presented an unsupervised approach for finding the most frequent sense for nouns by exploiting word embeddings. Our approach is tested on Hindi and English WSD. It is found that our approach outperforms the WFS baseline for Hindi. As the frequency of noun increases in the corpus, our approach outperforms the baseline for both Hindi and English WSD. Our approach can be easily ported to various domains and across languages. In future, we plan to improve on the performance of our model for English, even for infrequent words. Also, we will explore this approach for other languages and for other parts-of-speech.

7 Acknowledgments

We would like to thank Mrs. Rajita Shukla, Mrs. Jaya Saraswati and Mrs. Laxmi Kashyap for their enormous efforts in the creation of the WordNet First Baseline for the Hindi WordNet. We also thank TDIL, DeitY for their continued support.

Chain based RNN for Relation Classification

Javid Ebrahimi and **Dejing Dou**
Department of Computer and Information Science, University of Oregon
Eugene, Oregon 97403, USA
{javid,dou}@cs.uoregon.edu

Abstract

We present a novel approach for relation classification, using a recursive neural network (RNN), based on the shortest path between two entities in a dependency graph. Previous works on RNN are based on constituency-based parsing because phrasal nodes in a parse tree can capture compositionality in a sentence. Compared with constituency-based parse trees, dependency graphs can represent relations more compactly. This is particularly important in sentences with distant entities, where the parse tree spans words that are not relevant to the relation. In such cases RNN cannot be trained effectively in a timely manner. However, due to the lack of phrasal nodes in dependency graphs, application of RNN is not straightforward. In order to tackle this problem, we utilize dependency constituent units called *chains*. Our experiments on two relation classification datasets show that Chain based RNN provides a shallower network, which performs considerably faster and achieves better classification results.

1 Introduction

Relation extraction is the task of finding relations between entities in text, which is useful for several tasks such as information extraction, summarization, and question answering (Wu and Weld, 2010). For instance, in the sentence: those "cancers" were caused by radiation "exposures," the two entities have a *cause-effect* relation. As reported in detail (SaraWagi, 2008), one approach to the problem involves supervised methods where the models rely on lexical, syntactic, and semantic features to classify relations between pairs of entities. The downside of this approach is that one has to retrain the model for other domains with different target relations. Thus it is not scalable to the web, where thousands of (previously-unseen) relations exist (Banko et al., 2007). To address this problem, Open Information Extraction is proposed, which does not require supervision. In these systems (Banko et al., 2007; Mausam et al., 2012), patterns based on lexical, syntactic, POS, and dependency features are extracted. While these patterns give good precision, they suffer from low recall (Banko and Etzioni, 2008). This is because they fail to extract patterns which have not been pre-specified, and thereby are unable to generalize.

Recursive Neural Network (RNN) has proven to be highly successful in capturing semantic compositionality in text and has improved the results of several Natural Language Processing tasks (Socher et al., 2012; Socher et al., 2013). Previous applications of Recursive Neural Networks (RNN) to supervised relation extraction (Socher et al., 2012; Hashimoto et al., 2013; Khashabi, 2013) are based on constituency-based parsers. These RNNs may span words that do not contribute to the relation. We investigate the incorporation of dependency parsing into RNN that can give a more compact representation of relations.

Our contribution is introducing a compositional account of dependency graphs that can match RNN's recursive nature, and can be applied to relation classification. We study different data structures that incorporate dependency trees into RNNs.

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1244–1249,
Denver, Colorado, May 31 – June 5, 2015.

One of these structures produces a compact full binary tree that compared with the constituency-based RNN, has higher classification accuracy and saves up to 70% in the training time.

2 Related Work

At the core of deep learning techniques for NLP, lies the vector based word representation, which maps words to an n-dimensional space. Having word vectors as parameters makes neural models flexible in finding different word embeddings for separate tasks (Collobert and Weston, 2008). Recursive Neural Network (RNN) is a recursive deep architecture that can learn feature representation of words, phrases and sentences.

As an example, in (Socher et al., 2010), each node in the parse tree is associated with a vector and at each internal node p, there exists a composition function that takes its input from its children $c_1 \in \mathbb{R}^n$ and $c_2 \in \mathbb{R}^n$.

$$p = f(c_1, c_2) = tanh(W \begin{bmatrix} c_1 \\ c_2 \end{bmatrix} + b) \quad (1)$$

The matrix $W \in \mathbb{R}^{n \times 2n}$ is the global composition parameter, b is the bias term, and the output of the function $p \in \mathbb{R}^n$ is another vector in the space of inputs. Socher et al. (2012) propose Matrix-Vector Recursive Neural Network (MV-RNN), where instead of using only vectors for words, an additional matrix for each word is used to capture operator semantics in language. To apply RNN to relation classification, they find the path in the parse tree between the two entities and apply compositions bottom up. Hashimoto et al. (2013) follow the same design but introduce a different composition function. They make use of word-POS pairs and use untied weights based on phrase categories of the pair.

Socher et al. (2014) introduce a dependency-based RNN that extracts features from a dependency graph whose composition function has major differences from ours. Their function consists of a linear sum of unary compositions, while our function is a binary composition of children. Our work is also related to (Bunescu and Mooney, 2005), where the similarity between the words on the path connecting two entities in the dependency graph is used to devise a Kernel function.

3 Chain based RNN

While constituency-based parsing seems to be a reasonable choice for compositionality in general, it may not be the best choice for all NLP tasks. In particular, for relation classification, one may prefer to use a structure that encodes more information about the relations between the words in a sentence. To this end, we use dependency-based parsing that provides a one-to-one correspondence between nodes in a dependency graph (DG).

DGs are significantly different from constituency parse trees since they lack phrasal nodes. More precisely, the internal nodes where the nonlinear combinations take place, do not exist in DGs. Therefore, we modify the original RNN and present a dependency-based RNN for relation classification. In our experiments, we restrict ourselves to trees where each dependent has only one head. We also use the example in Figure 1 for better illustration; in this example the arguments of the relation are $child$ and $cradle$.

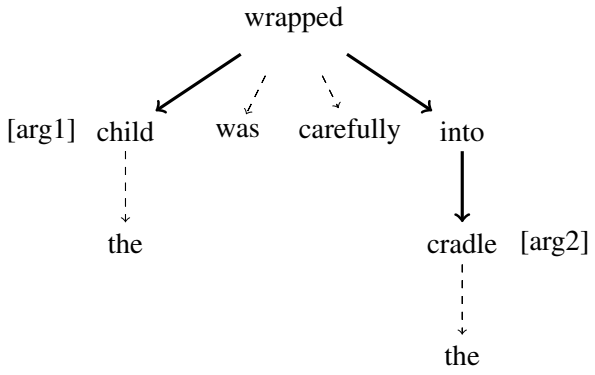

Figure 1: DG: the child was carefully wrapped into the cradle.

We apply compositions on the words on the shortest path between entities. From a linguistic point of view, this type of composition is related to the concept of $chain$ or dependency constituent unit in DGs (Osborne, 2005).

> **Chain**: The words A ... B ... C ... (order irrelevant) form a chain iff A immediately dominates (is the parent of) B and C, or if A immediately dominates B and B immediately dominates C.

Based on this definition, *child wrapped, into cradle, wrapped into cradle, child wrapped into cradle* all qualify as a chain while *child was* does not. To illustrate the motivation to use dependency parsing, consider the sentence:

> The hidden "camera," found by a security guard, was hidden in a business card-sized "box" placed at an unmanned ATM.

The shortest path between entities is:

> camera → found ← hidden ← in ← box

Using dependency parsing, we only need four compositions for this chain, which results in 86% decrease against constituency-based parsing.

Now with all words represented as vectors, we need to find a reduced dimensional representation of the chain in fixed size. To this end, we transform this chain to a data structure, the root of which represents the extracted features.

3.1 Fixed Structure

We cannot use an off-the-shelf syntax parser to create a tree for the chain because the chain may not necessarily be a coherent English statement. Thus, we build two Directed Acyclic Graph (DAG) structures by heuristics. The idea is to start from argument(s) and recursively combine dependent-head pairs to the (common) ancestor i.e., each head is combined with the subtree below itself. In the simplest case: $a \rightarrow b$ results in $p = f(a, b)$.

The subtlety of this approach lies in the treatment of the word with two dependents. We use two methods to handle such a node: 1) including it in only one composition as in Figure 2 or 2) including it in two compositions and sum their results as in Figure 3.

Both structures produce a DAG where each internal node has two children and there is only one node with two non-leaf children. We now prove that this greedy algorithm results in a full binary tree for the first case. We skip the proof of the algorithm for the second case which produces a full binary DAG.

Lemma: *There is at most one node with exactly two none-leaf children in the tree.*

Proof. If one of the arguments is an ancestor of the other argument e.g., arg1 → ... → arg2, then

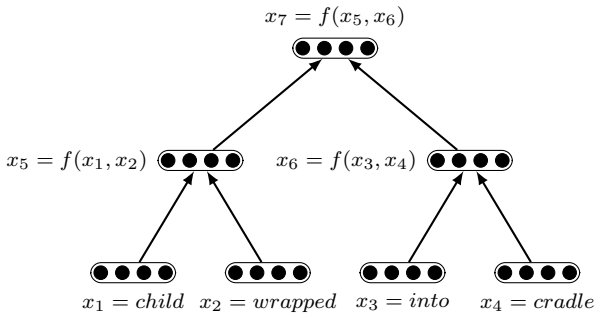

Figure 2: a fixed tree example

obviously every head on the chain has exactly one dependent. Combination of each head and its subtree's output vector results in a full binary node in the tree. If the arguments have a common ancestor p e.g., arg1 → ... p ... ← arg2, then that particular node has two dependents. In this case, the parent is combined with either its left or right subtrees, and its result is combined with the output of the other child. No other head has this property; otherwise, p is not the common ancestor.

Theorem: *The algorithm converts a chain to a full binary tree.*

Proof. The leaves of the tree are words of the chain. By applying the lemma, there exists one root and all internal nodes have exactly two children.

Note that we only consider dependency trees as the input; so each pair of arguments has a unique common ancestor. Concretely, having a connected graph leads to at least one such ancestor and having only one head for each node (being a tree) leads to exactly one such ancestor.

3.2 Predicted Tree Structure

Instead of using a deterministic approach to create the tree, we can use Recursive Autoencoders (RAE) to find the best representation of the chain. This model is similar to (Socher et al., 2011) with some modification in implementation. Socher et al. (2011) use a semi supervised method where the objective function is a weighted sum of the supervised and unsupervised error. We achieved better results with a pipeline where first, during pre-training, the unsupervised autoencoder predicts the structure of RNN and then during training, the supervised cross entropy error is minimized.

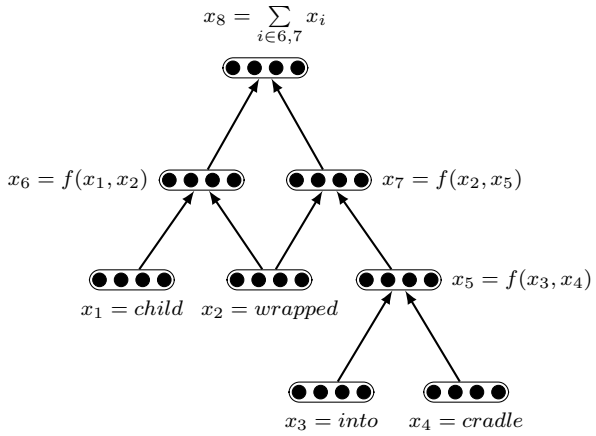

Figure 3: a fixed DAG example

4 Learning

To predict the label of the relation, a softmax classifier is added on top of the tree. i.e., $y_i = softmax(P_n^T W^{label})$ where $L \in \mathbb{R}^k$, k is the number of classes, and P_n is the final vector on top of the tree for sentence n. The objective function is the sum of cross entropy error at all the nodes, for all the sentences in the training set.

$$E(\theta) = -\sum_n \sum_k t_n^k \log y_n^k + \frac{\lambda}{2} \parallel \theta \parallel^2 \quad (2)$$

The vectors for target, predicted labels, and regularization parameters are denoted by t_n, y_n and λ respectively. We initialize the word vectors with pretrained 50-dimensional words from (Collobert and Weston, 2008) and initialize other parameters by a normal distribution with mean of 0 and standard deviation of 0.01. Derivatives are computed by backpropagation through structure (Goller and Kuchler, 1996) and L-BFGS is used for optimization.

5 Experiments

In this section we discuss our experimental results on two datasets for relation classification. To derive the dependency tree for each sentence, we use arc-eager MaltParser (Goldberg and Nivre, 2012). We set the hyper-parameters through a validation set for the first dataset and use them for the second dataset too. Similar to the previous works, a few internal features were also added e.g., depth of the tree, distance between entities, context words, and the type of dependencies in our model. We found that using dependency types inside the composition function as in typed functions worsens the results.

5.1 SemEval-2010 Task 8

This data set consists of 10017 sentences and nine types of relations between nominals (Hendrickx et al., 2010). Table 1 compares the results of our tree based chain RNN (C-RNN), DAG based chain RNN (DC-RNN) and the autoencoder based one (C-RNN-RAE) with other RNN models and the best system participating (Rink and Harabagiu, 2010) in the task. Evaluation of the systems is done by comparing the F-measure of their best runs. The best system (Rink and Harabagiu, 2010) uses SVM with many sets of features. We add some external features using supersense sequence tagger (Ciaramita and Altun, 2006). Adding POS tags, WordNet hypernyms, and named entity tags (NER) of the two arguments helps C-RNN improve the results.

We implement SDT-RNN (Socher et al., 2014) which has similar complexity as our model but has significantly lower F-measure. SDT-RNN also performs much better when considering only the words on the path between entities; confirming our hypothesis about the effectiveness of chains. This can be attributed to the intuitive advantage of dependency trees where the shortest path between entities captures most of the information about the relation (Bunescu and Mooney, 2005).

As it can bee seen in Table 1, C-RNN achieves the best results. The baseline RNN, uses a global composition function and $\mathbb{R}^{50}$ vectors for each word. We also use the same number of model parameters.

The advantage of our approach is that our models are computationally less expensive compared with other RNN models. MV-RNN (Socher et al., 2012) uses an additional matrix $\mathbb{R}^{50\times50}$ for each word, resulting in a 50 fold increase in the number of model parameters. POS-RNN (Hashimoto et al., 2013) uses untied weight matrices and POS based word vectors that results in about 100% increase in the number of model parameters compared with C-RNN.

Relations with long distances between entities are harder to classify. This is illustrated in Figure 4 where MV-RNN and C-RNN are compared. Considering three bins for the distance between two en-

Method	F-measure	Feature sets
RNN	74.8	-

MV-RNN	82.4	POS, NER, WordNet
C-RNN	**82.66**	POS, NER, WordNet

Table 1: Results on SemEval 2010 relation classification task with the feature sets used. C-RNN outperforms all RNN based models. By including three extra features, it achieves the state-of-the-art performance.

tities, the figure shows what fraction of test instances are misclassified in each bin. Both classifiers make more errors when the distance between entities is longer than 10. The performance of the two classifiers for distances less than five is quite similar while C-RNN has the advantage in classifying more relations correctly when the distance increases.

5.2 SemEval-2013 Task 9.b

To further illustrate the advantage of C-RNN over MV-RNN, we evaluate our work on another data set. See Table 2. In this task, the goal is to extract interactions between drug mentions in text. The corpus (Segura-Bedmar et al., 2013) consists of 1,017 texts that were manually annotated with a total of 5021 drug-drug interactions of four types: *mechanism, effect, advise* and *int*.

Method	Precision	Recall	F=measure
MV-RNN	74.07	65.53	67.84
C-RNN	**75.31**	**66.19**	**68.64**

Table 2: Results on SemEval 2013 Drug-Drug Interaction task

5.3 Training Time

Dependency graphs can represent relations more compactly by utilizing only the words on the shortest path between entities. C-RNN uses a sixth of neural computations of MV-RNN. More precisely, there is an 83% decrease in the number of *tanh* evaluations. Consequently, as demonstrated by Figure 5, C-RNN runs 3.21 and 1.95 times faster for SemEval 2010 and SemEval 2013 respectively.

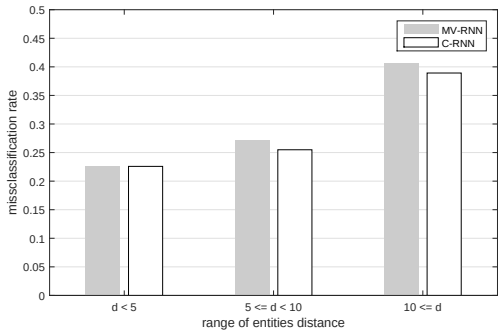

Figure 4: Misclassification based on entities distance in three bins. More errors occur with entities separated by more than ten words. C-RNN performs better in bottleneck long distances.

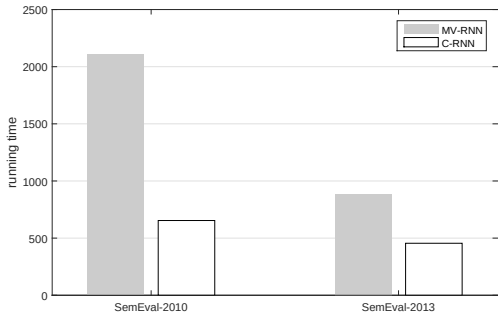

Figure 5: Training time measured by seconds. Experiments were run on a cluster node with 6 core 2.66GHz cpu.

6 Conclusions

Recently, Recursive Neural Network (RNN) has found a wide appeal in the Machine Learning community. This deep architecture has been applied in several NLP tasks including relation classification. We present an RNN architecture based on a compositional account of dependency graphs. The proposed RNN model is based on the shortest path between entities in a dependency graph. The resulting shallow network is superior for supervised learning in terms of speed and accuracy. We improve the classification results and save up to 70% in training time compared with a constituency-based RNN . The limitation of our Chain based RNN is that it assumes the named entities to be known in advance. This requires a separate named entity recognizer and cannot extract the entities jointly with the relation classifier.

LR Parsing for LCFRS

Laura Kallmeyer and **Wolfgang Maier**
Institute for Language and Information
University of Düsseldorf
Düsseldorf, Germany
{kallmeyer,maierwo}@phil.hhu.de

Abstract

LR parsing is a popular parsing strategy for variants of Context-Free Grammar (CFG). It has also been used for mildly context-sensitive formalisms, such as Tree-Adjoining Grammar. In this paper, we present the first LR-style parsing algorithm for Linear Context-Free Rewriting Systems (LCFRS), a mildly context-sensitive extension of CFG which has received considerable attention in the last years.

1 Introduction

LR parsing is an incremental shift-reduce parsing strategy in which the transitions between parser states are guided by an automaton which is compiled offline. LR parsers were first introduced for deterministic context-free languages (Knuth, 1965) and later generalized to context-free languages (Tomita, 1984) and tree-adjoining languages (Nederhof, 1998; Prolo, 2003).

Linear Context-Free Rewriting System (LCFRS) (Vijay-Shanker et al., 1987) is an immediate extension of CFG in which each non-terminal can cover more than one continuous span of the input string. LCFRS and equivalent formalisms have been used for the modeling of discontinuous constituents (Maier and Lichte, 2011) and non-projective dependencies (Kuhlmann, 2013), as well as for data-driven parsing of such structures (Maier and Kallmeyer, 2010; Kallmeyer and Maier, 2013; van Cranenburgh, 2012; Angelov and Ljunglöf, 2014). They have also been used for modeling non-concatenative morphology (Botha and Blunsom, 2013), for grammar engineering (Ranta, 2011), and for modeling alignments in machine translation (Søgaard, 2008; Kaeshammer, 2013). To our knowledge, so far, no LR strategy for LCFRS has been presented in the literature. In this paper, we present an LR-style parser for LCFRS. It is based on the incremental parsing strategy implemented by Thread Automata (Villemonte de la Clergerie, 2002).

The remainder of the article is structured as follows. In the following section, we introduce LCFRS and thread automata. Section 3 presents the algorithm along an example. In particular, section 3.2 gives the algorithms for automaton and parse table constructions, and section 3.3 presents the parsing algorithm. Section 4 concludes the article.

2 Preliminaries

2.1 LCFRS

In this paper, we restrict ourselves to string rewriting LCFRS and omit the more general definition (Weir, 1988).

In LCFRS, a single non-terminal can span $k \geq 1$ continuous blocks of a string. A CFG is simply a special case of an LCFRS in which $k = 1$. k is called the *fan-out* of the non-terminal. We notate LCFRS with the syntax of Simple Range Concatenation Grammars (SRCG) (Boullier, 1998), a formalism equivalent to LCFRS.

An LCFRS[1] (Vijay-Shanker et al., 1987; Seki et al., 1991) is a tuple $G = (N, T, V, P, S)$ where N

[1]Note that for purposes of exposition, we limit ourselves to ε-free LCFRS.

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1250–1255,
Denver, Colorado, May 31 – June 5, 2015.

is a finite set of non-terminals with a function dim: $N \to \mathbb{N}$ determining the *fan-out* of each $A \in N$; T and V are disjoint finite sets of terminals and variables; $S \in N$ is the start symbol with $dim(S) = 1$.

P is a finite set of rewriting rules with *rank* $m \geq 0$. All $\gamma \in P$ have the form

$$A(\alpha_0, \ldots, \alpha_{dim(A)-1}) \to A_1(X_0^{(1)}, \ldots, X_{dim(A_1)-1}^{(1)}) \\ \cdots A_m(X_0^{(m)}, \ldots, X_{dim(A_m)-1}^{(m)})$$

where $A, A_1, \ldots, A_m \in N$, $X_j^{(l)} \in V$ for $1 \leq l \leq m, 0 \leq j < dim(A_i)$ and $\alpha_i \in (V \cup T)^+$ for $0 \leq i < dim(A)$. All α_i and $X_j^{(l)}$ are called *arguments* (or sometimes *components*); the elements in α_i are called *argument elements*. $\mathcal{A}_\gamma$ is the set of all argument elements of γ. Variable occurrences in the arguments of the non-terminals of γ are ordered by a strict total order $\prec$. For all $X_1, X_2 \in V$ occurring in arguments of a non-terminal of γ, it holds that $X_1 \prec X_2$ iff either X_1 precedes X_2 in an argument of the non-terminal or the argument X_1 occurs in precedes the argument X_2 occurs in.

For all $\gamma \in P$, every variable X occurring in γ occurs exactly once in the left-hand side (LHS) and exactly once in the right-hand side (RHS). Furthermore, if for two variables $X_1, X_2 \in V$, it holds that $X_1 \prec X_2$ on the RHS, then also $X_1 \prec X_2$ on the LHS. The *rank* of G is the maximal rank of any of its rules, its *fan-out* is the maximal fan-out of any of its non-terminals.

We use the following additional notation: For a rule $\gamma \in P$, $lhs(\gamma)$ gives the LHS non-terminal; $lhs(\gamma, i)$ gives the ith argument of the LHS and $lhs(\gamma, i, j)$ its jth symbol; $rhs(\gamma, k)$ gives the kth RHS non-terminal; and $rhs(\gamma, k, l)$ gives the lth component of the kth RHS element (starting with index 0 in all four cases). These function have value $\perp$ whenever there is no such element. Furthermore, in the sense of dotted productions, we define for each $\gamma \in P$ a set of symbols denoting computation points of γ, $\mathcal{C}_\gamma = \{\gamma_{i.j} \mid 0 \leq i < dim_A, 0 \leq j \leq |\alpha_i|\}$, as well as the set $\mathcal{C} = \bigcup_{\gamma \in P} \mathcal{C}_\gamma$.

A non-terminal $A \in N$ can be *instantiated* w.r.t. an input string $w_1 \cdots w_{|w|}$ and a rule $\gamma \in P$ with $lhs(\gamma) = A$. An instantiation maps all argument elements of γ to spans of w ($(i-1, j)^w$ denotes the span $w_i \cdots w_j$, $1 \leq i \leq j \leq n$). All instantiations are given by a function $\sigma : \mathcal{A}_\gamma \to \mathbb{N} \times \mathbb{N}$ where

$\alpha : S(xy) \to A(x, y) \quad \gamma : A(a, b) \to \varepsilon$
$\beta : A(ax, ya) \to A(x, y)$

Figure 1: LCFRS for $\{a^n aba^n \mid n \geq 0\}$

for all $x, y \in \mathcal{A}_\gamma$ with $x \neq y$, $\sigma(x) = (i, j)^w$ and $\sigma(y) = (k, l)^w$ it holds that $i, k \geq 0$; $j, l \leq |w|$; if x (y) is a terminal, then $j = i + 1$ ($l = k + 1$), otherwise $j > i$ ($k > l$). Iff $x \prec y$ in γ, then $j \leq k$. A derivation rewrites strings of instantiated non-terminals, i.e., given an instantiated clause, the instantiated LHS non-terminal may be replaced with the sequence of instantiated RHS terminals. The language of the grammar is the set of strings which can be reduced to the empty word, starting with S instantiated to the input string.

See figure 1 for a sample LCFRS.

2.2 Thread Automata

Thread automata (TA) (Villemonte de la Clergerie, 2002) are a generic automaton model which can be parametrized to recognize different mildly context-sensitive languages. The TA for LCFRS (LCFRS-TA) implements a prefix-valid top-down incremental parsing strategy similar to the ones of Kallmeyer and Maier (2009) and Burden and Ljunglöf (2005).

An LCFRS-TA for some LCFRS $G = (N, T, V, P, S)$ works as follows. The processing of a single rule is handled by a single *thread* which will traverse the LHS arguments of the rule. A thread is given by a pair $p : X$, where $p \in \{1, \ldots, m\}^*$ with m the rank of G is the *address*, and $X \in N \cup \{ret\} \cup \mathcal{C}$ where $ret \notin N$ is the *content* of the thread. An automaton state is given by a tuple $\langle i, p, \mathcal{T} \rangle$ where $\mathcal{T}$ is a set of threads, the *thread store*, p is the address of the active thread, and $i \geq 0$ indicates that i tokens have been recognized. We introduce a new start symbol $S' \notin N$ that expands to S and use $\langle 0, \varepsilon, \{\varepsilon : S'\} \rangle$ as start state.

The specific TA for a given LCFRS $G = (N, T, V, P, S)$ can be defined as tuple $\langle N', T, S', ret, \delta, \Theta \rangle$ with $N' = N \cup \mathcal{C} \cup \{S', ret\}$; δ is a function from $\mathcal{C}$ to $\{1, \ldots, m\} \cup \{\perp\}$ such that $\delta(\gamma_{k,i}) = j$ if there is a l such that $lhs(\gamma, k, i) = rhs(\gamma, j-1, l)$, and $\delta(\gamma_{k,i}) = \perp$ if $lhs(\gamma, k, i) \in T \cup \{\perp\}$ (intuitively, a δ value j tells us that the next symbol to process is a variable that

Figure 2: TA transitions for the LCFRS from figure 1

is an argument of the jth RHS non-terminal); and Θ is a finite set of transitions. Every transition has the form $\alpha \xrightarrow{a} \beta$ with $a \in T \cup \{\varepsilon\}$ and they roughly indicate that in the thread store, α can be replaced with β while scanning a. Square brackets in α and β indicate parts that do not belong to the active thread. This will be made more precise below. Θ contains the following transitions (see figure 2):

- **Call** transitions start a new thread, either for the start symbol or for a daughter non-terminal. They move down in the parse tree.
  $S' \to [S']S$ (initial call), $\gamma_{k,i} \to [\gamma_{k,i}]A$ if $A = rhs(\gamma, j-1)$ and $lhs(\gamma, k, i) = rhs(\gamma, j-1, 0)$ where $j = \delta(\gamma_{k,i})$.
- **Predict** transitions predict a new rule for a non-terminal A: $A \to \gamma_{0,0}$ if $A = lhs(\gamma)$.
- **Scan** reads a LHS terminal while scanning the next input symbol:
  $\gamma_{k,i} \xrightarrow{lhs(\gamma,k,i)} \gamma_{k,i+1}$ if $lhs(\gamma, k, i) \in T$.
- **Publish** marks the completion of a production, i.e., its full recognition:
  $\gamma_{k,j} \to ret$ if $dim(lhs(\gamma)) = k+1$ and $j = |lhs(\gamma, k)|$.
- **Suspend** suspends a daughter thread and resumes the parent. i.e., moves up in the parse tree. There are two cases:
  (i) The daughter is completely recognized: $[\gamma_{k,i}]ret \to \gamma_{k,i+1}$ if $lhs(\gamma, k, i) = rhs(\gamma, \delta(\gamma_{k,i})-1, dim(rhs(\delta(\gamma_{k,i})-1))-1)$.
  (ii) The daughter is not yet completely recognized, we have only finished one of its components: $[\gamma_{k,i}]\beta_{l,j} \to \gamma_{k,i+1}[\beta_{l,j}]$ if $dim(lhs(\beta)) > l+1$, $|lhs(\beta, l)| = j$, $lhs(\gamma, k, i) = rhs(\gamma, \delta(\gamma_{k,i}) - 1, l)$ and $rhs(\gamma, \delta(\gamma_{k,i}) - 1) = lhs(\beta)$.
- **Resume** resumes an already present daughter thread, i.e., moves down into some daughter that has already been partly recognized.
  $\gamma_{k,i}[\beta_{l,j}] \to [\gamma_{k,i}]\beta_{l+1,0}$ if $lhs(\gamma, k, i) = rhs(\gamma, \delta(\gamma_{k,i}) - 1, l+1)$, $rhs(\gamma, \delta(\gamma_{k,i}) - 1) = lhs(\beta)$ and $\beta_{l,j+1} \notin \mathcal{C}$.

This is not exactly the TA for LCFRS proposed in Villemonte de la Clergerie (2002) but rather the one from Kallmeyer (2010), which is close to the Earley parser from Burden and Ljunglöf (2005).

The set of configurations for a given input $w \in T^*$ is then defined by the deduction rules in figure 3 (the use of set union $\mathcal{S}_1 \cup \mathcal{S}_2$ in these rules assumes that $\mathcal{S}_1 \cap \mathcal{S}_2 = \emptyset$). The accepting state of the automaton for some input w is $\langle |w|, 1, \{\varepsilon : S', 1 : ret\}\rangle$.

2.3 LR Parsing

In an LR parser, the parser actions are guided by an automaton, resp. a *parse table* which is compiled offline. Consider the context-free case. An LR parser for CFG is a guided shift-reduce parser, in which we first build the LR automaton. Its states are sets of dotted productions closed under prediction, and its transitions correspond to having recognized a part of the input, e.g., to moving the dot over a RHS element after having scanned a terminal or recognized a non-terminal. Given an automaton with n states, we build the *parse table* with n rows. Each row i, $0 \leq i < n$, describes the possible parser actions associated with the state q_i, i.e., for each state and each possible shift or reduce operation, it tells us in which state to go after the operation.

3 LR for LCFRS

3.1 Intuition

The states in the automaton are predict and resume closures of TA thread stores. In order to keep them finite, we allow the addresses to be regular expressions. A configuration of the parser consists of a

Initial configuration: $\dfrac{}{\langle 0, \varepsilon, \{\varepsilon : S'\}\rangle}$ Initial call: $\dfrac{\langle 0, \varepsilon, \{\varepsilon : S'\}\rangle}{\langle 0, 1, \{\varepsilon : S', 1 : S\}\rangle}$

Further calls: $\dfrac{\langle i, p, \mathcal{S} \cup p : \gamma_{k,i}\rangle}{\langle i, pj, \mathcal{S} \cup p : \gamma_{k,i} \cup pj : A\rangle}$ $\gamma_{k,i} \to [\gamma_{k,i}]A \in \Theta,\ A \in N, \delta(\gamma_{k,i}) = j+1$ Predict: $\dfrac{\langle i, p, \mathcal{S} \cup p : A\rangle}{\langle i, p, \mathcal{S} \cup p : \gamma_{0,0}\rangle}$ $A \in N,\ A \to \gamma_{1,0} \in \Theta$

Scan: $\dfrac{\langle j, p, \mathcal{S} \cup p : \gamma_{k,i}\rangle}{\langle j+1, p, \mathcal{S} \cup p : \gamma_{k,i+1}\rangle}$ $\gamma_{k,i} \overset{w_{j+1}}{\to} \gamma_{k,i+1} \in \Theta$ Publish: $\dfrac{\langle i, p, \mathcal{S} \cup \{p : \gamma_{k,i}\}\rangle}{\langle i, p, \mathcal{S} \cup \{p : ret\}\rangle}$ $\gamma_{k,j} \to ret \in \Theta$

Suspend 1: $\dfrac{\langle i, pj, \mathcal{S} \cup \{p : \gamma_{k,i}, pj : ret\}\rangle}{\langle i, p, \mathcal{S} \cup \{p : \gamma_{k,i+1}\}\rangle}$ $[\gamma_{k,i}]ret \to \gamma_{k,i+1} \in \Theta$

Suspend 2: $\dfrac{\langle i, pj, \mathcal{S} \cup \{p : \gamma_{k,i}, pj : \beta_{l,m}\}\rangle}{\langle i, p, \mathcal{S} \cup \{p : \gamma_{k,i+1}, pj : \beta_{l,m}\}\rangle}$ $[\gamma_{k,i}]\beta_{l,m} \to \gamma_{k,i+1}[\beta_{l,m}] \in \Theta$

Resume: $\dfrac{\langle i, p, \mathcal{S} \cup \{p : \gamma_{k,i}, p\delta(\gamma_{k,i}) : \beta_{l,j}\}\rangle}{\langle i, p\delta(\gamma_{k,i}), \mathcal{S} \cup \{p : \gamma_{k,i}, p\delta(\gamma_{k,i}) : \beta_{l+1,0}\}\rangle}$ $\gamma_{k,i}[\beta_{l,j}] \to [\gamma_{k,i}]\beta_{l+1,0} \in \Theta$

Figure 3: Deduction rules for TA configurations

stack, a set of completed components and the remaining input. The completed components are of the form $p : \gamma_i$ where p is an address and γ_i the component of a rule. The stack has the form $\Gamma_1 x_1 \Gamma_2 \dots x_{n-1} \Gamma_n$ where Γ_i is an address followed by a state and $x_i \in T \cup \{A_k \,|\, A \in N, 1 \le k \le dim(A)\}$.

Shift: Whenever we have $p : q$ on top of the stack and an edge from q to q' labeled with the next input symbol and an address p', we add the input symbol followed by $pp' : q'$ to the stack.

Suspend: Whenever the top of the stack is $p_1 : q$ such that there is a $\gamma_{i-1,k} \in q$ with $k = |lhs(\gamma, i-1)|$ and $i < dim(\gamma)$, we can suspend. If $i = 1$, we add $p_1 : \gamma_i$ to the set of completed components and we remove $|lhs(\gamma, i)|$ terminals/component nonterminals and their preceding states from the stack. If $i \ge 1$, we check whether there is a $p_2 : \gamma_{i-1}$ in the set of completed components such that the intersection $L(p_1) \cap L(p_2)$ is not empty.[2] We then remove $p_2 : \gamma_{i-1}$ from the set of complete components and we add $p : \gamma_i$ to it where p is a regular expression denoting $L(p_1) \cap L(p_2)$. Suppose the topmost state on the stack is now $p' : q'$. We then have to follow the edge leading from q' to some q'' labeled $A_i : p''$ where $A = lhs(\gamma)$. This means that we push A_i followed by $p'p'' : q''$ on the stack.

[2]Note that the corresponding finite state automata can be deterministic; in this case the intersection is quadratic in the size of the two automata.
In LCFRS without left recursion in any of the components, the intersection is trivial since the regular expressions denote only a single path each.

Reduce: Whenever there is a $\gamma_{i-1,k}$ in our current state with $k = |lhs(\gamma, i-1)|$ and $i = dim(\gamma)$, we can reduce, which is like suspend except that nothing is added to the set of completed components.

3.2 Automaton and parse table construction

The states of the LR-automaton are sets of pairs $p : X$ where p is a regular expression over $\{1, \dots, m\}$, m the rank of G, and $X \in \mathcal{C} \cup \{S'\}$. They represent predict and resume closures.The predict/resume closure $\overline{q}$ of some set q is described by the deduction rules in figure 4. This closure is not always finite.

$$\frac{\varepsilon : S'}{1 : \alpha_{0,0}} \quad lhs(\alpha) = S$$

$$\frac{p : \gamma_{i,j}}{pk : \gamma'_{l,0}} \quad \begin{array}{l} lhs(\gamma, i, j) = rhs(\gamma, k-1, l), \\ rhs(\gamma, k) = lhs(\gamma') \end{array}$$

Figure 4: Predict/resume closure

However, if it is not, we obtain a set of items that can be represented by a finite set of pairs $r : \gamma_{i,j}$ plus eventually $\varepsilon : S'$ such that r is a regular expression denoting a set of possible addresses. As an example for such a case, see q_3 in figure 5.

The reason why we can represent these closures by finite sets using regular expressions for paths is the following: There is a finite number of possible elements $\gamma_{i,j}$. For each of these, the set of possible addresses it might be combined with in a state that is the closure of $\{\varepsilon : X_1, \varepsilon : X_2, \dots, \varepsilon : X_n\}$ is generated by the CFG $\langle \mathcal{C} \cup \{S'\} \cup \{S_{new}\}, \{1, \dots, m\}, P, S_{new}\rangle$ with $S_{new} \to X_i \in P$ for all $1 \le i \le n$, $X \to Yk \in P$ for all in-

stances $\frac{p:X}{pk:Y}$ of deduction rules and $\gamma_{i,j} \to \varepsilon$. This is a regular grammar, its string language can thus be characterized by a regular expression.

The construction of the set of states starts with $q_0 = \overline{\{\varepsilon : S'\}}$. For every state q, every nonterminal A and every $1 \leq i \leq dim(A)$, we define $read(q, A_i, p) = \{\varepsilon : \gamma_{j,k+1} \,|\, p : \gamma_{j,k} \in q$ and there is some l such that $rhs(\gamma, l) = A$ and $lhs(\gamma, j, k) = rhs(\gamma, l, i{-}1)\}$ and $\overline{read}(q, A_i, p) = \overline{read(q, A_i, p)}$. Similarly, for every such q and every $a \in T$, we define $read(q, a, p) = \{\varepsilon : \gamma_{j,k+1} \,|\, p : \gamma_{j,k} \in q$ and $lhs(\gamma, j, k) = a\}$ and $\overline{read}(q, a, p) = \overline{read(q, a, p)}$. The set of states of our automaton is then the closure of $\{q_0\}$ under the application of the $\overline{read}$-functions. The edges in our automaton correspond to $\overline{read}$-transitions, where each edge is labeled with the corresponding pair A_i, p or a, p respectively. The automaton we obtain for the grammar in figure 1 is shown in figure 5. The number of possible states

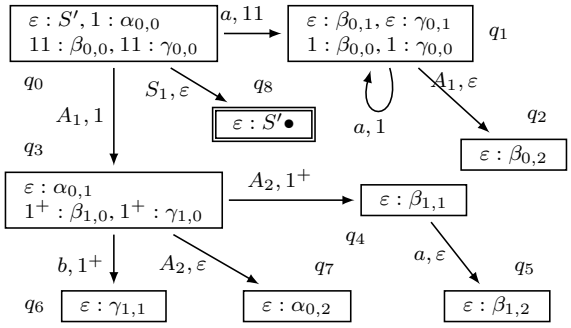

Figure 5: The automaton

is necessarily finite since each state is the closure of some set containing only items with address ε. There are only finitely many such sets.

In the parse table, our operations are $s(p, q)$ for shifting some terminal a followed by the old address concatenated with p and state q and $r(\alpha, i)$ for reducing the ith component of rule α. The two reduce operations can be distinguished by the component indices. Furthermore, the goto-part of the table tells where to go when traversing a component edge and which address to add then. The parse table can be read off the automaton as follows: $action(q, a) = s(p, q')$ iff $\overline{read}(q, a, p) = q'$; $action(q, -) = r(\gamma, i)$ iff there is some $p : \gamma_{i,k} \in q$ such that $k = |lhs(\gamma, i)|$. Concerning the goto part of the table, we have $goto(q, A_i) = \langle p, q' \rangle$ iff $\overline{read}(q, A_i, p) = q'$. Figure 6 shows the parse table

	a	b		A_1	A_2	S_1

Figure 7: Sample run with $w = aaba$

for our example.

3.3 Parsing

We run the automaton with $\langle \varepsilon : q_0, [\,], w \rangle$ and input $w = aaba$. The trace is shown in figure 7. We start in q_0, and shift two as, which leads to q_1. We have then fully recognized the first components of γ and β: We suspend them and keep them in the set of completed components, which takes us to q_3. Shifting the b takes us to q_6, from where we can reduce, which finally takes us to q_4. From there, we can shift the remaining a (to q_5), with which we have fully recognized β. We can now reduce both β and with that, α, which takes us to the accepting state q_8.

4 Conclusion

We presented the first LR style algorithm for LCFRS parsing. It offers a convenient factorization of predict/resume operations. We are currently exploring the possibility to use it in data-driven parsing.

Mining for unambiguous instances to adapt part-of-speech taggers to new domains

Abstract

We present a simple, yet effective approach to adapt part-of-speech (POS) taggers to new domains. Our approach only requires a dictionary and large amounts of unlabeled target data. The idea is to use the dictionary to mine the unlabeled target data for unambiguous word sequences, thus effectively collecting *labeled* target data. We add the mined instances to available labeled newswire data to train a POS tagger for the target domain. The induced models significantly improve tagging accuracy on held-out test sets across three domains (Twitter, spoken language, and search queries). We also present results for Dutch, Spanish and Portuguese Twitter data, and provide two novel manually-annotated test sets.

1 Introduction

Part-of-speech (POS) taggers are typically trained on newswire and exhibit severe out-of-domain performance drops (Blitzer et al., 2006; Daume III, 2007; Foster et al., 2011). When faced with a new domain, one option is to try to leverage available unlabeled data. However, rather than resorting to pure self-training approaches (self-labeling), we here resort to another source of information. One way to address the annotation problem is to use collaboratively created resources such as Wikipedia for *distant supervision* (Mintz et al., 2009), or the automatically derived dictionaries called *Wiktionary* (Li et al., 2012). We show how to leverage these resources to create labeled training data. It turns out that many entries in Wiktionary are actually *unambiguous*, i.e., there is only *one* possible tag for the word. In fact, for English Wiktionary (Li et al., 2012), we find that 93% of the unigram types are unambiguous (cf. Table 2).

Our idea here is simple: we mine for *unlabeled* sentences that contain only unambiguous items (according to Wiktionary), and use the resulting data as additional, *labeled* training material. Concretely, we mine unannotated corpora of tweets, transcribed speech, and search queries for sentences that contain only unambiguous tokens, and combine those instances with newswire data to train POS models that adapt better to the respective domains. We show that adding unambiguous data leads to considerable improvements over both unadapted and weakly-supervised baselines (Li et al., 2012).

Since Wiktionary has relatively low coverage for some of these domains, we also explore the use of Brown clusters to extend the coverage. This enables us to generalize across spelling variations and synonyms. Additionally, we evaluate our approach on Dutch, Portuguese and Spanish Twitter and present tow novel data sets for the latter two languages.

2 Data

2.1 Wiktionary

In our experiments, we use the (unigram) tag dictionaries from Wiktionary, as collected by Li et al. (2012).[1] The size and quality of our tag dictionaries crucially influence how much unambiguous data we can extract, and for some languages, the number of dictionary entries is small.

We can resort to normalization dictionaries to extend Wiktionary's coverage. We do so for English (Han and Baldwin, 2011). It replaces some

spelling variations with the standard form (*youuuuuuuuu* → *you*), which reduces the vocabulary size.

For languages where no such normalization dictionary is available, we use word clusterings based on Brown clusters (Brown et al., 1992) to generalize tags from unambiguous words to previously unseen words in the same class.

CLUSTER	TOKEN	TAG ∈ D	PROJ. TAG
01011110	offish	ADJ	—
01011110	alreadyyy	???	ADV
01011110	finali	???	ADV
01011110	aleady	???	ADV
01011110	previously	ADV	—
01011110	already	ADV	—
01011110	recently	ADV	—

Figure 1: Example of a Brown cluster with unambiguous tokens, as well as projected tags for new tokens (tokens marked "—" are unchanged in D').

In particular, to extend the dictionary D to D' using clusters, we first run clustering on the unlabeled data T, using Brown clustering.[2] We then assign to each unambiguous word in the cluster its tag from dictionary D. For all remaining tokens in the same cluster, we assign them the most frequently observed tag in the cluster, provided that label occurred at least twice as often as the second most frequent one, and the token itself was not already in Wiktionary.

As an example, consider the cluster in Figure 1. Since three tokens were unambiguously tagged as ADV in the original dictionary (*previously*, *already*, *recently*), we project ADV to all tokens in the cluster that were not already in D (here: *alreadyyy*, *finali*, *aleady*), and finally add all words to D'. The token *offish* remains an ADJ.

[2] https://github.com/percyliang/brown-cluster

2.2 Unlabeled data

For each domain and language, given dictionary D, we extract unambiguous sentences/tweets. User names and URLs are assumed to be nouns. If all words are unambiguous according to the dictionary, we include the sentence/tweet in our training data. For hashtags on Twitter, we remove the "#" sign and check the remainder against the dictionary. We exclude tweets that *only* contain users and URLs.

The unambiguous subsets of the unlabeled data represent very biased samples of the various domains. The ratio of unambiguous English tweets, for example, is only about 0.012 (or 1 in 84), and the distribution of tags in the Twitter data set is heavily skewed towards nouns, while several other labels are under-represented.

Twitter We collect the unlabeled data from the Twitter streaming API.[3] We collected 57m tweets for English, 8.2m for Spanish, 4.1m for Portuguese, and 0.5m for Dutch. We do not perform sentence splitting on tweets, but take them as unit sequences.

Spoken language We use the Switchboard corpus of transcribed telephone conversations (Godfrey et al., 1992), sections 2 and 3, as well as the English section of EuroParl (Koehn, 2005) and CHILDES (MacWhinney, 1997). We removed all meta-data and inline annotations (gestures, sounds, etc.), as well as dialogue markers. The final joint corpus contains transcriptions of 570k spoken sentences.

Search queries For search queries, we use a combination of queries from Yahoo[4] and AOL. We only use the search terms and ignore any additional information, such as user ID, time, and linked URLs. The resulting data set contains 10m queries.

[3] https://github.com/saffsd/langid.py

[4] http://webscope.sandbox.yahoo.com/

2.3 Labeled data

We train our models on newswire, as well as mined unambiguous instances. For English, we use the OntoNotes release of the WSJ section of the Penn Treebank as training data for Twitter, spoken data, and queries.[5] For Dutch, we use the training section of the Alpino treebank from the CoNLL task.[6] For Portuguese, we use the training section of the Bosque treebank.[7] For Spanish, we use the training section of the Cast3LB treebank.[8] In order to map between Wiktionary and the treebanks, we need a common coarse tag set. We thus map all data to the universal tag set (Petrov et al., 2012).

Dev and test sets Our approach is basically parameter free. However, we did experiment with different ways of extending Wiktionary and hence used an average over three English Twitter dev sections as development set (Ritter et al., 2011; Gimpel et al., 2011; Foster et al., 2011), all mapped and normalized following Hovy et al. (2014).

For evaluation, we use three domains: tweets, spoken data and queries. For Twitter, we performed experiments in four languages: English, Portuguese, Spanish and Dutch. The Spanish and Portuguese tweets were annotated in-house, which will be made available.[9] For the other languages, we use pre-existing datasets for English (Hovy et al., 2014) and Dutch (Avontuur et al., 2012). Table 2 lists the complete statistics for the different language data sets.

For the other two domains, we use the manually labeled data from Switchboard section 4 as spoken data test set. For queries, we use manually labeled data from Bendersky et al. (2010).

3 Experiments

3.1 Model

We use a CRF[10] model (Lafferty et al., 2001) with the same features as Owoputi et al. (2013) and default parameters. As baselines we consider a) a CRF model trained only on newswire; b) available off-the-shelf systems (TOOLS); and c) a weakly supervised model (LI10). For English, the off-the-shelf tagger is the Stanford tagger (Toutanova et al., 2003), for the other languages we use TreeTagger (Schmid, 1994) with pre-trained models.

The weakly supervised model trained is on the unannotated data. It is a second-order HMM model (Mari et al., 1997; Thede and Harper, 1999) (SOHMM) using logistic regression to estimate the emission probabilities. This method allows us to use feature vectors rather than just word identity, as in standard HMMs. In addition, we constrain the inference space of the tagger using type-level tag constraints derived from Wiktionary. This model, called LI10 in Table 3, was originally proposed by Li et al. (2012). We extend the model by adding continuous word representations, induced from the unlabeled data using the skip-gram algorithm (Mikolov et al., 2013), to the feature representations. Our logistic regression model thus works over a combination of discrete and continuous variables when estimating emission probabilities. This extended model is called LI10$^+$. For both models, we do 50 passes over the data as in Li et al. (2012).

4 Results

Table 3 presents results for various models on several languages. Our results show that our newswire-trained CRF model with target-specific Brown clusters already does better than *all* our other baseline models (TOOLS and weakly LI10) , with the exception of QUERIES, where the Stanford tagger does remarkably well. All improvements are statistically significant ($p < 0.005$, calculated using approximate randomization with 10k iterations).

Adding the unambiguous unlabeled data leads to further improvements, with error reductions (over CRF) of up to 20%. The exceptions here are Portuguese tweets and SPOKEN. For SPOKEN, this is due to the small amounts of unlabeled data, so we re-used the clusters induced on Twitter, reasoning that language use in these two domains is similar to each other. Despite this conjecture, we see small improvements. For English, Portuguese, and Spanish TWITTER, as well as QUERIES, we see further

considerable improvements by using our extended tag dictionaries.

The most obvious reason this approach should work is the decrease in unseen words in the in-domain evaluation data. Since the unambiguous data is in-domain, the out-of-vocabulary (OOV) rate goes down when we add the unambiguous data to the newswire training data. In fact, for English Twitter, the OOV rate is reduced by half, and for Portuguese and Spanish, it is reduced by about 40%. For Dutch Twitter, the reduction in OOV rate is much smaller, which probably explains the small gain for this dataset. The difference in reduction of OOV rates are due to sample biases in our unlabeled data. This probably also explains the difference in gains between SPEECH and QUERIES. For search queries, the OOV rate is reduced by 66%, whereas it stays roughly the same for speech transcripts.

5 Discussion

We have presented a simple, yet effective approach to adapt POS taggers to a new domain. It requires a) the availability of large amounts of unlabeled data and b) a lexicon to mine unambiguous sentences. As sentence length increases, the likelihood of being completely unambiguous drops. For this reason, our approach works well for domains with shorter average sentence length, such as Twitter, spoken language, and search queries.

We also experimented with allowing up to one ambiguous item per sentence, i.e., we include a sentence in our training data if it contains exactly one item that either a) has more than one licensed tag in the dictionary or b) is not in the dictionary. In the first case, we choose the tag randomly at training time from the set of licensed ones. In the second case, we assume the unknown word to be a NOUN, since unknown words mostly tend to be proper names. When added to newswire, this data

results in worse models, presumably by introducing too much noise. However, for low-resource languages or domains with longer sentences and no available newswire data, this might be a viable alternative.

6 Related Work

Our approach is similar to mining high-precision items. However, previous approaches on this in NLP have mainly focused on well-defined *classification* tasks, such as PP attachment (Pantel and Lin, 2000; Kawahara and Kurohashi, 2005), or discourse connective disambiguation (Marcu and Echihabi, 2002). In contrast, we mine for *sequences* of unambiguous tokens in a structured prediction task.

While we use the same dictionaries as in Li et al. (2012) and Täckström et al. (2013), our approach differs in several respects. First, we use Wiktionary to mine for *training data*, rather than as type constraints, and second, we use Brown clusters to extend Wiktionary. We did experiment with different ways of doing this, including using various forms of word embeddings, leading to models similar to the baseline models in Socher et al. (2013), but the approach based on Brown clusters led to the best results on our development data.

?) use a different approach to distant supervision to improve tagging accuracy for Twitter. They use hyperlinks to fetch additional un-annotated training data that can be used in a self-training loop. Our approach differs in that it produces annotated data and is more readily applicable to various domains.

7 Conclusion

We have presented a domain adaptation approach to POS tagging by augmenting newswire data with automatically mined unambiguous instances. We demonstrate our approach on Twitter (in several languages), spoken language transcripts, and search queries. We use dictionaries extended with Brown clusters to collect labeled training data from unlabeled data, saving additional annotation work.

Our models perform significantly better on held-out data than both off-the-shelf taggers and models trained on newswire data only. Improvements hold across several languages (English, Spanish, Portuguese, and Dutch). For spoken language transcripts and search queries, we see some improvements, but find that extending the dictionaries with clusters has less of an effect than for Twitter. Our method can provide a viable alternative to costly annotation when adapting to new domains where unlabeled data and dictionaries are available.

Abstract

Multi-document Summarization (MDS) is of great value to many real world applications. Many scoring models are proposed to select appropriate sentences from documents to form the summary, in which the clustering-based methods are popular. In this work, we propose a unified sentence scoring model which measures representativeness and diversity at the same time. Experimental results on DUC04 demonstrate that our MDS method outperforms the DUC04 best method and the existing clustering-based methods, and it yields close results compared to the state-of-the-art generic MDS methods. Advantages of the proposed MDS method are two-fold: (1) The density peaks clustering algorithm is firstly adopted, which is effective and fast. (2) No external resources such as Wordnet and Wikipedia or complex language parsing algorithms is used, making reproduction and deployment very easy in real environment.

1 Introduction

Document summarization is the process of generating a generic or topic-focused summary by reducing documents in size while retaining the main characteristics of original documents(Wang et al., 2011). The summary may be formed in a variety of different ways, which are generally categorized as abstractive and extractive(Shen et al., 2007). In this paper, we address the problem of generic multi-document summarization (MDS). An effective summarization method should properly consider the following three important issues: representativeness, diversity, conciseness.

Many scoring models are proposed to select appropriate sentences from documents to form the summary, in which the clustering-based methods are popular. Some researchers address the sentence scoring task in an *isolation* manner(Radev et al., 2004; Wang et al., 2008; Wan and Yang, 2008) (i.e., clustering and ranking are two independent steps). Others handle the sentence ranking task in a *mutuality* manner(Cai and Li, 2013; Cai et al., 2010; Wang et al., 2011) (i.e., clustering improves ranking and vice versa). Two drawbacks of the existing clustering-based methods are worth noting. First, extra algorithms are required to determine the number of clusters beforehand. Second, models are required to rank or score sentences within and across the clusters after clustering.

Our proposed MDS method is inspired by the recent work on density peaks clustering (DPC) algorithm published on *Science* (Rodriguez and Laio, 2014). The underlying assumption is that *cluster centers are characterized by a higher density than their neighbors and by a relatively large distance from points with higher densities*. In this paper, we adapt the density peaks clustering algorithm(Rodriguez and Laio, 2014) to simultaneously cluster sentences and rank them in the *mutuality* manner. Thanks to the density peaks clustering algorithm, we *do not* need to set the number of clusters and *do not* need a post-processing module to reduce redundancy. From the view of summarization task, *DPC* is superior to other clustering methods because it can not only find the best cluster centers, but also do rank all data points, including

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1262–1267,
Denver, Colorado, May 31 – June 5, 2015.

cluster centers, within and across clusters at the same time. Experimental results on the DUC2004 demonstrate that our method outperforms the best method in DUC04 and yields close results compared to the state-of-the-art unsupervised MDS methods.

The major contributions of this work are two-fold: Firstly, a unified sentence scoring model is proposed to consider representativeness, diversity and conciseness at the same time. Secondly, the density peaks clustering algorithm is first applied in the MDS task. We further revise the clustering algorithm to address the summary length constraint.

2 Related Work

A vast number of methods are reported in literatures on MDS. The MDS methods can be generally categorized into abstractive and extractive. The extractive MDS can be also categorised into supervised and unsupervised. Several supervised learning methods have been developed for training accurate model for extract-based summarization. The unsupervised methods, on the other hand, also contribute a lot to MDS. In this work, we put our contributions in context of the sentence ranking-based extractive MDS under the unsupervised framework.

Several clustering-based MDS methods have also been proposed. For example, ClusterHITS is proposed to incorporate the cluster-level information into the process of sentence ranking(Wan and Yang, 2008). RankClus is proposed to update sentence ranking and clustering interactively and iteratively with frequency relationships between two sentences, or sentences and terms (Cai et al., 2010). Some kinds of matrix factorization methods are also explored in MDS methods(Gong and Liu, 2001; Lee et al., 2009; Wang et al., 2008; Wang et al., 2011; Shen et al., 2011). For example, matrix factorization methods is adopted to generate sentence clusters, in which non-negative factorization is performed on the term-document matrix using the term-sentence matrix as the base so that the document-topic and sentence-topic matrices could be constructed(Wang et al., 2008).

We follow the idea of clustering-based sentence ranking. Different from the previous work, we attempt to design a unified sentence scoring model to rank sentences and reduce redundancy at the same time.

3 Method

In this work, the density peaks sentence clustering (DPSC) method is designed for multi-document summarization.

3.1 Density Peaks Sentence Clustering

The density peaks clustering (DPC) algorithm is achieved upon the object similarity matrix. Objects are finally assigned density values and mini-distance values. In this work, we consider sentences as objects and follow the framework to calculate representativeness score and diversity score of each sentence in a unified model.

To construct the sentence similarity matrix for the DPC algorithm, we first segment documents into sentences and remove the non-stop words in the sentences. We then represent the sentences using bag-of-words vector space model, thus the cosine equation is applicable to calculate sentence similarity. The terms can be weighted with different schemes such as $boolean$ (occurring or not), tf (term frequency) and $tf * isf$ (term frequency inverse sentence frequency). We finally choose the boolean scheme in our experiments because it performs best in our empirical study.

3.2 Representativeness Scoring

For document summarization, we need a representative score to quantify the degree how much a sentence is important in the documents. Enlightened by the DPC algorithm, we assume that when a sentence has more similar sentences (i.e., higher density), it will be considered more important or more representative. Thus we define the following function to calculate the representativeness score $s^{\text{REP}}(i)$ for each sentence s_i:

$$s^{\text{REP}}(i) = \frac{1}{K} \sum_{j=1, j \neq i}^{K} \chi(sim_{ij} - \delta), \qquad (1)$$

$$\chi(x) = \begin{cases} 1 & \text{if } x > 0 \\ 0 & \text{otherwise} \end{cases} \qquad (2)$$

where sim_{ij} denotes the similarity value between the i-th and j-th sentence, and K denotes the number of sentences in the datasets. δ denotes a prede-

fined density threshold. Note that we set the density threshold following (Rodriguez and Laio, 2014), which attempts to exclude the sentences holding lower similarity with the current sentence.

3.3 Diversity Scoring

Most of the previous work handles diversity via reduce redundancy in a post processing module after the sentences are ranked. In this work, we measure diversity in the ranking model.

Diversity score of a sentence is measured by computing the minimum distance between the sentence s_i and any other sentences with higher density score.

In order to reflect the above observation, we define the following function to calculate the diversity score $s^{\text{DIV}}(i)$:

$$s^{\text{DIV}}(i) = 1 - \max_{j:s^{\text{REP}}(j)>s^{\text{REP}}(i)} sim_{ij}. \quad (3)$$

For the sentence with the highest density, we conventionally take

$$s^{\text{DIV}}(i) = 1 - \min_{j\neq i} sim_{ij}. \quad (4)$$

The proposed diversity score looks similar to the famous *Maximum Marginal Relevance* (MMR) (Carbonell and Goldstein, 1998), which is widely used in removing redundancy by using a greedy algorithm to remove sentences that are too similar to the already selected ones. The difference lies that MMR selects a sentence by comparing it to those selected sentences while we compare it to all the other sentences in the dataset, thus it can enhance the diversity globally.

3.4 Length Scoring

It is widely accepted that summarization task has an important constraint, i.e., summary length. In order to satisfy this constraint, the length of selected sentences should be as short as possible. Based on this analysis, we propose the length score, which has relationship with the *effective length* and *real length*. The *real length* is defined as the number of word occurrences that a sentence contains. We then define the *effective length* as how many unique non-stop terms a sentence contains. We finally define the following function to calculate the length score $s^{\text{LEN}}(i)$.

The motivation to propose the length score is, shorter sentences with better representativeness score and diversity score are more favorable for the final summaries. Furthermore, as we use the Boolean scheme to measure sentence similarity, we only count unique words as effective sentence length.

$$s^{\text{LEN}}(i) = \frac{el(s_i)}{\max_{j=1}^{K} el(s_j)} \times \log \frac{\left(\max_{j=1}^{K} rl(s_j)\right)}{rl(s_i)}, \quad (5)$$

where $el(s_i)$ returns the *effective length* of sentence s_i, and $rl(s_i)$ the *real length* of sentence s_i.

3.5 Unified Sentence Scoring

Now we integrate representativeness score, diversity score and length score in the following unified sentence scoring function:

$$s^{\text{DPSC}}(i) = s^{\text{REP}}(i) \times s^{\text{DIV}}(i) \times s^{\text{LEN}}(i). \quad (6)$$

The assumption is obviously that we need those sentences which are as representative, diversified as possible and contain unique terms as many as possible within a limited length.

In calculation, we simply apply logarithm since:

$$s^{\text{DPSC}}(i) \sim \log s^{\text{REP}}(i) + \log s^{\text{DIV}}(i) + \log s^{\text{LEN}}(i) \quad (7)$$

3.6 Summary Generation

As three scores above including the representativeness, diversity and length constraint are measured in a unified sentence scoring model, generating a summary with out method is basically achieved by selecting the higher ranking sentences. In other words, our summary contains more representative and diversified information in the limited length.

Complexity Analysis: Suppose K is the total number of sentences in the document collection. The complexity in calculating the sentence similarity matrix is $O(K^2)$. As the complexity in the function of representativeness scoring, diversity scoring and length scoring are all $O(K)$, the total time complexity of our DPSC method is $O(K^2) + O(K) + O(K) \sim O(K^2)$.

4 Evaluation

Two experiments are reported in this paper: comparing the MDS methods and tuning the density threshold. For both experiments, we use the DUC2004(task 2)[1] dataset, which is annotated manually for generic MDS. We adopted ROUGE (Lin, 2004) version 1.5.5[2] and take F-measure of ROUGE-1, ROUGE-2 and ROUGE-SU as our evaluation metrics. In pre-processing, we use the Porter Stemmer[3] in sentence segmenting, stop-word removing and word stemming. Note that our MDS method is purely unsupervised, and uses no training or development data.

4.1 The MDS Methods

We selected three categories of baselines[4]:

(1) DUC04 MDS methods: *DUC04Best* (Conroy et al., 2004).

(2) Clustering-based MDS methods: *Centroid* (Radev et al., 2004), *ClusterHITS* (Wan and Yang, 2008), *SNMF* (Wang et al., 2008), *RTC* (Cai and Li, 2013), *FGB* (Wang et al., 2011), and *AASum* (Canhasi and Kononenko, 2013).

(3) Other state-of-the-art MDS methods: *LexRank* (graph-based method) (Erkan and Radev, 2004), *CSFO* (optimization-oriented method) (Lin and Bilmes, 2011) and *WCS* (aggregation-oriented method) (Wang and Li, 2012).

For our *DPSC* method, we adopt the following settings: (1) Density threshold is set 0.22 as it is empirically found as optimal in Section 4.2 in the DUC04 dataset. (2) Term weighting scheme is set *Boolean*. In our experiments, *Boolean* is found outperforming *tf* and *tfisf* in sentence representation, this is because term repetition happens less frequently in short text units like sentences than that in documents. Experimental results of the MDS methods are presented in Table 1. Note the ROUGE values of some MDS methods are not reported in the literatures and marked with $'-'$ in Table 1.

According to Table 1, *DPSC* outperforms *DUC04Best*, which ignores the cross-sentence information to solve the diversity problem. *DPSC* outperforms most clustering-based methods except for *AASum*, which performs slightly better than *DPSC* on ROUGE-1. *AASum* is a very complex MDS method which fully exploits the advantages of clustering and the flexibility of matrix factorization. A weakness of the approach is that the number of archetypes must be predefined, and a post-processing module is required to reduce redundancy (Canhasi and Kononenko, 2013).

Table 1: Experimental results of the MDS methods on DUC04.

System	ROUGE-1	ROUGE-2	ROUGE-SU
DUC04Best	0.38224	0.09216	0.13233
Centroid	0.36728	0.07379	0.12511
ClusterHITS	0.36463	0.07632	–
SNMF	–	0.08400	0.12660
RTC	0.37475	0.08973	–
FGB	0.38724	0.08115	0.12957
AASum	**0.41150**	0.09340	0.13760
LexRank	0.37842	0.08572	0.13097
CSFO	0.38900	–	–
WCS	0.39872	**0.09611**	0.13532
DPSC	0.39075	0.09376	**0.14000**

DPSC also outperforms *LexRank* and *CSFO*, and yields close results compared with *WCS*. According to Table 1, *DPSC* performs slightly worse than *WCS*. The marginal performance gain of *WCS* comes from the aggregation strategy, namely, multiple MDS systems are required. As a comparison, *DPSC* is a pure and simple MDS method, exhibiting much lower complexity.

DPSC method is also advantageous on usability, because it does not involve any external resources such as Wordnet and Wikipedia or very complex natural language processing algorithms such as sentence parsing. Moreover, DPSC is a very fast MDS method. Thus it can be easily reproduced and deployed in real environment.

4.2 Density Threshold

Following (Rodriguez and Laio, 2014), we design an experiment on DUC04 dataset to investigate how the density threshold influences quality of the summaries. We tune the density threshold by varying it from 0.10 to 0.40(see the X-axis in Figure 1).

Figure 1 shows that on the specific dataset (i.e., DUC04), *DPSC* reaches the best ROUGE score

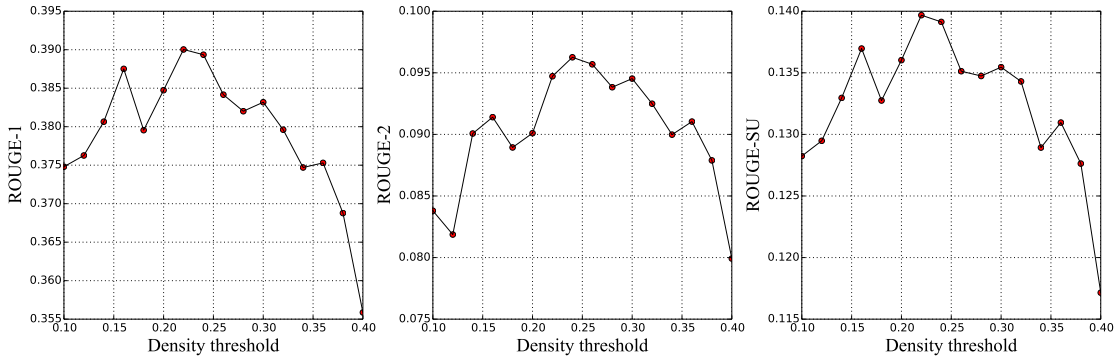

Figure 1: ROUGE curves of DPSC method varying the density threshold.

when the density threshold is set around 0.22 while starts to drop significantly after 0.30. This indicates that 0.22 is a good setting for the density threshold on DUC04.

5 Conclusion and Future Work

In this paper we report the density peaks sentence clustering (DPSC) method for multi-document summarization. Different from the prior work which deals with representativeness and redundancy independently, a unified sentence scoring model is designed in DPSC to combine the representativeness score, the diversity score and the length score of each sentence. Experimental results on DUC04 dataset show that DPSC outperforms the DUC04 best method and the existing clustering-based methods. Meanwhile, it yields close results when compared with the state-of-the-art generic MDS methods. It is thus verified that density peaks clustering algorithm is able to handle MDS effectively.

However, this work is still preliminary. We will study semantic text similarity to improve the sentence similarity matrix. We will then apply the proposed method in query-based multi-document summarization.

Abstract

This paper reports on our research to generate multilingual semantic lexical resources and develop multilingual semantic annotation software, which assigns each word in running text to a semantic category based on a lexical semantic classification scheme. Such tools have an important role in developing intelligent multilingual NLP, text mining and ICT systems. In this work, we aim to extend an existing English semantic annotation tool to cover a range of languages, namely Italian, Chinese and Brazilian Portuguese, by bootstrapping new semantic lexical resources via automatically translating existing English semantic lexicons into these languages. We used a set of bilingual dictionaries and word lists for this purpose. In our experiment, with minor manual improvement of the automatically generated semantic lexicons, the prototype tools based on the new lexicons achieved an average lexical coverage of 79.86% and an average annotation precision of 71.42% (if only precise annotations are considered) or 84.64% (if partially correct annotations are included) on the three languages. Our experiment demonstrates that it is feasible to rapidly develop prototype semantic annotation tools for new languages by automatically bootstrapping new semantic lexicons based on existing ones.

1 Introduction

In this paper, we report on an experiment to develop prototype semantic annotation tools for Italian, Chinese and Brazilian Portuguese based on an existing English annotation tool. Over the last twenty years, semantic lexical resources and semantic annotation tools, such as EuroWordNet (Vossen, 1998) and USAS (Rayson et al., 2004), have played an important role in developing intelligent NLP and HLT systems. Various applications of semantic annotation systems and annotated corpus resources have been reported, including empirical language studies at the semantic level (Rayson et al. 2004; Ooi et al., 2007; Beigman Klebanov et al., 2008; Potts and Baker, 2013) and studies in information technology (Volk, et al., 2002; Nakano et al, 2005; Doherty et al., 2006; Chitchyan et al., 2006; Taiani et al., 2008; Gacitua et al., 2008) among others.

While various semantic annotation tools are available for monolingual analysis, particularly for English, there are few such systems that can carry out semantic analysis of multiple languages with a unified semantic annotation scheme. We aim to address this issue by extending an existing English semantic annotation tool (Rayson et al., 2004) to cover a range of languages.

The USAS semantic annotation tool mentioned above adopts a lexical semantic classification scheme derived from Tom McArthur's Longman Lexicon of Contemporary English (McArthur, 1981), which consists of 21 main discourse fields and 232 sub-fields, such as "social actions, states and processes" and "emotion" etc. It also uses a set

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1268–1274,
Denver, Colorado, May 31 – June 5, 2015.

of auxiliary codes, such as ***m/f*** (male/female), **+/-** (positive/negative) etc. For example, it tags "happy" and "sad" with "E4.1+" and "E4.1-" respectively, indicating positive and negative sentiment. It also identifies many types of multi-word expressions, such as phrasal verbs, noun phrases, named entities and true non-compositional idioms, and annotates them with single semantic tags since this is highly significant for identifying contextual meaning. Recent applications of the USAS tagger include analysis of literary language (Balossi, 2014), the language of psychopaths (Hancock et al, 2013) and scientific deception (Markowitz and Hancock, 2014). There would be obvious benefits if such a semantic tool could cover a wide range of languages. Efforts have been made to port the existing semantic annotation system to other languages (Finnish and Russian) (Löfberg et al., 2005; Mudraya et al., 2006), so a prototype software framework could be used. However, manually developing semantic lexical resources for new languages from scratch is a time consuming task. In this experiment, we examine the feasibility of rapidly bootstrapping semantic lexical resources for new languages by automatically translating existing English semantic lexicons using bilingual dictionaries. We developed prototype semantic annotation tools for Italian, Chinese and Brazilian Portuguese based on automatically generated semantic lexicons. Our evaluation of the tools shows that it is feasible to rapidly develop prototype semantic tools via the aforementioned automatic method, which can be improved and refined manually to achieve a high performance.

2 Related Work

There exist various tools that can semantically annotate multilingual texts, including GATE (Cunningham et al., 2011) and KIM (Popov et al., 2003) which, combined together, provide multilingual semantic annotation functionalities based on ontologies. Freeling (Padró et al., 2012) provides multilingual annotations such as named entity recognition and WordNet sense tagging. Recent developments in this area include Zhang and Rettinger's work (2014) in which they tested a toolkit for Wikipedia-based annotation (wikification) of multilingual texts. However, in the work described here we employ a lexicographically-informed semantic classification scheme and we perform *all-words* annotation. In terms of porting tools from one language to another by translating lexicons, Brooke et al. (2009) obtained poor results from a small dictionary in cross-linguistic sentiment analysis.

3 Generating Multilingual Semantic Lexicons by Automatic Mapping

The USAS tagger relies heavily on the semantic dictionary as its knowledge source, so the main task in the development of our prototype semantic annotation tools for new languages was to generate semantic lexicons, both for single word and multiword expressions (MWE), in which words and MWEs can be associated with appropriate semantic tags. For this purpose, our approach involves mapping existing English semantic lexicons into target languages in order to transfer the semantic tags across translation equivalents. The entries of the English semantic lexicons are classified under the USAS semantic annotation scheme (Archer et al., 2004), which consists of 21 major semantic categories that are further divided into 232 subcategories.

In order to translate the English semantic lexicons into other languages, we needed a bilingual lexicon for each of the target languages, Italian, Chinese and Portuguese in our particular case. For this purpose, we first used two corpus-based frequency dictionaries compiled for Chinese (Xiao et al., 2009) and Portuguese (Davies and Preto-Bay, 2007), which cover the 5,000 most frequent Chinese and Portuguese words respectively. These dictionaries provided high-quality manually edited word translations. In addition, we used large English-Italian and English-Portuguese bilingual lexicons available from FreeLang site (http://www.freelang.net/dictionary) as well as an English-Chinese bilingual word list available from LDC (Linguistic Data Consortium). Compiled without professional editing, these bilingual word lists contain errors and inaccurate translations, and hence they introduced noise into the mapping process. However, they provided wider lexical coverage of the languages involved and complemented the limited sizes of the high-quality dictionaries used in our experiment. Table 1 lists the bilingual lexical resources employed for translating the English lexicons into each of the three languages involved in our experiment.

Language	Lexical resources
Italian	English-Italian FreeLang wordlist (33,700 entries);
Chinese	Chinese/English dictionary (5,000 entries); LDC Eng-Chi bilingual wordlist (110,800 entries)
Portuguese	Portuguese/English dictionary (5,000 entries); English-Portuguese (Brazilian version) FreeLang wordlist (20,980 entries)

Table 1: Bilingual lexical resources used.

The semantic lexicon translation process mainly involves transferring semantic tags from an English lexeme to its translation equivalent/s. For instance, given a pair of word/MWE translations, one of which is English, if the English headword is found in the English semantic lexicon, its semantic categories are passed to its translation equivalents. For the high-quality formal dictionaries, this approach worked very well in our experiment, thanks to the accurate translations and explicit part-of-speech (POS) information provided by such resources.

With the bilingual word lists from FreeLang and LDC, however, this translation process was not straightforward. Firstly, most of the entries of the word lists do not contain any POS information. To avoid losing any potentially relevant semantic tags, we have to consider all possible POS categories of each English headword, and the same applies to their translation equivalents. For example, the English headword "advance" has four possible *C7* POS tags (*JJ*-adjective, *NN1*-singular noun, *VV0*-base form of verb, *VVI*-infinitive verb) in the English semantic lexicon with different semantic categories including *N4* (linear order), *A9-* (giving), *M1* (moving, coming and going), *A5.1* (evaluation: good/bad), *A2.1* (affect: modify, change), Q2.2 (speech acts), *S8+* (helping), *Q2.1* (speech etc: communicative), although with some overlap, as shown below (in each line, the first code is a POS tag and the following ones denote USAS semantic categories[1]):

advance JJ N4
advance NN1 A9- M1 A5.1+/A2.1
advance VV0 M1 A9- Q2.2 A5.1+/A2.1
advance VVI M1 S8+ A9- A5.1+/A2.1 Q2.1

In such a case, for each of the possible translation equivalents of the word "advance", these four types of POS tags and their corresponding semantic tags need to be assigned to their corresponding translations in the target languages. Obviously this would lead to passing wrong and redundant semantic tags to the translation equivalents. Nevertheless, we have to accept such noise in order to increase the chances of obtaining correct semantic tags, as it would be easier to remove redundant/incorrect semantic tags than searching for missing ones in the manual improvement stage.

Another major challenge in the translation process was the mapping between the POS tagsets employed by different lexical resources and tools. Even for the same language, different lexicons and tools can employ different POS tagsets. For example, different Portuguese POS tagsets are used by the Portuguese frequency dictionary and the POS TreeTagger (Schmid, 1994). To bridge between the different POS tagsets, we designed a simplified common POS tagset for each language, into which other tags can be mapped. For example, the Portuguese POS tagset was simplified into 12 categories "adj, adv, det, noun, pnoun, verb, pron, conj, intj, prep, num, punc". Because a single semantic category tends to span similar POS categories, e.g. present/past/progressive tense of verbs, simplification of POS tagsets generally does not affect semantic annotation accuracy.

After applying all the resources and automatic mapping described above, we obtained approximately 38,720, 83,600 and 15,700 semantic lexicon entries for Italian, Chinese and Portuguese respectively. Our initial evaluation involved direct manual checking of these bootstrapped lexicons. For example, 5,622 Italian MWE entries and 1,763 Italian single word entries have been manually corrected. For the Chinese lexicon, the most frequent words were identified using the Chinese word frequency list of Internet Corpus (Sharoff, 2006), and the semantic tags of about 560 entries related to the most frequent words were manually corrected. For Portuguese, about 900 lexicon entries were manually checked.

The manual improvement mainly involves three processes: a) filtering lexicon entries having wrong POS tags, b) selecting correct semantic tags from candidates, c) adding missing semantic tags. The amount of effort needed depends on the quality of the bilingual dictionaries. For example, from the automatically generated 900 Chinese entries containing the most frequent (also highly ambiguous) words, 505 entries were selected after the POS filtering. In addition, 145 of them were improved by

[1] For definitions of the POS and semantic tags, see websites http://ucrel.lancs.ac.uk/claws7tags.html and http://ucrel.lancs.ac.uk/usas/USASSemanticTagset.pdf

adding missing semantic tags. Table 2 shows the sizes of the current lexicons.

Language	Single word entries	MWE entries
Italian	33,100	5,622
Chinese	64,413	19,039
Portuguese	13,942	1,799

Table 2: Sizes of current semantic lexicons.

4 Architecture of Annotation System

Based on the multilingual semantic lexicons described in the previous section, prototype semantic taggers were built for the three languages by deploying the lexicons into the existing software architecture, which employs disambiguation methods reported by Rayson et al. (2004). A set of POS tagging tools were incorporated to pre-process texts from the target languages. The TreeTagger (Schmid, 1994) was used for Italian and Portuguese, and the Stanford POS tagger (Toutanova et al., 2003) was used for Chinese. These tools and semantic lexicon look-up components form pipelines to annotate words in running texts. Figure 1 shows the architecture of the software framework.

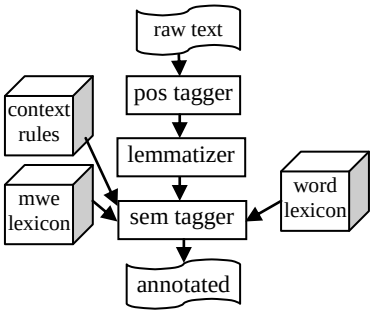

Figure 1: Architecture of the semantic tagger.

5 Evaluation of Prototype System

Following the initial manual evaluation of the prototype semantic taggers described in section 3, we then carried out larger scale automatic evaluations using a set of sample corpora. We conducted two complementary types of evaluations: lexical coverage and annotation precision. The lexical coverage is a particularly interesting metric for our evaluation, as we expect this is where an automatic approach can make significant contribution to the development of annotation systems. On the other hand, high annotation precision normally entails manual improvement of the lexical resources or a period of training on manually tagged corpora.

For the lexical coverage evaluation, three reference corpora were chosen: PAISÀ Italian corpus (Borghetti et al., 2011), LCMC Corpus (Lancaster Corpus of Mandarin Chinese) (McEnery and Xiao, 2004) and Lacio-Ref Portuguese corpus (Aluisio et al., 2003). Because PAISÀ and Lacio-Ref corpora are too large for our purpose, we extracted subsections of about 1.5 million Italian words and 1.7 million Portuguese words from them.

For the evaluation, we annotated the corpus data using the annotation tools of the corresponding target languages, and examined what percentage of the words were assigned with semantic tags. Punctuation marks were excluded in this evaluation process. Table 3 shows the statistics of the evaluation for each language.

Language	Number of words	Tagged words	Lexicon coverage (%)
Italian	1,479,394	1,265,399	85.53
Chinese	975,482	786,663	80.64
Portuguese	1,705,184	1,251,579	73.40
Average			79.86

Table 3: Lexical coverage of the semantic taggers.

As shown in the table, the annotation tools achieved an average lexical coverage of 79.86% over the three languages, with Italian having the highest coverage of 85.53% and Portuguese the lowest coverage of 73.40%. Due to the different types of data in the three sample corpora, this result is not conclusive. Homogeneous corpus data from all of the three languages will be needed to make more reliable comparison of the lexical coverage. Considering that the tools were built based on only three bilingual lexical resources over a short period of time, such lexical coverage is encouraging. This result also demonstrates that, if sufficiently large bilingual lexicons become available; our approach can potentially achieve high lexical coverage.

Next we conducted an evaluation of the precision of the prototype tools. We randomly selected sample texts for each language as follows. Italian sample texts were selected from domains of press, contemporary literature and blogs; Chinese sample texts from press, reviews and fiction; Portuguese sample texts from press and fiction. In the evaluation, we annotated the sample texts using the prototype annotation tools and manually checked the precision among the annotated words. We used two metrics: correctly tagged and partially cor-

rectly tagged. With the current tools, a word can be assigned with multiple candidate semantic tags. The first evaluation metric refers to the cases where the first candidate tag is correct, whereas the other metric refers to the cases where the other tags in the list are correct or closely related to the true word sense. Table 4 shows the statistics of the evaluation.

Lan.	Sample text size	Tagged words	Correct	Partially correct
Ita	4,510	3,266	1,826 (55.91%)	672 (20.58%)
Chi	1,053	813	616 (75.76%)	97 (11.93%)
Port	1,231	953	787 (82.58%)	68 (7.14%)
Avg			71.42%	13.22%

Table 4: Evaluation of precision.

As shown in the table, the Portuguese tagger obtained the highest first-tag precision (82.58%), while the Italian tagger produced a precision (55.91%) significantly lower than others. However, if we include the partially correct annotations, the precision scores become more consistent: 76.49%, 87.69% and 89.72% for the three languages respectively, with an average precision of 84.64%. We also estimated recall based on the numbers of tokens of the sample texts and those tagged correctly/partially correctly, obtaining 55.39%, 67.71% and 69.46% for Italian, Chinese and Portuguese respectively. Such a fairly close range of the precision and recall values indicates that our approach to developing prototype semantic annotation tools can be expected to achieve stable results across various languages, although we need larger-scale evaluations to draw a conclusion. It is worth noting that, although the recall is still low, these taggers are starting to approach the precision of the English system at 91% (Rayson et al., 2004).

Our further error analysis revealed that the main causes of the errors include the homonym translations (e.g. *bank* as river bank vs. money bank), translation errors and missing of the translation words in the English semantic lexicons. For example, the Chinese word "爸爸" (father) has a number of synonymous English translation equivalents in the bilingual lexicon: *dad* (with semantic tag *S4m*), *baba*, *da*, *dada*, *daddy* (*S4m*), *father* (*S4m S9/S2m*), *papa* (*S4m*). It is also translated into *presence* (*M6, A3+, S1.1.3+, S1.2, S9*) by mistake. Among the correct English translations, *baba*, *da*, *dada* (transliteration) are not included in the English semantic lexicons. Making things worse, *da* is a homonym which is classified as a discourse marker of exclamation (*Z4*) in English lexicons. Our current automatic process collects all the semantic tags derived from the English translation counterparts found in the bilingual lexicon and assigns them to the Chinese word "爸爸", resulting in an erroneous entry as shown below:

爸爸 *noun M6 A3+ S1.1.3+ S1.2 S9 S4/B1 S4m S9/S2.2m Z4*

In order to resolve such cases, we will need to consider contexts of each translation word pairs' usage via parallel or comparable corpora.

6 Conclusion and Future Work

In this paper, we have investigated the feasibility of rapidly bootstrapping semantic annotation tools for new target languages[2] by mapping an existing semantic lexicon and software architecture. In particular, we tested the possibility of automatically translating existing English semantic lexicons into other languages, Italian, Chinese and Brazilian Portuguese in this particular case. Our experiment demonstrates that, if appropriate high-quality bilingual lexicons are available, it is feasible to rapidly generating prototype systems with a good lexical coverage with our automatic approach. On the other hand, our experiment also shows that, in order to achieve a high precision, parallel/comparable corpus based disambiguation is needed for identifying precise translation equivalents, and a certain amount of manual cleaning and improvement of the automatically generated semantic lexicons is indispensible. We are continuing to improve the multilingual semantic taggers and extend them to cover more languages, such as Spanish and Dutch, aiming to develop a large-scale multilingual semantic annotation and analysis system. We also intend to perform task-based evaluation of the manually checked versus automatically generated lexicons.

Acknowledgments

Unsupervised Sparse Vector Densification for Short Text Similarity

Yangqiu Song and Dan Roth
Department of Computer Science
University of Illinois at Urbana-Champaign
Urbana, IL 61801, USA
{yqsong,danr}@illinois.edu

Abstract

Sparse representations of text such as bag-of-words models or extended explicit semantic analysis (ESA) representations are commonly used in many NLP applications. However, for short texts, the similarity between two such sparse vectors is not accurate due to the small term overlap. While there have been multiple proposals for dense representations of words, measuring similarity between short texts (sentences, snippets, paragraphs) requires combining these token level similarities. In this paper, we propose to combine ESA representations and word2vec representations as a way to generate denser representations and, consequently, a better similarity measure between short texts. We study three densification mechanisms that involve aligning sparse representation via many-to-many, many-to-one, and one-to-one mappings. We then show the effectiveness of these mechanisms on measuring similarity between short texts.

1 Introduction

Bag-of-words model has been used for many applications as the state-of-the-art method for tasks such as document classifications and information retrieval. It represents each text as a bag-of-words, and computes the similarity, e.g., cosine value, between two sparse vectors in the high-dimensional space. When the contextual information is insufficient, e.g., due to the short length of the document, explicit semantic analysis (ESA) has been used as a way to enrich the text representation (Gabrilovich and Markovitch, 2006; Gabrilovich and Markovitch, 2007). Instead of using only the words in a document, ESA uses a bag-of-concepts retrieved from Wikipedia to represent the text. Then the similarity between two texts can be computed in this enriched concept space.

Both bag-of-words and bag-of-concepts models suffer from the sparsity problem. Because both models use sparse vectors to represent text, when comparing two pieces of texts, the similarity can be zero even when the text snippets are highly related, but make use of different vocabulary. We can expect that these two texts are related but the similarity value does not reflect that. ESA, despite augmenting the lexical space with relevant Wikipedia concepts, still suffers from the sparsity problem. We illustrate this problem with the following simple experiment, done by choosing a documents from the "rec.autos" group in the 20-newsgroups data set[1]. For both documents and the label description "cars" (here we follow the description shown in (Chang et al., 2008; Song and Roth, 2014)), we computed 500 concepts using ESA. Then we identified the concepts that appear both in the document ESA representation and in the label ESA representation. The average sizes of this intersection (number of overlapping concepts in the document and label representation) are shown in Table 1. In addition to the original documents, we also split each document into 2, 4, 8, 16 equal length parts, computed the ESA representation of each, and then the intersection with the ESA representation of the label. Table 1 shows that the number of concepts shared by the label and the document representation decreases significantly, even if not as significantly

[1] http://qwone.com/~jason/20Newsgroups/

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1275–1280,
Denver, Colorado, May 31 – June 5, 2015.

Table 1: Average sizes of the intersection between the ESA concept representations of documents and labels. Both documents and label are represented with 500 Wikipedia concepts. Documents are split into different lengths.

# of split	Avg. # of words per doc.	Avg. # of concepts
1	209.6	23.1
2	104.8	18.1
4	52.4	13.8
8	26.2	10.6
16	13.1	8.4

as the drop in the document size. For example, there are on average 8 concepts in the intersection of two vectors with 500 non-zero concepts when we split each document into 16 parts.

When there are fewer overlapping terms between two pieces of texts, it can cause mismatch or biased match and result in less accurate comparison. In this paper, we propose to use unsupervised approaches to improve the representation, along with a corresponding similarity approach between these representations. Our contribution is twofold. First, we incorporate the popular word2vec (Mikolov et al., 2013a; Mikolov et al., 2013b) representations into ESA representation, and show that incorporating semantic relatedness between Wikipedia titles can indeed help the similarity measure between short texts. Second, we propose and evaluate three mechanisms for comparing the resulting representations. We verify the superiority of the proposed methods using three different NLP tasks.

2 Sparse Vector Densification

In this section, we introduce a way to compute the similarity between two sparse vectors by augmenting the original similarity measure, i.e., cosine similarity. Suppose we have two vectors $\mathbf{x} = (x_1, \ldots, x_V)^T$ and $\mathbf{y} = (y_1, \ldots, y_V)^T$ where V is the vocabulary size. Traditional cosine similarity computes the dot product between these two vectors and normalizes it by their norms: $\cos(\mathbf{x}, \mathbf{y}) = \frac{\mathbf{x}^T\mathbf{y}}{||\mathbf{x}||\cdot||\mathbf{y}||}$. This requires each dimension of $\mathbf{x}$ to be aligned with the same dimension of $\mathbf{y}$. Note that for sparse vectors $\mathbf{x}$ and $\mathbf{y}$, most of the the elements can be zero. Aligning the indices can result in zero similarity even though the two pieces of texts are related. Thus, we propose to align different indices of $\mathbf{x}$ and $\mathbf{y}$ together to increase the similarity value.

We can rewrite the vectors $\mathbf{x}$ and $\mathbf{y}$ as $\mathbf{x} = \{x_{a_1}, \ldots, x_{a_{n_x}}\}$ and $\mathbf{y} = \{y_{b_1}, \ldots, y_{b_{n_y}}\}$, where a_i and b_j are indices of the non-zero terms in $\mathbf{x}$ and $\mathbf{y}$ ($1 \leq a_i, b_j \leq V$). x_{a_i} and y_{b_i} are the weights associated to the terms in the vocabulary. Suppose there are non-zero terms n_x and n_y in $\mathbf{x}$ and $\mathbf{y}$ respectively. Then cosine similarity can be rewritten as:

$$\cos(\mathbf{x}, \mathbf{y}) = \frac{\sum_{i=1}^{n_x}\sum_{j=1}^{n_y}\delta(a_i - b_j)x_{a_i}y_{b_j}}{||\mathbf{x}|| \cdot ||\mathbf{y}||}, \quad (1)$$

where $\delta(\cdot)$ is the Dirac function $\delta(0) = 1$ and $\delta(\text{other}) = 0$. Suppose we can compute the similarity between terms a_i and b_j, which is denoted as $\phi(a_i, b_j)$, then the problem is how to aggregate the similarities between all a_i's and b_j's to augment the original cosine similarity.

2.1 Similarity Augmentation

The most intuitive way to integrate the similarities between terms is averaging them:

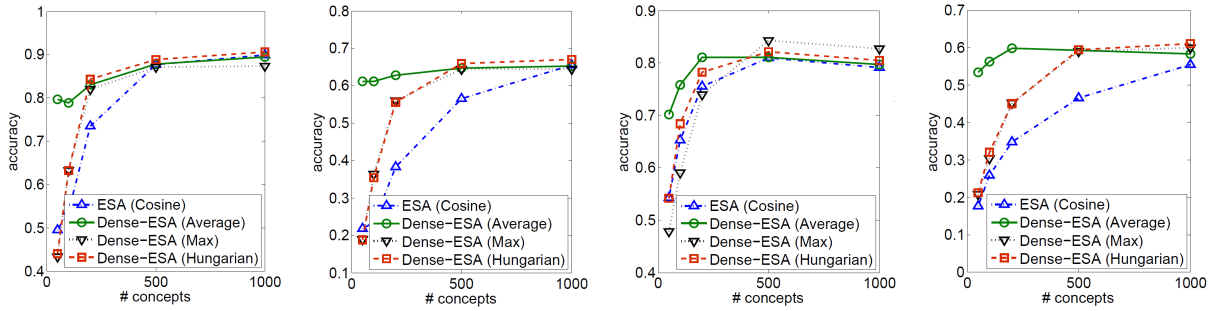
$$S_A(\mathbf{x}, \mathbf{y}) = \frac{1}{n_x||\mathbf{x}|| \cdot n_y||\mathbf{y}||}\sum_{i=1}^{n_x}\sum_{j=1}^{n_y}x_{a_i}y_{b_j}\phi(a_i, b_j). \quad (2)$$

This similarity averages all the pairwise similarities between terms a_i's and b_j's. However, we can expect a lot of the similarities $\phi(a_i, b_j)$ to be close to zero. In this case, instead of introducing the relatedness between nonidentical terms, it will also introduce noise. Therefore, we also consider an alignment mechanism that we implement greedily via a maximum matching mechanism:

$$S_M(\mathbf{x}, \mathbf{y}) = \frac{1}{||\mathbf{x}|| \cdot ||\mathbf{y}||}\sum_{i=1}^{n_x}x_{a_i}y_{b_j}\max_j \phi(a_i, b_j). \quad (3)$$

We choose j as $\text{argmax}_{j'}\,\phi(a_i, b_{j'})$ and substitute the similarity $\phi(a_i, b_j)$ between terms a_i and b_j into the final similarity between $\mathbf{x}$ and $\mathbf{y}$. Note that this similarity is not symmetric. Thus, if one needs a symmetric similarity, the similarity can be computed by averaging two similarities $S_M(\mathbf{x}, \mathbf{y})$ and $S_M(\mathbf{y}, \mathbf{x})$.

The above two similarity measurements are simple and intuitive. We can think about $S_A(\mathbf{x}, \mathbf{y})$ as leveraging term many-to-many mapping, while



(a) rec.autos vs. sci.electronics (full doc.) (b) rec.autos vs. sci.electronics (1/16 doc.) (c) rec.autos vs. rec.motorcycles (full doc.) (d) rec.autos vs. rec.motorcycles (1/16 doc.)

Figure 1: Accuracy of dataless classification using ESA and Dense-ESA with different numbers of concepts.

$S_M(\mathbf{x}, \mathbf{y})$ uses only one-to-many term mapping. $S_A(\mathbf{x}, \mathbf{y})$ can introduce small and noisy similarity values between terms. While $S_M(\mathbf{x}, \mathbf{y})$ essentially aligns each term in $\mathbf{x}$ with it's best match in $\mathbf{y}$, we run the risk that multiple components of $\mathbf{x}$ will select the same element in $\mathbf{y}$. To ensure that all the non-zero terms in $\mathbf{x}$ and $\mathbf{y}$ are matched, we propose to constrain this metric by disallowing many-to-one mapping. We do that by using a similarity metric based on the Hungarian method (Papadimitriou and Steiglitz, 1982). The Hungarian method is a combinatorial optimization algorithm that solves the bipartite graph matching problem by finding an optimal assignment matching the two sides of the graph on a one-to-one basis. Assume that we run the Hungarian method on the the pair $\{\mathbf{x}, \mathbf{y}\}$, and let $h(a_i) = b_j$ denote the outcome of the algorithm, that is a_i is aligned with b_j. (We assume here, for simplicity, that $n_x = n_y$; we can always achieve that by adding some zero weighted terms that are not aligned). The we define the similarity as:

$$S_H(\mathbf{x}, \mathbf{y}) = \frac{1}{||\mathbf{x}|| \cdot ||\mathbf{y}||} \sum_{i=1}^{n_x} x_{a_i} y_{h(a_i)} \phi(a_i, h(a_i)). \quad (4)$$

2.2 Term Similarity Measure

To evaluate the term similarity $\phi(\cdot, \cdot)$, we use local contextual similarity based on distributed representations. We adopt the word2vec (Mikolov et al., 2013a; Mikolov et al., 2013b) approach to obtain a dense representation of words. The representation of each word is predicted based on the context word distribution in a window around it. We trained word2vec on the Wikipedia dump data using the default parameters (CBOW model with window size as five). For each word, we finally obtained a 200 dimensional vector. If the term is a phrase, we simply average words' vectors of each phrase to obtain the representation following the original word2vec approach (Mikolov et al., 2013a; Mikolov et al., 2013b). We use two vectors $\mathbf{a}$ and $\mathbf{b}$ to represent the vectors for the two terms. To evaluate the similarity between two terms, for the average approach as Eq. (2), we use the RBF kernel over the two vectors $\exp\{-||\mathbf{a} - \mathbf{b}||^2/(0.03 \cdot ||\mathbf{a}|| \cdot ||\mathbf{b}||)\}$ as the similarity for all the experiments, since this will have a good property to cut the terms with small similarities. For the max and Hungarian approach as Eqs. (3) and (4), we simply use the cosine similarity between the two word2vec vectors. In addition, we cut off all similarities below threshold γ and map them to zero.

3 Experiments

We experiment on three data sets. We use dataless classification (Chang et al., 2008; Song and Roth, 2014) over 20-newsgroups data set to verify the correctness of our argument of short text problems, and use two short text data sets to evaluate document similarity measurement and event classification for sentences.

3.1 Dataless Classification

Dataless classification uses the similarity between documents and labels in an enriched "semantic" space to determine in which category the given document is. In this experiment, we used the label descriptions provided by (Chang et al., 2008). It has been shown that ESA outperforms other representations for dataless classification (Chang et al., 2008; Song and Roth, 2014). Thus, we chose ESA as our

Table 2: Accuracy of dataless classification using ESA and Dense-ESA with 500 dimensions.

	rec.autos vs. sci.electronics (easy)		rec.autos vs. rec.motorcycles (difficult)	
Method	Full document	Short (1/16 doc.)	Full document	Short (1/16 doc.)
ESA (Cosine)	87.75%	56.55%	80.95%	46.64%
Dense-ESA (Average)	87.80%	64.67%	81.11%	59.38%
Dense-ESA (Max)	87.10%	64.34%	**84.30%**	59.11%
Dense-ESA (Hungarian)	**88.85%**	**65.95%**	82.15%	**59.65%**

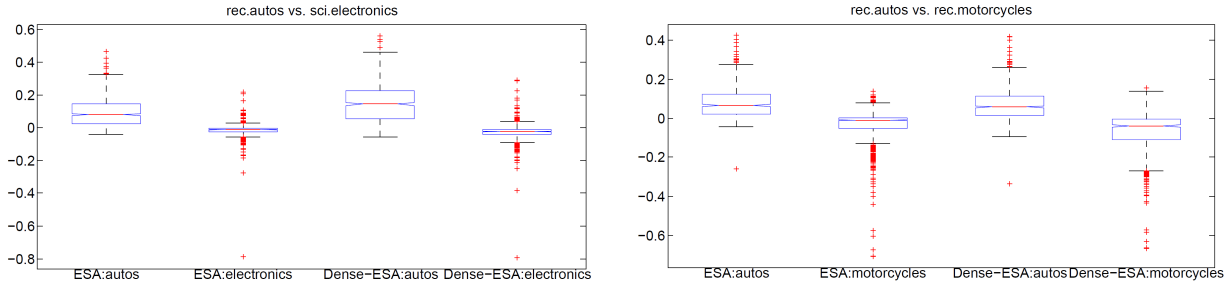


Figure 2: Boxplot of similarity scores for "rec.autos vs. sci.electronics" (easy, left) and "rec.autos vs. rec.motorcycles" (difficult, right). For each method of ESA and Dense-ESA with max matching in Eq. (3), we compute $S(d, l_1)$ and $S(d, l_2)$ between a document d and the labels l_1 and l_2. Then we compute $S(d) = S(d, l_1) - S(d, l_2)$. For each ground truth label, we draw the distribution of $S(\cdot)$ with outliers in the figures. For example, "ESA:autos" shows the $S(\cdot)$'s distribution of the data with label "rec.autos." The t-test results show that the distributions of different labels are significantly different (99%). We can see that Dense-ESA pulls apart the distributions of different labels and that the separation is more significant for the more difficult problem (right).

baseline method. To demonstrate how the length of documents affects the classification result, we used both full documents and the 16 split parts (the parts are associated with the same label as the original document). To demonstrate the impact of densification, we selected two problems as an illustration: "rec.autos vs. sci.electronics" and "rec.autos vs. rec.motorcycles." While the former problem is relatively easy since they belong to different super-classes, the latter problem is more difficult since they are under the same super-class. The value of threshold γ for max matching and Hungarian based densification is set to 0.85 empirically.

Figure 1 shows the results of the dataless classification using ESA and ESA with densification (Dense-ESA) with different numbers of Wikipedia concepts as the representation dimensionality. We can see that Dense-ESA significantly improves the dataless classification results. As shown in Table 2, while the max matching and Hungarian matching based methods are typically the best metrics the most significant results, the improvements are more significant for shorter documents, and for more difficult problems. Figure 2 highlights this observation.

Table 3: Spearman's correlation of document similarity using ESA and Dense-ESA with 500 concepts.

Method	Spearman's correlation
ESA (Cosine)	0.5665
Dense-ESA (Average)	0.5814
Dense-ESA (Max)	0.5888
Dense-ESA (Hungarian)	**0.6003**

3.2 Document Similarity

We used the data set provided by Lee et al.[2] (Lee et al., 2005) to evaluate pairwise short document similarity. There are 50 documents and the average number of words is 80.2. We averaged all the human annotations for the same document pair as the similarity score. After computing the scores for pairs of documents, we used Spearman's correlation to evaluate the results. Larger correlation score means that the similarity is more consistent with human annotation. The best word level based similarity result is close to 0.5 (Lee et al., 2005). We tried the cosine similarity between ESA representations and

[2]http://faculty.sites.uci.edu/mdlee/similarity-data/

Table 4: F_1 of sentence event type classification using ESA and Dense-ESA with 500 concepts.

Method	F_1 (mean±std)
ESA (Cosine)	0.469±0.011
Dense-ESA (Average)	0.451±0.010
Dense-ESA (Max)	**0.481±0.008**
Dense-ESA (Hungarian)	0.475±0.016

also Dense-ESA. The value of γ for max matching based densification is set to 0.95, and for Hungarian based densification it is set to 0.89. We can see that from Table 3, ESA is better than the word based method, and that all versions of Dense-ESA outperform the original ESA.

3.3 Event Classification

In this experiment, we chose the ACE2005[3] data set to test how well we can classify sentences into event types without any training. There are eight types of events: life, movement, conflict, contact, etc. We chose all the sentences that contain event information as the data set. Following the dataless classification protocol, we compare the similarity between sentences and label descriptions to determine the event types. There are 3,644 unique sentences with events, including 2,712 sentences having only one event type, 421 having two event types, and 30 having three event types. The average length of the sentences is 23.71. Thus, this is a multi-label classification problem. To test the approaches, we used five-fold cross validation to select the thresholds for each class to classify whether the sentence belongs to an event type. The value of threshold γ for both max matching and Hungarian based densification is also set to 0.85 empirically. Then we report the mean and standard derivation over five runs. The results are shown in Table 4. We can see that Dense-ESA also outperforms ESA.

4 Related Work

ESA (Gabrilovich and Markovitch, 2006; Gabrilovich and Markovitch, 2007) and distributed word representations (Ratinov and Roth, 2009; Turian et al., 2010; Collobert et al., 2011; Mikolov et al., 2013a; Mikolov et al., 2013b; Pennington et al., 2014) are popular text representations that encode world knowledge. Recently, several representations were proposed to extend word representations for phrases or sentences (Lu and Li, 2013; Hermann and Blunsom, 2014; Passos et al., 2014; Kalchbrenner et al., 2014; Le and Mikolov, 2014; Hu et al., 2014; Sutskever et al., 2014; Zhao et al., 2015). In this paper, we evaluate how to combine two off-the-shelf representations to densify the similarity between text data.

Yih et al. also used average matching and a different maximum matching for QA problem (Yih et al., 2013). However, their sparse representation is still at the word level while ours is based on ESA. Interestingly, related ideas to our average matching mechanism have been proposed also in the computer vision community, which is the set kernel (or set similarity) (Smola et al., 2007; Gretton et al., 2012; Xiong et al., 2013).

5 Conclusion

In this paper, we study the mechanisms of combining two popular representations of text, i.e., ESA and word2vec, to enhance computing short text similarity. Furthermore, we proposed three different mechanisms to compute the similarity between these representations, and demonstrated, using three different data sets that the proposed method outperforms the traditional ESA.

Abstract

In September 2014, Twitter users unequivocally reacted to the Ray Rice assault scandal by unleashing personal stories of domestic abuse via the hashtags `#WhyIStayed` or `#WhyILeft`. We explore at a macro-level firsthand accounts of domestic abuse from a substantial, balanced corpus of tweeted instances designated with these tags. To seek insights into the reasons victims give for staying in vs. leaving abusive relationships, we analyze the corpus using linguistically motivated methods. We also report on an annotation study for corpus assessment. We perform classification, contributing a classifier that discriminates between the two hashtags exceptionally well at 82% accuracy with a substantial error reduction over its baseline.

1 Introduction

Domestic abuse is a problem of pandemic proportions; nearly 25% of females and 7.6% of males have been raped or physically assaulted by an intimate partner (Tjaden and Thoennes, 2000). These numbers only include physical violence; psychological abuse and other forms of domestic abuse may be even more prevalent. There is thus an urgent need to better understand and characterize domestic abuse, in order to provide resources for victims and efficiently implement preventative measures.

Survey methods exploring domestic abuse involve considerable time and investment, and may suffer from under-reporting, due to the taboo and stressful nature of abuse. Additionally, many may not have the option of directly seeking clinical help. Social media may provide a less intimidating and more accessible channel for reporting, collectively processing, and making sense of traumatic and stigmatizing experiences (Homan et al., 2014; Walther, 1996). Such data has been used for analyzing and predicting distinct societal and health issues, aimed at improving the understanding of wide-reaching societal concerns. For instance, Choudhury et al. (2013) predicted the onset of depression from user tweets, while other studies have modeled distress (Homan et al., 2014; Lehrman et al., 2012). Xu et al. (2013) used Twitter data to identify bullying language, then analyzed the characteristics of these tweets, and forecasted if a tweet would be deleted out of regret.

In September 2014, in the wake of the Ray Rice assault scandal[1] and the negative public reaction to the victim's decision to stay and support her abuser, Twitter users unequivocally reacted in a viral discussion of domestic abuse, defending the victim using the hashtag #WhyIStayed and contrasting those with #WhyILeft. Such narrative sharing may have a cathartic and therapeutic effect, extending the viral reach of the trend.

Analysis of the linguistic structures embedded in these tweet instances provides insight into the critical reasons that victims of domestic abuse report for choosing to stay or leave. Trained classifiers agree with these linguistic structures, adding evidence that these social media texts provide valuable insights into domestic abuse.

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1281–1286,
Denver, Colorado, May 31 – June 5, 2015.

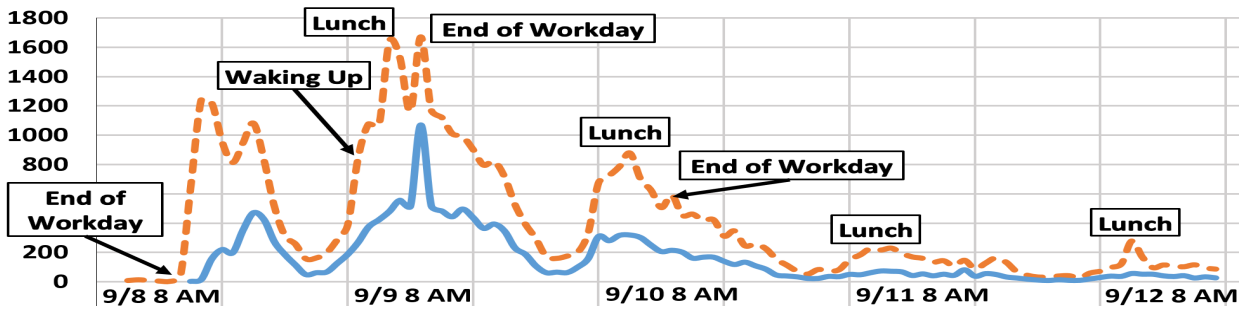

Figure 1: Tweet count per hour with #WhyIStayed (dotted) or #WhyILeft (solid) from 9/8 to 9/12. Times in EST, vertical lines mark 12 hour periods, with label corresponding to its left line. Spam removed, includes meta tweets.

2 Data

We collected a new corpus of tweets using the Twitter and Topsy[2] application programming interfaces. The corpus spans the beginning of September (the start of the trend) to the beginning of October, 2014. We fully rehydrated the tweets (to update the retweet count, etc.) at the end of the collection period. Figure 1 displays the behavior from the initial days of this trend. Due to its viral nature, the majority of tweets are from the first week of the trend's creation.

2.1 Preprocessing

We removed spam tweets based on the usernames of the most prevalent spammers, as well as key spam hashtags.[3] We also removed tweets related to a key controversy, in which the Twitter account for DiGiorno Pizza (ignorant of the trend's meaning) tweeted *#WhyIStayed You had pizza*.[4] This resulted in over 57,000 unique tweets in the corpus.

Many tweets in the dataset were reflections on the trend itself or contained messages of support to the users sharing their stories, for example, *Not usually a fan of hashtag trends, but #WhyIStayed is incredibly powerful. #NFL #RayRice*.[5] These tweets, here denoted *meta-tweets*, were often retweeted, but they rarely contained reasons for staying or leaving (our interest), so we filtered them out by keyword.[6] In section 2.3 we empirically explore the remaining instances.

[2]For outside Twitter's history, `http://topsy.com/`

[3]Such as *#MTVEMA, #AppleWatch, #CMWorld*.

[4]Removed by keywords *pizza, digiorno*.

[5]Illustrative tweet examples were anonymized and we purposefully attempted to minimize inclusion of sensitive content.

[6]Including *janay/ray rice, football, tweets, trend, video, etc.*

2.2 Extracting Gold Standard Labels

Typically, users provided reasons for staying and leaving, with the reasons prefixed by or appended with the hashtags #WhyIStayed or #WhyILeft as in this example: *#WhyIStayed because he told me no one else would love me. #WhyILeft because I gained the courage to love myself.* Regular expressions matched these structures and for tweets marked by both tags, split them into multiple instances, labeled with their respective tag. If the tweet contained only one of the target hashtags, the instance was labeled with that hashtag. If the tweet contained both hashtags but did not match with any of the regular expressions, it was excluded to ensure data quality.

The resulting corpus comprised 24,861 #WhyIStayed and 8,767 #WhyILeft labeled datapoints. The class imbalance may be a result of the origins of the trend rather than an indicator that more victims stay than leave. The tweet that started the trend contained only the hashtag #WhyIStayed, and media reporting on the trend tended to refer to it as the "#WhyIStayed phenomenon." As Figure 1 shows, the first #WhyILeft tweet occurred hours after the #WhyIStayed trend had taken off, and never gained as much use. By this reasoning, we concluded that an even set of data would be appropriate, and enable us to use the ratio metric in experiments discussed in this paper, as well as compare themes in the two sets. By random sampling of #WhyIStayed, a balanced set of 8,767 examples per class was obtained, resulting in a binary 50% baseline. From this set, 15% were held out as a final testset, to be considered after a tuning procedure with the remaining 85% devset.

2.3 Annotation Study

Four people (co-authors) annotated a random sample of 1000 instances from the devset, to further characterize the filtered corpus and to assess the automated extraction of gold standard labels. This random subset is composed of 47% #WhyIStayed and 53% #WhyILeft gold standard samples. Overall agreement overlap was 77% and Randolph's free-marginal multirater kappa (Warrens, 2010) score was 0.72. According to the annotations in this random sample, on average 36% of the instances are reasons for staying (S), 44% are reasons for leaving (L), 12% are meta comments (M), 2% are jokes (J), 2% are ads (A), and 4% do not match prior categories (O). Table 1 shows that most related directly to S or L, with annotators identifying more clearly L. Of interest are examples in which annotators did not agree, as these are indicative of problems in the data, and are samples that a classifier will likely label incorrectly. The tweet *because i was slowly dying anyway* was marked by two annotators as S and two annotators as L. Did the victim have no hope left and decide to stay? Or did the victim decide that since they were "slowly dying anyway" they could attempt to leave despite the possibility of potentially being killed in the attempt? The ground truth label is #WhyILeft. Another example with two annotators labeling as S and two as L is *two years of bliss, followed by uncertainty and fear*. This tweet's label is #WhyIStayed. The limited context from these samples makes it difficult to interpret fully, and causes human annotators to fail; however, most cases contain clear enough reasoning to interpret correctly.

		A	J	L	M	O	S
A1	#L	.01	.01	.78	.11	.03	.07
	#S	.01	.03	.10	.21	.02	.63

	#S	.03	.01	.16	.12	.05	.63

Table 1: Confusion matrices of all 4 annotators, compared to the gold standard. Annotators mostly identified reasons for staying or leaving, and only a small fraction were unrelated. #L=#WhyILeft, #S=#WhyIStayed.

3 Methods for Exploring Reasons

3.1 Cleaning and Classifier Tuning

All experiments used the same cleaned data: removing hashtags, replacing URLs with the token *url* and user mentions with *@mention*, and replacing common emoticons with a sentiment indicator: *emotsent*$\{p|n|neut\}$ for positive/negative/neutral. Informal register was expanded to standard English forms using a slang dictionary.[7] Classifier tuning involved 5-fold cross-validation and selecting the best parameters based on the mean accuracy. For held-out data testing the full devset was used for training.

3.2 Analysis of Vocabulary

We examined the vocabulary in use in the data of the two hashtag sets by creating a frequency distribution of all unigrams after stoplisting and lowercasing. The wordcloud unigrams in Figure 2 are weighted by their relative frequency. These wordclouds hint at the reasons; however, decontextualized unigrams lead to confusion. For example, why does *left* appear in both? Other experiments were done to provide context and expand analysis.

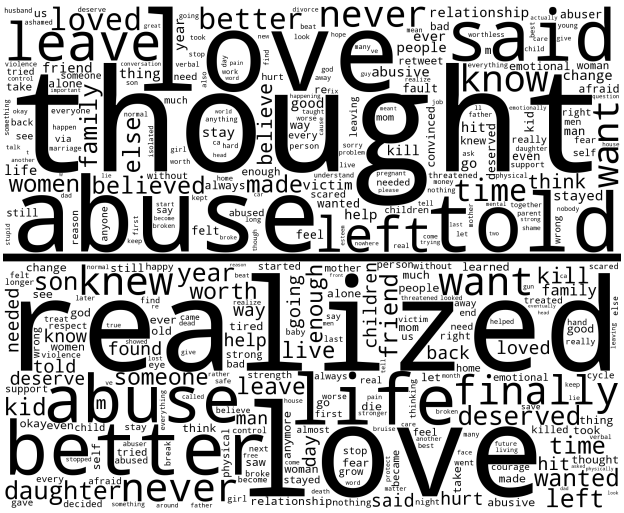

Figure 2: A wordcloud of unigrams, weighted by unigram frequencies, for (top) #WhyIStayed instances and (bottom) #WhyILeft instances.[8]

Most discriminative *victim as subject* verbs									
believe	choose	decide	felt	know	learn	realize	think	want	
0.81	1	1	0.79	0.82	1	0.99	0.93	0.83	

Table 2: Discriminative verbs for *abuser onto victim* and *victim as subject* structures.

3.3 Analysis of Subject-Verb-Object Structures

Data inspection suggested that many users explained their reasons using a Subject-Verb-Object (SVO) structure, in which the abuser is doing something to the victim, or the victim is explaining something about the abuser or oneself.[9] We used the open-source tools Tweeboparser (Kong et al., 2014) and TurboParser (Martins et al., 2013) to heuristically extract syntactic dependencies, constrained by pronomial usage. Both parsers performed similarly, most likely due to the well-formed English in the corpus. While tweets are known for non-standard forms, the seriousness of the discourse domain may have encouraged more standard writing conventions.

Using TurboParser, we conducted an analysis for both male and female genders acting as the abuser in the subject position. Starting at the lemmatized predicate verb in each dependency parse, if the predicate verb followed an abuser subject word[10] per the dependency links, and preceded a victim object word,[11] it was added to a conditional frequency distribution, with the two classes as conditions. These structures are here denoted *abuser onto victim*. We used similar methods to extract structures in which the victim is the subject. Instances with female abusers were rare, and statistical gender differences could not be pursued. Accordingly, both genders' frequency counts were combined. Discriminative predicates from these conditional frequency distributions were determined by equation (1). In Table 2 we report on those where the ratio is greater than 0.75 and the total count exceeds a threshold to avoid bias towards lower frequency verbs.

$$ratio = \frac{count_{largerOfCounts}}{count_{left} + count_{stayed}} \quad (1)$$

[9]Example: *He hurt my child* S: *He*, V: *hurt*, O: *my child*.

[10]Male abuser: *he, his, my bf*, etc. Female: *she, her*, etc.

[11]Male victim: *me, my, him*, etc. *Female: me, my, her*, etc.

3.4 Classification Experiments

We examined the usefulness of the SVO structures, using subsets of the devset and testset having SVO structures (10% of the instances in total). While 10% is not a large proportion overall, given the massive number of possible dependency structures, it is a pattern worth examining – not only for corpus analytics but also classification, particularly as these SVO structures provide insight into the abuser-victim relationship. A linear SVM using boolean SVO features performed best (C=1), obtaining $70\% \pm 2\%$ accuracy on the devset and 73% accuracy on the testset. The weights assigned to features by a Linear SVM are indicative of their importance (Guyon et al., 2002). Here, the top features presented as (S,V,O) for #WhyIStayed were: *(he, introduce, me)*, *(i, think, my)*, *(he, convince, me)*, *(i, believe, his)*, and *(he, beat, my)*. For #WhyILeft they were *(he, choke, me)*, *(i, beg, me)*, *(he, want, my)*, *(i, realize, my)*, and *(i, listen, my)*.

The SVO structures capture meaning related to staying and leaving, but are limited in their data coverage. Another experiment explored an extended feature set including uni-, bi-, and trigrams in sublinear $tf \times idf$ vectors, tweet instance character length, its retweet count, and SVO structures. We compared Naïve Bayes, Linear SVM, and RBF SVM classifiers from the Scikit-learn package (Pedregosa et al., 2011). The RBF SVM performed slightly better than the others, achieving a maximum accuracy of $81\% \pm .3\%$ on the devset and 82% on the testset.[12,13] Feature ablation, following the procedure in Fraser et al. (2014), was utilized to determine the most important features for the classifier, the results

[12]Tuned parameters: max df = 11%, C=10, gamma=1.

[13]Dimensionality reduction with Supervised Locality Preserving Projections (SLPP) (Ptucha and Savakis, 2014) was attempted, but this did not improve results.

of which can be seen in Table 3.

Removed	Remaining Features	% Acc
	NG+E+IR+TL+RT+SVO	81.90
SVO	NG+E+IR+TL+RT	82.09
TL	NG+E+IR+RT	82.21
E	NG+IR+RT	82.21
RT	NG+IR	82.13
IR	NG	81.48

Table 3: Feature ablation study with an RBF SVM and no dimensionality reduction. NG = ngrams, E = emoticon replacement, IR = informal register replacement, TL = tweet length, RT = retweet count, SVO = subject-verb-object structures. % Acc is accuracy on the testset.

Interestingly, the SVO features combined with ngrams worsened performance slightly, perhaps due to trigrams capturing the majority of SVO cases. The highest accuracy, 82.21% on the testset, could be achieved with a combination of ngrams, informal register replacement, and retweet count. However the vast majority of cases can be classified accurately with ngrams alone. Emoticons may not have contributed to performance since they were rare in the corpus. Standardizing non-standard forms presumably helped the SVM slightly by boosting the frequency counts of ngrams while removing non-standard ngrams. Tweet length reduced accuracy slightly, while the number of retweets helped.

4 Discussion

From the analyses of SVO structures, word-clouds, and Linear SVM weights, interesting micro-narratives of staying and leaving emerge. Victims report staying in abusive relationships due to cognitive manipulation, as indicated by a predominance of verbs including *manipulate, isolate, convince, think, believe, felt* while report leaving when experiencing or fearing physical violence, via predicates such as *kill* and *kick*. They also report staying when in dire financial straits (*money*), when attempting to keep the nuclear family united (*family, marriage*) or when experiencing shame about their situation (*ashamed, shame*). They report leaving when threats are made towards loved-ones (*son, daughter*), gain agency (*choose, decide*), realize their situation or self-worth (*realize, learn, worth, deserve, finally, better*), or gain support from friends or family (*courage, support, help*). Importantly, such reasons for staying are validated in the clinical literature (Buel, 1999).

5 Conclusion

We discuss and analyze a filtered, balanced corpus having the hashtags #WhyIStayed or #WhyILeft. Our analysis reveals micro-narratives in tweeted reasons for staying vs. leaving. Our findings are consistent across various methods, correspond to observations in the clinical literature, and affirm the relevance of NLP for exploring issues of social importance in social media. Future work will focus on improving SVO extraction, especially adding consideration for negations of predicate verbs. In addition we will analyse other hashtags in use in the trend and perform further analysis of the trend itself, implement advanced text normalization rather than relying on a dictionary, and determine the roles features from linked webpages and FrameNet or other semantic resources play in making sense of domestic abuse.

Abstract

Linguistic similarity is multi-faceted. For instance, two words may be similar with respect to semantics, syntax, or morphology *inter alia*. Continuous word-embeddings have been shown to capture most of these shades of similarity to some degree. This work considers guiding word-embeddings with morphologically annotated data, a form of semi-supervised learning, encouraging the vectors to encode a word's morphology, i.e., words close in the embedded space share morphological features. We extend the log-bilinear model to this end and show that indeed our learned embeddings achieve this, using German as a case study.

1 Introduction

Word representation is fundamental for NLP. Recently, continuous word-embeddings have gained traction as a general-purpose representation framework. While such embeddings have proven themselves useful, they typically treat words holistically, ignoring their internal structure. For morphologically impoverished languages, i.e., languages with a low morpheme-per-word ratio such as English, this is often not a problem. However, for the processing of morphologically-rich languages exploiting word-internal structure is necessary.

Word-embeddings are typically trained to produce representations that capture linguistic similarity. The general idea is that words that are close in the embedding space should be close in meaning. A key issue, however, is that meaning is a multi-faceted concept and thus there are multiple axes, along which two words can be similar. For example, `ice` and `cold` are *topically* related, `ice` and `fire` are *syntactically* related as they are both nouns, and `ice` and `icy` are *morphologically* related as they are both derived from the same root. In this work, we are interested in distinguishing between these various axes and guiding the embeddings such that similar embeddings are morphologically related.

We augment the log-bilinear model (LBL) of Mnih and Hinton (2007) with a multi-task objective. In addition to raw text, our model is trained on a corpus annotated with morphological tags, encouraging the vectors to encode a word's morphology. To be concrete, the first task is language modeling—the traditional use of the LBL—and the second is akin to unigram morphological tagging. The LBL, described in section 3, is fundamentally a language model (LM)—word-embeddings fall out as low dimensional representations of context used to predict the next word. We extend the model to jointly predict the next morphological tag along with the next word, encouraging the resulting embeddings to encode morphology. We present a novel metric and experiments on German as a case study that demonstrates that our approach produces word-embeddings that better preserve morphological relationships.

2 Related Work

Here we discuss the role morphology has played in language modeling and offer a brief overview of various approaches to the larger task of computational morphology.

2.1 Morphology in Language Modeling

Morphological structure has been previously integrated into LMs. Most notably, Bilmes and Kirch-

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1287–1292,
Denver, Colorado, May 31 – June 5, 2015.

ARTICLE	ADJECTIVE	NOUN
ART.DEF.NOM.SG.FEM	ADJ.NOM.SG.FEM	N.NOM.SG.FEM
die	größte	Stadt
the	biggest	city

Table 1: A sample German phrase in TIGER (Brants et al., 2004) annotation with an accompanying English translation. Each word is annotated with a complex morphological tag and its corresponding coarse-grained POS tag. For instance, Stadt is annotated with N.NOM.SG.FEM indicating that it is a *noun* in the *nominative* case and also both *singular* and *feminine*. Each tag is composed of meaningful *sub-tag units* that are shared across whole tags, e.g., the feature NOM fires on both adjectives and nouns.

hoff (2003) introduced *factored LMs*, which effectively add tiers, allowing easy incorporation of morphological structure as well as part-of-speech (POS) tags. More recently, Müller and Schütze (2011) trained a class-based LM using common suffixes—often indicative of morphology—achieving state-of-the-art results when interpolated with a Kneser-Ney LM. In neural probabilistic modeling, Luong et al. (2013) described a recursive neural network LM, whose topology was derived from the output of MORFESSOR, an unsupervised morphological segmentation tool (Creutz and Lagus, 2005). Similarly, Qiu et al. (2014) augmented WORD2VEC (Mikolov et al., 2013) to embed morphs as well as whole words—also taking advantage of MORFESSOR. LMs were tackled by dos Santos and Zadrozny (2014) with a convolutional neural network with a k-best max-pooling layer to extract character level n-grams, efficiently inserting orthographic features into the LM—use of the vectors in down-stream POS tagging achieved state-of-the-art results in Portuguese. Finally, most similar to our model, Botha and Blunsom (2014) introduced the additive log-bilinear model (LBL++). Best summarized as a neural factored LM, the LBL++ created separate embeddings for each constituent morpheme of a word, summing them to get a single word-embedding.

2.2 Computational Morphology

Our work is also related to morphological tagging, which can be thought of as ultra-fine-grained POS tagging. For morphologically impoverished languages, such as English, it is natural to consider a small tag set. For instance, in their universal POS tagset, Petrov et al. (2011) propose the coarse tag NOUN to represent all substantives. In inflectionally-rich languages, like German, considering other nominal attributes, e.g., case, gender and number, is also important. An example of an annotated German phrase is found in table 1. This often leads to a large tag set; e.g., in the morphological tag set of Hajič (2000), English had 137 tags whereas morphologically-rich Czech had 970 tags!

Clearly, much of the information needed to determine a word's morphological tag is encoded in the word itself. For example, the suffix ed is generally indicative of the past tense in English. However, distributional similarity has also been shown to be an important cue for morphology (Yarowsky and Wicentowski, 2000; Schone and Jurafsky, 2001). Much as contextual signatures are reliably exploited approximations to the semantics of the lexicon (Harris, 1954)—*you shall know the meaning of the word by the company it keeps* (Firth, 1957)—they can be similarly exploited for morphological analysis. This is not an unexpected result—in German, e.g., we would expect nouns that follow an adjective in the genitive case to also be in the genitive case themselves. Much of what our model is designed to accomplish is the isolation of the components of the contextual signature that are indeed predictive of morphology.

3 Log-Bilinear Model

The LBL is a generalization of the well-known log-linear model. The key difference lies in how it deals with features—instead of making use of hand-crafted features, the LBL *learns* the features along with the weights. In the language modeling setting, we define the following model,

$$p(w \mid h) \stackrel{\text{def}}{=} \frac{\exp\left(s_\theta(w, h)\right)}{\sum_{w'} \exp\left(s_\theta(w', h)\right)}, \qquad (1)$$

where w is a word, h is a history and s_θ is an energy function. Following the notation of Mnih and Teh (2012), in the LBL we define

$$s_\theta(w, h) \stackrel{\text{def}}{=} \left(\sum_{i=1}^{n-1} C_i r_{h_i}\right)^T q_w + b_w, \qquad (2)$$

where $n-1$ is history length and the parameters θ consist of C, a matrix of context specific weights, R, the context word-embeddings, Q, the target word-embeddings, and b, a bias term. Note that a subscripted matrix indicates a vector, e.g., q_w indicates the target word-embedding for word w and r_{h_i} is the embedding for the ith word in the history. The gradient, as in all energy-based models, takes the form of the difference between two expectations (LeCun et al., 2006).

4 Morph-LBL

We propose a multi-task objective that jointly predicts the next word w and its morphological tag t given a history h. Thus we are interested in a joint probability distribution defined as

$$p(w, t \mid h) \propto \exp((f_t^T S + \sum_{i=1}^{n-1} C_i r_{h_i})^T q_w + b_w), \tag{3}$$

where f_t is a hand-crafted feature vector for a morphological tag t and S is an additional weight matrix. Upon inspection, we see that

$$p(t \mid w, h) \propto \exp(f_t S^T q_w). \tag{4}$$

Hence given a fixed embedding q_w for word w, we can interpret S as the weights of a conditional log-linear model used to predict the tag t.

Morphological tags lend themselves to easy featurization. As shown in table 1, the morphological tag ADJ.NOM.SG.FEM decomposes into sub-tag units ADJ, NOM, SG and FEM. Our model includes a binary feature for each sub-tag unit in the tag set and only those present in a given tag fire; e.g., $F_{\text{ADJ.NOM.SG.FEM}}$ is a vector with exactly four non-zero components.

4.1 Semi-Supervised Learning

In the fully supervised case, the method we proposed above requires a corpus annotated with morphological tags to train. This conflicts with a key use case of word-embeddings—they allow the easy incorporation of large, unannotated corpora into supervised tasks (Turian et al., 2010). To resolve this, we train our model on a partially annotated corpus. The key idea here is that we only need a partial set of labeled data to steer the embeddings to ensure they capture morphological properties of the words. We marginalize out the tags for the subset of the data for which we do not have annotation.

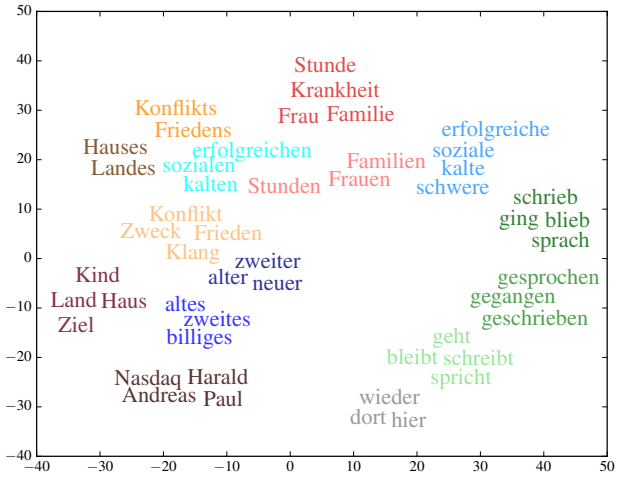

Figure 1: Projections of our 100 dimensional embeddings onto $\mathbb{R}^2$ through t-SNE (Van der Maaten and Hinton, 2008). Each word is given a distinct color determined by its morphological tag. We see clear clusters reflecting morphological tags and coarse-grained POS—verbs are in various shades of green, adjectives in blue, adverbs in grey and nouns in red and orange. Moreover, we see similarity across coarse-grained POS tags, e.g., the genitive adjective `sozialen` lives near the genitive noun `Friedens`, reflecting the fact that "sozialen Friedens" 'social peace' is a frequently used German phrase.

5 Evaluation

In our evaluation, we attempt to intrinsically determine whether it is indeed true that words similar in the embedding space are morphologically related. Qualitative evaluation, shown in figure 1, indicates that this is the case.

5.1 MorphoDist

We introduce a new evaluation metric for morphologically-driven embeddings to quantitatively score models. Roughly, the question we want to evaluate is: are words that are similar in the embedded space also morphologically related? Given a word w and its embedding q_w, let $\mathcal{M}_w$ be the set of morphological tags associated with w represented by bit vectors. This is a set because words may have several morphological parses. Our

measure is then defined below,

$$\text{MORPHODIST}(w) \stackrel{\text{def}}{=} - \sum_{w' \in \mathcal{K}_w} \min_{m_w, m_{w'}} d_h(m_w, m_{w'}),$$

where $m_w \in \mathcal{M}_w$, $m_{w'} \in \mathcal{M}_{w'}$, d_h is the Hamming distance and $\mathcal{K}_w$ is a set of words close to w in the embedding space. We are given some freedom in choosing the set $\mathcal{K}_w$—in our experiments we take $\mathcal{K}_w$ to be the k-nearest neighbors (k-NN) in the embedded space using cosine distance. We report performance under this evaluation metric for various k. Note that MORPHODIST can be viewed as a soft version of k-NN—we measure not just whether a word has the same morphological tag as its neighbors, but rather has a *similar* morphological tag.

Metrics similar to MORPHODIST have been applied in the speech recognition community. For example, Levin et al. (2013) had a similar motivation for their evaluation of fixed-length acoustic embeddings that preserve linguistic similarity.

6 Experiments and Results

To show the potential of our approach, we chose to perform a case study on German, a morphologically-rich language. We conducted experiments on the TIGER corpus of newspaper German (Brants et al., 2004). To the best of our knowledge, no previous word-embedding techniques have attempted to incorporate *morphological tags* into embeddings in a supervised fashion. We note again that there has been recent work on incorporating *morphological segmentations* into embeddings—generally in a pipelined approach using a segmenter, e.g., MORFESSOR, as a preprocessing step, but we distinguish our model through its use of a different view on morphology.

We opted to compare Morph-LBL with two fully unsupervised models: the original LBL and WORD2VEC (`code.google.com/p/word2vec/`, Mikolov et al. (2013)). All models were trained on the first 200k words of the train split of the TIGER corpus; Morph-LBL was given the correct morphological annotation for the first 100k words. The LBL and Morph-LBL models were implemented in Python using THEANO (Bastien et al., 2012). All vectors had dimensionality 200. We used the Skip-Gram model of the WORD2VEC toolkit with context $n = 5$. We initialized parameters of LBL and Morph-LBL randomly and trained them using stochastic gradient descent (Robbins and Monro, 1951). We used a history size of $n = 4$.

	Morph-LBL	LBL	WORD2VEC
All Types	81.5%	22.1%	10.2%
No Tags	44.8%	15.3%	14.8%

Table 2: We examined to what extent the individual embeddings store morphological information. To quantify this, we treated the problem as supervised multi-way classification with the embedding as the input and the morphological tag as the output to predict. Note that "All Types" refers to all types in the training corpus and "No Tags" refers to the subset of types, whose morphological tag was *not* seen by Morph-LBL at training time.

6.1 Experiment 1: Morphological Content

We first investigated whether the embeddings learned by Morph-LBL do indeed encode morphological information. For each word, we selected the most frequently occurring morphological tag for that word (ties were broken randomly). We then treated the problem of labeling a word-embedding with its most frequent morphological tag as a multi-way classification problem. We trained a k nearest neighbors classifier where k was optimized on development data. We used the `scikit-learn` library (Pedregosa et al., 2011) on all types in the vocabulary with 10-fold cross-validation, holding out 10% of the data for testing at each fold and an additional 10% of training as a development set. The results displayed in table 2 are broken down by whether MorphLBL observed the morphological tag at training time or not. We see that embeddings from Morph-LBL do store the proper morphological analysis at a much higher rate than both the vanilla LBL and WORD2VEC.

Word-embeddings, however, are often trained on massive amounts of unlabeled data. To this end, we also explored on how WORD2VEC itself encodes morphology, when trained on an order of magnitude more data. Using the same experimental setup as above, we trained WORD2VEC on the *union* of the TIGER German corpus and German section of Europarl (Koehn, 2005) for a total of ≈ 45 million tokens. Looking only at those types found in TIGER, we found that the k-NN classifier predicted the cor-

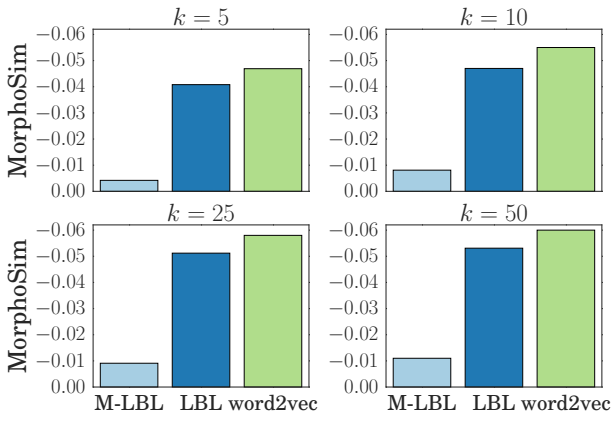

Figure 2: Results for the MORPHODIST measure for $k \in \{5, 10, 25, 50\}$. Lower MORPHODIST values are better—they indicate that the nearest neighbors of each word are closer morphologically.

rect tag with $\approx 22\%$ accuracy (not shown in the table).

6.2 Experiment 2: MORPHODIST

We also evaluated the three types of embeddings using the MORPHODIST metric introduced in section 5.1. This metric roughly tells us how similar each word is to its neighbors, where distance is measured in the Hamming distance between morphological tags. We only evaluated on words that MorphLBL did *not* observe at training time to get a fair idea of how well our model has managed to encode morphology purely from the contextual signature. Figure 2 reports results for $k \in \{5, 10, 25, 50\}$ nearest neighbors. We see that the values of k studied do not affect the metric—the closest 5 words are about as similar as the closest 50 words. We see again that the Morph-LBL embeddings generally encode morphology better than the baselines.

6.3 Discussion

The superior performance of Morph-LBL over both the original LBL and WORD2VEC under both evaluation metrics is not surprising as we provide our model with annotated data at training time. That the LBL outperforms WORD2VEC is also not surprising. The LBL looks at a local history thus making it more amenable to learning syntactically-aware embeddings than WORD2VEC, whose skip-grams often look at non-local context.

What is of interest, however, is Morph-LBL's ability to robustly maintain morphological relationships only making use of the distributional signature, *without* word-internal features. *This result shows that in large corpora, a large portion of morphology can be extracted through contextual similarity.*

7 Conclusion and Future Work

We described a new model, Morph-LBL, for the semi-supervised induction of morphologically guided embeddings. The combination of morphologically annotated data with raw text allows us to train embeddings that preserve morphological relationships among words. Our model handily outperformed two baselines trained on the same corpus.

While contextual signatures provide a strong cue for morphological proximity, orthographic features are also requisite for a strong model. Consider the words `loving` and `eating`. Both are likely to occur after `is`/`are` and thus their local contextual signatures are likely to be similar. However, perhaps an equally strong signal is that the two words end in the same substring `ing`. Future work will handle such integration of character-level features.

We are interested in the application of our embeddings to morphological tagging and other tasks. Word-embeddings have proven themselves as useful features in a variety of tasks in the NLP pipeline. Morphologically-driven embeddings have the potential to leverage raw text in a way state-of-the-art morphological taggers cannot, improving tagging performance downstream.

Abstract

In this paper we present our work on recognizing high level social constructs such as *Leadership* and *Status* from textual conversation using an approach that makes use of the background knowledge about social hierarchy and integrates statistical methods and symbolic logic based methods. We use a stratified approach in which we first detect lower level language constructs such as politeness, command and agreement that help us to infer intermediate constructs such as deference, closeness and authority that are observed between the parties engaged in conversation. These intermediate constructs in turn are used to determine the social constructs *Leadership* and *Status*. We have implemented this system successfully in both English and Korean languages and achieved considerable accuracy.

1 Introduction and Related Works

The traditional information extraction paradigm has seen success in extracting simplistic behaviors or emotions from text. However, to detect high-level social constructs such as leadership or status, we require robustly defined notions about language constructs that cannot always be directly inferred from text. Hence, in this paper we focus on extracting information from text that requires additional background knowledge and inference. There are a few works in this direction, such as (Tari et al., 2010), however our focus in this paper is to extract information pertaining to different social constructs from textual conversation. The earlier research in analyzing conversations includes developing annotated chat corpuses (Shaikh et al., 2010), and developing a socio-cultural phenomena model from discourse with a small-scale implementation (Strzalkowski et al., 2010). Other researchers have focused on automatically annotating social behavior in conversation using statistical approaches (Mayfield et al., 2013). The discourse structure of a conversation is modeled as a Hidden Markov Model in (Stolcke, 2000) to determine dialogue acts such as Statement, Question and Agreement. In (Prabhakaran et al., 2012) annotated email threads are presented for facilitating detection of social relations.

Among recent works, (Gilbert, 2012) uses linguistic cues to discover workplace hierarchy from emails. The use of phrases to detect *language use* such as "commands" is motivating. However, due to the lack of logical explanation and robust definition, the effectiveness of this method decreases in the semi-formally moderated Wikipedia community, which has interplay of several different *LU*s such as command, politeness and informal language. In (Danescu-Niculescu-Mizil et al., 2012), the authors explain how reflection of linguistic styles can shed light on power differentials; though, a social community like Wikipedia might not always conform to the *lingustic style coordination assumption*. For example, two friends who are coordinating on writing an article may have the same status socially, but difference in their expertise will drive the conversation. Other works such as (Gupte et al., 2011) have concentrated more on other features of the persons involved in social network, than linguistic cues. Also, we feel that, the hierarchy depends on the task or the context. In other words, one person could as-

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1293–1298,
Denver, Colorado, May 31 – June 5, 2015.

sume different roles in different context. The above works do not seem to address this. (Prabhakaran et al., 2012) achieves a commendable accuracy in detecting overt display of "power". However, by our definitions, this is a lower level attribute and is similar to *authoritative behavior* which is a lower level concept than Leadership or Status. Hence, their results are not directly comparable to ours.

In this paper, we use a mixture of logic-based and statistical approaches which better encodes the domain knowledge and infers higher-level constructs from indirect textual cues. The aim of this paper is to formalize the theory behind our work, highlight the advantages of integration of statistical and logic-based approaches and present results from an empirical study.

2 Motivation by a use-case

We start our discussion by presenting a use-case and explain how results of other traditional methods inspired us to come up with an integrated approach.

Consider the following conversation from Wikipedia where the participants discuss about a misleading animation that is used under the topic *Convolution*.

{*D: Put a message on the talk page of the guy who made it. You're right; g(t) should be g(tau - t), and (f*g)(t) should be (f*g)(tau).*

*T: I don't think he has a talk page. He's provided the code so I can reproduce it. I think he's right with (f*g)(t), though?*

D: Actually, I think we're both wrong. You need a variable of integration running opposite directions ....

T: I've updated ... I guess it's not important, but would be kind of cool. Feel free to suggest improvements to the animations.}

As we understand, these conversations suggest that participant D is supposed to hold a higher rank/status than T. If we analyze manually, we understand that phrases like *Put a message*, *You're right*, *I think we're both wrong* together supports our conclusion. Considered separately, the above phrases might be misleading. To conclude the example, our system outputs :

D has a higher status than T because D demonstrates more language uses associated with status than T. Confidence: high.

The above example illustrates the degree of context-sensitivity of our problem. The current statistical literature suggests methods such as Decision Trees, Boosting methods comprising of a collection of Weak classifiers (basically rules) and probabilistic generative models (Medhat et al., 2014), (Hutto and Gilbert, 2014), (Vanzo et al., 2014) and (Saif et al., 2012). While their accuracy on some datasets is quite satisfactory, it is not clear how well they do on completely unseen data.

From our experience on such classifiers, we believe that a higher level of accuracy with explainability can be achieved by imposing a structure that encodes background knowledge about the social hierarchy that is observed in nature. With this motivation, we built a system whose hierarchical architecture robustly defines the social constructs, the "hidden" concepts that induce them and their inter-connections. We define notions of intermediate *Language Use (LU)* and lower level *Language Indicator (LI)* categories[1]. With the help of these robust definitions, our system properly explains how different emotions and behaviors interact to express status and leadership among individuals.

3 Social Constructs

Our framework supports determination of various important *Social Constructs* such as *Leadership*, *Status*, *Group Cohesion* and *Sub-Group Formation*. However, due to the length constraints of the paper, we will only discuss **Leadership** and **Status**.

3.1 Definitions and Architecture

We begin by first formally defining the two Social Constructs and the different Language Use categories.

Leadership: A leader is someone who guides a group toward outcomes, controls the group actions, manages interactions between members and members usually recognize the leader.

Status: Status is defined as the social position of one person with respect to another in a group.

The principal *Language Use* categories that we detect are: Deference, Closeness, Authoritative Behavior and Motivational Behavior. The following intuitions are used to infer such *LU*s from text:

Deference is understood when one uses language that shows respect to another conversational participant or defers to another's expertise or knowledge or authority.

Closeness is understood when one uses language that shows familiarity with another conversationalist. It is also indicated by dialogues where conversationalists refer to similar events, experiences etc.

Authoritative Behavior is understood when one uses language that shows power, dominance and control over a situation.

Motivational Behavior is understood when one uses language that moves conversational participants toward

[1]These definitions were proposed as part of the IARPA Socio-Cultural Content In Language(SCIL) program.

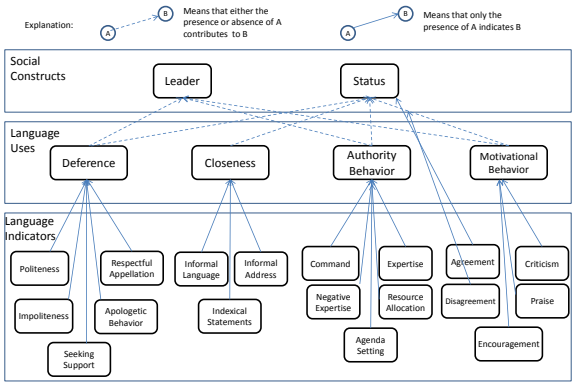

Figure 1: Social Construct-Language Use-Language Indicator hierarchy for English Language

sharing a common goal, collaboration, problem solving and solidarity.

In Figure 1, we present the entire hierarchy and how the categories are connected among each other. The arrows in the figure show which of the *LI* categories are used to infer a particular type of *LU*. It also demonstrates how each of the *LU* contributes to the Social Constructs.

4 Behind the Curtain: Our Intuitions

One of the fundamental contributions in this paper is formally describing the hierarchy to determine the Social Constructs, as shown in Figure 1. To come up with these interconnections and each of the different *pieces of the puzzle*, we went through an iterative process of discussions with many social scientists and linguists to analyze a large number of example conversations. In this process, we came up with the aforementioned hierarchy, definitions of *SC*, *LU* and *LI*s and most importantly, the following understanding:

- The *Language Indicators* as shown in the Figure 1, suffice for the detection of *Leadership* and *Status*.
- Each detected *LI* is associated with an *Intensity Level* that helps us to encode the dissimilar effects of different words in inferring *LI*s.
- Each *LI* is associated with a **Signed Language Use**. For example, the *LI politeness* is associated with the signed *LU positive deference*.
- Indicators of an *LU* with a certain sign are **counter-indicators** of the same *LU* with the opposite sign.
- A signed *LU* may contribute either **favorably or unfavorably** towards its associated *SC*. For example, positive authoritative behavior contributes favorably towards higher status.
- The signed *LU*s that contribute towards the *SC Status* are **ordered** based on their importance. We assume the following ordering exists: authoritative behavior > motivational behavior > negative deference > positive deference in the opposite direction > closeness. However, we do not assume such an ordering for the *SC Leadership*.

Our extensive research and successful implementation of our system for different natural languages leads us to believe that these notions are universal in application.

5 Fundamentals of the implementation

After we parse each sentence using Stanford Dependency parser to get the POS tags and mutual dependencies, the detection of individual *LI*s and the mapping of *LI*s, *LU*s to *SC*s are achieved using a combination of statistical and logic based approach. Many of the ideas and insights about the detection of *LI*s and their relations with the *LU*s are motivated from (Simon, 1946), (Pennebaker et al., 2003) , (Bernstein, 2010) , (Brown and Levinson, 1988) and a few others. Some of our ideas for textual inference have been inspired by (Scherl et al., 2010).

5.1 Determining the Language Indicators

The process of detection of language indicators from sentences uses a huge ensemble of complex rules. To create these rules, we borrowed ideas from the researchers of social science and psychology (Simon, 1946; Pennebaker et al., 2003).

With the help of POS tags, mutual dependencies and regular expressions, we create a framework where we detect individual events, verbs, other sentence constituents and their positive and negative sense. On top of this framework, we use two different methods to detect language indicators. The ideas are similar for all the LIs. We will only present a few examples for the LI "Command".

5.1.1 Using Regular Expressions Alone

We use regular expressions of the form "*.*\b[wW]hy don'?t (you|YOU) (start|read|submit|make|write|get)\s*\b.**" to detect LIs such as "Command". We employ a collection of such expressions to cover several different linguistic styles which indicates "Command" by an individual.

We achieved a very high recall (close to 1.0) for most indicators with these rules on test data. However, in few cases, the frequency of such indicators (such as politeness) were very low deeming the set of regular expressions as incomplete. This observation led us to refine the regular expressions with Logical rules so that we can incorporate our domain knowledge and remove such bias to the training set.

5.1.2 Using Logical rules on Regular Expression output and Sentence constituents

One example of the rules we use to detect "Command" is: *if the subject of the verb is second person and the verb is associated with a modal verb which indicates a question that suggests command, then the LI "Command" is detected.*

Examples of such verbs are "Would you" and "Could you" etc. It is to be noted that such a verb will denote both politeness and command depending on the rest of the sentence. This fascinating inter-dependency is one reason why we have to collect all such *Language Indicators* before we infer the higher level *Language Use*s.

5.2 Mapping of LIs to LUs and LUs to Social Constructs

Input: To encode one conversation we use a collection of facts of the form *participant(X)* and *addresses(X, Y, LI, Level)*.

These facts essentially encode the identity of the participants and the *Language Indicator*s observed in the overall conversation among a pair of participants.

Output: The module outputs a collection of claim, evidence and confidence mappings.

For example one such mapping is: *claim_mapping(X, "is the leader", "because", X, "demonstrates <language use>","(Confidence: <confidence level>)").* Here <language use> is one of the language uses, <confidence level> is either low, medium, or high.

Algorithm: We employ statistical and logic-based procedure in parallel to get the above output. On the statistical side, we adopt a regression technique to learn a function that can map the scores associated with *LI*s to individual *LUs* based on annotated training data and this function is then applied to test data to get confidence score on *LU*s. The same procedure is adopted for mapping *LU*s to *SC*s.

In parallel to this procedure, we also employ a rule-based technique that uses quantized confidence scores and outputs confidence levels along with explanations. As we are able to get the explanation from logical reasoning, we use the output confidence scores as votes from statistical learning to output the final confidence level.

The rules for logical reasoning are explained as definitions and intuitions in the following paragraphs.

Mapping LIs into LUs: A signed *LU* is said to be exhibited by participant X towards participant Y with a certain degree of confidence based on the number of indicators(*LI*) and counter-indicators(*LI*) of the signed *LU* used by X when addressing Y. The **confidence** in *LU* is directly proportional to the difference between the number of indicators and counter-indicators.

We categorize *LU*s according to the number of indicators and apply slight variation to the above rules for each such category. Also, there are a few *LI*s that, when used, automatically **override** the computed **confidence level** for an *LU* and increase it to high. For example, "criticism" increases confidence level of positive "motivational behavior" to high.

Mapping LUs to SCs: The relative status of two participants is determined based on i) the number of relevant signed LUs exhibited by each participant towards the other, ii) the ordering of relevant signed LUs and iii) the confidence level in each exhibited signed LU.

The leader is determined based on the number of exhibited relevant LUs (both favorable and unfavorable).

Mapping LIs to SCs: As shown in Figure 1, we directly associate some of the LIs to Social Constructs. For such an association, we again adopt the regression technique mentioned previously. In this case, the confidence scores from *LI*s are directly mapped to the confidence scores of *SC*s. We combine this confidence with the above confidence levels using simplistic rules to output final social constructs.

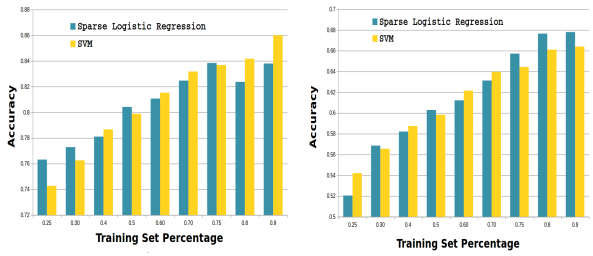
It should be noted *that the constants used in the rules are obtained from statistics on annotated conversations.* The annotation process involves labels about SCs, LUs and LIs for each conversation data.

5.3 Brief Details and Results of the Regression Technique

In this sub-section, we provide few details of the Sparse Logistic Regression technique we have used alongside the logical formulation and present few results from our experiments with relevant statistical methods. We have used a similar formulations for mapping LIs to LUs and LUs to SCs. Here, we provide the example of formulating the entire problem of detection of Social Constructs directly in the Classification paradigm.

Status and Leadership can be formulated as a three-class and two-class problem respectively. For Status, we had 102 samples with the $38(higher), 26(equal)$ and $38(lower)$ samples each for three classes. For Leadership, we had 149 samples with 108(not-leader) and 41(leader) samples for the two classes. For both the tasks, we extracted 28 textual features. We used the one-vs-rest scheme for multi-class problem. For each task, we evaluated the framework as follows: i. First, we randomly separate the dataset into training set(p) and test set(1-p). ii. In the training set, we use 10-fold cross validation to select proper parameters. iii. We iterate the above procedure for 100 times, and accuracy is evaluated on the predictions in all iterations. iv. We select different p (from 0.25 to 0.9) and observe the change of accuracy.

We compared the accuracy achieved using Sparse Logistic Regression with SVM(with RBF Kernel) among



(a) (b)

Figure 2: (a) Training set percentage vs Accuracy graph for Leadership problem, (b) Training set percentage vs Accuracy graph for Status classification problem.

others. The accuracy comparison of the SVM(with RBF kernel) and sparse Logistic Regression is provided in Figure 2. As we can observe, though the two methods are comparable, in most cases Sparse Logistic regression performs better.

5.4 Advantages from the integrated approach

The primary advantages are the following:

In general, statistical approaches need a "lot of data" to attain a certain level of accuracy. As the rules we use are quite universal and compact, we can achieve a comparable(or higher) accuracy with much less training data.

Using the *evidence* and *claim* mappings, we give an "explanation" as to why we detected such a particular SC in the dialogue. Knowldege of such depth is very hard to achieve with only statistical approaches.

Explicit representation of "context" specific information via rules results in improved accuracy in detection of LIs such as criticism, praise, command etc.

Statistical modules complement the rule-based approach where our domain knowledge is "incomplete".

We use ASP as the Logic Programming language of our choice as its ability to represent defaults and exceptions eases the implementation procedure.

6 Results

We have implemented this system using ASP(Gelfond and Lifschitz, 1988) and Java. The Wikipedia conversations are obtained by parsing the wiki dump from `http://dumps.wikimedia.org/`. We also evaluated on the NWTRB (US Nuclear Waste Technical Review Board) dataset. The accuracy and F1 measure are summarized in Table 1 for approximately two thousand English and one thousand Korean Wikipedia conversations. We evaluated two types of questions - i. *Yes-No* indicates questions like *Is John the leader?* and ii. *List* indicates questions such as *List all the leaders.*. Our work is perhaps unique in determining such social constructs and evaluating on familiar and unfamiliar datasets. Table 1 reports evaluations on wikipedia dump. These values are computed by comparing the results of our systems with annotated data. Note, in our experiments, we have performed strict evaluations. For example, the results are only marked positive if the complete list of leaders matches with a human-annotated list. Also, we consider the "explanation" too while performing the evaluation. The results are true positive only when the detected construct is correct alongwith the explanation provided by the reasoning module. In general, the previous research achieves an accuracy of 0.45 in comparable tasks such as dialog act tagging (Stolcke, 2000).

Table 1: Results

SC	Q-Type	Language	Accuracy	F1
Task Leader	Y-N	EN	0.8900	0.6700
Task Leader	List	EN	0.6700	0.9900
Status	Y-N	EN	0.4700	0.3457
Status	List	EN	0.6923	0.5200
Task Leader	Y-N	KO	0.5667	0.4338
Status	Y-N	KO	0.4074	0.3900

7 Conclusion

In this paper, we have proposed a novel approach for logically recognizing social constructs from textual conversations. We have used both statistical classification and logical reasoning to robustly detect status and leadership as observed in virtual social networks. From our experiments, we show empirically how our approach achieves a significant accuracy and provides logical explanation of construct detection.

This research shows the merits of using logical rules along with statistical techniques to determine Social Constructs. As per our understanding, this level of accuracy and explainability needs integration of both statistical and logic based methods. Our observations suggest that there is an increasing need for such integration in various domains. We believe that this work is one of the early steps in that direction.

Two/Too Simple Adaptations of Word2Vec for Syntax Problems

Abstract

We present two simple modifications to the models in the popular Word2Vec tool, in order to generate embeddings more suited to tasks involving syntax. The main issue with the original models is the fact that they are insensitive to word order. While order independence is useful for inducing semantic representations, this leads to suboptimal results when they are used to solve syntax-based problems. We show improvements in part-of-speech tagging and dependency parsing using our proposed models.

1 Introduction

Word representations learned from neural language models have been shown to improve many NLP tasks, such as part-of-speech tagging (Collobert et al., 2011), dependency parsing (Chen and Manning, 2014; Kong et al., 2014) and machine translation (Liu et al., 2014; Kalchbrenner and Blunsom, 2013; Devlin et al., 2014; Sutskever et al., 2014). These low-dimensional representations are learned as parameters in a language model and trained to maximize the likelihood of a large corpus of raw text. They are then incorporated as features along side hand-engineered features (Turian et al., 2010), or used to initialize the parameters of neural networks targeting tasks for which substantially less training data is available (Hinton and Salakhutdinov, 2012; Erhan et al., 2010; Guo et al., 2014).

One of the most widely used tools for building word vectors are the models described in (Mikolov et al., 2013), implemented in the Word2Vec tool, in particular the "skip-gram" and the "continuous bag-of-words" (CBOW) models. These two models make different independence and conditioning assumptions; however, both models discard word order information in how they account for context. Thus, embeddings built using these models have been shown to capture semantic information between words, and pre-training using these models has been shown to lead to major improvements in many tasks (Collobert et al., 2011). While more sophisticated approaches have been proposed (Dhillon et al., 2011; Huang et al., 2012; Faruqui and Dyer, 2014; Levy and Goldberg, 2014; Yang and Eisenstein, 2015), Word2Vec remains a popular choice due to their efficiency and simplicity.

However, as these models are insensitive to word order, embeddings built using these models are suboptimal for tasks involving syntax, such as part-of-speech tagging or dependency parsing. This is because syntax defines "what words go where?", while semantics than "what words go together". Obviously, in a model where word order is discarded, the many syntactic relations between words cannot be captured properly. For instance, while most words occur with the word *the*, only nouns tend to occur exactly afterwords (e.g. *the cat*). This is supported by empirical evidence that suggests that order-insensitivity does indeed lead to substandard syntactic representations (Andreas and Klein, 2014; Bansal et al., 2014), where systems using pre-trained with Word2Vec models yield slight improvements while the computationally far more expensive which use word order information embeddings of Collobert et al. (2011) yielded much better results.

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1299–1304,
Denver, Colorado, May 31 – June 5, 2015.

In this work, we describe two simple modifications to `Word2Vec`, one for the skip-gram model and one for the CBOW model, that improve the quality of the embeddings for syntax-based tasks[1]. Our goal is to improve the final embeddings while maintaining the simplicity and efficiency of the original models. We demonstrate the effectiveness of our approaches by training, on commodity hardware, on datasets containing more than 50 million sentences and over 1 billion words in less than a day, and show that our methods lead to improvements when used in state-of-the-art neural network systems for part-of-speech tagging and dependency parsing, relative to the original models.

2 Word2Vec

The work in (Mikolov et al., 2013) is a popular choice for pre-training the projection matrix $W \in \Re^{d \times |V|}$ where d is the embedding dimension with the vocabulary V. As an unsupervised task that is trained on raw text, it builds word embeddings by maximizing the likelihood that words are predicted from their context or vice versa. Two models were defined, the skip-gram model and the continuous bag-of-words model, illustrated in Figure 1.

The skip-gram model's objective function is to maximize the likelihood of the prediction of contextual words given the center word. More formally, given a document of T words, we wish to maximize

$$\mathcal{L} = \frac{1}{T} \sum_{t=1}^{T} \sum_{\substack{-c \leq j \leq c, \\ j \neq 0}} \log p(w_{t+j} \mid w_t) \qquad (1)$$

Where c is a hyperparameter defining the window of context words. To obtain the output probability $p(w_o|w_i)$, the model estimates a matrix $O \in \Re^{|V| \times d_w}$, which maps the embeddings r_{w_i} into a $|V|$-dimensional vector o_{w_i}. Then, the probability of predicting the word w_o given the word w_i is defined as:

$$p(w_o \mid w_i) = \frac{e^{o_{w_i}(w_o)}}{\sum_{w \in V} e^{o_{w_i}(w)}} \qquad (2)$$

This is referred as the softmax objective. However, for larger vocabularies it is inefficient to compute o_{w_i}, since this requires the computation of a $|V| \times d_w$ matrix multiplication. Solutions for problem are addressed in the `Word2Vec` by using the hierarchical softmax objective function or resorting to negative sampling (Goldberg and Levy, 2014).

The CBOW model predicts the center word w_o given a representation of the surrounding words $w_{-c}, ..., w_{-1}, w_1, w_c$. Thus, the output vector $o_{w_{-c},...,w_{-1},w_1,w_c}$ is obtained from the product of the matrix $O \in \Re^{|V| \times d_w}$ with the sum of the embeddings of the context words $\sum_{-c \leq j \leq c, j \neq 0} r_{w_j}$.

We can observe that in both methods, the *order of the context words does not influence the prediction output*. As such, while these methods may find similar representations for semantically similar words, they are less likely to representations based on the syntactic properties of the words.

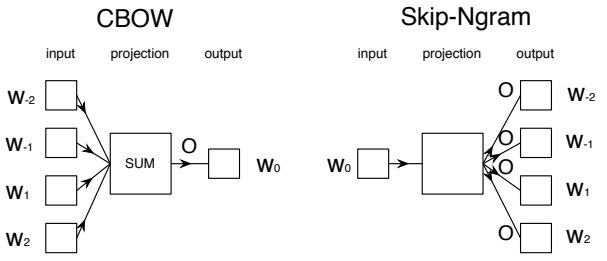

Figure 1: Illustration of the Skip-gram and Continuous Bag-of-Word (CBOW) models.

3 Structured Word2Vec

To account for the lack of order-dependence in the above models, we propose two simple modifications to these methods that include ordering information, which we expect will lead to more syntactically-oriented embeddings. These models are illustrated in Figure 2.

3.1 Structured Skip-gram Model

The skip-gram model uses a single output matrix $O \in \Re^{|V| \times d}$ to predict every contextual word $w_{-c}, ..., w_{-1}, w_1, ..., w_c$, given the embeddings of the center word w_0. Our approach adapts the model so that it is sensitive to the positioning of the words. It defines a set of $c \times 2$ output predictors $O_{-c}, ..., O_{-1}, O_1, O_c$, with size $O \in \Re^{(|V|) \times d}$. Each of the output matrixes is dedicated to predicting the

[1]The code developed in this work is made available in https://github.com/wlin12/wang2vec.

output for a specific relative position to the center word. When making a prediction $p(w_o \mid w_i)$, we select the appropriate output matrix O_{o-i} to project the word embeddings to the output vector. Note, that the number of operations that must be performed for the forward and backward passes in the network remains the same, as we are simply switching the output layer O for each different word index.

3.2 Continuous Window Model

The Continuous Bag-Of-Words words model defines a window of words $w_{-c}, ..., w_c$ with size c, where the prediction of the center word w_0 is conditioned on the remaining words $w_{-c}, ..., w_{-1}, w_1, ..., w_c$. The prediction matrix $O \in \Re^{(|V|)\times d}$ is fed with the sum of the embeddings of the context words. As such, the order of the contextual words does not influence the prediction of the center word. Our approach defines a different output predictor $O \in \Re^{(|V|\times 2cd}$ which receives as input a $(2c \times d)$-dimensional vector that is the concatenation of the embeddings of the context words in the order they occur $[e(w_{-c}), \ldots, e(w_{-1}), e(w_1), \ldots, e(w_c)]$. As matrix O defines a parameter for the word embeddings for each relative position, this allows the words to be treated differently depending on where they occur. This model, denoted as CWindow, is essentially the window-based model described in (Collobert et al., 2011), with the exception that we do not project the vector of word embeddings into a window embedding before making the final prediction.

In both models, we are increasing the number of parameters of matrix O by a factor of $c \times 2$, which can lead to sparcity problems when training on small datasets. However, these models are generally trained on datasets in the order of 100 millions of words, where these issues are not as severe.

4 Experiments

We conducted experiments in two mainstream syntax-based tasks part-of-speech Tagging and Dependency parsing. Part-of-speech tagging is a word labeling task, where each word is to be labelled with its corresponding part-of-speech. In dependency parsing, the goal is to predict a tree built of syntactic relations between words. In both tasks, it has been shown that pre-trained embeddings can be used to achieve better generalization (Collobert et al., 2011; Chen and Manning, 2014).

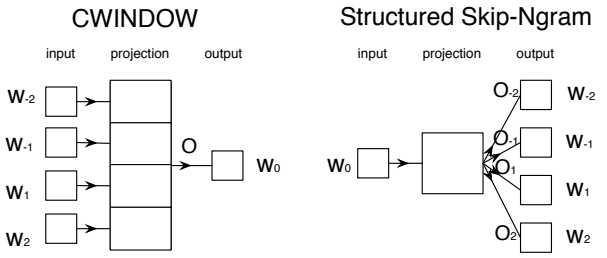

Figure 2: Illustration of the Structured Skip-gram and Continuous Window (CWindow) models.

4.1 Building Word Vectors

We built vectors for English in two very different domains. Firstly, we used an English Wikipedia dump containing 1,897 million words (60 million sentences), collected in September of 2014. We built word embeddings using the original and our proposed methods on this dataset. These embeddings will be denoted as *WIKI(L)*. Then, we took a sample of 56 million English tweets with 847 million words collected in (Owoputi et al., 2013), and applied the same procedure to build the *TWITTER* embeddings. Finally, we also use the Wikipedia documents, with 16 million words, provided in the `Word2Vec` package for contrastive purposes, denoted as *WIKI(S)*. As preprocessing, the text was lowercased and groups of contiguous digits were replaced by a special word. For all corpora, we trained the network with a $c = 5$, with a negative sampling value of 10 and filter out words with less than 40 instances. WIKI(L) and TWITTER have a vocabulary of 424,882 and 216,871 types, respectively, and embeddings of 50 dimensions.

Table 1 shows the similarity for a few selected keywords for each of the different embeddings. We can see hints that our models tend to group words that are more syntactically related. In fact, for the word *breaking*, the CWindow model's top five words are exclusively composed by verbs in the continuous form, while the Structured Skip-gram model tends to combine these with other forms of the verb break. The original models tend to be less keen on

Embeddings	WIKI(S)	TWITTER	WIKI(L)
query	*breaking*	*amazing*	*person*
CBOW	breaks	incredible	someone
	turning	awesome	anyone
	broke	fantastic	oneself
	break	phenomenal	woman
	stumbled	awsome	if
Skip-gram	break	incredible	harasser
	breaks	awesome	themself
	broke	fantastic	declarant
	down	phenominal	someone
	broken	phenomenal	right-thinking
CWindow	putting	incredible	woman
(this work)	turning	amaaazing	man
	sticking	awesome	child
	pulling	amzing	grandparent
	picking	a-mazing	servicemember
Structured	break	incredible	declarant
Skip-gram	turning	awesome	circumstance
(this work)	putting	amaaazing	woman
	out	ah-mazing	schoolchild
	breaks	amzing	someone

Table 1: Most similar words using different word embedding models for the words *breaking*, *amazing* and *person*. Each word is queried in a different dataset.

preserving such properties. As for the TWITTER embeddings, we can observe that our adapted embeddings are much better at finding lexical variations of the words, such as *a-mazing*, resembling the results obtained using brown clusters (Owoputi et al., 2013). Finally, for the query *person*, we can see that our models tend to associate this term to other words in the same class, such as *man*, *woman* and *child*, while original models tend to include unrelated words, such as *if* and *right-thinking*.

In terms of computation speed, the Skip-gram and CBOW models, achieve a processing rate of 71.35k and 342.17k words per second, respectively. The Structured Skip-gram and CWindow models can process 34.64k and 124.43k words per second, respectively. There is a large drop in computational speed in the CWindow model compared to the CBOW model, as it uses a larger output matrix, which grows with the size of the window. The Structured Skip-gram model processes words at almost half the speed of the Skip-gram model. This is explained by the fact that the Skip-gram model subsamples context words, varying the size of the window size stochastically, so that words closer to the center word are sampled more frequently. That is, when defining a window size of 5, the actual window size used for each sample is a random value between 1 and 5. As we use a separate output layer for each position, we did not find this property to be useful as it provides less training samples for output matrixes with higher indexes. While our models are slower they are still suitable for processing large datasets as all the embeddings we use were all built within a day.

4.2 Part-Of-Speech Tagging

We reimplemented the window-based model proposed in (Collobert et al., 2011), which defines a 3-layer perceptron. In this network, words are first projected into embeddings, which are concatenated and projected into a window embedding. These are finally projected into an output layer with size of the POS tag vocabulary, followed by a softmax. In our experiments, we used a window size of 5, word embeddings of size 50 and window embeddings of size 500. Word embeddings were initialized using the pre-trained vectors and these parameters are updated as the rest of the network. Additionally, we also add a capitalization feature which indicates whether the first letter of the work is uppercased, as all word features are lowercased words. Finally, for words unseen in the training set and in the pre-trained embeddings, we replace them with a special unknown token, which is also modelled as a word type with a set of 50 parameters. At training time, we stochastically replace word types that only occur once in the training dataset with the unknown token. Evaluation is performed with the part-of-speech tag accuracy, which denotes the percentage of words labelled correctly.

Experiments are performed on two datasets, the English Penn Treebank (PTB) dataset using the standard train, dev and test splits, and the ARK dataset (Gimpel et al., 2011), with 1000 training, 327 dev and 500 labelled English tweets from Twitter. For the PTB dataset, we use the WIKI(L) embeddings and use TWITTER embeddings for the ARK dataset. Finally, the set of parameters with the highest accuracy in the dev set are used to report the score for the test set.

Results are shown in Table 2, where we observe that our adapted models tend to yield better re-

	PTB		Twitter	
	Dev	Test	Dev	Test
CBOW	95.89	96.13	87.85	87.54
Skip-gram	96.62	96.68	88.84	88.73
CWindow	**96.99**	97.01	**89.72**	89.63
Structured Skip-gram	96.62	**97.05**	89.69	**89.79**
SENNA	96.54	96.58	84.96	84.85

Table 2: Results for part-of-speech tagging using different word embeddings (rows) on different datasets (PTB and Twitter). Cells indicate the part-of-speech accuracy of each experiment.

	Dev		Test	
	UAS	LAS	UAS	LAS
CBOW	91.74	88.74	91.52	88.93
Skip-gram	92.12	89.30	91.90	89.55
CWindow	92.38	89.62	92.00	89.70
Structured Skip-gram	**92.49**	**89.78**	**92.24**	**89.92**
SENNA	92.24	89.30	92.03	89.51

Table 3: Results for dependency parsing on PTB using different word embeddings (rows). Columns UAS and LAS indicate the labelled attachment score and the unlabelled parsing scores, respectively.

sults than the original models in both datasets. In the Twitter dataset, our results slightly higher than the accuracy reported using only Brown clusters in (Owoputi et al., 2013), which was 89.50. We also try initializing our embeddings with those in (Collobert et al., 2011), which are in the "Senna" row. Even though results are higher in our models, we cannot conclude that our method is better as they are trained crawls from Wikipedia in different time periods. However, it is a good reference to show that our embeddings are on par with those learned using more sophisticated models.

4.3 Dependency Parsing

The evaluation on dependency parsing is performed on the English PTB, with the standard train, dev and test splits with Stanford Dependencies. We use neural network defined in (Chen and Manning, 2014), with the default hyper-parameters[2] and trained for 5000 iterations. The word projections are initialized using WIKI(L) embeddings. Evaluation is performed with the labelled (LAS) and unlabeled (UAS) attachment scores.

In Table 3, we can observe that results are consistent with those in part-of-speech tagging, where our models obtain higher scores than the original models and with competitive results compared to Senna embeddings. This suggests that our models are suited at learning syntactic relations between words.

5 Conclusions

In this work, we present two modifications to the original models in Word2Vec that improve the word embeddings obtained for syntactically motivated tasks. This is done by introducing changes that make the network aware of the relative positioning of context words. With these models we obtain improvements in two mainstream NLP tasks, namely part-of-speech tagging and dependency parsing, and results generalize in both clean and noisy domains.

Estimating Numerical Attributes by Bringing Together Fragmentary Clues

Hiroya Takamura and **Jun'ichi Tsujii**
Tokyo Institute of Technology Microsoft Research Asia
takamura@pi.titech.ac.jp jtsujii@microsoft.com

Abstract

This work is an attempt to automatically obtain numerical attributes of physical objects. We propose representing each physical object as a feature vector and representing sizes as linear functions of feature vectors. We train the function in the framework of the combined regression and ranking with many types of fragmentary clues including absolute clues (e.g., A is 30cm long) and relative clues (e.g., A is larger than B).

1 Introduction

We know how large surfboards usually are and also that an inner pocket of any jacket is much smaller than a surfboard. Since we know about these numerical attributes, nobody of sound mind has probably ever tried to vainly put a surfboard into an inner pocket of a jacket. However, computers do not have comprehensive knowledge of this sort. This lack of comprehensive knowledge of the numerical attributes is one obstacle to flexible and natural man-machine communication. This work is an attempt to automatically obtain knowledge on numerical attributes so that computers can use it.

The knowledge on numerical attributes is also very useful on many other occasions. For example, it enables computers to alert their users when the users input incorrect numbers that are outside of the normal range of the attribute. In image recognition, a large red object will unlikely be recognized as a strawberry if the computer knows its normal size. In natural language processing, QA systems can use numerical knowledge to eliminate the out-of-range answer candidates to numerical questions.

A number of attempts similar to the current work have been made in some other fields such as psychology or fuzzy theory. However, such attempts heavily rely on costly experiments such as giving questionnaires to human subjects and have a problem in their scalability. In contrast, the current work attempts to use NLP techniques on large text data both online and offline in order to obtain such knowledge without relying on costly experiments such as questionnaires. A possible criticism of this project is that simply examining an existing knowledge source such as Wikipedia might accomplish this purpose without much effort. Indeed Wikipedia provides numerical information of some physical objects, but not all. For example, the Wikipedia page for *watches* provides descriptions on their function and their history, but no information on their size.

Clues to the numerical attributes are rather scattered over corpora and other linguistic resources. In a corpus, we can find informative descriptions such as "*X is 35cm tall*". We can also find text fragments suggesting an order relation between two physical objects with regard to the size as in "*X is larger than Y*", as well as implicit clues such as "*I put X into Y*", which usually means X is smaller than Y. Holonymy relations (X is a part of Y) in a thesaurus suggest an order relation in size (X is smaller than Y). Glosses in a dictionary also provide subtle clues to the sizes of entry words. Each of these clues alone is not sufficient for precisely determining the size, so we have to bring them together. We have therefore developed a mathematical model that uses these

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1305–1310,
Denver, Colorado, May 31 – June 5, 2015.

clues and determines the sizes of many physical objects simultaneously. The approach consists of two steps: (i) many different types of clues to the numerical attribute are collected from various linguistics resources, and (ii) those collected clues are brought together by a combined regression and ranking.

2 Related Work

Hovy et al. (2002) pointed out the importance of the knowledge on the numerical attributes in question answering. They hand-coded the possible range of a numerical attribute. Akiba et al. (2004), Fujihata et al. (2001), Aramaki et al. (2007), and Bakalov et al. (2011) made similar attempts. Their target, however, is the fixed numerical attributes of the named entities, while our target is the numerical attributes of general physical objects, not restricted to the named entities.

Davidov and Rappoport (2010) collected various types of text fragments indicating values of numerical attributes of physical objects. Our work differs from theirs in that we explore more subtle linguistic clues in addition to those used in the previous work, by using a global mathematical model that brings together all the clues.

Narisawa et al. (2013) tried to determine whether a given amount is large, small, or normal as a size of an object, making good use of clue words such as $only$; The sentence "*This laptop weighs only 0.7kg*" means that laptops are usually heavier than 0.7kg.

3 Fragmentary clues to sizes

3.1 Physical objects

We first collect physical objects, i.e., objects for which the size can be defined. However, the numerical attribute of a word depends on the sense in which the word is being used. We will therefore determine the size of each sense instead of each word. Specifically, we determine the size of each noun synset in the Japanese WordNet (Bond et al., 2009). We basically regard as physical objects the synsets that are descendants of the synset corresponding to "physical objects" (00002684-n). We filter out the physical objects that are descendants of any of the following synsets (09334396-n, 00027167-n, 09239740-n, 09287968-n, 09277686-n, 09335240-n, 04564698-n, and 03670849-n), since their sizes would be hard to define (e.g., earth, location, soil).

We further filter out approximately 400 synsets for various reasons such as ambiguity.[1]

3.2 Collecting absolute clues

We collect *absolute clues*, which indicate a value of a physical object without reference to other physical objects.

We used a search engine[2] with a query such as ' "*the size of A*" AND *meter*' (AND represents a logical conjunction) and decompose the retrieved snippets into text fragments with "..." as a delimiter. We used only the first 1,000 pages (the maximum amount allowed by the terms of use for API users) for the query comprising a pattern ("*the size of A*", "*the length of A*", or "*the height of A*") and a length unit (millimeter, centimeter, meter, or kilometer).

Note that absolute clues are corpus-based.

3.3 Collecting relative clues

We also collect *relative clues*, which suggest a numerical order relation between two physical objects, i.e., A should be larger than B. Note that holonymy and comparative sentences below are explicit relative clues as opposed to implicit relative clues that follow. Note also that holonymy is WordNet-based while comparative sentences and implicit relative clues are corpus-based.

3.3.1 Holonymy

If A is a part of B, it usually means that A is smaller than B. We can obtain such part-of (holonymy) relations from the WordNet. Specifically, for each physical object obtained in Section 3.1, we retrieve its holonymy synsets. If a synset is a holonym of another synset, it suggests that the former is larger than the latter.

3.3.2 Comparative sentences

The sentence "*the middle finger is longer than the ring finger*" suggests that the relation 'middle finger $>$ ring finger' holds for the size attribute. We collect such comparative sentences. Specifically, we search

[1] The list of those synsets and textual patterns and Japanese search keywords used in this work are available from `http://www.lr.pi.titech.ac.jp/~takamura/core9.html`.

[2] Yahoo!JAPAN API.

an n-gram corpus (Kudo and Kazawa, 2007) for the textual patterns including "*A is longer than B*".[3]

3.3.3 Implicit relative clues

People tend not to write out clues explicitly when most readers are expected to have the relevant knowledge. Since absolute clues and comparative sentences are explicit, we cannot expect a sufficient amount of such clues.

We argue that people unintentionally put many pieces of common knowledge into some specific textual patterns. The sentence "*I put my wallet into the pocket*" suggests that 'pocket > wallet' holds for the numerical attribute. We collect from the n-gram corpus such textual patterns (*A in B, put A in B, take A out of B, store A in B, put A on B, drop A from B, A go into B, and A go out of B*).

4 Bringing together the clues

4.1 Feature representation and linear model

To bring together the clues introduced in Section 3, we first represent physical objects with feature vectors and employ a linear model in which the size $f(\boldsymbol{w}, \boldsymbol{x})$ is represented as the inner product $\boldsymbol{w} \cdot \boldsymbol{x}$ of feature vector $\boldsymbol{x}$ and weight vector $\boldsymbol{w}$.

We use the following features: the synsets that are ancestors of the target synset (i.e., synsets that can be found by traversing up through hypernym-hyponym relations or instance-of relations), the synsets that the target synset is a member of (hmem in WordNet), the hypernym synsets of the target synset (hype in WordNet), the synsets that the target synset is an instance of (inst in WordNet), the synsets that the target synset has as a component (mprt in WordNet), the synsets that the target synset is a component of (hprt in WordNet), the head word in the gloss in a dictionary, and the synonyms in the target synset.

4.2 Formalization

We discuss how to estimate weight vector $\boldsymbol{w}$.

Some physical objects are given absolute clues. If multiple absolute clues are found for an object, we regard their average (actually, its logarithm) as the approximate size used for training. Since the size is a real number, the machine learning framework to be employed should be regression. Additionally, relative clues are incorporated into the training by means of ranking framework. We henceforth use the combined regression and ranking.

Our formalization is similar to the combined regression and ranking model developed by Sculley (2010). Let D_a and D_r denote respectively the training datasets consisting of absolute clues and relative clues. Each element in D_a is represented as a pair of a feature vector $\boldsymbol{x}$ and its average size y. Each element in D_r is represented as a tuple of feature vectors $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$, and the order relation z; z indicates whether $\boldsymbol{x}_1$ is larger ($z = +1$), or $\boldsymbol{x}_2$ is larger ($z = -1$). We minimize the following function:

$$(1-\alpha)L_a(\boldsymbol{w}, D_a) + \alpha L_r(\boldsymbol{w}, D_r) + \frac{\lambda}{2}||\boldsymbol{w}||^2, \quad (1)$$

where α is a trade-off parameter between regression loss $L_a(\boldsymbol{w}, D_a)$ and pairwise loss $L_r(\boldsymbol{w}, D_r)$. $(\lambda/2)||\boldsymbol{w}||^2$ is the regularization term.

The regression loss $L_a(\boldsymbol{w}, D_a)$ is decomposed as

$$\frac{1}{|D_a|} \sum_{(\boldsymbol{x},y)\in D_a} l_a(y, f(\boldsymbol{w}, \boldsymbol{x})), \quad (2)$$

where $l_a(y, f(\boldsymbol{w}, \boldsymbol{x}))$ is the loss of the pair $(\boldsymbol{x}, y)$ under the model $\boldsymbol{w}$, and is represented by *squared loss* $(y - f(\boldsymbol{w}, \boldsymbol{x}))^2$, indicating the difference between the target value and the model output.

The pairwise loss $L_r(\boldsymbol{w}, D_r)$, is decomposed as

$$\frac{1}{|D_r|} \sum_{(\boldsymbol{x}_1,\boldsymbol{x}_2,z)\in D_r} l_r(z, \boldsymbol{x}_1, \boldsymbol{x}_2, \boldsymbol{w}), \quad (3)$$

where $l_r(z, \boldsymbol{x}_1, \boldsymbol{x}_2, \boldsymbol{w})$ is the loss of the tuple $(\boldsymbol{x}_1, \boldsymbol{x}_2, z)$ under the model $\boldsymbol{w}$, and is represented by *hinge loss*, $\max(0, 1 - z \cdot f(\boldsymbol{w}, \boldsymbol{x}_1 - \boldsymbol{x}_2))$.

While a single type of loss function was used for the regression loss and the pairwise loss in the previous work (Sculley, 2010), the current framework relies on two different types of loss functions, i.e., squared loss and hinge loss, so that both absolute and relative clues can be used in the model.

5 Experiments

5.1 Experimental setting

We followed the process in Section 3.1 and eliminated infrequent ones from the obtained synsets. For

[3] We also used "shorter", "larger", and "smaller".

the remaining synsets, we performed a search for absolute and relative clues and obtained 1,329 absolute clues and 7,335 relative clues. This set of relative clues stems from 848 WordNet-based clues and 6,496 corpus-based clues with a small overlap. We note that fewer than 1% of these 6,496 corpus-based clues are explicit. The synsets for which no clues are found are removed from the following process, leaving 3,598 synsets. Thoroughly using the web data might provide a larger overall amount, but the current result suggests that there are fewer absolute clues than relative ones and fewer explicit clues than implicit ones.

We evaluate the methods in two different ways. One is the difference: the sizes of the 262 randomly sampled synsets without absolute clues are manually determined, and we calculated the difference between the estimated size and the manually determined size for each of those synsets. The other is the order relation classification: the size relations of 1,152 randomly sampled pairs of synsets are manually annotated, and we employ as an evaluation metric the accuracy indicating how many of those relations are correctly predicted.

We implemented our combined regression and ranking method by modifying a package.[4] We used the logarithms of sizes as the target value. We tuned λ in Equation (1) to the value that optimizes the accuracy out of 11 values[5]: $10^{-7}, 10^{-6}, \cdots, 10^{3}$.

We tested different numbers of absolute clues in training (namely, 300, 500, 800, 1,000) in order to examine its effect.

5.2 Results

Figure 1 shows how the average difference for each number of absolute clues changes as α in Equation (1) is varied. All types of clues and features are used for Figure 1 (a), while the clues and features extracted from WordNet except for glosses are excluded for Figure 1 (b). The latter emulates the situation where the dictionary is available, but the large-scale thesaurus such as WordNet is not. The left-most point ($\alpha = 0$) for each figure corresponds to simple regression. The curves show that the difference can be reduced by using the combined regression and ranking. The improvement is more remarkable when fewer absolute clues are used.

Similarly, Figure 2 shows how the accuracy of the order relation classification for each number of absolute clues changes as α is varied. The accuracy of the order relation classification was around 70 to 80 %. The benefit of using combined regression and ranking is more remarkable in Figure 2 (b), i.e., when the thesaurus is not available.

Table 1 shows a sample of physical objects and their estimated sizes. We can see that the overall trend of the size has been successfully captured.

We also examine some features with small or large weights in Table 2. Very small weights are given to, for example, elementary particles in the field of particle physics, hydrons, and bacteria.[6]

Size (cm)	Synset	Example word
1.35×10^{-1}	11678768-n	ovum
2.68×10^{0}	02312744-n	silkworm
3.26×10^{0}	02206856-n	bee
7.16×10^{0}	04453037-n	tooth of gear
9.09×10^{0}	03209910-n	floppy disk
1.14×10^{1}	03378442-n	foot
3.01×10^{1}	04586225-n	wind chime
3.35×10^{1}	03485794-n	hand towel
4.57×10^{1}	04590553-n	windshield
1.56×10^{2}	09189157-n	nest of hawk or eagle
1.65×10^{2}	04152829-n	screen
4.31×10^{4}	02687992-n	airport

Table 1: Sample of the estimated sizes

Feature	Weight
Synset for baryon, as ancestor	-7.75
Hydron as synonym	-7.75
Synset for fermion, as ancestor	-7.13
Electron, as synonym	-6.06
Bacteria, as synonym	-6.06
Bell tower, hprt feature	+7.15
Railroad as synonym,	+8.16
Means of transportation as ancestor	+8.38

6 Conclusion

We addressed the task of automatically extracting numerical attributes of physical objects. We propose representing the sizes of objects using a linear function. We used the combined regression and ranking model with both absolute and relative clues.

Currently, many features are extracted from a thesaurus WordNet. If we can extract effective features from other resources, we would be able to apply our method to the objects that are not in the thesaurus. Future work also includes the following:

· more accurately collecting physical objects,
· sense disambiguation of words in clues,
· use of superlative sentences,
· filtering out descriptions of rare events,
· a more effective way of using glosses,
· application to other attributes, e.g., weight,
· handling idioms.

Unsupervised POS Induction with Word Embeddings

Abstract

Unsupervised word embeddings have been shown to be valuable as features in supervised learning problems; however, their role in unsupervised problems has been less thoroughly explored. In this paper, we show that embeddings can likewise add value to the problem of unsupervised POS induction. In two representative models of POS induction, we replace multinomial distributions over the vocabulary with multivariate Gaussian distributions over word embeddings and observe consistent improvements in eight languages. We also analyze the effect of various choices while inducing word embeddings on "downstream" POS induction results.

1 Introduction

Unsupervised POS induction is the problem of assigning word tokens to syntactic categories given only a corpus of untagged text. In this paper we explore the effect of replacing words with their vector space embeddings[1] in two POS induction models: the classic first-order HMM (Kupiec, 1992) and the newly introduced conditional random field autoencoder (Ammar et al., 2014). In each model, instead of using a conditional multinomial distribution[2] to generate a word token $w_i \in V$ given a POS tag $t_i \in T$, we use a conditional Gaussian distribution and generate a d-dimensional word embedding $\mathbf{v}_{w_i} \in \mathbb{R}^d$ given t_i.

[1]Unlike Yatbaz et al. (2014), we leverage easily obtainable and widely used embeddings of word types.

[2]Also known as a categorical distribution.

Our findings suggest that, in both models, substantial improvements are possible when word embeddings are used rather than opaque word types. However, the independence assumptions made by the model used to induce embeddings strongly determines its effectiveness for POS induction: embedding models that model short-range context are more effective than those that model longer-range contexts. This result is unsurprising, but it illustrates the lack of an evaluation metric that measures the syntactic (rather than semantic) information in word embeddings. Our results also confirm the conclusions of Sirts et al. (2014) who were likewise able to improve POS induction results, albeit using a custom clustering model based on the the distance-dependent Chinese restaurant process (Blei and Frazier, 2011).

Our contributions are as follows: (i) reparameterization of token-level POS induction models to use word embeddings; and (ii) a systematic evaluation of word embeddings with respect to the syntactic information they contain.

2 Vector Space Word Embeddings

Word embeddings represent words in a language's vocabulary as points in a d-dimensional space such that nearby words (points) are similar in terms of their distributional properties. A variety of techniques for learning embeddings have been proposed, e.g., matrix factorization (Deerwester et al., 1990; Dhillon et al., 2011) and neural language modeling (Mikolov et al., 2011; Collobert and Weston, 2008).

For the POS induction task, we specifically need embeddings that capture syntactic similarities. Therefore we experiment with two types of embeddings

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1311–1316,
Denver, Colorado, May 31 – June 5, 2015.

that are known for such properties:

- **Skip-gram embeddings** (Mikolov et al., 2013) are based on a log bilinear model that predicts an unordered set of context words given a target word. Bansal et al. (2014) found that smaller context window sizes tend to result in embeddings with more syntactic information. We confirm this finding in our experiments.
- **Structured skip-gram embeddings** (Ling et al., 2015) extend the *standard* skip-gram embeddings (Mikolov et al., 2013) by taking into account the relative positions of words in a given context.

We use the tool `word2vec`[3] and Ling et al. (2015)'s modified version[4] to generate both plain and structured skip-gram embeddings in nine languages.

3 Models for POS Induction

In this section, we briefly review two classes of models used for POS induction (HMMs and CRF autoencoders), and explain how to generate word embedding observations in each class. We will represent a sentence of length ℓ as $\boldsymbol{w} = \langle w_1, w_2, \ldots, w_\ell \rangle \in V^\ell$ and a sequence of tags as $\boldsymbol{t} = \langle t_1, t_2, \ldots, t_\ell \rangle \in T^\ell$. The embeddings of word type $w \in V$ will be written as $\mathbf{v}_w \in \mathbb{R}^d$.

3.1 Hidden Markov Models

The hidden Markov model with multinomial emissions is a classic model for POS induction. This model makes the assumption that a latent Markov process with discrete states representing POS categories emits individual words in the vocabulary according to state (i.e., tag) specific emission distributions. An HMM thus defines the following joint distribution over sequences of observations and tags:

$$p(\boldsymbol{w}, \boldsymbol{t}) = \prod_{i=1}^{\ell} p(t_i \mid t_{i-1}) \times p(w_i \mid t_i) \qquad (1)$$

where distributions $p(t_i \mid t_{i-1})$ represents the transition probability and $p(w_i \mid t_i)$ is the emission probability, the probability of a particular tag generating the word at position i.[5]

We consider two variants of the HMM as baselines:

- $p(w_i \mid t_i)$ is parameterized as a "naïve multinomial" distribution with one distinct parameter for each word type.
- $p(w_i \mid t_i)$ is parameterized as a multinomial logistic regression model with hand-engineered features as detailed in (Berg-Kirkpatrick et al., 2010).

Gaussian Emissions. We now consider incorporating word embeddings in the HMM. Given a tag $t \in T$, instead of generating the observed word $w \in V$, we generate the (pre-trained) embedding $\mathbf{v}_w \in \mathbb{R}^d$ of that word. The conditional probability density assigned to $\mathbf{v}_w \mid t$ follows a multivariate Gaussian distribution with mean $\boldsymbol{\mu}_t$ and covariance matrix $\boldsymbol{\Sigma}_t$:

$$p(\mathbf{v}_w; \boldsymbol{\mu}_t, \boldsymbol{\Sigma}_t) = \frac{\exp\left(-\frac{1}{2}(\mathbf{v}_w - \boldsymbol{\mu}_t)^\top \boldsymbol{\Sigma}_t^{-1} (\mathbf{v}_w - \boldsymbol{\mu}_t)\right)}{\sqrt{(2\pi)^d |\boldsymbol{\Sigma}_t|}} \qquad (2)$$

This parameterization makes the assumption that embeddings of words which are often tagged as t are concentrated around some point $\boldsymbol{\mu}_t \in \mathbb{R}^d$, and the concentration decays according to the covariance matrix $\boldsymbol{\Sigma}_t$.[6]

Now, the joint distribution over a sequence of observations $\mathbf{v} = \langle \mathbf{v}_{w_1}, \mathbf{v}_{w_2} \ldots, \mathbf{v}_{w_\ell} \rangle$ (which corresponds to word sequence $\boldsymbol{w} = \langle w_1, w_2, \ldots, w_\ell, \rangle$) and a tag sequence $\boldsymbol{t} = \langle t_1, t_2 \ldots, t_\ell \rangle$ becomes:

$$p(\mathbf{v}, \boldsymbol{t}) = \prod_{i=1}^{\ell} p(t_i \mid t_{i-1}) \times p(\mathbf{v}_{w_i}; \boldsymbol{\mu}_{t_i}, \boldsymbol{\Sigma}_{t_i})$$

We use the Baum–Welch algorithm to fit the $\boldsymbol{\mu}_t$ and $\boldsymbol{\Sigma}_{t_i}$ parameters. In every iteration, we update $\boldsymbol{\mu}_{t^*}$ as follows:

$$\boldsymbol{\mu}_{t^*}^{new} = \frac{\sum_{\mathbf{v} \in \mathcal{T}} \sum_{i=1\ldots\ell} p(t_i = t^* \mid \mathbf{v}) \times \mathbf{v}_{w_i}}{\sum_{\mathbf{v} \in \mathcal{T}} \sum_{i=1\ldots\ell} p(t_i = t^* \mid \mathbf{v})} \qquad (3)$$

where $\mathcal{T}$ is a data set of word embedding sequences $\mathbf{v}$ each of length $|\mathbf{v}| = \ell$, and $p(t_i = t^* \mid \mathbf{v})$ is the posterior probability of label t^* at position i in the sequence $\mathbf{v}$. Likewise the update to $\boldsymbol{\Sigma}_{t^*}$ is:

$$\boldsymbol{\Sigma}_{t^*}^{new} = \frac{\sum_{\mathbf{v} \in \mathcal{T}} \sum_{i=1\ldots\ell} p(t_i = t^* \mid \mathbf{v}) \times \boldsymbol{\delta}\boldsymbol{\delta}^\top}{\sum_{\mathbf{v} \in \mathcal{T}} \sum_{i=1\ldots\ell} p(t_i = t^* \mid \mathbf{v})} \qquad (4)$$

where $\boldsymbol{\delta} = \mathbf{v}_{w_i} - \boldsymbol{\mu}_{t^*}^{new}$.

3.2 Conditional Random Field Autoencoders

The second class of models this work extends is called CRF autoencoders, which we recently proposed in (Ammar et al., 2014). It is a scalable family of models for feature-rich learning from unlabeled examples. The model conditions on one copy of the structured input, and generates a reconstruction of the input via a set of interdependent latent variables which represent the linguistic structure of interest. As shown in Eq. 5, the model factorizes into two distinct parts: the encoding model $p(\boldsymbol{t} \mid \boldsymbol{w})$ and the reconstruction model $p(\hat{\boldsymbol{w}} \mid \boldsymbol{t})$; where $\boldsymbol{w}$ is the structured input (e.g., a token sequence), $\boldsymbol{t}$ is the linguistic structure of interest (e.g., a sequence of POS tags), and $\hat{\boldsymbol{w}}$ is a generic reconstruction of the input. For POS induction, the encoding model is a linear-chain CRF with feature vector $\boldsymbol{\lambda}$ and local feature functions $\mathbf{f}$.

$$p(\hat{\boldsymbol{w}}, \boldsymbol{t} \mid \boldsymbol{w}) = p(\boldsymbol{t} \mid \boldsymbol{w}) \times p(\hat{\boldsymbol{w}} \mid \boldsymbol{t})$$
$$\propto p(\hat{\boldsymbol{w}} \mid \boldsymbol{t}) \times \exp \boldsymbol{\lambda} \cdot \sum_{i=1}^{|\boldsymbol{w}|} \mathbf{f}(t_i, t_{i-1}, \boldsymbol{w}) \quad (5)$$

In (Ammar et al., 2014), we explored two kinds of reconstructions $\hat{\boldsymbol{w}}$: surface forms and Brown clusters (Brown et al., 1992), and used "stupid multinomials" as the underlying distributions for re-generating $\hat{\boldsymbol{w}}$.

Gaussian Reconstruction. In this paper, we use d-dimensional word embedding reconstructions $\hat{w}_i = \mathbf{v}_{w_i} \in \mathbb{R}^d$, and replace the multinomial distribution of the reconstruction model with the multivariate Gaussian distribution in Eq. 2. We again use the Baum–Welch algorithm to estimate $\boldsymbol{\mu}_{t^*}$ and $\boldsymbol{\Sigma}_{t^*}$ similar to Eq. 3. The only difference is that posterior label probabilities are now conditional on both the input sequence $\boldsymbol{w}$ and the embeddings sequence $\mathbf{v}$, i.e., replace $p(t_i = t^* \mid \mathbf{v})$ in Eq. 2 with $p(t_i = t^* \mid \boldsymbol{w}, \mathbf{v})$.

4 Experiments

In this section, we attempt to answer the following questions:

- §4.1: Do syntactically-informed word embeddings improve POS induction? Which model performs best?
- §4.2: What kind of word embeddings are suitable for POS induction?

4.1 Choice of POS Induction Models

Here, we compare the following models for POS induction:

- Baseline: HMM with multinomial emissions (Kupiec, 1992),
- Baseline: HMM with log-linear emissions (Berg-Kirkpatrick et al., 2010),
- Baseline: CRF autoencoder with multinomial reconstructions (Ammar et al., 2014),[7]
- Proposed: HMM with Gaussian emissions, and
- Proposed: CRF autoencoder with Gaussian reconstructions.

Data. To train the POS induction models, we used the plain text from the training sections of the CoNLL-X shared task (Buchholz and Marsi, 2006) (for Danish and Turkish), the CoNLL 2007 shared task (Nivre et al., 2007) (for Arabic, Basque, Greek, Hungarian and Italian), and the Ukwabelana corpus (Spiegler et al., 2010) (for Zulu). For evaluation, we obtain the corresponding gold-standard POS tags by deterministically mapping the language-specific POS tags in the aforementioned corpora to the corresponding universal POS tag set (Petrov et al., 2012). This is the same set up we used in (Ammar et al., 2014).

Setup. In this section, we used skip-gram (i.e., `word2vec`) embeddings with a context window size = 1 and with dimensionality $d = 100$, trained with the largest corpora for each language in (Quasthoff et al., 2006), in addition to the plain text used to train the POS induction models.[8] In the proposed models, we only show results for estimating $\boldsymbol{\mu}_t$, assuming a diagonal covariance matrix $\boldsymbol{\Sigma}_t(k,k) = 0.45 \forall k \in \{1, \ldots, d\}$.[9] While the CRF autoencoder with multinomial reconstructions were carefully initialized as

[7] We use the configuration with best performance which reconstructs Brown clusters.

[8] We used the `corpus/tokenize-anything.sh` script in the cdec decoder (Dyer et al., 2010) to tokenize the corpora from (Quasthoff et al., 2006). The other corpora were already tokenized. In Arabic and Italian, we found a lot of discrepancies between the tokenization used for inducing word embeddings and the tokenization used for evaluation. We expect our results to improve with consistent tokenization.

[9] Surprisingly, we found that estimating $\boldsymbol{\Sigma}_t$ significantly degrades the performance. This may be due to overfitting (Shinozaki and Kawahara, 2007). Possible remedies include using a prior (Gauvain and Lee, 1994).

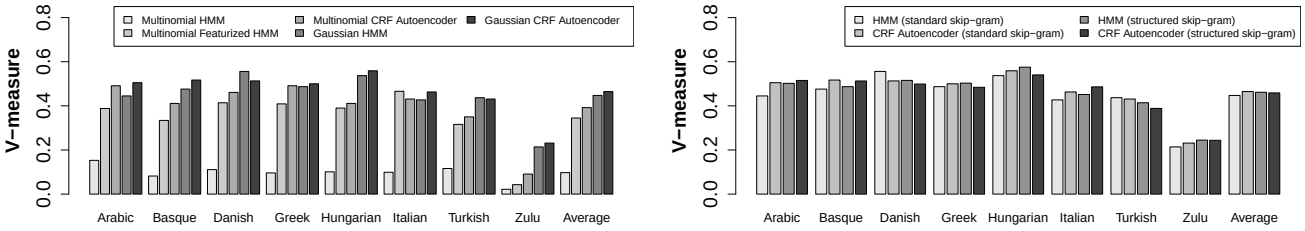

Figure 1: POS induction results. (V-measure, higher is better.) Window size is 1 for all word embeddings. **Left**: Models which use standard skip-gram word embeddings (i.e., Gaussian HMM and Gaussian CRF Autoencoder) outperform all baselines on average across languages. **Right**: comparison between standard and structured skip-grams on Gaussian HMM and CRF Autoencoder.

discussed in (Ammar et al., 2014), CRF autoencoder with Gaussian reconstructions were initialized uniformly at random in $[-1, 1]$. All HMM models were also randomly initialized. We tuned all hyperparameters on the English PTB corpus, then fixed them for all languages.

Evaluation. We use the V-measure evaluation metric (Rosenberg and Hirschberg, 2007) to evaluate the predicted syntactic classes at the token level.[10]

Results. The results in Fig. 1 clearly suggest that we can use word embeddings to improve POS induction. Surprisingly, the feature-less Gaussian HMM model outperforms the strong feature-rich baselines: Multinomial Featurized HMM and Multinomial CRF Autoencoder. One explanation is that our word embeddings were induced using larger unlabeled corpora than those used to train the POS induction models. The best results are obtained using both word embeddings and feature-rich models using the Gaussian CRF autoencoder model. This set of results suggest that word embeddings and hand-engineered features play complementary roles in POS induction. It is worth noting that the CRF autoencoder model with Gaussian reconstructions did not require careful initialization.[11]

[10]We found the V-measure results to be consistent with the many-to-one evaluation metric (Johnson, 2007). We only show one set of results for brevity.

[11]In (Ammar et al., 2014), we found that careful initialization for the CRF autoencoder model with multinomial reconstructions is necessary.

4.2 Choice of Embeddings

Standard skip-gram vs. structured skip-gram. On Gaussian HMMs, structured skip-gram embeddings score moderately higher than standard skip-grams. And as context window size gets larger, the gap widens (as shown in Fig. 2.) The reason may be that structured skip-gram embeddings give each position within the context window its own project matrix, so the smearing effect is not as pronounced as the window grows when compared to the standard embeddings. However the best performance is still obtained when window size is small.[12]

Dimensions = 20 vs. 200. We also varied the number of dimensions in the word vectors ($d \in \{20, 50, 100, 200\}$). The best V-measure we obtain is 0.504 ($d = 20$) and the worst is 0.460 ($d = 100$). However, we did not observe a consistent pattern as shown in Fig. 3.

Window size = 1 vs. 16. Finally, we varied the window size for the context surrounding target words ($w \in \{1, 2, 4, 8, 16\}$). $w = 1$ yields the best average V-measure across the eight languages as shown in Fig. 2. This is true for both standard and structured

[12]In preliminary experiments, we also compared standard skip-gram embeddings to SENNA embeddings (Collobert et al., 2011) (which are trained in a semi-supervised multi-task learning setup, with one task being POS tagging) on a subset of the English PTB corpus. As expected, the induced POS tags are much better when using SENNA embeddings, yielding a V-measure score of 0.57 compared to 0.51 for skip-gram embeddings. Since SENNA embeddings are only available in English, we did not include it in the comparison in Fig. 1.

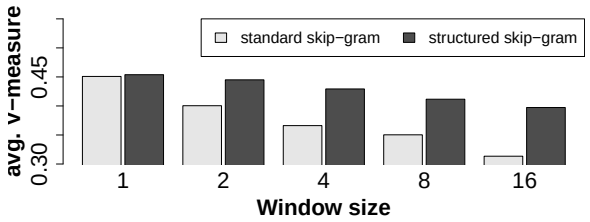

Figure 2: Effect of window size and embeddings type on POS induction over the languages in Fig. 1. d = 100. The model is HMM with Gaussian emissions.

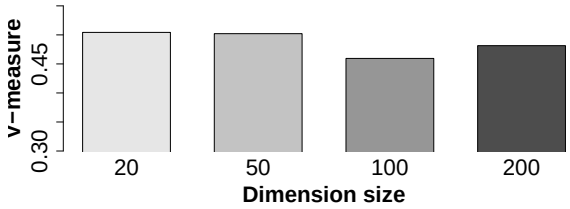

Figure 3: Effect of dimension size on POS induction on a subset of the English PTB corpus. w = 1. The model is HMM with Gaussian emissions.

skip-gram models. Notably, larger window sizes appear to produce word embeddings with less syntactic information. This result confirms the observations of Bansal et al. (2014).

4.3 Discussion

We have shown that (re)generating word embeddings does much better than generating opaque word types in unsupervised POS induction. At a high level, this confirms prior findings that unsupervised word embeddings capture syntactic properties of words, and shows that different embeddings capture more syntactically salient information than others. As such, we contend that unsupervised POS induction can be seen as a diagnostic metric for assessing the syntactic quality of embeddings.

To get a better understanding of what the multivariate Gaussian models have learned, we conduct a hill-climbing experiment on our English dataset. We seed each POS category with the average vector of 10 randomly sampled words from that category and train the model. Seeding unsurprisingly improves tagging performance. We also find words that are the nearest to the centroids generally agree with the correct category label, which validate our assumption that syntactically similar words tend to cluster in the high-dimensional embedding space. It also shows that careful initialization of model parameters can bring further improvements.

However we also find that words that are close to the centroid are not necessarily representative of what linguists consider to be prototypical. For example, Hopper and Thompson (1983) show that physical, telic, past tense verbs are more prototypical with respect to case marking, agreement, and other syntactic behavior. However, the verbs nearest our centroid all seem rather abstract. In English, the nearest 5 words in the verb category are *entails, aspires, attaches, foresees, deems*. This may be because these words seldom serve functions other than verbs; and placing the centroid around them incurs less penalty (in contrast to physical verbs, e.g. *bite*, which often also act as nouns). Therefore one should be cautious in interpreting what is prototypical about them.

5 Conclusion

We propose using a multivariate Gaussian model to generate vector space representations of observed words in generative or hybrid models for POS induction, as a superior alternative to using multinomial distributions to generate categorical word types. We find the performance from a simple Gaussian HMM competitive with strong feature-rich baselines. We further show that substituting the emission part of the CRF autoencoder can bring further improvements. We also confirm previous findings which suggest that smaller context windows in skip-gram models result in word embeddings which encode more syntactic information. It would be interesting to see if we can apply this approach to other tasks which require generative modeling of textual observations such as language modeling and grammar induction.

Abstract

Integer Linear Programming (ILP) based summarization methods have been widely adopted recently because of their state-of-the-art performance. This paper proposes two new modifications in this framework for update summarization. Our key idea is to use discriminative models with a set of features to measure both the salience and the novelty of words and sentences. First, these features are used in a supervised model to predict the weights of the concepts used in the ILP model. Second, we generate preliminary sentence candidates in the ILP model and then rerank them using sentence level features. We evaluate our method on different TAC update summarization data sets, and the results show that our system performs competitively compared to the best TAC systems based on the ROUGE evaluation metric.

1 Introduction

Update summarization has attracted significant research focus recently. Different from generic extractive summarization, update summarization assumes that users already have some information about a given topic from an old data set, and thus for a new data set the system aims to generate a summary that contains as much novel information as possible. This task was first introduced at DUC 2007 and then continued until TAC 2011. It is very useful to chronological events in real applications.

Most basic update summarization methods are variants of multi-document summarization methods, with some consideration of the difference between the earlier and later document sets (Boudin et al., 2008; Fisher and Roark, 2008; Long et al., 2010; Bysani, 2010). One important line is to use graph-based co-ranking. They rank the sentences in the earlier and later document sets simultaneously by considering the sentence relationship. For example, Li et al. (2008) was inspired by the intuition that "a sentence receives a positive influence from the sentences that correlate to it in the same collection, whereas receives a negative influence from the sentences that correlates to it in the different (or previously read) collection', and proposed a graph based sentence ranking algorithm for update summarization. Wan (2012) integrated two co-ranking processes by adding some strict constraints, which led to more accurate computation of sentences' scores for update summarization. A similar method was also applied earlier by (Wan et al., 2011) for multilingual news summarization. In addition, generative models, such as topic models, have also been adopted for this task. For example, Delort and Alfonseca (2012) proposed a novel nonparametric Bayesian approach, a variant of Latent Dirichlet Allocation (LDA), aiming to distinguish between common information and novel information. Li et al. (2012) borrowed the idea of evolutionary clustering and proposed a three-level HDP (Hierarchical Dirichlet Process) model to represent the diversity and commonality between aspects discovered from two different document data sets.

One of the most competitive summarization methods is based on Integer Linear Programming (ILP). It has been widely adopted in the generic summarization task (Martins and Smith, 2009; Berg-Kirkpatrick et al., 2011; Woodsend and Lapata, 2012; Li et al., 2013a; Li et al., 2013b; Li et al., 2014). In this paper, we use the ILP summarization

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1317–1322,
Denver, Colorado, May 31 – June 5, 2015.

framework for the update summarization task, and make improvement from two aspects, with the goal to more discriminatively represent both the salience and novelty of words and sentences. First, we use supervised models and a rich set of features to learn the weights for the bigram concepts used in the ILP model. Second, we design a sentence reranking component to score the summary candidate sentences generated by the ILP model. This second reranking approach allows us to explicitly model a sentence's importance and novelty, which complements the bigram centric view in the first step of ILP sentence selection. Our experimental results on multiple TAC data sets demonstrate the effectiveness of our proposed method.

2 Proposed Update Summarization System

2.1 ILP Framework for Summarization

The core idea of the ILP based summarization method is to select the summary sentences by maximizing the sum of the weights of the language concepts that appear in the summary. Bigrams are often used as the language concepts in this method. Gillick et al. (2009) stated that the bigrams gave consistently better performance than unigrams or trigrams for a variety of ROUGE measures. The association between the language concepts and sentences serves as the constraints. This ILP method is formally represented as below (see (Gillick et al., 2009) for more details):

$$\begin{aligned} \max \quad & \textstyle\sum_i w_i c_i \\ s.t. \quad & c_i \in \{0,1\}\ \forall i \quad s_j \in \{0,1\}\ \forall j \\ & s_j Occ_{ij} \le c_i \quad \sum_j s_j Occ_{ij} \ge c_i \\ & \textstyle\sum_j l_j s_j \le L \end{aligned} \tag{1}$$

where c_i and s_j are binary variables that indicate the presence of a concept and a sentence respectively. l_j is the sentence length and L is the maximum length (word number) of the generated summary. w_i is a concept's weight and Occ_{ij} means the occurrence of concept i in sentence j. The first two inequalities associate the sentences and concepts. They ensure that selecting a sentence leads to the selection of all the concepts it contains, and selecting a concept only happens when it is present in at least one of the selected sentences.

2.2 Bigrams Weighting for Salience and Novelty

In the above ILP-based summarization method, how to determine the concepts and measure their weights is the key factor impacting the system performance. Intuitively, if we can successfully identify the important key bigrams used in the ILP system, or assign large weights to those important bigrams, the generated summary sentences will contain as many important bigrams as possible, and thus resulting in better summarization performance. The oracle experiment in (Gillick et al., 2008) showed that if they use the bigrams extracted from the human written summaries as the input of the ILP system, much better ROUGE scores can be obtained than using the automatically selected bigrams, suggesting the importance of using the right concepts. (Gillick et al., 2009) used document frequency as the weight of a bigram. They also provided some justification for document frequency as a weighting function in that paper.

For update summarization, intuitively we need to not only identify the salience of the bigram, but also incorporate bigrams' novelty in their weights. Therefore, only using the document frequency as the weight in the objective function is insufficient. We thus propose to use a supervised framework for the bigram weight estimation in the ILP model. The new objective function is:

$$\max \quad \textstyle\sum_i (\theta \cdot \mathbf{f}(b_i))\, c_i \tag{2}$$

We replace the heuristic w_i in Formula (1) with a feature based one: $f(b_i)$ represents the features for a bigram b_i, and θ is a weight vector for these features. Constraints remain the same as before in the ILP method.

There are two kinds of features for each bigram: one set is related to the bigrams themselves; the other set is related to the sentences containing the bigram. Table 1 shows the features we design. For both the bigram and the sentence level features, we separate the features based on whether they represent the importance or the novelty. For

Feature 8 and 17, the summary is generated by a general unsupervised ILP-based summarization system from the given old data set. The idea of Feature 9 and 10 was first introduced by (Bysani, 2010); here we applied it to bigrams. df_{max} is the number of documents in the data set (10 in the TAC data), which can be thought of the maximum value of document frequency for a bigram. Feature 11 is interpolated n-gram document frequency, which was first introduced by (Ng et al., 2012): $\frac{\alpha \sum_{w_u \in S} df_{new}(w_u) + (1-\alpha) \sum_{w_b \in S} df_{new}(w_b)}{|S|}$, where w_u and w_b are unigrams and bigrams respectively in sentence S. Feature 18 and 19 are variants of Features 11, where instead of document frequency (df in the formula above), bigram and unigram's novelty and uniqueness values are used. Among these features, the feature values of feature 4, 5 and 6 are discrete. In this study, we discretized all the other continuous values into ten categories according to the value range in the training data.

To train the model (feature weights), we use the average perceptron strategy (Collins, 2002) to update the feature weights whenever the hypothesis by the ILP decoding process is incorrect. Binary class labels are used for bigrams in the learning process, that is, we only consider whether a bigram is in the system generated summary or human summaries, not their term or document frequency. We use a fixed learning rate (0.1) in training.

2.3 Sentence Reranking on ILP Results

In the ILP method, sentence selection is done by considering the concepts that a sentence contains. It is difficult to add indicative features in this framework to explicitly represent the sentence's salience, and more importantly, its novelty for the update summarization task. This information is only captured by the weights of the bigrams using the method described above. Therefore, we propose to use a two-step approach, where an initial ILP module first selects some sentences and then a reranking module uses sentence level features to rerank them to generate the final summary. We expect this step of modeling sentences directly can complement the bigram centric view in the first ILP summarization module.

[1]Note that we do not use all the sentences in the ILP module. The 'relevant' sentences are those that have at least one bigram with document frequency larger than or equal to three.

Bigram Level Features
Importance Related Features
1. $df_{new}(b)$: document frequency in new data set
2. normalized term frequency in all filtered relevant sentences[1]
3. sentence frequency in all relevant sentences
4. do bigram words appear in topic's query ?
5. is the bigram in the first 1/2/3 position of that sentence?
6. is the bigram in the last 1/2/3 position of that sentence?
Novelty Related Features
7. $df_{old}(b)$: document frequency in old data set
8. normalized term frequency in the summary from old data set
9. bigram novelty value $n(b) = \frac{df_{new}(b)}{df_{old}(b)+df_{max}}$
10. bigram uniqueness value $u(b) = 0$ if $df_{old}(b) > 0$; otherwise $u(b) = \frac{df_{new}(b)}{df_{max}}$
Sentence Level Features
Importance Related Features
11. interpolated n-gram document frequency
12. sentence position in that document
13. is the sentence in the first 1/2/3 position in that document?
14. is the sentence in the last 1/2/3 position in that document?
15. sentence length
16. sentence similarity with topic's query
Novelty Related Features
17. sentence similarity with the summary from old data set
18. interpolated n-gram novelty
19. interpolated n-gram uniqueness

Table 1: Features in the supervised ILP model for weighting bigrams.

For the first step, we use the ILP framework with our supervised bigram weighting method to obtain a summary of N words (N is greater than the required summary length L). Note that the ILP model selects these output sentences as a set that optimizes the objective function, and there are no scores for each individual sentence. Second, we use sentence level features listed in Table 1 to rerank the can-

didate sentences. This is expected to better evaluate the salience and the novelty of the sentences. We use a regression model (SVR) for this reranking purpose. When training the model, a sentence's ROUGE2 score compared with the human generated summary is used as the regression target. After reranking, we just select the top sentences that satisfy the length constraint to form the final summary. In this work we do not use any redundancy removal (e.g., MMR method). This is because the ILP decoding process tries to find a global optimal set maximizing the concept coverage, subject to the length constraint, and thus already considers redundancy among sentences. Typically when the initial set (i.e., the output from the first ILP step) is not too big, redundancy is not a big problem.

3 Experiments and Results

3.1 Data and Experiment Setup

We evaluate our methods using several recent TAC data sets, from 2008 to 2011. Every topic has two sets of 10 documents (Set A and B). The update task aims to create a 100-word summary from Set B given a topic query and Set A. When evaluating on one year's data, we use the data from the other three years as the training set. This applies to both the supervised ILP method and the sentence reranking regression model. All the summaries are evaluated using ROUGE (Lin, 2004). An academic free solver[2] does all the ILP decoding and libsvm[3] is used for SVR implementation.

3.2 Results

Table 2 and Table 3 show the R2 and R-SU4 values on different TAC data sets for the following systems.

- ILP baseline. This is the unsupervised ILP-based summarization system (Gillick et al., 2009), in which only bigrams with document frequency greater than 2 are used in the ILP summarization process, and weight w_i is the document frequency of that bigram.
- TAC best. This is the best result in the TAC update summarization evaluation.[4] Note that there is limited research on update summarization and we cannot find better published results for these data sets than the TAC best systems.
- Supervised ILP. This is our supervised ILP method where bigram weights are learned discriminately. It is the one-step system that generates the summary with the target length. We use the same bigram set as the ILP baseline system. For this method, we show results using different features: only using the importance features; and using all the features. This is used to evaluate the impact of the novelty features on the update summarization task.
- Two-step method: supervised ILP followed by sentence reranking. We generate 200 (value of N) words summary in the ILP system. Two different configurations are also used: with and without the sentence novelty features in the sentence ranking module. All the features (including the novelty features) are used in the ILP pre-selection step.
- Sentence ranking without ILP. In this experiment, we do not use the ILP summarization module to generate candidate sentences first, but just apply sentence ranking to the entire data set. Then MMR is leveraged to select the final summary sentences. Again, we present results using different feature sets.

We can see from the tables that the supervised ILP model outperforms the unsupervised one. After including the novelty related features, the model can assign higher weights for the bigrams with novel information, resulting in improved summarization performance. There is further improvement when using our 2-step approach with the sentence reranking model. Our proposed method (ILP followed by sentence reranking, and using all the features) outperforms the TAC best result in 2010 and 2011, and also yields competitive results in the other data sets. The gain of ROUGE-2 of our proposed system compared with the ILP baseline is statistically significant based on ROUGE's 95% confidence. When using sentence ranking on the entire document set, without the ILP pre-selection step, its performance is worse than our proposed method. This shows the benefit of doing pre-selection using the ILP module. Finally,

w all features	12.85	13.31	11.50	12.90

Table 3: ROUGE-SU4 results on TAC 2008-2011 data.

for all the methods, adding the novelty related features always performs better than that without them, proving the effect of our novelty features for update summarization.

Lastly we evaluate the effect of the summary length from the ILP module on the two-step summarization systems. Figure 1 shows the performance when N changes from 150 to 400. We can see that there is some difference in the patterns for different data sets, and the best results are obtained when N is around 150 to 250. When the first ILP module produces many sentence candidates, it is likely that there is redundancy among them. In this case, redundancy removal approaches such as MMR need to be used to generate the final summary. In addition, for a large candidate set, our current regression model also faces some challenges due to its limited features used in sentence reranking. Addressing these problems is our future work.

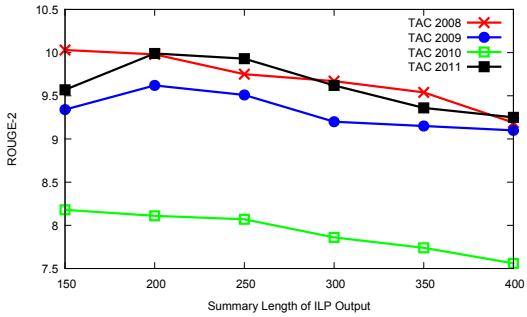

Figure 1: ROUGE-2 results when varying the output length for the first ILP selection step.

4 Conclusions

In this paper, we adopt the supervised ILP framework for the update summarization task. A set of rich features are used to measure the importance and novelty of the bigram concepts used in the ILP model. In addition, we proposed a re-selection component to rank candidate sentences generated by the ILP model based on sentence level features. Our experiment results show that our features and the reranking procedure both help improve the summarization performance. This pilot research points out new directions for generic or update summarization based on the ILP framework.

Abstract

This paper presents an annotation scheme for adding entity and event target annotations to the MPQA corpus, a rich span-annotated opinion corpus. The new corpus promises to be a valuable new resource for developing systems for entity/event-level sentiment analysis. Such systems, in turn, would be valuable in NLP applications such as Automatic Question Answering. We introduce the idea of entity and event targets (*eTargets*), describe the annotation scheme, and present the results of an agreement study.

1 Introduction

Much work in sentiment analysis and opinion mining is at the document level (Pang et al., 2002; Turney, 2002). There is increasing interest in more fine-grained levels - sentence-level (Yu and Hatzivassiloglou, 2003; McDonald et al., 2007), phrase-level (Choi and Cardie, 2008), aspect-level (Hu and Liu, 2004; Titov and McDonald, 2008), etc. We specifically address sentiments toward entities and events (i.e., *eTargets*) expressed in data such as blogs, newswire, and editorials. A system that could recognize sentiments toward entities and events would be valuable in an application such as Automatic Question Answering, to support answering questions such as "Toward whom/what is X negative/positive?" "Who is negative/positive toward X?" (Stoyanov et al., 2005). Or, to augment an automatic wikification system (Ratinov et al., 2011) – in addition to relationships such as *spouse* and *parents*, the system could include information about whom or what the subject supports or opposes. A recent NIST evaluation – The Knowledge Base Population (KBP) Sentiment track[1] — aims at using corpora to collect information regarding sentiments expressed toward or by named entities.

Annotated corpora of reviews (e.g., (Hu and Liu, 2004; Titov and McDonald, 2008)), widely used in NLP, often include target annotations. Such targets are often aspects or features of products or services, and as such are somewhat limited.[2]

Recently, to create the Sentiment Treebank (Socher et al., 2013), researchers crowdsourced annotations of movie review data and then overlaid the annotations onto syntax trees. Thus, the targets are not limited to aspects of products/services. However, annotators were asked to annotate small and then increasingly larger segments of the sentence. Thus, the annotations are mixed in the degree to which context was considered when making the judgements. Previously, we (Deng et al., 2013) annotated a corpus of non-review data with sentiments toward entities, but only for those that participate in certain types of events. In all of the above corpora, the only sentiments considered are those of the writer, excluding sentiments attributed to other entities.

The MPQA opinion annotated corpus (Wiebe et al., 2005; Wilson, 2007) is entirely span-based, and contains no eTarget annotations. However, it provides an infrastructure for sentiment annotation that is not provided by other sentiment NLP corpora, and

[1] http://www.nist.gov/tac/2014/KBP/Sentiment/index.html

[2] For example, as stated in SemEval-2014: "We annotate only aspect terms naming particular aspects."

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1323–1328,
Denver, Colorado, May 31 – June 5, 2015.

is much more varied in topic, genre, and publication source. This paper addresses adding eTarget annotations to the MPQA corpus; we believe that the result will be a valuable new resource for the community.

2 From MPQA 2.0 to MPQA 3.0

To create MPQA 3.0, entity-target and event-target (*eTarget*) annotations are added to the MPQA 2.0 annotations.[3] The MPQA annotations consist of *private states*, which are states of *sources* holding *attitudes* toward *targets*. In the MPQA 2.0 annotations, the top-level annotations are *direct subjective* (*DS*) and *objective speech event* annotations. DS annotations are for private states, and objective speech event annotations are for objective statements attributed to a source. An important property of sources is that they are nested, reflecting the fact that private states and speech events are often embedded in one another.

As shown in Figure 1, one DS may contain links to multiple *attitude* annotations, meaning that all of the attitudes share the same nested source. The attitudes differ from one another in their attitude types, polarities, and/or targets. There are several types of attitudes included in MPQA 2.0 (Wilson, 2007; Somasundaran et al., 2007), including sentiment and arguing. This work focuses on sentiments, which are defined in (Wilson, 2007) as positive and negative evaluations, emotions, and judgements.

MPQA 2.0 also contains *expressive subjective element* (*ESE*) annotations, which pinpoint specific expressions used to express subjectivity (Wiebe et al., 2005). An ESE also has a nested-source annotation. Since we focus on sentiments, we only consider ESEs whose polarity is positive or negative (excluding those marked neutral).

The *target-span* annotations in MPQA 2.0 are linked to from the attitudes. More than one target may be linked to from an attitude, but most attitudes have only one target. The MPQA 2.0 annotators identified the main/most important target(s) they perceive in the sentence. If there is no target, the target-span annotation is "none". However, there are many other eTargets to be identified. First, while ESE annotations have nested sources, they do not have any target annotations. Second, there are many

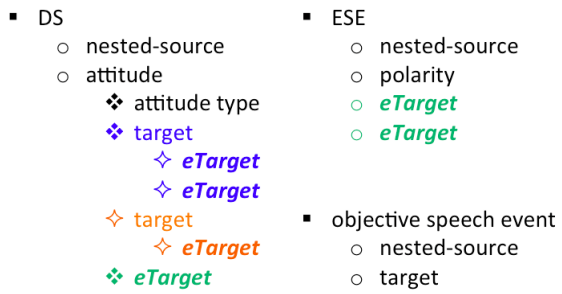

Figure 1: Structure in MPQA 3.0.

more targets that may be marked than the major ones identified in MPQA 2.0. In Figure 1, the eTargets are what we add in MPQA 3.0. We identify the blue (orange) eTargets that are in the span of a blue (orange) target in MPQA 2.0. We also identify the green eTargets that are not in the scope of any target.

Since our priority was to add eTargets to sentiments, no eTargets have yet been added to objective speech events, as shown in Figure 1.

To create MPQA 3.0, the corpus is first parsed, and *potential* eTarget annotations are automatically created from the heads of NPs and VPs. The annotators then consider each sentiment attitude and each polar ESE, and decide for each which eTargets to add. By adding eTargets to the existing annotations, the information in MPQA 2.0 is retained. Before presenting the scheme, we first give some examples.

2.1 Examples

For each example, a subset of the annotations are shown. The phrase in blue is an attitude span, the phrase in red is a target span, the tokens in yellow are the eTargets which are newly annotated in MPQA 3.0. The underlined phrases are ESE spans. Each example is followed by the MPQA structure of the annotations.

In Ex(1), a negative attitude is shown, *issued the fatwa against*. The source is *the Imam*. The target is the event *Rushdie insulting the Prophet*. However, the assertion that the Imam is negative toward the insult event is within the scope of this article. This is captured by an objective speech event annotation (not shown) whose target span includes the insult event, and whose source is the writer (*w*). Thus, the complete interpretation of this negative attitude is, according to the writer, the Imam is negative to-

[3] Available at http://mpqa.cs.pitt.edu

ward the insult event. And, the nested source is *w, imam*.

Ex(1) When the Imam issued the fatwa against Salman Rushdie for insulting the Prophet ...

DS: issued the fatwa
nested-source: w, imam
attitude: issued the fatwa against
attitude-type: sentiment-negative
target: Salman...insult...Prophet
eTarget : Rushdie, insulting

We find two eTargets in the target-span: "Rushdie" himself plus his act of "insulting."

In the same sentence, there is another negative attitude, *insulting*, as shown in Ex(2). The source is *Salman Rushdie* and the target is *the Prophet*. Note that the span covering this event is the target span of the attitude in Ex(1) — the private state of Ex(2) is nested in the private state of Ex(1). Thus, the complete interpretation of the negative attitude in Ex(2) is: according to the writer, the Imam is negative toward Rushdie insulting the Prophet. The nested source is *w, Imam, Rushdie*.

Ex(2) When the Imam issued the fatwa against Salman Rushdie for insulting the Prophet ...

DS: insulting
nested-source: w, imam, rushdie
attitude: insulting
attitude-type: sentiment-negative
target: the Prophet
eTarget : Prophet

We add an eTarget for the Prophet, anchored to the head "Prophet." Interestingly, "Prophet" is an eTarget for *w,Iman,Rushdie* (i.e., Rushdie is negative toward the Prophet), but not for *w,Imam* (i.e., the Imam is not negative toward the Prophet).

In the following example, the target span is short.

Ex(3) He is therefore planning to trigger wars ...

DS: (entire sentence)
nested-source: w
attitude: planning to trigger wars
attitude-type: sentiment-negative
target: He
eTarget : He
eTarget : planning, trigger, wars

"He" is George W. Bush; this article appeared in the early 2000s. The writer is negative toward Bush because (the writer claims) he is planning to trigger wars. As shown in the example, the MPQA 2.0 target span is only "He," for which we do create an eTarget. But there are three additional eTargets, which are not included in the target span. The writer is negative toward Bush planning to trigger wars; we make sense of this by inferring that the writer is negative toward the idea of triggering wars and thus toward war itself.

Ex(4) Three leading international organisations warned jointly Thursday that the international fight against terrorism should not be a pretext for the violation of human rights.

DS: warned
nested-source: w, threeint
attitude: warned
attitude-type: sentiment-negative
target: the international ... rights
eTarget :be, pretext, violation
ESE: pretext
nested-source: w, threeint
polarity: negative
eTarget : pretext

The viewpoints in the article of Ex(4) are not against fighting terrorism (another sentence begins "While we recognize that the threat of terrorism requires specific measures ...") but against doing so in certain ways. Here the three organizations are against the fight being used as a pretext for civil rights violations. Thus, "be", "pretext", and "violation" are eTargets, but "fight" and "terrorism" are not. We mark "be" as an eTarget because the source is negative toward the **state** of the fight being a pretext for the violation of human rights. This makes sense with the source also being negative toward "pretext" and "violation." The fact that "pre-

text" is identified as a negative ESE annotation in the MPQA 2.0 supports this as well.

There is a difference between ESE and attitude eTarget annotations. Since ESE annotations pinpoint specific wording used to express subjectivity, ESE eTargets are annotated more narrowly than attitude eTargets. For ESEs, the eTargets are the entities and events that are directly evaluated by the expression, while, for attitudes, the eTargets include all entities and events toward which the attitude holds (as we saw in the examples above). For example:

> Ex(5) ... because the hard-line wing in the US administration comprising Vice President Dick Cheney ...
>
> **DS**: (entire sentence)
> **nested-source**: w
> **attitude**: hard-line
> **attitude-type**: sentiment-negative
> **target**: wing in the .. Dick Cheney
> **eTarget**: wing, Cheney
> **ESE**: hard-line wing
> **nested-source**: w
> **polarity**: negative
> **eTarget**: wing

The ESE has only one eTarget, "wing," while the attitude has two: "wing" and "Cheney."

2.2 MPQA 3.0 Annotation Scheme

An **eTarget** is an entity or event that is the target of a sentiment (identified in MPQA 2.0 by a sentiment attitude or polar ESE span). The eTarget annotation is anchored to the head word of the NP or VP that refers to the entity or event, and has **three slots**: *id* (unique within the document), *isNegated* (*yes* or *no*), and *type* (*entity* or *event*; note that *event* includes both states and events). The *isNegated* = *yes* option is for the case where the eTarget is the negation of the event referred to by the head word, for example, when the source is positive toward someone **not** doing something.

An **attitude** has one or more target-span annotations in MPQA 2.0. We provide two slots for the k^{th} target annotation. *k-targetSpan* shows the k^{th} target span. *k-eTarget-link* is to be filled with a list of ids of eTargets whose text anchors are within the k^{th} target span. An additional slot *new-eTarget-link* is to be filled with a list of ids of other eTargets.

Each eTarget of an **ESE** has two slots, one for the eTarget id, and one for an attribute, *isReferedInSpan* (*yes*, or *no*). The value is *yes* if the eTarget is referred to in the ESE span.

3 Agreement Study

We developed the manual via iterative annotation, discussion, and revision. Once the manual was developed, we participated in an agreement study.

For the formal agreement study, one document was randomly selected from each of the four topics of the OPQA subset (Stoyanov et al., 2005) of the MPQA corpus. They were not any of the documents used to develop the manual. We then independently annotated the four documents. There are 292 eTargets in the four documents in total.

To evaluate the results, the same agreement measure is used for both attitude and ESE eTargets. Given an attitude or ESE, let set A be the set of eTargets annotated by annotator X, and set B be the set of eTargets annotated by annotator Y. Following (Wilson and Wiebe, 2003; Johansson and Moschitti, 2013), which treat each set A and B in turn as the gold-standard, we calculate the average F-measure, denoted $agr(A, B)$. The $agr(A, B)$ is 0.82 on average over the four documents, showing good agreement: $agr(A, B) = (|A \cap B|/|B| + |A \cap B|/|A|)/2$.

4 Disagreement Analysis

One issue is whether an attitude toward an entity or event is indeed communicated in the sentence. Consider this sentence: "President **Mugabe**'s **reelection** has been *praised by* OAU." The *OAU* is positive toward "reelection," which is an eTarget both annotators mark. The question is whether it is also communicated in this sentence that the OAU is also positive toward "Mugabe." X did not mark Mugabe as an eTarget, whereas Y did. During the subsequent discussion, X now agrees that it should be marked. In general, X was using what we now consider to be a too conservative policy. Overall, 29% of all disagreements are of this type of borderline case.

8% of the disagreements arise when there are multiple attitudes with overlapping spans, the same source, the same polarity, but different targets and

intensities[4]. When there are new eTargets which are not in any target span, annotator X splits the new eTargets into different attitudes based on the intensity, while annotator Y adds the new eTargets to all the attitudes regardless of intensity. Later the annotators discuss to decide which attitude each new eTarget should be linked to in the final version.

31% of the disagreements are caused by negligence, meaning an annotator realized, during later discussion, that she should have included an eTarget when she saw that the other annotator had included it.

The remaining disagreements are due to annotator mistakes such as filling in the wrong id.

5 Current Corpus

The current corpus consists of 70 documents, including the subset of the documents in MPQA 2.0 that come from English-language sources (i.e., that are not translations) and a subset of the OPQA subset in MPQA 2.0. A subset contains consensus annotations of X and Y and the rest were annotated by Y. The 70 documents have 1,029 ESEs, 1,287 attitudes, and 1,213 target spans of attitudes (excluding the target span that are marked as "none") from MPQA 2.0; they have 4,459 eTargets in total. We added 1,366 eTargets to the ESEs and 1,608 eTargets to the target spans. We added 1,485 eTargets which are not in any target span.

6 An Example

In this section, we present an example from the OPQA subset (Stoyanov et al., 2005) to demonstrate how eTargets could help to automatically answer a question. There are opinion and fact questions for each document in the OPQA subset. The sentence below is annotated in MPQA 2.0 to answer the question, "Is the US Annual Human Rights Report received with universal approval around the world?" Here the writer is negative toward the report.

> It is due to this hegemony, which the United States wants to maintain, that its State Department makes an assessment of the human rights situation in different countries and prepares a report on their violations all over the world.
>
> The annotations in MPQA 2.0:
> S1: ⟨writer-US, positive, hegemony⟩
> S2: ⟨writer, negative, the United States⟩
> ESE1: ⟨writer, negative, N/A⟩

First, it is possible for a state-of-the-art system to be trained to recognize the sentiment S1, by the *maintaining* phrase and syntax information. But it would be difficult to find S2. There is no direct sentiment modifying the US, nor is there any sentiment or ESE annotation toward *maintain* or *hegemony* in MPQA 2.0. Now, in MPQA 3.0, we add the eTarget of the ESE1, so that it becomes ⟨writer, negative, hegemony⟩. This is a critical step, because the complete ESE bridges the two sentiments together.

Second, even though we have the two sentiments and the ESE, there is still a gap between *the United States* in the sentence and *report* in the question. One of the eTargets we add is "report." It is more feasible for a co-reference system to recognize *report* in both the sentence and the question as the same thing, than recognizing that *the United States* and *report* refer to the same concept.

Third, in this sentence, according to the newly added eTargets, the system knows the writer is negative toward both *the United States* and *State Department*. When building a knowledge base about the human rights report, this reveals that the two entities have the same stance toward this topic, even without any world knowledge.

7 Conclusion

This paper presents an annotation scheme for adding entity and event target annotations to the MPQA corpus. A subset of MPQA has already been annotated according to the new scheme. We believe that the corpus will be a valuable new resource for developing entity/event-level sentiment analysis systems to facilitate NLP applications such as Automatic Question Answering.

Acknowledgements. This work was supported in part by DARPA-BAA-12-47 DEFT grant #12475008. We thank the anonymous reviewers for their helpful comments.

[4] In MPQA 2.0, an attitude is marked with an intensity (low, medium, or high) representing the intensity.

Everyone Likes Shopping!
Multi-class Product Categorization for e-Commerce

Zornitsa Kozareva
Yahoo! Labs
701 First Avenue
Sunnyvale, CA 94089
zornitsa@kozareva.com

Abstract

Online shopping caters the needs of millions of users on a daily basis. To build an accurate system that can retrieve relevant products for a query like "*MB252 with travel bags*" one requires product and query categorization mechanisms, which classify the text as *Home&Garden>Kitchen&Dining>Kitchen Appliances>Blenders*. One of the biggest challenges in e-Commerce is that providers like Amazon, e-Bay, Google, Yahoo! and Walmart organize products into different product taxonomies making it hard and time-consuming for sellers to categorize goods for each shopping platform.

To address this challenge, we propose an automatic product categorization mechanism, which for a given product title assigns the correct product category from a taxonomy. We conducted an empirical evaluation on $445,408$ product titles and used a rich product taxonomy of 319 categories organized into 6 levels. We compared performance against multiple algorithms and found that the best performing system reaches $.88$ f-score.

1 Introduction and Related Work

Over the past decade, e-Commerce has rapidly grown enabling customers to purchase any product with a click of a button. A key component for the success of such online shopping platforms is their ability to quickly and accurately retrieve the desired products for the customers. To be able to do so, shopping platforms use taxonomies (Kanagal et al., 2012), which hierarchically organize products from general to more specific classes. Taxonomies support keyword search and guarantee consistency of the categorization of similar products, which further enables product recommendation (Ziegler et al., 2004; Weng et al., 2008) and duplicate removal.

Shopping platforms like Amazon, e-Bay, Google, Yahoo!, Walmart among others use different taxonomies to organize products making it hard and labor-intensive for sellers to categorize the products. Sometimes sellers are encouraged to find similar products to those they sell and adopt this category to their products. However, this mechanism leads to two main problems: (1) it takes a lot of time for a merchant to categorize items and (2) such taggings can be inconsistent since different sellers might categorize the same product differently. To solve these problems, ideally one would like to have an automated procedure, which can classify any product title into a product taxonomy. Such process will both alleviate human labor and further improve product categorization consistency in e-Commerce websites.

Recently, a lot of interest has been developed around the induction of taxonomies using hierarchal LDA models (Zhang et al., 2014) and the categorization of products using product descriptions (Chen and Warren, 2013). Despite these efforts, yet no study focuses on classifying products using only titles. The question we address in this paper is: *Given a product title and a product taxonomy, can we accurately identify the corresponding category (root-to-leaf path in the taxonomy) that the title belongs to?*

The main contributions of the paper are:

- We built multi-class classification algorithm that classifies product titles into 319 distinct classes organized in 6 levels.
- We conducted an empirical evaluation with $445,408$ product titles and reach $.88$ f-score.

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1329–1333,
Denver, Colorado, May 31 – June 5, 2015.

- During the error analysis we found out that our algorithm predicted more specific and fine-grained categories compared to those provided by humans.

2 Product Categorization Task Definition

We define our task as:

> **Task Definition**: Given a set of titles describing products and a product taxonomy of 319 nodes organized into 6 levels, the goal is to build a multi-class classifier, which can accurately predict the product category of a new unlabeled product title.

The algorithm takes as input a product title "*MB22B 22 piece with bonus travel/storage bag*" and returns as output the whole product category hierarchy "*Home and Garden >Kitchen&Dining>Kitchen Appliances>Blenders*" as illustrated in Figure 1.

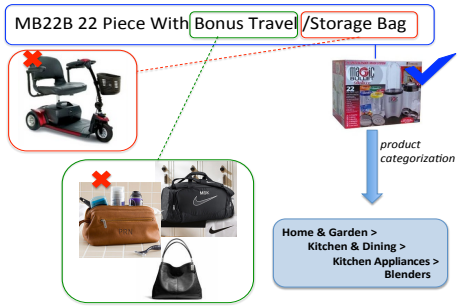

Figure 1: Example of Product Title Categorization.

3 Classification Methods

We model the product categorization task as classification problem, where for a given collection of labeled training examples P, the objective is to learn a classification function $f : p_i \rightarrow c_i$. Here, p_i is a product title and $c_i \in \{1, ..., K\}$ is its corresponding category (one of 319 product taxonomy classes).

We learn a linear classifier model f (parametrized by a weight vector $\mathbf{w}$) that minimizes the misclassification error on the training corpus P:

$$\min_{\mathbf{w}} \sum_{p_i \in P} \delta(c_i \neq f(\mathbf{w}, p_i)) + \lambda ||\mathbf{w}||_2^2$$

where, $\delta(.)$ is an indicator function which is 1 iff the prediction matches the true class and λ is a regularization parameter.

For our experiments, we used two multi-classification algorithms from the large scale machine learning toolkit Vowpal Wabbit (Beygelzimer et al., 2009): one-against-all (OAA) and error correction tournament (ECT). OAA reduces the K-way multi-classification problem into multiple binary classification tasks by iteratively classifying each product title for category K and comparing it against all other categories. ECT also reduces the problem to binary classification but employs a single-elimination tournament strategy to compare a set of K players and repeats this process for $O(\log K)$ rounds to determine the multi-class label.

4 Feature Modeling

Next we describe the set of features we used to train our model.

4.1 Lexical Information

N-grams are commonly used features in text classification. As a baseline system, we use unigram and bigram features.

4.2 Mutual Information Dictionary

Lexical features require very large amount of training data to produce accurate predictions. To generalize the categorization models, we use semantic dictionaries, which capture the presence of a term with a product category. Ideally, we would like to use existing dictionaries for each product category, however such information is not available. For instance, WordNet provides at most synonyms/hyponyms/hypernyms for a given category name, but it does not provide products, brand names and the meaning of abbreviations.

We decided to generate our own dictionaries, by taking all product titles and estimating the mutual information $MI(w, C_i) = log\frac{f(w,C_i)}{f(w,*).f(*,C_i)}$ of every word w and product category C_i. For the dictionary, we keep all word-category pairs with MI above 5. During feature generation, for each title we estimate the percentage of words found with each category C_i according to our automatically generated dictionary. The dimensions of the feature vector is equal to the total number of categories. The size of the generated lexicon is $34,337$ word-category pairs.

4.3 LDA Topics

We also incorporate latent information associated with product titles using topic modeling techniques.

We learn latent topics corresponding to terms occurring in the titles using Latent Dirichlet Allocation (David Blei and Jordan, 2003). We capture the meaning of a title using the learned topic distribution. For our experimental setting, we use the MALLET (McCallum, 2002) implementation of LDA and build it in the following manner.

Method: Given a set of titles and descriptions D of products from different categories, find K latent topics. The generative story is modeled as follows:

for each product category s_k where $k \in \{1, ..., K\}$ **do**
  Generate β_{s_k} according to $Dir(\eta)$
end for

Inference: We perform inference on this model using collapsed Gibbs sampling, where each of the hidden sense variables $z_{i,j}$ are sampled conditioned on an assignment for all other variables, while integrating over all possible parameter settings (Griffiths and Steyvers, 2002). We set the hyperparameter η to the default value of 0.01 and α=50. During feature generation, we take all words in the title and estimate the percentage of words associated with each topic s_k. The topic-word mapping is constructed from the word distribution learnt for a given topic. The number of features is equal to the number of topics.

Figure 2 shows an example of the different topics associated with the word *bag* for different product titles.

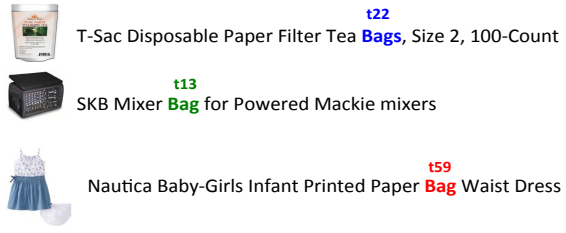

Figure 2: Learnt Topic Assignments for *bag*.

4.4 Neural Network Embeddings

While LDA allows us to capture the latent topics of the product titles, recent advances in unsupervised algorithms have demonstrated that deep neural network architectures can be effective in learning semantic representation of words and phrases from large unlabeled corpora.

To model the semantic representations of product titles, we learn embeddings over the corpus P using the technique of (Mikolov et al., 2013a; Mikolov et al., 2013b). We use a feedforward neural network architecture in which the training objective is to find word (vector) representations that are useful for predicting the current word in a product title based on the context. Formally, given a sequence of training words $w_1, w_2, ..., w_T$ the objective is to maximize the average log probability

$$\frac{1}{T}\sum_{t=1}^{T}\sum_{-n\leq j\leq n, j\neq 0} \log p(w_t|w_{t+j})$$

where n is the size of the training context and $p(w_t|w_{t+j})$ predicts the current position w_t using the surrounding context words w_{t+j} and learned with hierarchical softmax algorithm.

Since word2vec provides embeddings only for words or at most two word phrases, to represent a product title p containing a sequence of M word tokens $(w_1, ..., w_M)$, we retrieve the embeddings of all words and take the average score.

$$p = [e^1, ..., e^d]$$
$$where, e^i = \frac{1}{M}\sum_{j=1}^{M} e^i_{w_j}$$

Here, d is the embedding vector size, e^i and $e^i_{w_j}$ are the vector values at position i for the product p and word w_j in p, respectively.

To build the embeddings, we use a vector size of 200 and context of 5 consecutive words in our experiments. We then use the new vector representation $[e^1, ..., e^d]$ (d features per title) to train and test the machine learning model.

5 Data Description

To conduct our experimental studies, we have used and manually annotated product titles from Yahoo's shopping platform. For each title, we asked two annotators to provide the whole product category from the root to the leaf and used these annotations as a gold standard.

We split the data into a training set of $353,809$ examples and a test set of $91,599$ examples. Our

product taxonomy consists of 6 hierarchical levels. Figure 3 shows the total number of categories per level. The highest density is at levels 3 and 4.

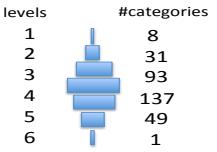

Figure 3: Product Taxonomy.

6 Experiments and Results

In this section, we describe the evaluation metric and the sets of experiments we have conducted.

6.1 Evaluation Metric

To evaluate the performance of the product categorization algorithms, we calculate *f-score* on the test set. The results are on exact match from top-to-leaf path of the gold and predicted categories.

6.2 Results

Table 1 shows the obtained results. For each feature we report the performance of the two machine learning algorithms one-against-all (OAA) and error correcting tournament (ECT).

features	OAA	ECT
unigram	.72	.63
unigram+bigram	.67	.58
MI Dictionary	.85	.77
LDA Dictionary	.79	.67
NN-Embeddings	**.88**	.80

Table 1: *Results on Product Categorization.*

The highest performance is achieved with the neural network embedding representation. Between the two classifiers one-against-all consistently achieved the highest scores for all different feature sets. We also studied various feature combinations, however embeddings reached the highest performance.

6.3 Error Analysis

We analyzed the produced outputs and noticed that sometimes the predicted category could be different from the gold one, but often the predicted category was semantically similar or more descriptive than those provided by humans. Figure 4 shows some examples of the errors we discovered.

Figure 4: Examples of Categorized Products.

For instance, the title *cabela's tipped beer como comfy cup* was classified as *Small Animal Bedding*, while the gold standard category was *Dog Beds*. In our case we penalized such predictions, but still the two top level categories of *Animals* and *Pet Supplies* are similar. The major difference between the prediction and gold label is that the humans annotated *bed* as belonging to *Dog Beds*, while our algorithm predicted it as *Small Animal Bedding*. During manual inspection, we also noticed that often our classifier produces more descriptive categories compared to humans. For example, *flat slat sleigh crib espresso 8022n* had gold category *Baby & Toddler*, while our algorithm correctly identified the more descriptive category *Cribs and Toddler Beds*.

7 Conclusions

In this paper we have presented the first product categorization algorithm which operates on product title level. We classified products into a taxonomy of 319 categories organized into a 6 level taxonomy. We collected data for our experiments and conducted multiple empirical evaluations to study the effect of various features. Our experiments showed that neural network embeddings lead to the best performance reaching .88 f-score. We manually inspected the produced classification outputs and found that often the predicted categories are more specific and fine-grained compared to those provided by humans.

GPU-Friendly Local Regression for Voice Conversion

Taylor Berg-Kirkpatrick **Dan Klein**
Computer Science Division
University of California, Berkeley
{tberg,klein}@cs.berkeley.edu

Abstract

Voice conversion is the task of transforming a source speaker's voice so that it sounds like a target speaker's voice. We present a GPU-friendly local regression model for voice conversion that is capable of converting speech in real-time and achieves state-of-the-art accuracy on this task. Our model uses a new approximation for computing local regression coefficients that is explicitly designed to preserve memory locality. As a result, our inference procedure is amenable to efficient implementation on the GPU. Our approach is more than 10X faster than a highly optimized CPU-based implementation, and is able to convert speech 2.7X faster than real-time.

1 Introduction

Voice conversion is the task of transforming an utterance from a source speaker's voice into a target speaker's voice. The primary setup in recent work has been to learn this transformation from a parallel corpus consisting of recordings of the same sequence of sentences read by both source and target speakers (Stylianou et al., 1998). The converted speech is evaluated by how well its spectral properties match those of the target voice.

While various models have been proposed (Stylianou et al., 1998; Toda et al., 2007; Toda et al., 2005), the most accurate ones are non-parametric because the mapping between two voices' spectra can be highly non-linear (Helander et al., 2012; Popa et al., 2012). Unfortunately, while non-parametric methods are accurate, they are also slow – current non-parametric approaches to voice conversion are too compute-intensive for the real-time speed required by many voice conversion applications. In this paper, we begin with the state-of-the-art local linear regression (LLR) model used by by Popa et al. (2012) for voice conversion, and present a new GPU-based inference approach that greatly accelerates it, to much faster than real-time.

LLR, in principle, requires each new model prediction to be a function of the entire set of training examples. In practice, LLR depends most strongly on nearby points, so a standard CPU implementation will skip distant points, with limited loss of accuracy. A GPU cannot exploit sparsity in the same way (scan and skip) without suffering from memory bottlenecks, but even a GPU will be relatively slow if all training points are included in each computation. Our primary algorithmic change is to make use of a new sparsity structure that allows the GPU to skip major sections of the training data while still using dense memory access patterns on the points it does process. In experiments, this inference technique is more than 10X faster than a highly-optimized CPU-based implementation, operates almost three times faster than real-time, and is only slightly less accurate than the CPU-based method.

2 Background and Model

Most representations of speech that are useful for speech processing break the acoustic signal into separate components that represent the sound source (the lungs and vocal folds) and sound filter (the vocal tract) portions of the vocal apparatus. Work on voice conversion is generally focused on transforming the representation of the vocal tract. We follow this approach and learn a transformation of a mel-cepstral representation of the acoustic signal (Kawahara, 2006).

We treat the task as a multiple regression problem. In order to produce the transformed signal, we break the source signal into a sequence of frames, each of which is a 24-dimensional vector of mel-

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1334–1338,
Denver, Colorado, May 31 – June 5, 2015.

cepstral coefficients. We denote a single frame of input mel-cepstral coefficients as x. In order to produce the transformed signal, we simply predict frame-by-frame. Specifically, for a frame x of the input we predict a transformed frame $\hat{y}$ as the mode of density $p(y|x)$, which we estimate from training data. A naive approach would be to use a linear model:

$$y = Ax + \epsilon$$

Here, ϵ is a Gaussian noise term, and the model is parameterized by the transformation matrix, A. For now, we assume training data are already frame-aligned (see Section 4). Let y_i be frame i of the target signal in the training data. Similarly, let x_i be the corresponding frame of the source signal in the training data. Thus, using this linear model, we would estimate the transformation as:

$$\hat{A} = \underset{A}{\operatorname{argmin}} \sum_i \|y_i - Ax_i\|^2$$

This very simple approach works, to some extent, but, because it cannot capture important non-linear relationships between x and y, it is far from state-of-the-art. A more popular approach is to use a Gaussian mixture model (GMM) to jointly generate both source and target cepstral features (Stylianou et al., 1998; Toda et al., 2007; Toda et al., 2005). This approach essentially learns different linear transformations for different regions of the input space, capturing some non-linearity. However, the GMM introduces a new problem: the posterior over the latent clusters learned by the GMM can be highly peaked (Popa et al., 2012) and as a result distortion is introduced by discontinuities at cluster boundaries. Thus, we adopt neither the simple linear approach nor the GMM. We instead the state-of-the-art fully non-parametric approach introduced by Popa et al. (2012). This method, described in the next section, learns transformations that capture non-linearity but vary smoothly as the input changes.

2.1 Local Regression

Like Popa et al. (2012), we use local linear regression (LLR) (Cleveland, 1979) to estimate $p(y|x)$. LLR is a non-parametric method that estimates $p(y|x)$ as a linear transformation that varies slowly with the input x. Specifically, $p(y|x)$ is estimated as follows:

$$y = A(x) \cdot x + \epsilon$$
$$\hat{A}(x) = \underset{A}{\operatorname{argmin}} \sum_i \left[w(x, x_i) \cdot \|y_i - Ax_i\|^2 \right]$$

The transformation $\hat{A}$ is a function of x, and is computed by solving a weighted least squares problem that depends on x. w is a kernel function that measures similarity between the current input, x, and each of the source training frames, x_i. We use a Gaussian kernel:

$$w(x, x_i) = \exp\left(\frac{-\|x - x_i\|^2}{2\sigma^2}\right)$$

Intuitively, for each input frame x we solve a separate least squares regression where each training datum is weighted by its similarity to the input. As the input varies, so will the weighting, and thus so will the linear transformation.

3 Inference

Exact inference using LLR is too computationally expensive for most applications since it means solving a least squares problem over the entire training set for each input frame x. A common approach is to define a neighborhood function that, for each input frame x, selects K training frames x_i that are most relevant to x. Then, $\hat{A}(x)$ is computed by only solving the least squares problem over this neighborhood. This approach can work well in practice since the support for each local least squares problem is relatively sparse. By choosing the right neighborhood function, work can be skipped without substantially impacting learning.

3.1 Inference on the CPU

The standard approach when using a CPU is to let the neighborhood function pick out the indices of the K training frames x_i that maximize $w(x, x_i)$. We let this particular neighborhood function be called $g(x)$, depicted in Figure 1. Using this approach, for input frame x, $\hat{A}(x)$ has the following closed form expression:

$$\hat{A}(x) = H(x)^\top W(x) G(x) \Big(G(x)^\top W(x) G(x) \Big)^{-1}$$

$G(x)$ is a matrix formed by appending the training source vectors in the neighborhood of x. More specifically, $G(x)$ is a matrix that has the vectors $x_i^\top$ s.t. $i \in g(x)$ as its rows. Similarly, $H(x)$ is a matrix that has the vectors $y_i^\top$ s.t. $i \in g(x)$ as its rows (in the corresponding order). $W(x)$ is a matrix that has the weights $w(x, x_i)$ s.t. $i \in g(x)$ along its diagonal (also in the corresponding order).

This approach is much faster than the exhaustive method, but at typical audio sampling frequencies, inferring the transformation of the signal for an entire sentence can take over 30 seconds on a modern CPU, which is too slow for real-time conversion. In order to transform the signal for a new sentence, $\hat{A}(x)$ must be computed for each frame. This means that for each frame x, the distance to all training source frames must be computed, neighborhood matrices $G(x)$ and $H(x)$ must be formed, followed by several matrix multiplies, an LU decomposition, and a triangular solve operation.

3.2 Inference on the GPU

The computation of $\hat{A}(x)$ for a block of multiple input frames can be done in parallel if a fixed amount of lag is tolerated in the conversion process. The parallel computation of large number of small dense matrix operations (multiply, LU decomposition, triangular solve) is a perfect fit for implementation a GPU, which can achieve vastly more throughput than modern CPUs can. However, using the CPU's neighborhood structure on the GPU has a crippling bottleneck. The extraction of the neighborhood matrices $G(x)$ and $H(x)$ from the training data requires a large number of memory accesses that are effectively random. The indices of the closest K training source vectors to an input x are generally non-contiguous. As a result, the K vectors in each of the neighborhood matrices must be copied with separate memory accesses, and since random access time on modern GPUs is very slow, extraction becomes a bottleneck. In initial experiments, we found that when this approach is implemented on a GPU it is even slower than the CPU-based implementation.

In contrast, memory bandwidth is extremely high on modern GPUs. Thus, if it were possible to order the training vectors x_i and y_i in GPU memory such that neighborhood matrices $G(x)$ and $H(x)$ were composed of contiguous blocks of training vectors, extraction on the GPU could be made very efficient. Unfortunately, with the current definition of the neighborhood function, g, such an ordering does not exist. Therefore, we define a new GPU-friendly neighborhood function, $\tilde{g}$, for which an ordering that permits contiguous extraction does exist.

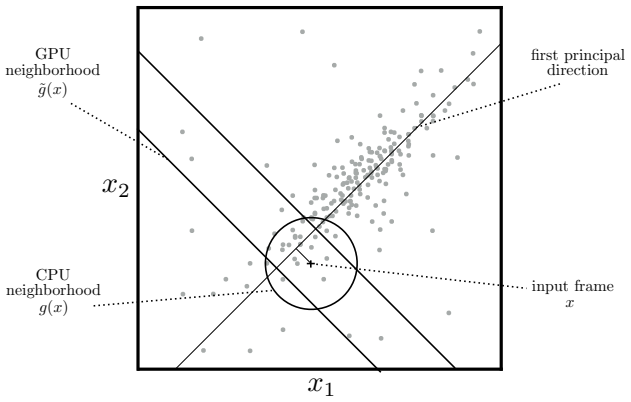

Figure 1: Depiction of standard neighborhood function $g(x)$ used for local regression on the CPU and surrogate neighborhood function $\tilde{g}(x)$ used for inference on the GPU, plotted for two-dimensional input data.

Let $u(x)$ be the projection of source vector x onto the first principal component resulting from running PCA on the source side of the training data. Now, we define $\tilde{g}$ as follows: $\tilde{g}(x)$ is the set of K indices for which $|u(x) - u(x_i)|$ is the smallest, or, in other words, the set of training indices with source projections closest to the projection of the input frame. By ordering the training data by their projection onto the first principal component, we can ensure that $G(x)$ and $H(x)$ are contiguous in memory.

The hope is that this approach yields substantial speedups on the GPU without negatively impacting the learned transformation (see Section 4). Figure 1 depicts the difference between the CPU neighborhood function g and the GPU function $\tilde{g}$. Intuitively, when most of the variance in the training data occurs along the first principal direction, the CPU and GPU neighborhood functions may be similar since the distance between projections is a good proxy for distance in the original space. The weighting function, w, is still computed in the original space, so distant training vectors that are inadvertently included in the neighborhood will be severely down-weighted. The potential pitfall is that for a fixed neighborhood size, $\tilde{g}$ may be less efficient at collecting training points that are relevant to the input.

System	Scottish Male to US Female			US Female to Scottish Male		
	CD	Time	Frac. RT	CD	Time	Frac. RT
GMM	7.05	1.1	3.7X	7.01	0.7	3.9X
CPU LLR	5.99	12.2	0.3X	6.51	8.75	0.3X
GPU LLR	5.98	1.4	2.7X	6.55	0.9	2.9X

Table 1: Voice conversion results for the GMM baseline system, CPU-based local linear regression baseline system, and the GPU-based local linear regression method. The cepstral distortion (CD), average inference time per sentence in seconds (Time), and fraction of real-time (Frac. RT) are shown. Smaller cepstral distortion corresponds to more accurate transformations and fractions of real-time that exceed one imply faster than real-time operation.

4 Experiments

We run a series of experiments to determine whether our GPU-based inference technique offers speeds-ups and at what cost to accuracy.

Baselines We compare our LLR-based conversion system that performs inference on the GPU (using the GPU-friendly neighborhood function) with two different baseline systems. The first baseline system also uses LLR, but performs inference on the CPU using the standard neighborhood function. The second baseline is the GMM model of Toda et al. (2007), which is known to be fast and is widely used in practice. The size, K, of both CPU and GPU neighborhoods was set on a development data to the smallest value that did not show degraded performance compared to exact local regression.

Implementation We implemented our GPU-based LLR technique using the CUDA API (Nickolls et al., 2008), and the CUBLAS API which contains bindings for GPU BLAS routines. We ran the system using an NVIDIA Tesla K40c GPU. We built a multi-threaded implementation of CPU-based inference for local regression using calls to CPU BLAS routines, and ran this system on a 4.4GHz 4-core Intel CPU.

Data We train and test on a portion of the CMU Arctic database. The training data consists of 70 sentences spoken by both a US female speaker and a Scottish male speaker. The testing data consists of 20 sentences spoken by the same two speakers. We give results for converting in both directions, from the female voice to the male voice, and from the male voice to the female voice.

Frame Alignment Since the source and target speakers speak at slightly different rates, our training data consist of different numbers of frames for each training sentence. We use dynamic time warping to induce the frame alignment. Specifically, we find the minimum cost monotonic alignment from source frames into target frames where the cost of each alignment edge is the L2 distance between the corresponding vectors. We use a distortion limit of 2, and a linear distortion cost.

Analysis and Synthesis We use the CMU implementation of the STRAIGHT analysis and synthesis methods introduced by Kawahara (2006). This is the same method used many state-of-the-art voice conversion systems, included our GMM baseline of Toda et al. (2007). We transform the top 24 cepstral coefficients using our system, but process the power coefficient and fundamental frequency separately, using simple transformations for the latter two components.

Evaluation In order to evaluate the accuracy of our model we measure the cepstral distortion between the predicted ceptstral frames $\hat{y}$ and the actual cepstral frames for the target voice y. The cepstral distortion is calculated as follows:

$$\text{distortion}(\hat{y}, y) \propto \|\hat{y} - y\|$$

We using dynamic time warping to align the predicted frame sequence to the target frame sequence.

4.1 Results

The results of our experiments are displayed in Table 1. For the Scottish male to US female and the US female to Scottish male transformations the systems that use local regression outperform the parametric

GMM baseline in terms of average cepstral distortion. The GMM baseline, is however, the fastest of the compared systems. For both experiments, it is able to produce transformations substantially faster than real-time. The CPU-based local regression baseline achieves the best overall cepstral distortion, but is also the slowest method. In both experiments, it operates at 0.3X real-time speed. The GPU-based local regression method performs only slightly worse overall than the exact method in terms of cepstral distortion, yet in both experiments it operates substantially faster than real-time, nearly as fast as the parametric baseline.

5 Conclusion

We have demonstrated a method for substantially speeding-up inference using a non-parametric estimator for spectral voice conversion. Related approaches may prove useful for making non-parametric estimators more efficient in other areas of speech and language processing.

Abstract

Response-based learning allows to adapt a statistical machine translation (SMT) system to an extrinsic task by extracting supervision signals from task-specific feedback. In this paper, we elicit response signals for SMT adaptation by executing semantic parses of translated queries against the Freebase database. The challenge of our work lies in scaling semantic parsers to the lexical diversity of open-domain databases. We find that parser performance on incorrect English sentences, which is standardly ignored in parser evaluation, is key in model selection. In our experiments, the biggest improvements in F1-score for returning the correct answer from a semantic parse for a translated query are achieved by selecting a parser that is carefully enhanced by paraphrases and synonyms.

1 Introduction

In response-based learning for SMT, supervision signals are extracted from an extrinsic response to a machine translation, in contrast to using human-generated reference translations for supervision. We apply this framework to a scenario in which a semantic parse of a translated database query is executed against the Freebase database. We view learning from such task-specific feedback as adaptation of SMT parameters to the task of translating open-domain database queries, thereby grounding SMT in the task of multilingual database access. The success criterion for this task is F1-score in returning the correct answer from a semantic parse of the translated query, rather than BLEU. Since the semantic parser provides feedback to the response-based learner and defines the final evaluation criterion, the challenge of the presented work lies in scaling the semantic parser to the lexical diversity of open-domain databases such as Freebase. Riezler et al. (2014) showed how to use response-based learning to adapt an SMT system to a semantic parser for the Geoquery domain. The state-of-the-art in semantic parsing on Geoquery achieves a parsing accuracy of over 82% (see Andreas et al. (2013) for an overview), while the state-of-the-art in semantic parsing on the Free917 data (Cai and Yates, 2013) achieves 68.5% accuracy (Berant and Liang, 2014). This is due to the lexical variability of Free917 (2,036 word types) compared to Geoquery (279 word types).

In this paper, we compare different ways of scaling up state-of-the-art semantic parsers for Freebase by adding synonyms and paraphrases. First, we consider Berant and Liang (2014)'s own extension of the semantic parser of Berant et al. (2013) by using paraphrases. Second, we apply WordNet synonyms (Miller, 1995) for selected parts of speech to the queries in the Free917 dataset. The new pairs of queries and logical forms are added to the dataset on which the semantic parsers are retrained. We find that both techniques of enhancing the lexical coverage of the semantic parsers result in improved parsing performance, and that the improvements add up nicely. However, improved parsing performance does not correspond to improved F1-score in answer retrieval when using the respective parser in a response-based learning framework. We show that in order to produce helpful feedback for response-based learning, parser performance on incorrect En-

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1339–1344,
Denver, Colorado, May 31 – June 5, 2015.

glish queries needs to be taken into account, which is standardly ignored in parser evaluation. That is, for the purpose of parsing translated queries, a parser should retrieve correct answers for correct English queries (true positives), and must not retrieve correct answers for incorrect translations (false positives). In order to measure false discovery rate, we prepare a test set of manually verified incorrect English in addition to a standard test set of original English queries. We show that if false discovery rate on incorrect English queries is taken into account in model selection, the semantic parser that yields best results for response-based learning in SMT can be found reliably.

2 Related Work

Our work is most closely related to Riezler et al. (2014). We extend their application of response-based learning for SMT to a larger and lexically more diverse dataset and show how to perform model selection in the environment from which response signals are obtained. In contrast to their work where a monolingual SMT-based approach (Andreas et al., 2013) is used as semantic parser, our work builds on existing parsers for Freebase, with a focus on exploiting paraphrasing and synonym extension for scaling semantic parsers to open-domain database queries.

Response-based learning has been applied in previous work to semantic parsing itself (Kwiatowski et al. (2013), Berant et al. (2013), Goldwasser and Roth (2013), *inter alia*). In these works, extrinsic responses in form of correct answers from a database are used to alleviate the problem of manual data annotation in semantic parsing. Saluja et al. (2012) integrate human binary feedback on the quality of an SMT system output into a discriminative learner.

Further work on learning from weak supervision signals has been presented in the machine learning community, e.g., in form of coactive learning (Shivaswamy and Joachims, 2012), reinforcement learning (Sutton and Barto, 1998), or online learning with limited feedback (Cesa-Bianchi and Lugosi, 2006).

3 Response-based Online SMT Learning

We denote by $\phi(x, y)$ a joint feature representation of input sentences x and output translations $y \in Y(x)$, and by $s(x, y; w) = \langle w, \phi(x, y) \rangle$ a linear scoring function for predicting a translation $\hat{y}$. A response signal is denoted by a binary function $\mathrm{e}(y) \in \{1, 0\}$ that executes a semantic parse against the database and checks whether it receives the same answer as the gold standard parse. Furthermore, a cost function $\mathrm{c}(y^{(i)}, y) = (1 - \mathrm{BLEU}(y^{(i)}, y))$ based on sentence-wise BLEU (Nakov et al., 2012) is used. Algorithm 1, called "Response-based Online Learning" in Riezler et al. (2014), is based on contrasting a "positive" translation y^+ that receives positive feedback, has a high model score, and a low cost of predicting y instead of $y^{(i)}$, with a "negative" translation y^- that leads to negative feedback, has a high model score, and a high cost:

$$y^+ = \underset{y \in Y(x^{(i)}): \mathrm{e}(y)=1}{\arg\max} \Big(\mathrm{s}(x^{(i)}, y; w) - \mathrm{c}(y^{(i)}, y) \Big),$$

$$y^- = \underset{y \in Y(x^{(i)}): \mathrm{e}(y)=0}{\arg\max} \Big(\mathrm{s}(x^{(i)}, y; w) + \mathrm{c}(y^{(i)}, y) \Big).$$

The central algorithm operates as follows: The SMT system predicts translation $\hat{y}$, and in case of positive task feedback, the prediction is accepted and stored as positive example by setting $y^+ \leftarrow \hat{y}$. In that case, y^- needs to be computed in order to perform the stochastic gradient descent update of the weight

Algorithm 1 Response-based Online Learning

repeat
  for $i = 1, \ldots, n$ **do**
    Receive input string $x^{(i)}$
    Predict translation $\hat{y}$
    Receive task feedback $\mathrm{e}(\hat{y}) \in \{1, 0\}$
    if $\mathrm{e}(\hat{y}) = 1$ **then**
      $y^+ \leftarrow \hat{y}$
      Store $\hat{y}$ as reference $y^{(i)}$ for $x^{(i)}$
      Compute y^-
    else
      $y^- \leftarrow \hat{y}$
      Receive reference $y^{(i)}$

  end for
until Convergence

vector. If the feedback is negative, the prediction is treated as y^- and y^+ needs to be computed for the update. If either y^+ or y^- cannot be computed, the example is skipped.

4 Scaling Semantic Parsing to Open-domain Database Queries

The main challenge of grounding SMT in semantic parsing for Freebase lies in scaling the semantic parser to the lexical diversity of the open-domain database. Our baseline system is the parser of Berant et al. (2013), called SEMPRE. We first consider the approach presented by Berant and Liang (2014) to scale the baseline to open-domain database queries: In their system, called PARASEMPRE, pairs of logical forms and utterances are generated from a given query and the database, and the pair whose utterance best paraphrases the input query is selected. These new pairs of queries and logical forms are added as ambiguous labels in training a model from query-answer pairs.

Following a similar idea of extending parser coverage by paraphrases, we extend the training set with synonyms from WordNet. This is done by iterating over the queries in the FREE917 dataset. To ensure that the replacement is sensible, each sentence is first POS tagged (Toutanova et al., 2003) and WordNet lookups are restricted to matching POS between synonym and query words, for nouns, verbs, adjectives and adverbs. Lastly, in order to limit the number of retrieved words, a WordNet lookup is performed by carefully choosing from the first three synsets which are ordered from most common to least frequently used sense. Within a synset all words are taken. The new training queries are appended to the training portion of FREE917.

5 Model Selection

The most straightforward strategy to perform model selection for the task of response-based learning for SMT is to rely on parsing evaluation scores that are standardly reported in the literature. However, as we will show experimentally, if precision is taken as the percentage of correct answers out of instances for which a parse could be produced, recall as the percentage of total examples for which a correct answer could be found, and F1 score as their harmonic mean, the metrics are not appropriate for model selection in our case. This is because for our goal of learning the language of correct English database queries from positive and negative parsing feedback, the semantic parser needs to be able to parse and retrieve correct answers for correct database queries, but it must not do so for incorrect queries.

However, information about incorrect queries is ignored in the definition of the metrics given above. In fact, retrieving correct answers for incorrect database queries hurts response-based learning for SMT. The problem lies in the incomplete nature of semantic parsing databases, where terms that are not parsed into logical forms in one context make a crucial difference in another context. For example in Geoquery, the gold standard queries "People in Boulder?" and "Number of people in Boulder?" parse into the same logical form, however, the queries "Give me the cities in Virginia" and "Give me the number of cities in Virginia" have different parses and different answers. While in the first case, for example in German-to-English translation of database queries, the German "Anzahl" may be translated incorrectly without consequences, it is crucial to translate the term into "number" in the second case. On an example from Free917, the SMT system translates the German "Steinformationen" into "kind of stone", which is incorrect in the geological context, where it should be "rock formations". If during response-based learning, the error slips through because of an incomplete parse leading to the correct answer, it might hurt on the test data. Negative parser feedback for incorrect translations is thus crucial for learning how to avoid these cases in response-based SMT.

In order to evaluate parsing performance on incorrect translations, we need to extend standard evaluation data of correct English database queries with evaluation data of incorrect English database queries. For this purpose, we took translations of an out-of-domain SMT system that were judged either grammatically or semantically incorrect by the authors to create a dataset of negative examples. On this dataset, we can define *true positives (TP)* as correct English queries that were given a correct answer by the semantic parser, and *false positives (FP)* as wrong English queries that obtained the correct answer. The crucial evaluation metric is the *false*

Model	#data	F1	FDR
S	620	56.8	28.00
P	620	66.54	25.22
P1	3,982	65.38	**24.89**
P2	6,740	**66.92**	26.38
P3	8,465	66.15	25.97

Table 1: Parsing F1 scores and False Discovery Rate (FDR) for SEMPRE (S), PARASEMPRE (P), and extensions of the latter with synonyms from first one (P1), first two (P2) and first three (P3) synsets, evaluated on the FREE917 test set of correct database queries for F1 and including the test set of incorrect database queries for FDR, and trained on #data training queries. Best results are indicated in **bold face**.

discovery rate (FDR) (Murphy, 2012), defined as *FP/FP+TP*, i.e., as the ratio of false positives out of all positive answer retrieval events.

6 Experiments

We use a data dump of Freebase[1] which was has been indexed by the Virtuoso SPARQL engine[2] as our knowledge base. The corpus used in the experiments is the FREE917 corpus as assembled by Cai and Yates (2013) and consists of 614 training and 276 test queries in English and corresponding logical forms.[3] The dataset of negative examples, i.e., incorrect English database queries that should receive incorrect answers, consists of 166 examples that were judged either grammatically or semantically incorrect by the authors.

The translation of the English queries in FREE917 into German, in order to provide a set of source sentences for SMT, was done by the authors. The SMT framework used is CDEC (Dyer et al., 2010) with standard dense features and additional sparse features as described in Simianer et al. (2012)[4]. Training of the baseline SMT system was performed on the COMMON CRAWL[5] (Smith et al., 2013) dataset consisting of 7.5M parallel English-German segments extracted from the web. Response-based learning for SMT uses the code described in Riezler et al. (2014)[6].

For semantic parsing we use the SEMPRE and PARASEMPRE tools of Berant et al. (2013) and Berant and Liang (2014) which were trained on the training portion of the FREE917 corpus[7]. Further models use the training data enhanced with synonyms from WordNet as described in Section 4. Following Jones et al. (2012), we evaluate semantic parsers according to *precision*, defined as the percentage of correctly answered examples out of those for which a parse could be produced, *recall*, defined as the percentage of total examples answered correctly, and *F1-score*, defined as harmonic mean of precision and recall. Furthermore, we report *false discovery rate (FDR)* on the combined set of 276 correct and 166 incorrect database queries.

Table 1 reports standard parsing evaluation metrics for the different parsers SEMPRE (S), PARASEMPRE (P), and extensions of the latter with synonyms from the first one (P1), first two (P2) and first three (P3) synsets which are ordered according to frequency of use of the sense. As shown in the second column, the size of the training data is increased up to 10 times by using various synonym extensions. As shown in the third column, PARASEMPRE improves F1 by nearly 10 points over SEMPRE. Another 0.5 points are added by extending the training data using two synsets. The third column shows that the system P1 that scored second-worst in terms of F1 score, scores best under the FDR metric[8].

Table 2 shows an evaluation of the use of different parsing models to retrieve correct answers from the FREE917 test set of correct database queries. The systems are applied to translated queries, but evaluated in terms of standard parsing metrics. Statistical significance is measured using an Approximate Randomization test (Noreen, 1989; Riezler and Maxwell, 2005). The baseline system is CDEC as described above. It never sees the FREE917 data during training. As a second baseline method we use a stochastic (sub)gradient descent variant of RAMPION (Gimpel and Smith, 2012). This system is

trained by using the correct English queries in the FREE917 training data as references. Neither CDEC nor RAMPION use parser feedback in training. REBOL (**Re**sponse-**b**ased **O**nline **L**earning) is an implementation of Algorithm 1 described in Section 3. This algorithm makes use of positive parser feedback to convert predicted translation into references, in addition to using the original English queries as references. Training for both RAMPION and REBOL is performed for 10 epochs over the FREE917 training set, using a constant learning rate η that was chosen via cross-validation. All methods then proceed to translate the FREE917 test set. Best results in Table 2 are obtained by using an extension of PARASEMPRE with one synset as parser in response-based learning with REBOL. This parsing system scored best under the FDR metric in Table 1.

Table 3 shows the Spearman rank correlation (Siegel and Castellan, 1988) between the F1 / FDR ranking of semantic parsers from Table 1 and their contribution to F1 scores in Table 2 for parsing query translations of CDEC, RAMPION or REBOL. The system CDEC cannot learn from parser performance based on query translations, thus best results on translated queries correlate positively with good parsing F1 score per se. RAMPION can implicitly take advantage of parsers with good FDR score since learning to move away from translations dissimilar to the reference is helpful if they do not lead to correct answers. REBOL can make the best use of parsers with low FDR score since it can learn to prevent incorrect translations from hurting parsing performance at test time.

7 Conclusion

We presented an adaptation of SMT to translating open-domain database queries by using feedback of a semantic parser to guide learning. Our work highlights an important aspect that is often overlooked in parser evaluation, namely that parser model selection in real-world applications needs to take the possibility of parsing incorrect language into account. We found that for our application of response-based learning for SMT, the key is to learn to prevent cases where the correct answer is retrieved despite the translation being incorrect. This can be avoided by performing model selection on semantic parsers that parse and retrieve correct answers for correct database queries, but do not do retrieve correct answers for incorrect queries.

In our experiments, we found that the parser that contributes most to response-based learning in SMT is one that is carefully extended by paraphrases and synonyms. In future work, we would like to investigate additional techniques for paraphrasing and synonym extension. For example, a good fit for our task of response-based learning for SMT might be Bannard and Callison-Burch (2005)'s approach to paraphrasing via pivoting on SMT phrase tables.

Abstract

Developing a system that can automatically respond to a user's utterance has recently become a topic of research in natural language processing. However, most works on the topic take into account only a single preceding utterance to generate a response. Recent works demonstrate that the application of statistical machine translation (SMT) techniques towards monolingual dialogue setting, in which a response is treated as a translation of a stimulus, has a great potential, and we exploit the approach to tackle the context-dependent response generation task. We attempt to extract relevant and significant information from the wider contextual scope of the conversation, and incorporate it into the SMT techniques. We also discuss the advantages and limitations of this approach through our experimental results.

1 Introduction

Various approaches have been applied to the response generation task, each with its own merits and drawbacks. While one of the main concerns on the topic has been the semantic relevance of the response, it has mostly been discussed in terms of a limited conversational scope, mostly a single utterance. This provides us with a room for research on a wider scope of conversation, which reflects not only a single preceding utterance, but the overall context of the current conversation.

SMT-based data-driven approach to the response generation task was recently introduced by Ritter et al. (2011). They demonstrated that it was better-suited for response generation than some of the previous approaches, including information retrieval approach. We exploit this model to address the above-mentioned problem of reflecting a wider scope of conversation.

We present a context-dependent model where we attempt to generate more semantically relevant and diverse responses by adding the semantically important words from previous utterances to the most recent one. By doing so, we hope not only to diversify the responses, but also to be able to take semantics from broader scope of the conversation into account.

2 Response Generation using SMT

2.1 Overview

Ritter et al. (2011) remarked that stimulus-response pairs in the same language often have a strong structural resemblance, as shown in the example conversation below, that may be exploited in SMT platforms. In the usual SMT setting, a string f in a source language is translated into a string e in a target language according to probability distribution $p(e|f)$ (Brown et al., 1993). Ritter et al. applied the SMT techniques to monolingual conversation setting, and treated the response as the *translation* of the stimulus.

Stimulus: What is your hobby?
Response: My hobby is hiking.

2.2 Challenges

Although the application of SMT to the response generation task demonstrates potentials, it has a few drawbacks due to its nature.

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1345–1350,
Denver, Colorado, May 31 – June 5, 2015.

First, the lengths of the source and target utterances are not correlated in the conversational setting, and there is hardly any general tendency towards the relative length of the utterances, as shown in the example conversation below. SMT usually works on the data in which the ratio between the lengths of the source and target utterances stays relatively constant (Och and Ney, 2000). However, conversational setting, in which such constant ratio is absent, jeopardizes the functionality of the usual SMT models to make alignments. Although it is highly probable that some of the semantic elements in the source utterance are reflected in the target utterance, it is rarely on a one-to-one basis.

A: Is something going on today? (S_1)

B: Of course, it's dad's birthday. (S_2)

A (most recent stimulus) **:** What?! (S_3)

B (target) **:** Oh, you didn't know? (S_4)

Second, it cannot take into account what was previously discussed in the conversation. Unless the most recent utterance brings a completely new topic, or it has sufficient information in itself, such problem is evident.

Both problems regarding the context and the alignment become more pronounced especially in cases where the source utterance is short as shown in the above example. Clearly, no meaningful response can be derived from the most recent stimulus alone, and it is highly unclear how the alignments should be made. Indeed, the response generated by applying SMT to the most recent stimulus "What?" in this example is "that," which only mimics the syntactic structure but fails to deliver any meaningful content.

3 Context-Dependent Model

3.1 Overview

In order to deal with the issues of context and the lengths of the utterances without correlation, we work on building a context-dependent model, in which we balance the utterance lengths by selecting contextually important words from the previous part of the conversation, and adding them to the source utterance. For example, applying one of our models to the most recent stimulus (S_3) of the previous example conversation results in the following utterance, where the words in the parenthesis are newly added:

A: (today birthday) What?!

The rationale behind this approach is that the topic of a conversation can be characterized by a number of contextually important words, which provide semantic information to be reflected in the response generation process.

This approach seemingly reduces the grammatical integrity of the source utterance, and it may seem as if we risk confusing the translation model and losing grammaticality of the output. However, grammaticality of the output is handled by the language model, and the language model is constructed upon the target language only, which in our case corresponds to the target utterances that remain untouched. Also, the newly added words are of high relevance to the topic, so the new source utterance frequently demonstrates high semantic coherence both within itself, and in parallel with the target utterance.

The question now is how to determine which words are contextually important throughout the conversation. Since finding such contextually important words is our main concern, we find simple statistical significance test models more suitable than conventional methods from discourse modeling or dialogue systems (Oh et al., 2002). We examine two approaches, namely the pair-based approach, and the token-based approach. The pair-based approach uses Fisher's Exact Test (Moore, 2004), which is reported to give more accurate p-values than χ^2 or G^2 when the counts are small (Ritter et al., 2011). This approach takes advantage of the proximity of utterances, and assumes that a utterance whose distance to the source utterance is shorter is likely to be more contextually related to the source utterance, i.e. S_{n-1} is more likely than S_{n-2} to be semantically relevant to S_n. The token-based approach considers at the entire conversation, and selects the words most characteristic of the conversation, using the most widely used term weighting algorithm, *tf-idf*.

3.2 Pair-Based Model

Given a conversation consisting of utterances S_1,...,S_{n+1}, where S_n is the source utterance and S_{n+1} is the target utterance, we start by computing the p-value from Fisher's Exact Test for every possible word pair between S_n and S_{n-1}. If the p-value

is less than the threshold, implying a significant relevance between the words constituting the pair, we store the words. We then add the stored words to the source utterance, avoiding duplicates with words already in the source utterance, until its length is the same as that of the target utterance. Words are added in a reversed order of their appearance, i.e., we give priority to words that appeared in the later part of the discourse, in light of the previously mentioned assumption. If, after adding all stored words to the source utterance, the length of the source utterance is still less than the length of the target utterance, we repeat the process with word pairs between S_{n-1} and S_{n-2}, and so forth. This "crawling-up" is necessary because S_n is often short or semantically trivial that further comparison of S_n with other previous utterances fails to capture the contextually important words that are continuously discussed in the previous part of the conversation. The procedure ends when there are no more pairs whose p-value is less than the threshold, or the source utterance has the same length as the target utterance.

Note that, for training, we limit the application of our model only to the cases where source utterances are shorter than target utterances, since adding words in the opposite case will exacerbate the difficulty of alignment. In the test setting, however, we do not know the length of the actual target utterance, and thus selectively apply our model based on the absolute length of the source utterance, where the threshold is set to the average length of the source utterance throughout the training data. Also, since it is evident that we are not dealing with grammatically well-formed utterances whose ordering should matter, we opt not to use the reordering table (Bisazza et al., 2011).

3.3 Token-Based Model

The assumption behind the pair-based approach is that a topic of a conversation is something that continues to be discussed throughout the conversation, i.e. something that gets reflected/matched in the later part of the conversation. Finding collocated words using significant test does just that. However, there may be a trade-off here in terms of representing the diversity of context; for example, there may be a characteristic word that is not directly reflected/matched in the later part of the conversation. That provides the motivation for our token-based approach, using tf-idf.

This approach follows a similar manner of adding words to the source utterance until its length is equal to the target utterance, but differs in that it picks contextually important words by examining individual tokens, rather than pairs of words, using *tf-idf*. For *idf*, the total number of documents was set to the number of conversations in our training data.

Also, instead of crawling up the conversation from the source utterance, it scans through the entire conversation and selects characteristic words within the given scope of the conversation. This is intended to reflect that there could be words that are highly relevant to the overall topic of the conversation, yet not very close to the current source utterance. For example, in the following conversation, both (S_3) and (S_4) lack any element characteristic of the conversation that leads to the final response (S_5), while "NBA" or "fans" in (S_1) and (S_2) is indicative of the topic of the conversation, and will be relevant to words like "LeBron" or "dominating" in the target utterance.

A: Well, the NBA season is near again.(S_1)

B: Yeah! So excited for all the NBA fans!(S_2)

A: I'm not. (S_3)

B (source) **:** How come? (S_4)

A (target) **:** It's just gonna be LeBron dominating again. (S_5)

Although we examine the entire conversation, words that are too far from the source utterance (for example, 50 utterances apart) will rarely have much semantic impact to the current topic. Thus, it is necessary to keep the size of the conversation reasonably small, and we restrict it to be at most 8 utterances.

4 Experiment

4.1 Setting

We first built our baseline model following the procedure proposed by Ritter et al. (2011). In accordance with the paper, we also filtered out the phrase table by Fisher's Exact Test. We then implemented our model using Moses (Koehn et al., 2007) toolkit with KenLM (Heafield, 2011) as the language model in 5-gram setting. In accordance with the baseline, we built our training, tuning, and test data set from

Model A	Model B	A>B	A=B	A<B	p-value	Agreement
Pair	Baseline	287	32	81	4.0e-28	.488
	Actual	58	28	314	1.2e-43	.543
	Token	175	52	173	0.96	.373
Token	Baseline	280	35	85	2.0e-25	.462
	Actual	62	35	303	3.2e-39	.529

Table 1: Performances against Each Model

Twitter, except we collected conversations, consisting of a tweet and successive replies, rather than pairs of tweets. We also restricted each conversation to have 3 to 8 utterances with only two speakers taking turns, to make it more likely that the topic of the conversation is preserved. Although there were some cases in which the topic deviated, our validation of the dataset showed that the amount of such cases was negligible. We ended up having approximately 1.4M pairs of utterances in the training data, which constitute 425,547 conversations. The threshold p-value for Fisher's Exact Test was set to 0.0001, to well-balance the number of selected words with the lengths of the utterances.

4.2 Evaluation

One of the challenging aspects of the researches on conversation is its distinct nature in which there is an extremely wide range of acceptable candidate responses to a stimulus, unlike usual bilingual translation tasks where there are typically pre-set candidates to be referenced with high reliability. Using the automatic evaluation metrics, we obtained slight improvements; for example, BLEU score (Papineni et al., 2002), with the actual responses from Twitter as the gold standard, increased from 0.82 for baseline to 0.89 for the pair-based approach. For the above-mentioned reason, however, we found it dubious whether a higher score in these metrics corresponds to better responses, and we thus resort to human manual evaluation as our primary source of evaluation.

We performed a human evaluation on Amazon Mechanical Turk (Buhrmester et al., 2011). The evaluation task consisted of four different sets of 100 questions, each set of which was handled by 10 workers. Each question was a ranking task, and the workers were shown a part of conversation and were instructed to rank the responses that followed the conversation in consideration of their relevance to the topic of the conversation. For all questions, workers were given four responses; the actual response from Twitter, one generated by the baseline model, and two by each of our context-dependent models.

Model	1st	2nd	3rd	4th	Avg. Rank
Actual	.664	.129	.087	.120	1.66
Baseline	.092	.232	.271	.406	2.99
Pair	.112	.323	.346	.220	2.67
Token	.134	.315	.297	.255	2.67

Table 2: Rankings from Human Evaluation

The order of responses was randomized for each question. In addition, in order to filter out the workers who do not take the tasks seriously, generating noise answers, we selected 10 questions that had obvious answers, and rejected the answers by the workers who failed to achieve 70% or higher accuracy on those questions. As stated in Section 3.1, the threshold for length of source sentence to determine whether to add words or not was set to the average length of source sentences throughout the training data, which in our case was 10. In roughly half of 400 questions, no words were added to the source sentence, and 1 to 6 words were added for roughly 25 to 30 questions respectively. Beyond 6 words, the number of questions begins to decline.

4.3 Results

Table 1 shows how our models performed against the actual responses, the baseline model, and each other, in regards to the number of questions for which our models were ranked higher. Overall, the table shows that our models were preferred over the baseline model, but performed poorly against the actual responses as expected. Yet, it was able to perform better than the actual responses in roughly

Conversation	Response*	Avg. Rank
A: if youre following today maybe follow me **B:** lol ur off to an early start	**1:** im at the bus stop how was your night	2.1
	2: i dont fancy hame pass for	3.6
	3: lmao i got my second home	3.2
	4: updating haha I get u off too	1.9
A: like you're talking about the stupidest things ever. its annoying **B:** who is this about	**1:** the ppl behind you	1.9
	2: I want tie you	3.6
	3: like I said Im talking seriously are you	2.3
	4: one of them is that you	2.9
A: Aww man happy birthday bro!! Lol you know you gotta die right? **B:** What? Lol	**1:** you gotta damn near die from drinking today	1.2
	2: lol yea	3.8
	3: thank you man you know me	2.4
	4: lol I know I know	2.8

* 1 is the actual response on Twitter, while 2,3 and 4 are responses generated by the baseline, pair-based, token-based models respectively.

Table 3: Examples of Responses

15% of the questions, especially when the actual responses were grammatically poor, or irrelevant to the topic of the conversation. There was no significant difference between the performances of our models. It also shows the p-value and mutual agreement between two models. Using S coefficient (Bennett et al., 1954) as a measurement of agreement yields the following result. Most of them fall into "moderate agreement" range of 0.4 to 0.6, except Token-based model against Pair-based model is slightly lower and falls into "fair agreement" range (Landis and Koch, 1977).

Table 2 shows the distribution of each model over each ranking and their average rankings. Our models outperform the baseline model in higher rankings. Table 3 features examples of responses generated by each model and the actual responses on Twitter, along with their average ranking in the final evaluation. In the first conversation, one of our models was ranked higher than both the baseline model and the actual response. In other conversations, our models were ranked higher than the baseline model, but lower than the actual response. Generally, our models have a wider range of topic-relevant vocabularies, and sound comparatively coherent than the baseline model, without too much grammatical violations.

5 Conclusion and Future Work

As we observed in the experimental results, our context-dependent model outperformed the baseline model when examined in a wider scope of conversations. Although its performance against the actual responses was not as satisfactory, it could outperform them when the actual responses diverted from the topic, or had poor coherence and grammaticality.

Possible applications include chatterbots or conversational agents. Most such applications are based on one-turn conversation, where user says something, system gives some response, and that is technically the end of the conversation of current topic, which will not be referred to in later conversations. Our work can, for example, provide the system with possible topics to talk about, especially when the input from the user is short or trivial. Diversity of the responses is obtained because, even when the system is given the same input, it will return completely different responses depending on what was previously talked about, as opposed to the applications where certain responses can be expected given an input.

An improvement is likely to come from attempting different methods to extract the core tokens from the past utterances. We relied on the Fisher's Exact Test and *tf-idf* throughout the research, but other approaches may perform better. Alternatively, we may try different weighting systems depending on whether a token is from the same speaker as the current utterance or a different speaker, since it would generally make more sense for a particular speaker not to repeat him/herself.

Abstract

Open domain relation extraction systems identify relation and argument phrases in a sentence without relying on any underlying schema. However, current state-of-the-art relation extraction systems are available only for English because of their heavy reliance on linguistic tools such as part-of-speech taggers and dependency parsers. We present a cross-lingual annotation projection method for language independent relation extraction. We evaluate our method on a manually annotated test set and present results on three typologically different languages. We release these manual annotations and extracted relations in ten languages from Wikipedia.

1 Introduction

Relation extraction (RE) is the task of assigning a semantic relationship between a pair of arguments. The two major types of RE are closed domain and open domain RE. While closed-domain RE systems (Bunescu and Mooney, 2005; Bunescu, 2007; Mintz et al., 2009; Yao and Van Durme, 2014; Berant and Liang, 2014) consider only a closed set of relationships between two arguments, open domain systems (Yates et al., 2007; Carlson et al., 2010; Fader et al., 2011; Mausam et al., 2012) use an arbitrary phrase to specify a relationship. In this paper, we focus on open-domain RE for multiple languages. Although there are advantages to closed domain RE (Banko and Etzioni, 2008), it is expensive to construct a closed set of relation types which would be meaningful across multiple languages.

Open RE systems extract patterns from sentences in a given language to identify relations. For learning these patterns, the sentences are analyzed using a part of speech tagger, a dependency parser and possibly a named-entity recognizer. In languages other than English, these tools are either unavailable or not accurate enough to be used. In comparison, it is easier to obtain parallel bilingual corpora which can be used to build machine translation systems (Resnik and Smith, 2003; Smith et al., 2013).

In this paper, we present a system that performs RE on a sentence in a source language by first translating the sentence to English, performing RE in English, and finally projecting the relation phrase back to the source language sentence. Our system assumes the availability of a machine translation system from a source language to English and an open RE system in English but no any other analysis tool in the source language. The main contributions of this work are:

- A pipeline to develop relation extraction system for any source language.
- Extracted open relations in ten languages based on Wikipedia corpus.
- Manual judgements for the projected relations in three languages.

We first describe our methodology for language independent cross-lingual projection of extracted relations (§2) followed by the relation annotation procedure and the results (§3). The manually annotated relations in 3 languages and the automatically extracted relations in 10 languages are available at: http://cs.cmu.edu/~mfaruqui/soft.html.

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1351–1356,
Denver, Colorado, May 31 – June 5, 2015.

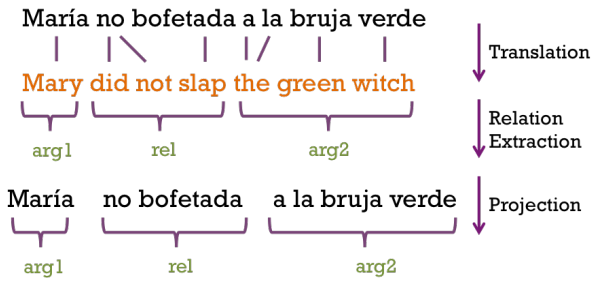

Figure 1: RE in a Spanish sentence using the cross-lingual relation extraction pipeline.

2 Multilingual Relation Extraction

Our method of RE for a sentence $\mathbf{s} = \langle s_1, s_2, \ldots s_N \rangle$ in a non-English language consists of three steps: (1) Translation of **s** into English, that generates a sentence $\mathbf{t} = \langle t_1, t_2, \ldots t_M \rangle$ with word alignments **a** relative to **s**, (2) Open RE on **t**, and (3) Relation projection from **t** to **s**. Figure 1 shows an example of RE in Spanish using our proposed pipeline. We employ OLLIE[1] (Mausam et al., 2012) for RE in English and GOOGLE TRANSLATE[2] API for translation from the source language to English, although in principle, we could use any translation system to translate the language to English. We next describe each of these components.

2.1 Relation Extraction in English

Suppose $\mathbf{t} = \langle t_1, t_2, \ldots, t_M \rangle$ is a tokenized English sentence. Open relation extraction computes triples of non-overlapping phrases (**arg1**; **rel**; **arg2**) from the sentence **t**. The two arguments **arg1** and **arg2** are connected by the relation phrase **rel**.

We utilized OLLIE (Mausam et al., 2012) to extract the relation tuples for every English sentence. We chose OLLIE because it has been shown to give a higher yield at comparable precision relative to other open RE systems such as REVERB and WOE$^{\text{parse}}$ (Mausam et al., 2012). OLLIE was trained by extracting dependency path patterns on annotated training data. This training data was bootstrapped from a set of high precision seed tuples extracted from a simpler RE system REVERB (Fader et al., 2011). In *Godse killed Gandhi*, the extracted relation (Godse; killed; Gandhi) can be expressed by the dependency pattern: **arg1** ↑ nsubj ↑ **rel**:postag=VBD ↓ dobj ↓ **arg2**.[3] OLLIE also normalizes the relation phrase for some of the phrases, for example *is president of* is normalized to *be president of*. [4]

Data: **s**, **t**, **a**, p_t
Result: p_s
$P \leftarrow$ PhraseExtract(**s**, **t**, **a**)
$p_s = \emptyset$, $score = -\infty$, $overlap = 0$
for $(phr_s, phr_t) \in P$ **do**
  if *BLEU*$(phr_t, p_t) > score$ **then**
    if $phr_t \cap p_t \neq \emptyset$ **then**
      $p_t \leftarrow phr_t$
      $score \leftarrow$ BLEU(phr_t, p_t)
      $overlap \leftarrow phr_t \cap p_t$
if $overlap \neq 0$ **then**
  $length = \infty$
  for $(phr_s, p_t) \in P$ **do**
    if $len(phr_s) < length$ **then**
      $length \leftarrow len(phr_s)$
      $p_s \leftarrow phr_s$;
else
  $p_s \leftarrow$ WordAlignmentProj(**s**, **t**, **a**, p_t);

Algorithm 1: Cross-lingual projection of phrase p_t from a target sentence **t** to a source sentence **s** using word alignments **a** and parallel phrases P.

2.2 Cross-lingual Relation Projection

We next describe an algorithm to project the extracted relation tuples in English back to the source language sentence. Given a source sentence, the GOOGLE TRANSLATE API provides us its translation along with the word-to-word alignments relative to the source. If $\mathbf{s} = s_1^N$ and $\mathbf{t} = t_1^M$ denote the source and its English translation, then the alignment $\mathbf{a} = \{a_{ij} : 1 \leq i \leq N; 1 \leq j \leq M\}$ where, $a_{ij} = 1$ if s_i is aligned to t_j, and is 0 otherwise. A

[1] http://knowitall.github.io/ollie/
[2] https://developers.google.com/translate/
[3] Example borrowed from Mausam et al. (2012)
[4] For sentences where the veracity of a relation depends on a clause, OLLIE also outputs the clause. For example, in *Early astronomers believed that Earth is the center of the universe*, the relation (Earth; be center of; universe) is supplemented by an (*AttributedTo:* believe; Early astronomers) clause. We ignore this clausal information.

naive word-alignment based projection would map every word from a phrase extracted in English to the source sentence. This algorithm has two drawbacks: first, since the word alignments are many-to-many, each English word can be possibly mapped to more than one source word which leads to ambiguity in its projection; second, a word level mapping can produce non-contiguous phrases in the source sentence, which are hard to interpret semantically.

To tackle these problems, we introduce a novel algorithm that incorporates a BLEU score (Papineni et al., 2002) based phrase similarity metric to perform cross-lingual projection of relations. Given a source sentence, its translation, and the word-to-word alignment, we first extract phrase-pairs P using the phrase-extract algorithm (Och and Ney, 2004). In each extracted phrase pair $(phr_s, phr_t) \in P$, phr_s and phr_t are contiguous word sequences in **s** and **t** respectively. We next determine the translations of **arg1**, **rel** and **arg2** from the extracted phrase-pairs.

For each English phrase $p \in \{\text{arg1}, \text{rel}, \text{arg2}\}$, we first obtain the phrase-pair $(phr_s, phr_t) \in P$ such that phr_t has the highest BLEU score relative to p subject to the condition that $p \cap phr_t \neq \emptyset$ i.e, there is at least one word overlap between the two phrases. This condition is necessary since we use BLEU score with smoothing and may obtain a non-zero BLEU score even with zero word overlap. If there are multiple phrase-pairs in P that correspond to the same target phrase phr_t, we select the shortest source phrase (phr_s). However, if there is no word overlap between the target phrase p and any of the target phrases in P, we project the phrase using the word-alignment based projection. The cross-lingual projection method is presented in Algorithm 1.

3 Experiments

Evaluation for open relations is a difficult task with no standard evaluation datasets. We first describe the construction of our multilingual relation extraction dataset and then present the experiments.

Annotation. The current approach to evaluation for open relations (Fader et al., 2011; Mausam et al., 2012) is to extract relations from a sentence and manually annotate each relation as either valid (1) or invalid (0) for the sentence. For example, in the sentence: *"Michelle Obama, wife of Barack Obama was born in Chicago"*, the following are possible annotations: a) (Michelle Obama; born in; Chicago): 1, b) (Barack Obama; born in; Chicago): 0. Such binary annotations are not available for languages apart from English. Furthermore, a binary 1/0 label is a coarse annotation that could unfairly penalize an extracted relation which has the correct semantics but is slightly ungrammatical. This could occur either when prepositions are dropped from the relation phrase or when there is an ambiguity in the boundary of the relation phrase.

Therefore to evaluate our multilingual relation extraction framework, we obtained annotations from professional linguists for three typologically different languages: French, Hindi, and Russian. The annotation task is as follows: *Given a sentence and a pair of arguments (extracted automatically from the sentence), the annotator identifies the most relevant contiguous relation phrase from the sentence that establishes a plausible connection between the two arguments*. If there is no meaningful contiguous relation phrase between the two arguments, the arguments are considered invalid and hence, the extracted relation tuple from the sentence is considered incorrect.

Given the human annotated relation phrase and the automatically extracted relation phrase, we can measure the similarity between the two, thus alleviating the problem of coarse annotation in binary judgments. For evaluation, we first report the percentage of valid arguments. Then for sentences with valid arguments, we use smoothed sentence-level BLEU score (max n-gram order = 3) to measure the similarity of the automatically extracted relation relative to the human annotated relation.[5]

Results. We extracted relations from the entire Wikipedia[6] corpus in Russian, French and Hindi from all sentences whose lengths are in the range of $10 - 30$ words. We randomly selected $1,000$ relations for each of these languages and annotated them. The results are shown in table 1. The percentage of valid extractions is highest in French (81.6%)

[5] We obtained two annotations for ≈ 300 Russian sentences. Between the two annotations, the perfect agreement rate was 74.5% and the average BLEU score was 0.85.

[6] www.wikipedia.org

Language	Argument 1	Relation phrase	Argument 2
French	Il *He*	fut enrôlé de force au *was conscripted to*	RAD *RAD*
Hindi	bahut se log *Many people*	aaye *came to*	cailifornia *California*
Russian	Автокатастрофа *Crash*	произошла *occured*	Черногории *Montenegro*

Table 3: Examples of extracted relations in different languages with English translations (Hindi is transliterated).

Language	% valid	BLEU	Relation length	
			Gold	Auto
French	81.6%	0.47	3.6	2.5
Hindi	64.9%	0.38	4.1	2.8
Russian	63.5%	0.62	1.8	1.7

Table 1: % of valid relations and BLEU score of the extracted relations across languages with the average relation phrase length (in words).

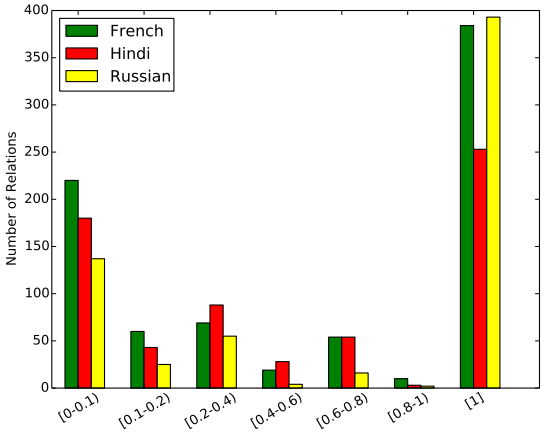

Figure 2: Number of automatically extracted relations binned by their BLEU scores computed relative to the manually annotated relations.

followed by Hindi and Russian (64.0%). Surprisingly, Russian obtains the lowest percentage of valid relations but has the highest BLEU score between the automatic and the human extracted relations. This could be attributed to the fact that the average relation length (in number of words) is the shortest for Russian. From table 1, we observe that the length of the relation phrase is inversely correlated with the BLEU score.

Figure 2 shows the distribution of the number of extracted relations across bins of similar BLEU scores. Interestingly, the highest BLEU score bin (1) contains the maximum number of relations in

Language	Size	Language	Size
French	6,743	Georgian	497
Hindi	367	Latvian	491
Russian	7,532	Tagalog	102
Chinese	2,876	Swahili	114
Arabic	707	Indonesian	1,876

Table 2: Number of extracted relations (in thousands) from Wikipedia in multiple languages.

all three languages. This is an encouraging result since it implies that the majority of the extracted relation phrases are identical to the manually annotated relations. Table 2 lists the sizes of automatically extracted relations on 10 different languages from Wikipedia that we are going to make publicly available. These were selected to include a mixture of high-resource, low-resource, and typologically different languages. Table 3 shows examples of randomly selected relations in different languages along with their English translations.

4 Related Work

Cross-lingual projection has been used for transfer of syntactic (Yarowsky and Ngai, 2001; Hwa et al., 2005) and semantic information (Riloff et al., 2002; Padó and Lapata, 2009). There has been a growing interest in RE for languages other than English. Gamallo et al. (2012) present a dependency-parser based open RE system for Spanish, Portuguese and Galician. RE systems for Korean have been developed for both open-domain (Kim et al., 2011) and closed-domain (Kim and Lee, 2012; Kim et al., 2014) using annotation projection. These approaches use a Korean-English parallel corpus to project relations extracted in English to Korean. Following projection, a Korean POS-tagger and a dependency parser are employed to learn a RE system for Korean.

Tseng et al. (2014) describe an open RE for Chinese that employs word segmentation, POS-tagging, dependency parsing. Lewis and Steedman (2013) learn clusters of semantically equivalent relations across French and English by creating a semantic signature of relations by entity-typing. These relations are extracted using CCG parsing in English and dependency parsing in French. Blessing and Schütze (2012) use inter-wiki links to map relations from a relation database in a pivot language to the target language and use these instances for learning in a distant supervision setting. Gerber and Ngomo (2012) describe a multilingual pattern extraction system for RDF predicates that uses pre-existing knowledge bases for different languages.

5 Conclusion

We have presented a language independent open domain relation extraction pipeline and have evaluated its performance on three typologically different languages: French, Hindi and Russian. Our cross-lingual projection method utilizes OLLIE and GOOGLE TRANSLATE to extract relations in the language of interest. Our approach does not rely on the availability of linguistic resources such as POS-taggers or dependency parsers in the target language and can thus be extended to multiple languages supported by a machine translation system. We are releasing the manually annotated judgements for open relations in the three languages and the open relations extracted over the entire Wikipedia corpus in ten languages. The resources are available at: `http://cs.cmu.edu/~mfaruqui/soft.html`.

Acknowledgment

This work was performed when the first author was an intern at Google. We thank Richard Sproat for providing comments on an earlier draft of this paper. We thank Hao Zhang for helping us with the relation extraction framework, and Richard Zens and Kishore Papineni for their feedback on this work. We are grateful to Bruno Cartoni, Vitaly Nikolaev and their teams for providing us annotations of multilingual relations.

Abstract

Natural language processing (NLP) annotation projects employ guidelines to maximize inter-annotator agreement (IAA), and models are estimated assuming that there is one single ground truth. However, not all disagreement is noise, and in fact some of it may contain valuable linguistic information. We integrate such information in the training of a cost-sensitive dependency parser. We introduce five different factorizations of IAA and the corresponding loss functions, and evaluate these across six different languages. We obtain robust improvements across the board using a factorization that considers dependency labels and directionality. The best method-dataset combination reaches an average overall error reduction of 6.4% in labeled attachment score.

1 Introduction

Typically, NLP annotation projects employ guidelines to maximize inter-annotator agreement. Possible inconsistencies are resolved by adjudication, and models are induced assuming there is one single ground truth. However, there exist linguistically hard cases where there is no clear answer (Zeman, 2010; Manning, 2011), and incorporating such disagreements into the training of a model has proven helpful for POS tagging (Plank et al., 2014a; Plank et al., 2014b).

Inter-annotator agreement (IAA) is straightforward to calculate for POS, but not for dependency trees. There is no well-established standard for computing agreement on trees (Skjærholt, 2014). For a dependency tree, annotators can disagree in attachment, labeling, or both. We implement different strategies, i.e., *factorizations* (§2), to capture disagreement on specific syntactic phenomena.

Our hypothesis is that a dependency parser can be informed of disagreements to regularize over annotators' biases. Testing our hypothesis requires the availability of doubly-annotated data, and involves two steps: i) how to *factorize* attachment or labeling disagreements; and ii) how to *inform* the parser of them during learning (§3).

2 Factorizations

Assume a sample of sentences annotated by annotators A_1 and A_2. With such a sample we can estimate probabilities of the two annotators' disagreeing on the annotation of a word or span, relative to some dependency tree factorization. We factorize disagreement on dependency tree annotations relative to four properties of the annotated dependency edges: the POS of the dependent, the POS of the head, the label of the edge and the direction (left or right) of the head with regards to the dependent. This section describes the different factorizations.

We present five factorizations, depicted in Figure 1. With artificial root notes, all words in a dependency tree have one incoming edge. This means that in our sample, any word w_i has two $\langle headId, label\rangle$ annotations, i.e., $\langle h_1, l_1\rangle$ and $\langle h_2, l_2\rangle$ given by A_1 and A_2, respectively, with POS$(\cdot)$ being a function from word indices to POS. The five factorizations are as follows:

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1357–1361,
Denver, Colorado, May 31 – June 5, 2015.

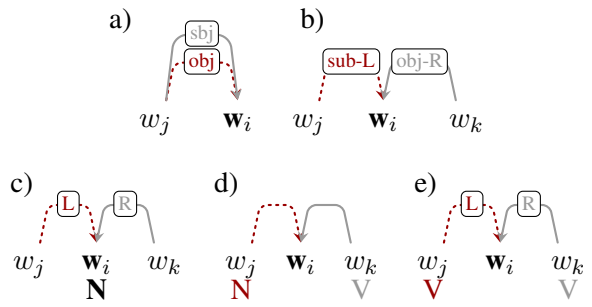

Figure 1: Factorizations: a) LABEL, b) LABELD; c) CHILDPOSD, d) HEADPOS and e) HEADPOSD. Red and green depict different choices by annotators A_1 and A_2.

a) LABEL: disagreement over label pairs, regardless of attachment (h_1,h_2). That is, $\langle h_1, l_1 \rangle$ and $\langle h_2, l_2 \rangle$ count as disagreement, iff $l_1 \neq l_2$.

b) LABELD, same as LABEL, but incorporating edge direction. That is, $\langle h_1, l_1 \rangle$ and $\langle h_2, l_2 \rangle$ count as disagreement, for any $j, k \in h_1, h_2$, iff $h_j < i < h_k$ *or* $l_1 \neq l_2$.

c) CHILDPOSD, i.e., disagreement on attachment direction given POS(i). That is, for POS(i), $\langle h_1, l_1 \rangle$ and $\langle h_2, l_2 \rangle$ count as disagreement, iff $h_j < i < h_k$.

d) HEADPOS: disagreement on head POS. That is, $\langle h_1, l_1 \rangle$ and $\langle h_2, l_2 \rangle$ count as disagreement, iff POS(h_1)≠POS(h_2).

e) HEADPOSD, i.e., HEADPOS, plus direction. That is, $\langle h_1, l_1 \rangle$ and $\langle h_2, l_2 \rangle$ count as disagreement, iff POS(h_1)≠POS(h_2) *or* $h_j < i < h_k$.

Each factorization yields a symmetric confusion matrix. In our Norwegian data (§4), for instance, for LABEL there are 834 words that have been labeled as ATR (attribute) by both annotators, while there are 44 cases where one annotator has given the ATR label and the other has given the ADV (adverbial) label. For LABELD, there are 968 words that have been labeled as ADV where both annotators agree on the head being on the left side of the word, whereas there are 9 cases where the annotators agree on ADV label but not on the direction of the head. These 9 cases count as disagreements for LABELD but not for LABEL.

3 Cost-sensitive updates

We use the cost-sensitive perceptron classifier, following Plank et al. (2014a), but extend it to transition-based dependency parsing, where the predicted values are transitions (Goldberg and Nivre, 2012). Given a gold y_i and predicted label $\hat{y}_i$ (POS tags or transitions), the loss is weighted by $\gamma(\hat{y}_i, y_i)$:

$$L_{\mathbf{w}}(\hat{y}_i, y_i) = \gamma(\hat{y}_i, y_i) \max(0, -y_i \mathbf{w} \cdot \mathbf{x}_i)$$

Whenever a transition has been wrongly predicted, we retrieve the predicted edge and compare it to the gold dependency to calculate γ. $\gamma(y_i, y_j)$ is then the inverse of the confusion probability estimated from our sample of doubly-annotated data. For example, using the factorization LABEL, if the parser predicts w_i to be SUBJECT and the gold annotation is OBJECT, the confusion probability is the number of times one annotator said SUBJECT while the other said OBJECT out of the times one annotator said one of them. In LABELD, A_1 and A_2 can disagree even if both say the grammatical function of some word w_i is SUBJECT, namely if one says the subject is left of w_i, and the other says it is right of w_i. The confusion probability is then the count of disagreements over the total number of cases where both annotators said a word was SUBJECT.

In our baseline model, $\gamma(\hat{y}_i, y_i) = 1$. The values for our cost-sensitive systems (LABEL, LABELD, CHILDPOSD, HEADPOS, HEADPOSD) are never above 1, which means that we are selectively underfitting the parser for specific syntactic phenomena. In other words, we use the doubly-annotated data to regularize our model, hopefully preventing overfitting to annotators' biases.

4 Data

We use six treebanks (Buch-Kromann et al., 2003; Buch-Kromann et al., 2007; Arias et al., 2014; Solberg et al., 2014; Agić and Merkler, 2013; Haverinen et al., 2010) for which we could get a sample of doubly-annotated data. All these treebanks are directly developed as dependency treebanks, instead of being converted from constituent treebanks. Table 1 gives overview statistics of the treebanks, Table 2 lists the sizes of the doubly-annotated samples, as well as F1 scores between annotators and α values (Skjærholt, 2014). The doubly-annotated samples are solely used to estimate confusion probabilities, and not for training or testing. When a treebank had no canonical train/test split, we took the final 30% for testing.

5 Experiments

In our experiments, we use `redshift`,[1] a transition-based arc-eager dependency parser that implements the dynamic oracle (Goldberg and Nivre, 2012) with averaged perceptron training. We modified the parser[2] to read confusion matrices and weigh the updates with the respective γ. We compare the five (§2) factorized systems to a baseline system that does not take confusion probabilities into account, i.e., standard `redshift`. Throughout the experiments, we fix the number of iterations to 5, and we use pseudo-projectivization (Nivre and Nilsson, 2005).[3] The parser does not include morphological features, which lowers performance for morphological rich languages like FI. We report labeled attachment scores (LAS) incl. punctuation.

[1] `https://github.com/syllog1sm/redshift`

[2] The modified code, as well as the confusion matrices for all factorizations, is available at `https://bitbucket.org/lowlands/iaa-parsing`

[3] 15–33% of the sentences contain non-projectivities.

We use bootstrap sampling in all our experiments in order to get more reliable results. This method allows abstracting away from biases—in sampling and annotation—of training and test splits. We use two complementary evaluation methods: cross-validation within the training data, and learning curves against the test set. We calculate significance using the approximate randomization test (Noreen, 1989) with 10k iterations.

Cross-validation In this setup, we perform 50 runs of 5-fold cross validation on bootstrap-based samples of the training data. This allows us to gauge the effect of our factorization without committing to a certain test set. We report on the average of the total of 250 runs.

Learning curve To calculate the learning curves, we train the parser on increasing amounts of training data, bootstrap-sampled in steps of 10%, and evaluate against the test set. Each 10% increment is repeated $k = 50$ times. We finally report average overall error reduction over the baseline.

6 Results

Cross-validation The results for cross-validation are shown in Table 3. For 5 out of the 6 languages we get significant improvements over the baseline with some factorization. We obtain improvements on all treebanks using LABELD, and on five out of six using CHILDPOSD. For CA, with the smallest doubly-annotated sample, results are not as consistent across the two evaluation methods.

Learning curve Table 4 summarizes the overall average error reduction over the 10-step bootstrap-based learning curve (with 50 runs at each step). We get consistent improvements for languages for which we have a sample of 100+ sentences (Table 2). Again, the most robust factorization is LABELD. Figure 2 shows the learning curves for the system with the highest error reduction (NO with CHILDPOSD).

Additional studies In order to evaluate whether our results are meaningful and not just artifacts of random regularization, we performed a sanity check for the best performing system and factorization (i.e., NO with CHILDPOSD factorization). We

Table 4: Overall avg. error red. across learning curves.

shuffled the confusion matrix and ran the bootstrap learning curve with $k = 50$ repetitions, for five different shufflings. The mean over the five runs for the overall average error reductions is negative (-0.38%, compared to the 2.4% mean for the original, non-shuffled version). We thus conclude that our factorizations capture linguistically plausible information rather than random noise.

7 Related Work

Plank et al. (2014a) propose IAA-weighted cost-sensitive learning for POS tagging. We extend their line of work to dependency parsing.

A single sentence can have more than one plausible dependency annotation. Some researchers have proposed evaluation metrics that do not penalize disagreements (Schwartz et al., 2011; Tsarfaty et al., 2011), while others have argued that we should instead ensure the consistency of treebanks (Dickinson, 2010; Manning, 2011; McDonald et al., 2013). Others have claimed that because of these ambiguities, only downstream evaluations are meaningful (Elming et al., 2013).

Syntactic annotation disagreement has typically been studied in the context of treebank development. Haverinen et al. (2012), for example, analyze annotator disagreement for Finnish dependency syntax, and compare it against parser performance. Skjærholt (2014) use doubly-annotated data to evaluate various agreement metrics. Our paper differs from both lines of research in that we leverage disagreements from doubly-annotated data to obtain more robust models. While we agree that evaluation metrics should probably reflect disagreements, we show that our learning algorithms can indeed benefit from information about disagreement, also using standard performance metrics.

8 Conclusions

We have evaluated five different factorizations on six treebanks to evaluate the impact of IAA-weighted learning for dependency parsing, obtaining promising results. The findings support our hypothesis that annotator disagreement is informative for parsing. The LABELD factorization—which takes both labeling and word order into account—is the overall most robust factorization across all languages. However, the best factorization for each language varies. This variation can be a result of the morphosyntax of the language, but also of the dependency annotation formalisms, annotation method, training corpus and size of the doubly-annotated sample.

Abstract

Research on automatically geolocating social media users has conventionally been based on the text content of posts from a given user or the social network of the user, with very little crossover between the two, and no benchmarking of the two approaches over comparable datasets. We bring the two threads of research together in first proposing a text-based method based on adaptive grids, followed by a hybrid network- and text-based method. Evaluating over three Twitter datasets, we show that the empirical difference between text- and network-based methods is not great, and that hybridisation of the two is superior to the component methods, especially in contexts where the user graph is not well connected. We achieve state-of-the-art results on all three datasets.

1 Introduction

There has recently been a spike in interest in the task of inferring the location of users of social media services, due to its utility in applications including location-aware information retrieval (Amitay et al., 2004), recommender systems (Noulas et al., 2012) and rapid disaster response (Earle et al., 2010). Social media sites such as Twitter and Facebook provide two primary means for users to declare their location: (1) through text-based metadata fields in the user's profile; and (2) through GPS-based geotagging of posts and check-ins. However, the text-based metadata is often missing, misleading or imprecise, and only a tiny proportion of users geotag their posts (Cheng et al., 2010). Given the small number of users with reliable location information, there has been significant interest in the task of automatically geolocating (predicting lat/long coordinates) of users based on their publicly available posts, metadata and social network information. These approaches are built on the premise that a user's location is evident from their posts, or through location homophily in their social network.

Our contributions in this paper are: *a*) the demonstration that network-based methods are generally superior to text-based user geolocation methods due to their robustness; *b*) the proposal of a hybrid classification method that backs-off from network- to text-based predictions for disconnected users, which we show to achieve state-of-the-art accuracy over all Twitter datasets we experiment with; and *c*) empirical evidence to suggest that text-based geolocation methods are largely competitive with network-based methods.

2 Related Work

Past work on user geolocation falls broadly into two categories: text-based and network-based methods. Common to both methods is the manner of framing the geolocation prediction problem. Geographic coordinates are real-valued, and accordingly this is most naturally modelled as (multiple) regression. However for modelling convenience, the problem is typically simplified to classification by first pre-partitioning the regions into discrete sub-regions using either known city locations (Han et al., 2012; Rout et al., 2013) or a k-d tree partitioning (Roller et al., 2012; Wing and Baldridge, 2014). In the k-d tree methods, the resulting discrete regions are treated either as a flat list (as we do here) or a nested hierarchy.

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1362–1367,
Denver, Colorado, May 31 – June 5, 2015.

2.1 Text-based Geolocation

Text-based approaches assume that language in social media is geographically biased, which is clearly evident for regions speaking different languages (Han et al., 2014), but is also reflected in regional dialects and the use of region specific terminology. Text based models have predominantly used bag of words features to learn per-region classifiers (Roller et al., 2012; Wing and Baldridge, 2014), including feature selection for location-indicative terms (Han et al., 2012).

Topic models have also been applied to model geospatial text usage (Eisenstein et al., 2010; Ahmed et al., 2013), by associating latent topics with locations. This has a benefit of allowing for prediction over continuous space, i.e., without the need to render the problem as classification. On the other hand, these methods have high algorithmic complexity and their generative formulation is unlikely to rival the performance of discriminative methods on large datasets.

2.2 Network-based Geolocation

Although online social networking sites allow for global interaction, users tend to befriend and interact with many of the same people online as they do off-line (Rout et al., 2013). Network-based methods exploit this property to infer the location of users from the locations of their friends (Jurgens, 2013; Rout et al., 2013). This relies on some form of friendship graph, through which location information can be propagated, e.g., using label propagation (Jurgens, 2013; Talukdar and Crammer, 2009). A significant caveat regarding the generality of these techniques is that friendship graphs are often not accessible, e.g., secured from the public (Facebook) or hidden behind a heavily rate-limited API (Twitter).

While the raw accuracies reported for network-based methods (e.g., Jurgens (2013) and Rout et al. (2013)) are generally higher than those reported for text-based methods (e.g., Wing and Baldridge (2014) and Han et al. (2014)), they have been evaluated over different datasets and spatial representations, making direct comparison uninformative. Part of our contribution in this paper is direct comparison between the respective methods over standard datasets. In this, we propose both text- and network-based methods, and show that they achieve state-of-the-art results on three pre-existing Twitter geolocation corpora. We also propose a new hybrid method incorporating both textual and network information, which also improves over the state-of-the-art, and outperforms the text-only or network-only methods over two of the three datasets.

3 Data

We evaluate on three Twitter corpora, each of which uses geotagged tweets to derive a geolocation for each user. Each user is represented by the concatenation of their tweets, and is assumed to come from a single location.

GEOTEXT: around 380K tweets from 9.5K users based in contiguous USA, of which 1895 is held out for development and testing (Eisenstein et al., 2010); the location of each user is set to the GPS coordinates of their first tweet.

TWITTER-US: around 39M tweets from 450K users based in the contiguous USA. 10K users are held out for each of development and testing (Roller et al., 2012); again users' locations are taken from their first tweet.

TWITTER-WORLD: around 12M English tweets from 1.4M users based around the world, of which 10K users are held out for each of development and testing (Han et al., 2012); users are geotagged with the centre of the closest city to their tweets.

In each case, we use the established training, development and testing partitions, and follow Cheng et al. (2010) and Eisenstein et al. (2010) in evaluating based on: (1) accuracy at 161km ("Acc@161"); (2) mean error distance, in kilometres ("Mean"); and (3) median error distance, in kilometres ("Median").

4 Methods

4.1 Text-based Classification

Our baseline method for text based geolocation is based on Wing and Baldridge (2014), who formulate the geolocation problem as classification using k-d

trees. In summary, their approach first discretises the continuous space of geographical coordinates using a k-d tree such that each sub-region (leaf) has similar numbers of users. This results in many small regions for areas of high population density and fewer larger regions for country areas with low population density. Next, they use these regions as class labels to train a logistic regression model ("LR"). Our work is also subject to a sparse l_1 regularisation penalty (Tibshirani, 1996). In their work, Wing and Baldridge (2014) showed that hierarchical logistic regression with a beam search achieves higher results than logistic regression over a flat label set, but in this research, we use a flat representation, and leave experiments with hierarchical classification to future work.

For our experiments, the number of users in each region was selected from $\{300, 600, 900, 1200\}$ to optimise median error distance on the development set, resulting in values of 300, 600 and 600 for GEOTEXT, TWITTER-US and TWITTER-WORLD, respectively. The l_1 regularisation coefficient was also optimised in the same manner.

As features, we used a bag of unigrams (over both words and @-mentions) and removed all features that occurred in fewer than 10 documents, following Wing and Baldridge (2014). The features for each user were weighted using tf-idf, followed by per-user l_2 normalisation. The normalisation is particularly important because our 'documents' are formed from all the tweets of each user, which vary significantly in size between users; furthermore, this adjusts for differing degrees of lexical variation (Lee, 1995). The number of features was almost 10K for GEOTEXT and about 2.5M for the other two corpora. For evaluation we use the median of all training locations in the sub-region predicted by the classifier, from which we measure the error against a test user's gold standard location.

4.2 Network-based Label Propagation

Next, we consider the approach of Jurgens (2013) who used label propagation ("LP"; Zhu and Ghahramani (2002)) to infer user locations using social network structure. Jurgens (2013) defined an undirected network from interactions among Twitter users based on @-mentions in their tweets, a mechanism typically used for conversations between friends. Consequently these links often correspond to offline friendships, and accordingly the network will exhibit a high degree of location homophily. The network is constructed by defining as nodes all users in a dataset (train and test), as well as other external users mentioned in their tweets. Unlike Jurgens (2013) who only created edges when both users mentioned one another, we created edges if either user mentioned the other. For the three datasets used in our experiments, bi-directional mentions were too rare to be useful, and we thus used the (weaker) uni-directional mentions as undirected edges instead. The edges between users are undirected and weighted by the number of @-mentions in tweets by either user.[1]

	GEOTEXT	TWITTER-US	TWITTER-WORLD
User mentions	109K	3.63M	16.8M
Disconnected test users:	23.5%	27.7%	2.36%

Table 1: The graph size and proportion of test users disconnected from training users for each dataset.

The mention network statistics for each of our datasets is shown in Table 1.[2] Following Jurgens (2013), we ran the label propagation algorithm to update the location of each non-training node to the weighted median of its neighbours. This process continues iteratively until convergence, which occurred at or before 10 iterations.

4.3 A Hybrid Method

Unfortunately many test users are not transitively connected to any training node (see Table 1), meaning that LP fails to assign them any location. This can happen when users don't use @-mentions, or when a set of nodes constitutes a disconnected component of the graph.

In order to alleviate this problem, we use the text for each test user in order to estimate their location, which is then used as an initial estimation during label propagation. In this hybrid approach, we first

[1] As our datasets don't have tweets for external users, these nodes do not contribute to the weight of their incident edges.

[2] Note that @-mentions were removed in the published TWITTER-US and TWITTER-WORLD datasets. To recover these we rebuilt the corpora from the Twitter archive.

	GeoText			Twitter-US			Twitter-World

Table 2: Geolocation accuracy over the three Twitter corpora comparing Logistic Regression (LR), Label Propagation (LP) and LP over LR initialisation (LP–LR) with the state-of-the-art methods for the respective datasets ("—" signifies that no results were published for the given dataset, and "???" signifies that no results were reported for the given metric).

estimate the location for each test node using the LR classifier described above, before running label propagation over the mention graph. This iteratively adjusts the locations based on both the known training users and guessed test users, while simultaneously inferring locations for the external users. In such a way, the inferred locations of test users will better match neighbouring users in their sub-graph, or in the case of disconnected nodes, will retain their initial classification estimate.

5 Results

Table 2 shows the performance of the three methods over the test set for the three datasets. The results are also compared with the state of the art for Twitter-US and Twitter-World (Wing and Baldridge, 2014), and GeoText (Ahmed et al., 2013).

Our methods achieve a sizeable improvement over the previous state of the art for all three datasets. LP–LR performs best over GeoText and Twitter-US, while LR performs best over Twitter-World; the reduction in median error distance over the state of the art ranges from around 40% to over 95%. Even for Twitter-World, the results for LP–LR are substantially better than the best-published results for that dataset.

Comparing LR and LP, no strong conclusion can be drawn — the text-based LP actually outperforms the network-based LR for two of the three datasets, but equally, the combination of the two (LP–LR) performs better than either component method over two of the three datasets. For the third (Twitter-World), LR outperforms LP–LR due to a combination of factors. First, unlike the other two datasets, the label set is pre-discretised (everything is aggregated at the city level), meaning that LP and LR use the same label set.[3] This annuls the representational advantage that LP has in the case of the other two datasets, in being able to capture a more fine-grained label set (i.e., all locations associated with training users). Second, there are substantially fewer disconnected test users in Twitter-World (see Table 1), meaning that the results for the hybrid LP–LR method are dominated by the empirically-inferior LP.

Although LR is similar to Wing and Baldridge (2014), we achieved large improvements over their reported results. This might be due to: (a) our use of @-mention features; (b) l_1 regularisation, which is essential to preventing overfitting for large feature sets; or (c) our use of l_2 normalisation of rows in the design matrix, which we found reduced errors by about 20% on GeoText, in keeping with results from text categorisation (Lee, 1995). Preliminary experiments also showed that lowering the term frequency threshold from 10 can further improve the LR results on all three datasets.

LP requires few hyper-parameters and is relatively robust. It converged on all datasets in fewer than 10 iterations, and geolocates not only the test users but all nodes in the mention graph. Another advantage of LP over LR is the relatively modest amount of memory and processing power it requires.

[3] For consistency, we learn a k-d tree for Twitter-World and use the merged representation for LR, but the k-d tree largely preserves the pre-existing city boundaries.

6 Conclusion

We proposed a series of approaches to social media user geolocation based on: (1) text-based analysis using logistic regression with regularisation; (2) network-based analysis using label propagation; and (3) a hybrid method based on network-based label propagation, and back-off to text-based analysis for disconnected users. We achieve state-of-the-art results over three pre-existing Twitter datasets, and find that, overall, the hybrid method is superior to the two component methods.The LP−LR method is a hybrid approach that uses the LR predictions as priors. It is not simply a backoff from network information to textual information in the sense that it propagates the LR geolocations through the network. That is, if a test node is disconnected from the training nodes but still has connections to other test nodes, the geolocation of the node is adjusted and propagated through the network. It is possible to add extra nodes to the graph after applying the algorithm and to geolocate only these nodes efficiently, although this approach is potentially less accurate than inferencing over the full graph from scratch.

Label propagation algorithms such as Modified Adsorption (Talukdar and Crammer, 2009) allow for different levels of influence between prior/known labels and propagated label distributions. These algorithms require a discretised output space for label propagation, while LP can work directly on continuous data. We leave label propagation over discritised output and allowing different influence levels between prior and propagated label distributions to future work.

There is no clear consensus on whether text- or network-based methods are empirically superior at the user geolocation task. Our results show that the network-based method (LP) is more robust than the text-based (LR) method as it requires a smaller number of hyper-parameters, uses less memory and computing resources, converges much faster and geolocates not only test users but all mentioned users. The drawback of LP is that it fails to geolocate disconnected test users. So for connected nodes – the majority of test nodes in all our datasets – LP is more robust than LR. Text-based methods are very sensitive to the regularisation settings and the types of textual features. That said, with thorough parameter tuning, they might outperform network-based method in terms of accuracy.

In future work, we hope to look at different types of network information for label propagation, more precise propagation methods to deal with non-local interactions, and also efficient ways of utilising both textual and network information in a joint model.

Discriminative Phrase Embedding for Paraphrase Identification

Wenpeng Yin and **Hinrich Schütze**

Abstract

This work, concerning paraphrase identification task, on one hand contributes to expanding deep learning embeddings to include continuous and discontinuous linguistic phrases. On the other hand, it comes up with a new scheme TF-KLD-KNN to learn the discriminative weights of words and phrases specific to paraphrase task, so that a weighted sum of embeddings can represent sentences more effectively. Based on these two innovations we get competitive state-of-the-art performance on paraphrase identification.

1 Introduction

This work investigates representation learning via deep learning in paraphrase identification task, which aims to determine whether two sentences have the same meaning. One main innovation of deep learning is that it learns distributed word representations (also called "word embeddings") to deal with various Natural Language Processing (NLP) tasks. Our goal is to use and refine embeddings to get competitive performance.

We adopt a supervised classification approach to paraphrase identification like most top performing systems. Our focus is representation learning of sentences. Following prior work (e.g., Blacoe and Lapata (2012)), we compute the vector of a sentence as the sum of the vectors of its components. But unlike prior work we use *single words, continuous phrases and discontinuous phrases* as the components, not just single words. Our rationale is that many semantic units are formed by multiple words – e.g., the continuous phrase "side effects" and the discontinuous phrase "pick ... off". The better we can discover and represent such components, the better the compositional sentence vector should be. We use the term *unit* to refer to single words, continuous phrases and discontinuous phrases.

Ji and Eisenstein (2013) show that not all words are equally important for paraphrase identification. They propose TF-KLD, a discriminative weighting scheme to address this problem. While they do not represent sentences as vectors composed of other vectors, TF-KLD is promising for a vector-based approach as well since the insight that units are of different importance still applies. A shortcoming of TF-KLD is its failure to define weights for words that do not occur in the training set. We propose TF-KLD-KNN, an extension of TF-KLD that computes the weight of an unknown unit as the average of the weights of its k nearest neighbors. We determine nearest neighbors by cosine measure over embedding space. We then represent a sentence as the sum of the vectors of its units, weighted by TF-KLD-KNN.

We use (Madnani et al., 2012) as our baseline system. They used simple features – eight different machine translation metrics – yet got good performance. Based on above new sentence representations, we compute three kinds of features to describe a pair of sentences – cosine similarity, element-wise sum and absolute element-wise difference – and show that combining them with the features from Madnani et al. (2012) gets state-of-the-art performance on the Microsoft Research Paraphrase (MSRP) corpus (Dolan et al., 2004).

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1368–1373,
Denver, Colorado, May 31 – June 5, 2015.

In summary, our first contribution lies in embedding learning of continuous and discontinuous phrases. Our second contribution is the weighting scheme TF-KLD-KNN.

This paper is structured as follows. Section 2 reviews related work. Section 3 describes our method for learning embeddings of units. Section 4 introduces a measure of unit discriminativity that can be used for differential weighting of units. Section 5 presents experimental setup and results. Section 6 concludes.

2 Related work

The key for good performance in paraphrase identification is the design of good features. We now discuss relevant prior work based on the linguistic granularity of feature learning.

The first line is compositional semantics, which learns representations for words and then composes them to representations of sentences. Blacoe and Lapata (2012) carried out a comparative study of three word representation methods (the simple distributional semantic space (Mitchell and Lapata, 2010), distributional memory tensor (Baroni and Lenci, 2010) and word embedding (Collobert and Weston, 2008)), along with three composition methods (addition, point-wise multiplication, and recursive autoencoder (Socher et al., 2011)). They showed that addition over word embeddings is competitive, despite its simplicity.

The second category directly seeks sentence-level features. Ji and Eisenstein (2013) explored unigrams, bigrams and dependency pairs as sentence features. They proposed TF-KLD to weight features and used non-negative factorization to learn latent sentence representations. Our method TF-KLD-KNN is an extension of their work.

The third line directly computes features for sentence pairs. Wan et al. (2006) used N-gram overlap, dependency relation overlap, dependency tree-edit distance and difference of sentence lengths. Finch et al. (2005) and Madnani et al. (2012) combined several machine translation metrics. Das and Smith (2009) presented a generative model over two sentences' dependency trees, incorporating syntax, lexical semantics, and hidden loose alignments between the trees to model generating a paraphrase of a given sentence. Socher et al. (2011) used recursive autoencoders to learn representations for words and word sequences on each layer of the sentence parsing tree, and then proposed dynamic pooling layer to form a fixed-size matrix as the representation of the two sentences. Other work representative of this line is by Kozareva and Montoyo (2006), Qiu et al. (2006), Ul-Qayyum and Altaf (2012).

Our work, first learning unit embeddings, then adding them to form sentence representations, finally calculating pair features (cosine similarity, absolute difference and MT metrics) actually is a combination of above three lines.

3 Embedding learning for units

As explained in Section 1, "units" in this work include single words, continuous phrases and discontinuous phrases. Phrases have a larger linguistic granularity than words and thus will in general contain more meaning aspects for a sentence. For example, successful detection of continuous phrase "side effects" and discontinuous phrase "pick $\cdots$ off" is helpful to understand the sentence meaning correctly. This section focuses on how to detect phrases and how to represent them.

3.1 Phrase collection

Phrases defined by a lexicon have not been investigated extensively before in deep learning. To collect canonical phrase set, we extract two-word phrases defined in Wiktionary[1] and Wordnet (Miller and Fellbaum, 1998) to form a collection of size 95,218. This collection contains *continuous phrases* – phrases whose parts always occur next to each other (e.g., "side effects") – and *discontinuous phrases* – phrases whose parts more often occur separated from each other (e.g., "pick ... off").

3.2 Identification of phrase continuity

Wiktionary and WordNet do not categorize phrases as continuous or discontinuous. So we need a heuristic to determine this automatically.

For each phrase "A_B", we compute [c_1, c_2, c_3, c_4, c_5] where $c_i, 1 \leq i \leq 5$, indicates there are c_i occurrences of A and B in that order with a distance

[1] http://en.wiktionary.org

of i. We compute these statistics for a corpus consisting of English Gigaword (Graff et al., 2003) and Wikipedia. We set the maximal distance to 5 because discontinuous phrases are rarely separated by more than 5 tokens.

If c_1 is 10 times higher than $(c_2+c_3+c_4+c_5)/4$, we classify "A_B" as *continuous*, otherwise as *discontinuous*. For example, $[c_1, \ldots, c_5]$ is [1121, 632, 337, 348, 4052] for "pick_off", so c_1 is smaller than the average 1342.25 and "pick_off" is set as "discontinuous"; $[c_1, \ldots, c_5]$ is [14831, 16, 177, 331, 3471] for "Cornell University", c_1 is 10 times larger than the average and this phrase is set to "continuous".

We found that that this heuristic for distinguishing between continuous and discontinuous phrases works well and leave the development of a more principled method for future work.

3.3 Sentence reformatting

Sentence "... A ... B ..." is

- reformatted as "... A_B ..." if A and B form a continuous phrase and no word intervenes between them and
- reformatted as "... A_B ... A_B ..." if A and B form a discontinuous phrase and are separated by 1 to 4 words. We replace each of the two component words with A_B to make the context of both constituents available to the phrase in learning.

This method of phrase detection will generate some false positives, e.g., if "pick" and "off" occur in a context like "she picked an island off the coast of Maine". However, our experimental results indicate that it is robust enough for our purposes.

We run word2vec (Mikolov et al., 2013) on the reformatted Wikipedia corpus to learn embeddings for all units. Embedding size is set to 200.

4 Measure of unit discriminativity

We will represent a sentence as the sum of the embeddings of its units. Building on Ji and Eisenstein (2013)'s TF-KLD, we want to weight units according to their ability to discriminate two sentences specific to the paraphrase task.

TF-KLD assumes a training set of sentence pairs in the form $\langle u_i, v_i, t_i \rangle$, where u_i and v_i denote the binary unit occurrence vectors for the sentences in the ith pair and $t_i \in \{0, 1\}$ is the gold tag. Then, we define p_k and q_k as follows.

- $p_k = P(u_{ik}|v_{ik} = 1, t_i = 1)$. This is the probability that unit w_k occurs in sentence u_i given that w_k occurs in its counterpart v_i and they are paraphrases.
- $q_k = P(u_{ik}|v_{ik} = 1, t_i = 0)$. This is the probability that unit w_k occurs in sentence u_i given that w_k occurs in its counterpart v_i and they are not paraphrases.

TF-KLD computes the discriminativity of unit w_k as the Kullback-Leibler divergence of the Bernoulli distributions (p_k, 1-p_k) and (q_k, 1-q_k)

TF-KLD has a serious shortcoming for unknown units. Unfortunately, the test data of the commonly used MSPR corpus in paraphrase task has about 6% unknown words and 62.5% of its sentences contain unknown words. It motivates us to design an improved scheme TF-KLD-KNN to reweight the features.

TF-KLD-KNN weights are the same as TF-KLD weights for known units. For a unit that did not occur in training, TF-KLD-KNN computes its weight as the average of the weights of its k nearest neighbors in embedding space, where unit similarity is calculated by cosine measure.[2]

Word2vec learns word embeddings based on the word context. The intuition of TF-KLD-KNN is that words with similar context have similar discriminativities. This enables us to transfer the weights of features in training data to the unknown features in test data, greatly helping to address problems of sparseness.

5 Experiments

5.1 Data and baselines

We use the MSRP corpus (Dolan et al., 2004) for evaluation. It consists of a training set of 2753 true paraphrase pairs and 1323 false paraphrase pairs and a test set of 1147 true and 578 false pairs.

[2]Unknown words without embeddings (only seven cases in our experiments) are ignored. This problem can be effectively relieved by training embedding on larger corpora.

For our new method, it is interesting to measure the improvement on the subset of those MSRP sentences that contain at least one phrase. In the standard MSRP corpus, 3027 training pairs (2123 true, 904 false) and 1273 test pairs (871 true, 402 false) contain phrases; we denote this subset as *subset*. We carry out experiments on *overall* (all MSRP sentences) as well as *subset* cases.

We compare six methods for paraphrase identification.

- **NOWEIGHT.** Following Blacoe and Lapata (2012), we simply represent a sentence as the unweighted sum of the embeddings of all its units.

- **MT** is the method proposed by Madnani et al. (2012): the sentence pair is represented as a vector of eight different machine translation metrics.

- **Ji and Eisenstein (2013)**. We reimplemented their "inductive" setup which is based on matrix factorization and is the top-performing system in paraphrasing task.[3]

  The following three methods not only use this vector of eight MT metrics, but use three kinds of additional features given two sentence representations s_1 and s_2: cosine similarity, element-wise sum $s_1 + s_2$ and element-wise absolute difference $|s_1 - s_2|$. We now describe how each of the three methods computes the sentence vectors.

- **WORD.** The sentence is represented as the sum of all single-word embeddings, weighted by TF-KLD-KNN.

- **WORD+PHRASE.** The sentence is represented as the sum of the embeddings of all its units (including phrases), weighted by TF-KLD-KNN.

- **WORD+GOOGLE.** Mikolov et al. (2013) use a data-driven method to detect statistical phrases which are mostly continuous bigrams. We implement their system by first exploiting word2phrase[4] to reformat Wikipedia, then using word2vec skip-gram model to train phrase embeddings.

We use the same weighting scheme TF-KLD-KNN for the three weighted sum approaches: WORD, WORD+PHRASE and WORD+GOOGLE. Note however that there is an interaction between representation space and nearest neighbor search. We limit the neighbor range of unknown words for WORD to single words; in contrast, we search the space of all single words and linguistic (resp. Google) phrases for WORD+PHRASE (resp. WORD+GOOGLE).

We use LIBLINEAR (Fan et al., 2008) as our linear SVM implementation. 20% training data is used as development data. Parameter k is fine-tuned on development set and the best value 3 is finally used in following reported results.

5.2 Experimental results

Table 1 shows performance for the six methods as well as for the majority baseline. In the *overall* (resp. *subset*) setup, WORD+PHRASE performs best and outperforms (Ji and Eisenstein, 2013) by .009 (resp. .052) on accuracy. Interestingly, Ji and Eisenstein (2013)'s method obtains worse performance on $subset$. This can be explained by the effect of matrix factorization in their work: it works less well for smaller datasets like $subset$. This is a shortcoming of their approach. WORD+GOOGLE has a slightly worse performance than WORD+PHRASE; this suggests that linguistic phrases might be more effective than statistical phrases in identifying paraphrases.

Cases *overall* and *subset* both suggest that phrase embeddings improve sentence representations. The accuracy of WORD+PHRASE is lower on *overall* than on *subset* because WORD+PHRASE has no advantage over WORD for sentences without phrases.

5.3 Effectiveness of TF-KLD-KNN

The key contribution of TF-KLD-KNN is that it achieves full coverage of feature weights in the face of data sparseness. We now compare four weighting methods on overall corpus and with the combi-

[3] They report even better performance in a "transductive" setup that makes use of test data. We only address paraphrase identification for the case that the test data are not available for training the model in this paper.

TF-KLD-KNN	**.787**	**.848**

Table 2: Effects of different reweighting methods on overall.

nation of MT features: NOWEIGHT, TF-IDF, TF-KLD, TF-KLD

Table 2 suggests that task-specific reweighting approaches (including TF-KLD and TF-KLD-KNN) are superior to unspecific schemes (NOWEIGHT and TF-IDF). Also, it demonstrates the effectiveness of our weight learning solution for unknown units in paraphrase task.

5.4 Reweighting schemes for unseen units

We compare our reweighting scheme **KNN** (i.e., TF-KLD-KNN) with three other reweighting schemes. **Zero**: zero weight, i.e., ignore unseen units; **Type-average**: take the average of weights of all known unit types in test set; **Context-average**: average of the weights of the adjacent known units of the unknown unit (two, one or defaulting to Zero, depending on how many there are). Figure 1 shows that KNN performs best.

6 Conclusion

This work introduced TF-KLD-KNN, a new reweighting scheme that learns the discriminativities of known as well as unknown units effectively. We further improved paraphrase identification performance by the utilization of continuous and discontinuous phrase embeddings.

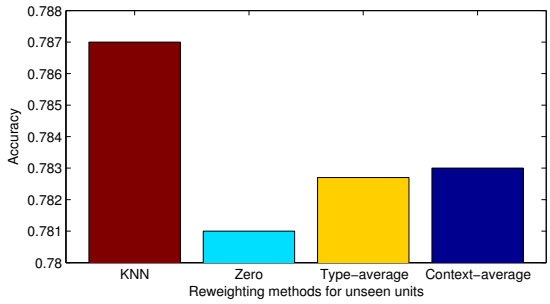

Figure 1: Performance of different reweighting schemes for unseen units on overall.

In future, we plan to do experiments in a cross-domain setup and enhance our algorithm for domain adaptation paraphrase identification.

Abstract

Compositional embedding models build a representation for a linguistic structure based on its component word embeddings. While recent work has combined these word embeddings with hand crafted features for improved performance, it was restricted to a small number of features due to model complexity, thus limiting its applicability. We propose a new model that conjoins features and word embeddings while maintaing a small number of parameters by learning feature embeddings jointly with the parameters of a compositional model. The result is a method that can scale to more features and more labels, while avoiding overfitting. We demonstrate that our model attains state-of-the-art results on ACE and ERE fine-grained relation extraction.

1 Introduction

Word embeddings represent words in some low-dimensional space, where each dimension might intuitively correspond to some syntactic or semantic property of the word.[1] These embeddings can be used to create novel features (Miller et al., 2004; Koo et al., 2008; Turian et al., 2010; Sun et al., 2011; Nguyen and Grishman, 2014; Roth and Woodsend, 2014), and can also be treated as model parameters to build representations for higher-level structures in some compositional embedding models (Collobert et al., 2011; Collobert, 2011; Socher et al., 2012; Socher et al., 2013b; Hermann et al., 2014). Applications of embedding have boosted the performance of many NLP tasks, including syntax (Turian et al., 2010; Collobert et al., 2011), semantics (Socher et al., 2012; Socher et al., 2013b; Hermann et al., 2014), question answering (Bordes et al., 2014) and machine translation (Devlin et al., 2014).

While compositional models aim to learn higher-level structure representations, composition of embeddings alone may not capture important syntactic or semantic patterns. Consider the task of relation extraction, where decisions require examining long-distance dependencies in a sentence. For the sentence in Figure 1, "*driving*" is a strong indicator of the "ART" (ACE) relation because it appears on the dependency path between a person and a vehicle. Yet such conjunctions of different syntactic/semantic annotations (dependency and NER) are typically not available in compositional models.

In contrast, hand-crafted features can easily capture this information, e.g. feature f_{i3} (Figure 1). Therefore, engineered features should be combined with learned representations in compositional models. One approach is to use the features to select specific transformations for a sub-structure (Socher et al., 2013a; Hermann and Blunsom, 2013; Hermann et al., 2014; Roth and Woodsend, 2014), which can conjoin features and word embeddings, but is impractical as the numbers of transformations will exponentially increase with additional features. Typically, less than 10 features are used. A solution

* The work was done while the author was visiting JHU.

[1] Such embeddings have a long history in NLP, such as term co-occurrence frequency matrices and their low-dimensional counterparts obtained by linear algebra tools (LSA, PCA, CCA, NNMF) and word clusters. Recently, neural networks have become popular methods for obtaining such embeddings (Bengio et al., 2006; Collobert et al., 2011; Mikolov et al., 2013).

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1374–1379,
Denver, Colorado, May 31 – June 5, 2015.

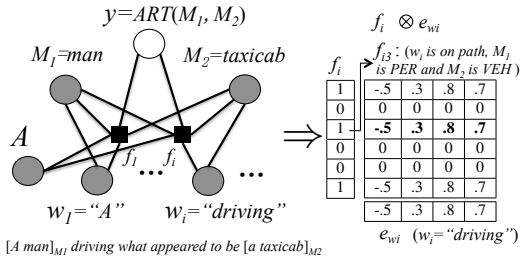

Figure 1: Example of input structure. Left: a sentence with target entities (M_1, M_2) and annotations A (e.g. dependency tree). Right: outer product representation of a single word w_i with an example of useful features f_{i3}.

is provided by the recent work of Yu et al. (2014), which reduces this complexity by using a tensor to transform the input feature vectors to a matrix transformation. The model is equivalent to treating the outer product between word embeddings and features as input to a parameter tensor, thus model parameters increase linearly with the number of features. Yet this model also uses too many parameters when a large number of features (e.g. over 1000) are used. This limits the applicability of their method to settings where there are a large number of training examples. For smaller training sets, the variance of their estimator will be high resulting in increased generalization error on test data. We seek to use many more features (based on rich annotations such as syntactic parsing and NER) and larger label sets, which further exacerbates the problem of overfitting.

We propose a new method of learning interactions between engineered features and word embeddings by combining the idea of the outer product in FCM (Yu et al., 2014) with learning feature embeddings (Collobert et al., 2011; Chen and Manning, 2014).[2] Our model jointly learns feature embeddings and a tensor-based classifier which relies on the outer product between features embeddings and word embeddings. Therefore, the number of parameters are dramatically reduced since features are only represented as low-dimensional embeddings, which alleviates problems with overfitting. The resulting model benefits from both approaches: conjunctions between feature and word embeddings allow model expressiveness, while keeping the number of parameters small. This is especially beneficial when considering tasks with many labels, such as fine-grained relation extraction. We demonstrate these advantages on two relation extraction tasks: the well studied ACE 2005 dataset and the new ERE relation extraction task. We consider both coarse and fine-grained relations, the latter of which has been largely unexplored in previous work.

2 Factor-based Compositional Embedding Models (FCM)

We begin by briefly summarizing the FCM model proposed by Yu et al. (2014) in the context of relation extraction. In relation extraction, for a pair of mentions in a given sentence, the task is to determine the type of relation that holds between the two entities, if any. For each pair of mentions in a sentence, we have a training instance $(\mathbf{x}, y)$; $\mathbf{x}$ is an annotated sentence, including target entity mentions M_1 and M_2, and a dependency parse. We consider directed relations: for relation type Rel, $y = Rel(M_1, M_2)$ and $y' = Rel(M_2, M_1)$ are different.

FCM has a log-linear form, which defines a particular utilization of the features and embeddings. FCM decomposes the structure of $\mathbf{x}$ into single words. For each word w_i, a binary feature vector $\mathbf{f_i}$ is defined, which considers the ith word and any other substructure of the annotated sentence $\mathbf{x}$. We denote the dense word embedding by e_{w_i} and the label-specific model parameters by matrix T_y, e.g. in Figure 1, the gold label corresponds to matrix T_y where y=*ART*(M_1, M_2). FCM is then given by:

$$P(y|\mathbf{x}; T) \propto \exp(\textstyle\sum_i T_y \odot (\mathbf{f_i} \otimes e_{w_i})) \quad (1)$$

where $\otimes$ is the outer-product of the two vectors and $\odot$ is the 'matrix dot product' or Frobenious inner product of the two matrices. Here the model parameters form a tensor $T = [T_1 : ... : T_{|L|}]$, which transforms the input matrix to the labels.

The key idea in FCM is that it gives similar words (i.e. those with similar embeddings) with similar functions in the sentence (i.e. those with similar features) similar matrix representations. Thus, this model generalizes its model parameters across words with similar embeddings only when they share similar functions in the sentence. For the

[2] Collobert et al. (2011) and Chen and Manning (2014) also capture interactions between word embeddings and features by using deep convolutional networks with max-pooling or cube activate function, but they cannot directly express conjunctions of word embeddings and features.

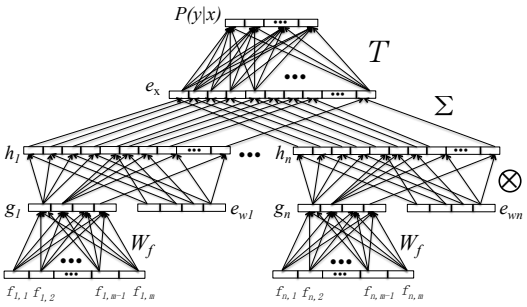

Figure 2: Neural network representation of LRFCM.

example in Figure 1, FCM can learn parameters which give words similar to "driving" with the feature $f_3 = 1$ (`is-on-dependency-path` $\wedge$ `type(`M_1`)=PER` $\wedge$ `type(`M_2`)=VEH`) high weight for the *ART* label.

3 Low-Rank Approximation of FCM

FCM achieved state of the art performance on SemEval relation extraction (Yu et al., 2014), yet its generalization ability is limited by the size of the tensor T, which cannot easily scale to large number of features. We propose to replace features with feature embeddings (Chen and Manning, 2014), thereby reducing the dimensionality of the feature space, allowing for more generalization in learning the tensor. This will be especially beneficial with an increased number of output labels (i.e. more relation types), as this increases the number of parameters.

Our task is to determine the label y (relation) given the instance $\mathbf{x}$. For each word $w_i \in \mathbf{x}$, there exists a list of m associated features $\mathbf{f}_i = f_{i,1}, f_{i,2}, ..., f_{i,m}$. The model then transforms the feature vector into a d_g-dimensional ($d_g \ll m$) vector with a matrix (i.e. a lookup table) $\mathbf{W_f}$ as: $\mathbf{g}_i = \mathbf{f_i} \cdot \mathbf{W_f}$. Here we use a linear transformation for computational efficiency. We score label y given $\mathbf{x}$ as (replacing Eq. 1):

$$P(y|\mathbf{x}; T, \mathbf{W_f}) \propto \exp(\textstyle\sum_i T_y \odot (\mathbf{g_i} \otimes e_{w_i})) \quad (2)$$

We call this model low-rank FCM (LRFCM). The result is a dramatic reduction in the number of model parameters, from $O(md|L|)$ to $O(d_g d|L| + d_g m)$, where d is the size of the word embeddings. This reduction is intended to reduce the variance of our estimator, possibly at the expense of higher bias. Consider the case of 32 labels (fine-grained relations in §4), 3,000 features, and 200 dimensional word embeddings. For FCM, the size of T is 1.92×10^7; potentially yielding a high variance estimator. However, for LRFCM with 20-dimensional feature embeddings, the size of T is 1.28×10^5, significantly smaller with lower variance. Moreover, feature embeddings can capture correlations among features, further increasing generalization.

Figure 2 shows the *vectorized* form of LRFCM as a multi-layer perceptron. LRFCM constructs a dense low-dimensional matrix used as the input to Eq. 2. By contrast, FCM does not have a feature embedding layer and both feature vector f and word embedding e_w are feed forward directly to the outer product layer.

Training We optimize the following log-likelihood (of the probability in Eq. 2) objective with AdaGrad (Duchi et al., 2011) and compute gradients via back-propagation:

$$\mathcal{L}(T, \mathbf{W_f}) = \tfrac{1}{|D|} \textstyle\sum_{(y,\mathbf{x}) \in D} \log P(y|\mathbf{x}; T, \mathbf{W_f}), \quad (3)$$

where D is the training set. For each instance $(y, \mathbf{x})$ we compute the gradient of the log-likelihood $\ell = \log P(y|\mathbf{x}; T, \mathbf{W_f})$. We define the vector $\mathbf{s} = [\sum_i T_y \odot (\mathbf{g_i} \otimes e_{w_i})]_{1 \le y \le L}$, which yields $\partial \ell / \partial \mathbf{s} = \left[(I[y = y'] - P(y'|\mathbf{x}; T, \mathbf{W_f}))_{1 \le y' \le L} \right]^T$, where $I[x]$ is the indicator function equal to 1 if x is true and 0 otherwise. Then we have the following stochastic gradients, where $\circ$ is the tensor product:

$$\frac{\partial \ell}{\partial T} = \frac{\partial \ell}{\partial \mathbf{s}} \otimes \sum_{i=1}^{n} \mathbf{g}_i \otimes \mathbf{e}_{w_i}, \quad (4)$$

$$\frac{\partial \ell}{\partial \mathbf{W}_f} = \sum_{i=1}^{n} \frac{\partial \ell}{\partial \mathbf{g}_i} \frac{\partial \mathbf{g}_i}{\partial \mathbf{W}_f} = \sum_{i=1}^{n} \left(T \circ \frac{\partial \ell}{\partial \mathbf{s}} \circ \mathbf{e}_{w_i} \right) \otimes \mathbf{f_i}.$$

4 Experiments

Datasets We consider two relation extraction datasets: ACE2005 and ERE, both of which contain two sets of relations: coarse relation types and fine relation (sub-)types. Prior work on English ACE 2005 has focused only on coarse relations (Plank and Moschitti, 2013; Nguyen and Grishman, 2014; Li and Ji, 2014); to the best of our knowledge, this paper establishes the first baselines for the other datasets. Since the fine-grained relations require a large number of parameters, they will test the ability

of LRFCM to scale and generalize. As is standard, we report precision, recall, and F1 for all tasks.

ACE 2005 We use the English portion of the ACE 2005 corpus (Walker et al., 2006). Following Plank and Moschitti (2013), we train on the union of the news domains (Newswire and Broadcast News), hold out half of the Broadcast Conversation (bc) domain as development data, and evaluate on the remainder of bc. There are 11 coarse types and 32 fine (sub-)type classes in total. In order to compare with traditional feature-based methods (Sun et al., 2011), we report results in which the gold entity spans *and* types are available at both train and test time. We train the models with all pairs of entity mentions in the training set to yield 43,518 classification instances. Furthermore, for comparison with prior work on embeddings for relation extraction (Plank and Moschitti, 2013), we report results using gold entity spans but no types, and generate negative relation instances from all pairs of entities within each sentence with three or fewer intervening entities.

ERE We use the third release of the ERE annotations from Phase 1 of DEFT (LDC, 2013) . We divided the proxy reports summarizing news articles (pr) into training (56,889 relations), development (6,804 relations) and test data (6,911 relations). We run experiments under both the settings with and without gold entity types, while generating negative relation instances just as in ACE with the gold entity types setting. To the best of our knowledge, we are the first to report results on this task.

Following the annotation guidelines of ERE relations, we treat all relations, except for "social.business", "social.family" and "social.unspecified", as asymmetric relations. For coarse relation task, we treat all relations as asymmetric, including the "social" relation. The reason is that the asymmetric subtype, "social.role", dominates the class: 679 of 834 total "social" relations.

Setup We randomly initialize the feature embeddings W_f and pre-train 200-dimensional word embeddings on the NYT portion of Gigaword 5.0 (Parker et al., 2011) with word2vec (default setting of the toolkit) (Mikolov et al., 2013). Dependency parses are obtained from the Stanford Parser (De Marneffe et al., 2006). We use the same feature templates as Yu et al. (2014). When gold entity types are unavailable, we replace them with WordNet tags annotated by Ciaramita and Altun (2006). Learning rates, weights of L2-regularizations, the number of iterations and the size of the feature embeddings d are tuned on dev sets. We selected d from $\{12, 15, 20, 25, 30, 40\}$. We used d=30 for feature embeddings for fine-grained ACE without gold types, and d=20 otherwise. For ERE, we have d=15. The weights of L2 λ was selected from {1e-3, 5e-4, 1e-4}. As in prior work (Yu et al., 2014), regularization did not significantly help FCM. However for LRFCM, λ=1e-4 slightly helps. We use a learning rate of 0.05.

We compare to two baselines. First, we use the features of Sun et al. (2011), who build on Zhou et al. (2005) with additional highly tuned features for ACE-style relation extraction from years of research. We implement these in a logistic regression model BASELINE, excluding country gazetteer and WordNet features. This baseline includes gold entity types and represents a high quality feature rich model. Second, we include results from Plank and Moschitti (2013) (PM'13), who obtained improve-

ERE ($\|L\|$=18)		LRFCM	
		Correct	**Incorrect**
FCM	**Correct**	423	34
	Incorrect	57	246

Table 2: Confusion Matrix between the results of FCM and LRFCM on the test set of ERE fine relation task. Each item in the table shows the number of relations on which the two models make correct/incorrect predictions.

ments for coarse ACE relations with word embeddings (Brown clusters and LSA) without gold entity types. To demonstrate improvements of the low rank approximation of LRFCM, we compare to FCM [3].

Results Both FCM and LRFCM outperform Plank and Moschitti (2013) (no gold entities setting) (Table 1). With gold entity types, the feature-rich baseline beats both composition models for ACE coarse types. However, as we consider more labels, LRFCM improves over this baseline, as well as for ERE coarse types. Furthermore, LRFCM outperforms FCM on all tasks, save ACE coarse types, both with and without gold entity types. The fine-grained settings demonstrate that our model can better generalize by using relatively fewer parameters. Additionally, the gap between train and test F1 makes this clear. For coarse relations, FCM's train to test F1 gap was 35.2, compared to LRFCM with 25.4. On fine relations, the number increases to 40.2 for FCM but only 31.2 for LRFCM. In both cases, LRFCM does not display the same degree of overfitting.

Analysis To highlight differences in the results we provide the confusion matrix of the two models on ERE fine relations. Table 2 shows that the two models are complementary to each other to a certain degree. It indicates that the combination of FCM and LRFCM may further boost the performance. We leave the combination of FCM and LRFCM, as well as their combination with the baseline method, to future work.

5 Conclusion

Our LRFCM learns conjunctions between features and word embeddings and scales to many features and labels, achieving improved results for relation extraction tasks on both ACE 2005 and ERE.

To the best of our knowledge, we are the first to report relation extraction results on ERE. To make it easier to compare to our results on these tasks, we make the data splits used in this paper and our implementation available for general use[4].

Abstract

We present a new context-aware method for lexical simplification that uses two free language resources and real web frequencies. We compare it with the state-of-the-art method for lexical simplification in Spanish and the established simplification baseline, that is, the most frequent synonym. Our method improves upon the other methods in the detection of complex words, in meaning preservation, and in simplicity. Although we use Spanish, the method can be extended to other languages since it does not require alignment of parallel corpora.

1 Introduction

Simplified text is crucial for some populations to read effectively, especially for cognitively impaired people such as people with autism spectrum disorder (Evans et al., 2014; Orasan et al., 2013), aphasia (Carroll et al., 1999), dyslexia (Rello et al., 2013a), Down syndrome (Saggion et al., 2015; Saggion et al., 2011), or other intellectual disabilities (Huenerfauth et al., 2009).

In fact, the United Nations (1994) proposed a set of standard rules to leverage document accessibility for persons with disabilities. Text simplification attempts to solve this problem automatically by reducing the complexity of the lexicon, syntax, or semantics while attempting to preserve its meaning and information content (Siddharthan, 2006). Among all the types of text simplification this paper focuses on lexical simplification.

Lexical simplification methods require language resources, such as simplified corpora or synonyms dictionaries. For languages with less resources than English, *e.g.* no Simple Wikipedia (Biran et al., 2011; Yatskar et al., 2010) or less representation in WordNet, such as Spanish,[1] the creation of lexical simplification methods is more challenging.

Our approach makes use of two free resources, Google Books Ngram Corpus and the Spanish OpenThesaurus, as well as real web frequencies to create a lexical simplification system. Our system improves upon the state of the art for lexical simplification in Spanish and the established simplification baseline, *i.e.*, the most frequent synonym, in several aspects: complex word detection, meaning preservation, and simplicity. We also show the coverage of our technique in a collection of books in Spanish, as this is another relevant measure of a simplification algorithm. The method is language independent and given that these resources are available in other languages, it could be easily extended to other languages with similar language resources.

The rest of the paper is organized as follows. The next section presents related work. Then in Section 3 we present the simplification algorithm while in Sections 4 and 5 we present our experimental evaluation. Finally, in Section 6 we discuss our results, extensions to other languages, and outline future work.

[1]The Spanish part of EuroWordNet contains only 50,526 word meanings and 23,370 synsets, in comparison to 187,602 meanings and 94,515 synsets in the English WordNet 1.5. (Vossen, 2004).

2 Related Work

Lexical simplification is a kind of text simplification that aims at the word level. It can be performed through the substitution of words by simpler synonyms, by adding a definition, or by showing simpler synonyms. Most of the approaches aim at the substitution of complex words.

To find appropriate synonyms, many approaches use WordNet (Burstein et al., 2007; Carroll et al., 1999; Lal and Ruger, 2002). De Belder *et al.* (2010) apply explicit word sense disambiguation with a latent words language model. Devlin and Unthank (2006) use dictionaries. Aluisio and Gasperin (2010) use a thesaurus and lexical ontologies.

More recently, Biran *et al.* (2011) and Yatskar *et al.* (2010) used Simple English Wikipedia, in combination with the standard English Wikipedia for their lexical simplification algorithms using machine learning.

There are also machine translation based approaches (Coster and Kauchak, 2011; Specia, 2010) as well as hybrid approaches (Narayan and Gardent, 2014; Siddharthan and Angrosh, 2014) that are also able to handle lexical simplification, since the translation model maps words from the non-simplified language to words of the simplified language.

The closest algorithm to ours is LexSiS (Bott et al., 2012; Saggion et al., 2013), that uses the Spanish OpenThesaurus and a corpus that contains 6,595 words of original and 3,912 words of manually simplified news articles. To the best of our knowledge this is the first and only lexical simplification algorithm for Spanish. Hence, we use it here as the state-of-the-art in our evaluation.

To the best of our knowledge, our approach is novel in using the Google Books Ngram corpus for the word context, Open Thesaurus for the synonyms, and real web frequencies for disambiguating synonym candidates. However, Google Ngram have been previously used to find synonyms, for instance to expand user queries by including synonyms (Baker and Lamping, 2011).

3 Method

CASSA (Context-Aware Synonym Simplification Algorithm) is a method that generates simpler synonyms of a word. It takes into consideration the context and the web frequency of the complex word for disambiguation.

3.1 Resources

Our method uses the following two resources:

– **Spanish OpenThesaurus** (version 2): The thesaurus is freely available[2] to be used with OpenOffice.org. This thesaurus provides 21,378 target words (lemmas) with a total of 44,348 different word senses for them. The following is a part of the thesaurus entry for *farol*, which is ambiguous, as it could mean *'lie'*, *'lamp'*, or the adjective *'flashy'*, among others.

```
farol
- embuste|mentira ('lie')
- luz|lámpara|fuego|bombilla ('lamp')
- ostentoso|jactancioso|farolero ('flashy')
```

– **Google Books Ngram Corpus for Spanish** (2012 edition): The corpus consists of n-grams and their usage frequency over time,[3] and is derived from 8,116,746 books, over 6% of all books ever published. The corpus has 854,649 volumes and 83,967,471,303 tokens (Lin et al., 2012).

3.2 Algorithm Description

First, we modified and enriched the Spanish OpenThesaurus and created our List of Senses. Instead of having a target word with different senses, we included the target word in each sense, and we kept a list of unique senses, including for each word its frequency in the Web using a large search engine index. The Spanish OpenThesaurus contains single-word and multi-word expressions. We only treated single-word units, which represent 98% of the cases, leaving out only 399 multi-word expressions, such as *de esta forma ('in this manner')*.

We lemmatized the words because the frequencies were all for inflected word forms as they appear in the Web while we were interested in the lemma frequencies for the synonyms, adding all the

[2] http://openthes-es.berlios.de

[3] http://books.google.com/ngrams

frequencies for each lemma. We take into account the frequency of the words, because previous studies have shown that less frequent words were found to be more challenging for people with and without the most frequent reading disorder, that is, dyslexia (Rello et al., 2013b).

Second, we use the 5-grams in the Google Books Ngram Corpus, where we use the third token of each 5-gram as our target words. The other tokens are the context of the target word. A context is considered valid if all words, including the target word, consist only of lowercase alphabetic characters, to filter for proper names, and is not a stop word, using a standard list of stop words in Spanish.

The lemmatized token is included in the list of target words only if it appears in our List of Senses. The remaining four tokens are the context, kept in a context list. We count the frequency of the target word appearing with that context in the corpus, as well as the frequency of the same context appearing with different target words. See two possible contexts for *noche* and *fortuna* in the examples below:

`era una` *noche* `oscura de` *('it was a dark night of')*
`de probar` *fortuna* `en el` *('to try fortune in the')*

Third, we define the complexity of a word using the relative frequency of the synonyms within the same sense in the List of Senses.

That is, our definition is tailored to web text. For this we use a parameter k such that if a word is k or more times less frequent than one or more of its synonyms, is considered a complex word. We used $k = 10$ as the default threshold to get that 27% of the words have simpler synonyms. We later show how this percentage changes with smaller k.

Finally, for each complex word and the contexts it appears in, we select as simpler synonym the most frequent synonym of the sense that appears most frequently for the n-gram corresponding to that $(word, context)$ pair. That is, to disambiguate the sense, our method uses the context where the target word appears. If the context is not found, we use the most frequent sense (baseline below).

4 Quality Evaluation

4.1 Comparison Points

Baseline: replaces a word with its most frequent synonym (presumed to be the simplest). This baseline has been broadly used in previous lexical simplification studies (Burstein et al., 2007; Carroll et al., 1999; Devlin and Unthank, 2006; Lal and Ruger, 2002), with the exception of (Bott et al., 2012) that used word frequency and length. It is very hard to beat this baseline for simpler synonyms generation. For instance, in SemEval task for English lexical simplification (Specia et al., 2012), only one system out of nine outperformed the frequency baseline. For the complexity part we use the same as our new method. That is, both algorithms consider the same words as complex.

Original	Él **contemplaba** en silencio aquella cruz.
	He was contemplating in silence that cross.
Baseline	Él **veía** en silencio aquella cruz.
	He was seeing in silence that cross.
LexSis	Él **consideraba** en silencio aquella cruz.
	He was considering in silence that cross.
CASSA	Él **miraba** en silencio aquella cruz.
	He was looking in silence that cross.

Figure 1: Example of substitutions performed by the three algorithms.

LexSiS: replaces a word with the output of the state-of-the-art method for Spanish lexical simplification (Bott et al., 2012).

4.2 Frequency Bands

We divided the selected complex words methods into two groups: [LOW], that includes very low frequency complex words, and [HIGH], that contains high frequency complex words. The word frequency ranges from 40 to 2,000 occurrences in Google Books Ngram Corpus for the [LOW] group, and from 2,001 to 1,300,000 for the [HIGH] group.

4.3 Evaluation Datasets

Main dataset: From a set of texts of scientific and literature genres (37,876 words), we randomly selected 20 [LOW] and 20 [HIGH] complex words within the sentence they appear, together with their corresponding candidate for substitution generated by the Baseline, LexSiS, and ours (a valid sentence must had at least 2 different substitutions). We had in total 120 simplification examples (composed by an original and a simplified sentence). Figure 1

shows a set of substitutions along with the original sentence.

Similar studies had smaller or slightly larger evaluation data sets. In Yatskar *et al.* (2010), 200 simplification examples were rated by six annotators (three native, three non-native speakers of English), although only the native speakers annotations were used for the results because they yielded higher inter-annotator agreement. Biran *et al.* (2011) used 130 examples that were judged by three annotators (native English speakers). In Bott *et al.* (2012), three annotators (native speakers of Spanish) rated 69 sentences each of the Spanish lexical simplification performed by LexSiS.

Complexity dataset: This dataset was created to evaluate the degree of complexity of the words selected by the algorithms. Using the same texts as before we extracted 40 random complex words according to LexSiS and 40 according to our method (recall that those also are complex for the baseline).

4.4 Judgment Guidelines

We presented the 200 examples in two different online tests, one for each evaluation dataset. The examples were presented in random order to three native Spanish speakers, frequent readers and non-authors of this paper. For the Main Dataset each annotator rated the simplification examples on two scales: Meaning Preservation –does the transformation preserve the original meaning of the sentence (yes/no); and Simplification –does the transformation result in a simpler sentence (more complex, same complexity or simpler). For the Complexity Dataset the annotators rated the examples on a three point scale (complex, neither complex or simple and simple).

We used Fleiss Kappa (Fleiss, 1971) to measure the inter-annotator agreement for multiple raters. We obtained a reasonable agreement: 0.46 for meaning preservation, 0.54 for simplicity ratings, and 0.41 for complexity. Hence, we have a moderate agreement (Landis and Koch, 1977), comparable with agreements in related literature (Biran et al., 2011; Bott et al., 2012; Yatskar et al., 2010).

4.5 Results

In Table 1 we show the results for the Main Dataset, where in the last column we consider only the simpler synonym substitutions (21 for Baseline, 16 for LexSiS, and 32 for ours) that preserved their meaning (agreement of 2 annotators). In this case, the simplicity performance improves for all the methods. In Table 2 we give the results for the two band frequencies for meaning preservation and simplicity. In the dataset our method overlaps in 15.79% with LexSiS candidates and in 65.79% with the baseline.

Type	**Mean.** (%)	**Simp.** (%)	**SimpSyn.** (%)
Baseline	49.17	60.00	65.08
LexSiS	42.50	35.83	45.83
CASSA	**74.17**	**70.83**	**77.08**

Table 1: Average percentage scores in meaning preservation (Mean.), simplification (Simp.), and simplification among the synonyms (SimpSyn.).

The results of LexSiS are consistent with the ones presented in Bott *et al.* (2012) for the news genre. In that study only for one dataset among three improved upon the frequency baseline in some measures (meaning preservation and global simplicity). As it can be observed from the frequency band results and the complexity measure, LexSiS offers better synonyms for high frequency and not for low frequency words. On the other hand, our method improves with low frequency complex words.

In the complexity evaluation, the prediction accuracy for complex words was only 13.33% for LexSis while was more than double, 34.17%, for ours (idem for the baseline as it used the same complexity criteria). The percentages for the complexity are low as the annotators were regular readers and non-impaired native speakers. For people with language difficulties or cognitive disabilities the accuracy should be higher because people which cognitive disabilities are more sensitive to text simplifications, such as people with Down Syndrome (Saggion et al., 2015), dyslexia (Rello and Baeza-Yates, 2014), or mild intellectual disabilities (Huenerfauth et al., 2009).

5 Coverage Evaluation

As not all possible contexts appear in Google Books Ngrams, we created a corpus made of 195 classic literature books from the 15th century to the 20th century of over 100Mb, to check the coverage of our

Type	Freq.	Meaning (%)	Simp. (%)
Baseline	[HIGH]	40.00	58.33
LexSiS	[HIGH]	41.67	36.67
CASSA	[HIGH]	**73.33**	**70.00**
Baseline	[LOW]	58.33	61.67
LexSiS	[LOW]	43.33	35.00
CASSA	[LOW]	**75.00**	**71.67**

Table 2: Average percentage scores by frequency band.

Case	$k = 10$	$k = 5$	$k = 2$	No k
Comp. words	27.16	38.80	54.24	100.00
Baseline (abs.)	24.07	35.32	50.14	84.43
Baseline (rel.)	88.62	91.03	92.04	84.43
Comp. contexts	27.95	40.03	55.84	100.00
CASSA (abs.)	2.67	4.14	6.44	12.14
CASSA (rel.)	9.55	10.34	11.53	12.14

Table 3: Coverage of the baseline and our method.

method. We included the books that are compulsory readings for secondary and high school in Spain. This corpus is composed by 16,495,885 tokens and 5,886,366 lexical words (without stop words, proper names and punctuation marks).[4]

The coverage of the Spanish Open Thesaurus in our corpus is 88.34%.[5] This is the maximum that any simplification algorithm that uses this resource can obtain. In Table 3 we present the coverage of the baseline and our method depending on the threshold k used to decide what a complex word is and hence a complex content, including the absolute percentages as well as the relative percentages with respect to the complex words or contexts.

For smaller k, the coverage of the baseline increases significantly being the maximum possible 84.43% when all words are considered complex (more than three times the default coverage). On the other hand, our method does not increase much the coverage as that is limited by the context coverage reaching a maximum of 12.14%, only 27% more than the default case ($k = 10$). This maximum, compared with the baseline is a bit more than 14% of the cases, implying that our method is equal to the baseline around 85% of the time.

[4]All the book titles used for this corpus are given in the Appendix of Rello (2014).

[5]Note that this only applies to the corpus used in the coverage, not for the evaluation dataset.

Considering the maximum possible coverage of the baseline and assuming that all non covered sentences contain complex words (most probable case), the simplicity performance of the baseline drops to 53.1% while for ours would be 54.2% (that is, a 2.1% improvement). This should improve if any of the resources used grow.

6 Conclusions and Future Work

Our method improves upon LexSiS and the baseline for all the measures. As we mentioned earlier, even beating the baseline is very hard and we improve upon both other methods by more than 50% in meaning preservation and is 11.8% better than the baseline, the second best, for simplicity. Compared to the results for English of Biran *et al.* (2011) using WordNet, our method has better simplicity scores for low frequency words as well as is in meaning preservation, although they are not directly comparable as different resources are used.

Although Open Thesaurus is available in nine languages and Google Books Ngrams in seven, there are only two languages in both sets: Spanish and German. Hence our method should be easily extended to German. Other languages are also possible with language resources, in particular English.

Simple task-specific bilingual word embeddings*

soegaard@hum.ku.dk

Abstract

We introduce a simple wrapper method that uses off-the-shelf word embedding algorithms to learn task-specific bilingual word embeddings. We use a small dictionary of easily-obtainable task-specific word equivalence classes to produce mixed context-target pairs that we use to train off-the-shelf embedding models. Our model has the advantage that it (a) is independent of the choice of embedding algorithm, (b) does not require parallel data, and (c) can be adapted to specific tasks by re-defining the equivalence classes. We show how our method outperforms off-the-shelf bilingual embeddings on the task of unsupervised cross-language part-of-speech (POS) tagging, as well as on the task of semi-supervised cross-language super sense (SuS) tagging.

1 Introduction

Using multi-layered neural networks to learn word embeddings has become standard in NLP (Turian et al., 2010; Guo et al., 2014). While there is still some controversy whether such methods are superior to older methods (Levy and Goldberg, 2014; Baroni et al., 2014), there is little doubt that continuous word representations can potentially solve some of the data sparsity problems inherent in NLP.

Most research on word embeddings has focused on learning representations for the words in a single language, making syntactically or semantically similar words appear close in the embedding space. Embeddings have been applied to many tasks, from named entity recognition (Turian et al., 2010) to dependency parsing (Bansal et al., 2014). It has furthermore been shown that weakly supervised embedding algorithms can also lead to huge improvements for tasks like sentiment analysis (Tang et al., 2014). In this work, we also use weak or distant supervision, relying on small dictionary seeds.

This paper, however, considers the problem of learning *bilingual* word embeddings, i.e., word embeddings such that similar words in two different languages end up close in the embedding space. Such bilingual word embeddings can potentially be used for better cross-language transfer of NLP models, as we show in this paper. Previous work on bilingual word embeddings have defined similar words as translation equivalents and evaluated embeddings in the context of document classification tasks (Klementiev et al., 2012; Kocisky et al., 2014). In this paper, we present a simple wrapper method to existing monolingual word embedding algorithms that can learn task-specific bilingual embeddings, e.g., for POS tagging, named entity recognition, or sentiment analysis. Our algorithm is simpler and performs better on the tasks where we could compare performance to existing algorithms. Also, we note that our approach, unlike existing algorithms (Klementiev et al., 2012), is as fast as learning monolingual embeddings.

Our contributions In this paper we introduce a new approach for learning bilingual word embeddings and revisit the task of unsupervised cross-language POS tagging (Das and Petrov, 2011). Our bilingual embedding model, which we call *Bilingual Adaptive Reshuffling with Individual Stochastic Alternatives* (BARISTA), takes two (non-parallel) corpora and a small dictionary as input. The dictio-

Denver, Colorado, May 31 – June 5, 2015.

nary is essentially a list of words in the two languages that are equivalent with respect to some task, e.g., English *car* and French *maison* ('house') are both nouns, and hence "equivalent" in POS tagging; English *clerk* and *chauffeur* are both persons, and hence "equivalent" in SuS tagging; *house* and *maison* are equivalent in machine translation. BARISTA has the advantage that it (a) is independent of the choice of embedding algorithm, (b) does not require parallel data, and (c) can be adapted to specific tasks by using appropriate dictionaries. We use the bilingual embeddings directly to train a target language POS tagger on source language training data. Instead of lexical features, we use the bilingual embeddings. We show our bilingual embedding method outperforms using off-the-shelf bilingual embeddings on this task, and that our system is competitive to state-of-the-art approaches for cross-language POS tagging. Finally, we show that the same embeddings also lead to significantly better performance in semi-supervised cross-language SuS tagging. The code will be made publicly available at `https://github.com/gouwsmeister/barista`.

2 Our approach

Standard monolingual neural language models are unsupervised models that train on raw text, learning word features that enable the model to predict the next word (the target) from a sequence of words (the context). In the process, the model learns to cluster words into soft equivalence classes (words that have similar distributions).

Several authors have proposed bilingual clustering and embedding algorithms based on parallel data (Täckström et al., 2012; Klementiev et al., 2012; Zou et al., 2013; Kocisky et al., 2014; Hermann and Blunsom, 2014b). These authors have all evaluated their embeddings on document classification and machine translation, and not yet structured prediction tasks like POS/SuS tagging or syntactic parsing. A notable exception is Hermann and Blunsom (2014a), who do not rely on parallel data and do not use word alignments, but they still use comparable data and sentence alignments, and they only evaluate their embeddings in document classification.

The assumption that large amounts of parallel data exists for a language pair of interest is sometimes too strong (Hermann and Blunsom, 2014a). On the other hand, we often have access to small samples of near-equivalences from knowledge bases of various forms. For example, for POS tagging, we often have access to small-to-sizeable crowd-sourced tag dictionaries (e.g. Wiktionary). For SuS tagging, which is the other example considered in this paper, we sometimes have access to WordNets or similar resources. If we have such resources for both source and target language, we can extract word-equivalences from them and use these to learn bilingual embeddings using our proposed method.

In this paper, we experiment with using *both* equivalences based on word alignments (e.g., *house* $\sim$ *maison*), and equivalences based on knowledge bases (e.g., *car* $\sim$ *maison*). Crucially, our approach to learning bilingual embeddings only assumes a small seed of equivalences, no parallel data. It then uses these to produce a set of mixed context-target pairs.

Our input is a source corpus C_s and a target corpus C_t, as well as a set of bilingual equivalences $R_\sim$. We begin by shuffling the concatenation of C_s and C_t. We then pass over this mixed corpus, and for each word w, if $\{w' \mid w, w' \in R_\sim\}$ is non-empty and of cardinality k, i.e., w is in the seed list of equivalences, we replace w with w' with probability $1/2k$. In other words, we flip a coin whether to replace w, and then randomly choose one of its equivalences as our replacement. For example, using translation equivalence classes, one could generate any of the following mixed texts from the English sentence *build the house*: *construire the house*, *build la maison*, *build the maison*, etc., or any other combination of English and French words with the English word order. With POS equivalence classes, any of the words in *build the house* can be replaced with words with overlapping syntactic categories, e.g., *build the voiture*.

3 Experiments

In our experiments we balance the source and target corpora, by subsampling from the bigger corpus. The vocabularies for all models are kept unrestricted, and result in around $1M$ words per language pair. We train with a window of 4 words on either side of the target word, using linear discounting of the initial learning rate of 0.1. These parameters were set on the Spanish POS data (see §3.2). We

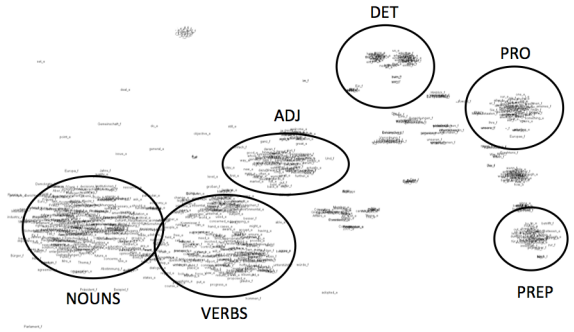

Figure 1: t-SNE visualization of BARISTA embeddings trained with POS classes.

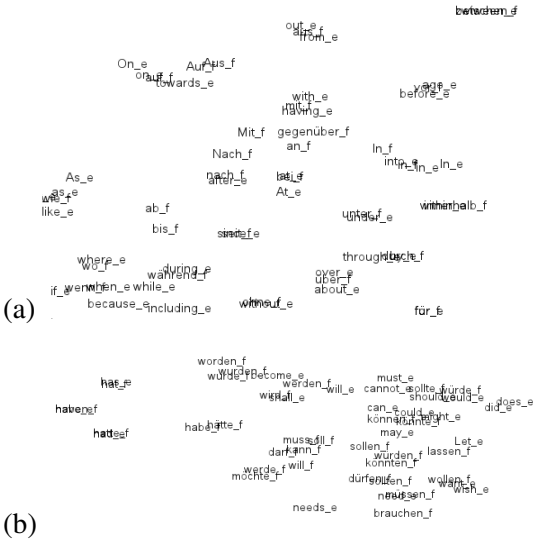

Figure 2: t-SNE visualizations of BARISTA embedding subspaces for (a) prepositions and (b) modals.

use the CBOW model in `word2vec` for training the word embeddings.[1]

Both our POS tagging evaluation datasets, as well as the Wiktionaries,[2] are mapped to Google's universal tagset (Petrov et al., 2011). We use the derived dictionaries for extracting bilingual POS equivalence classes. For SuS tagging, we only consider English-Danish and extract equivalence classes from Princeton WordNet and DanNet. For translation equivalents, we made use of Google Translate.

3.1 Qualitative Evaluation

In our main experiments (§3.2–3.3), we use data from Wikipedia, but we first present a qualitative evaluation of English-German bilingual embeddings learned from the smaller Europarl corpus.[3] Note that while this is parallel data, we do not exploit its parallel nature.

POS classes The embeddings learned from English-German Europarl using POS classes from Wiktionary were visualized using the t-SNE technique (Van der Maaten and Hinton, 2008), and are shown in Fig 1. The model learns to cluster words very distinctively by their POS tag. Monolingual word embedding models with short context windows typically cluster by POS, but here we see the same effect for bilingual embeddings, i.e. words from **both** languages with the same POS tag cluster together. Individual words, on the other hand, do not appear to retain the fine-grained relationships we normally observe in word embeddings (where similar words cluster closer together). The question thus is whether such embeddings are more or less useful for cross-language POS tagging than bilingual embeddings based on translation equivalencies.

Translation classes Next, we induced English-German bilingual embeddings on Europarl using translations obtained from Google Translate. We derived a dictionary of the top $20k$ most frequent words in English, translated into German. The embeddings are shown in Fig 2. The visualizations show that the models are able to extract very fine-grained bilingual relationships, and some clusters still correspond to POS.

3.2 Cross-language part-of-speech tagging

Next we evaluated the embeddings in the context of unsupervised cross-language POS tagging (Das and Petrov, 2011). The goal is to train a tagger – in our case, we use SEARN (Daume et al., 2009), following (Johannsen et al., 2014)– on labeled English data decorated with bilingual embeddings, and then evaluate the model on another target language. We use data from Danish, German, Spanish, Italian, Dutch, Portuguese, and Swedish. Training and test data, which are the same used in Das and Petrov (2011), were converted to use the same 12 universal parts of speech proposed by Petrov et al. (2011).

All results in this section were obtained by training bilingual embedding models on the publicly-

Avg	75.3	77.7	-	78	78.3	79	80.7	**83.6**	73.2

Table 1: Cross-language POS tagging. TC-Perc: type-constrained structured perceptron.

available, pre-tokenized versions of Wikipedia,[4] and then using the trained embeddings as features in a publicly available implementation of the structured perceptron.[5] We use ortographic features, as well as the embedding vector of the target word. In addition, we use type constraints from Wiktionary to prune the search lattice during decoding (Täckström et al., 2013). We scaled the embedding features in the same way as Turian et al. (2010) with scaling parameter 0.01 (set on Spanish POS data).

Our baseline method is a type-constrained structured perceptron with only ortographic features, which are expected to transfer across languages. We also experiment with using *random* embeddings, as well as the embeddings provided by Klementiev et al. (2012) (Klmtv).[6] Our results are displayed in Table 1. POS-X refer to X-dimensional BARISTA embeddings trained with POS equivalence classes, and Tr-X is X-dimensional BARISTA embeddings trained using translation equivalence classes. We note that random embeddings improve over our baseline, suggesting that the random features act as regularizers. The embeddings provided by Klementiev et al. (2012) seem to lead to worse performance than random embeddings, presumably because they capture mostly semantic (topic) similarity. We also compare our results to those reported by Berg-Kirkpatrick et al. (2010) (B-K) and Das and Petrov (2011) (DP), but note that their approaches require in-sample unlabeled data, and in the latter case, also parallel bilingual data.

While training with POS classes improves over the random baseline, training with translation equivalence classes gives even better performance. For both approaches, using more embedding features improves the performance (500 dimensions did not improve significantly over 300). Our model is generally better than Berg-Kirkpatrick et al. (2010) – but worse than Das and Petrov (2011).

3.3 Cross-language super sense tagging

Finally, we also tried using the BARISTA-embeddings for English-Danish (with parameters still set on Spanish POS) on *another* task, namely super sense tagging (Ciaramita and Altun, 2006). We train a system on a mixture of 1000 randomly sampled sentences from English SemCor[7]and 320 labeled Danish sentences (see below) and compare using bilingual embeddings trained with equivalence classes from English and Danish wordnets (WN-300), to embeddings trained using translation equivalence classes (Tr-300). We use 300 dimensional embeddings. We use a POS-sensitive most frequent sense baseline (MFS), as well as structured perceptron model trained only with ortographic and POS features, as well as MFS features (Johannsen et al., 2014). Our metric is a weighted average over F_1-scores for the (41) semantic classes. Note that using the knowledge base is superior to using translation equivalences, but both embeddings are superior to both our baselines. The Danish training (newswire only) and test data (six different domains) – is made publicly available.[8]

4 Conclusions

We presented a simple approach, BARISTA, to learning bilingual embeddings. BARISTA has the advantages that it (a) is independent of the choice of embedding algorithm, (b) does not require parallel data, and (c) can be adapted to specific tasks by using appropriate dictionaries. Our embeddings proved useful for cross-language POS/SuS tagging.

Sampling Techniques for Streaming Cross Document Coreference Resolution

Abstract

We present the first truly streaming cross document coreference resolution (CDC) system. Processing infinite streams of mentions forces us to use a constant amount of memory and so we maintain a representative, fixed sized sample at all times. For the sample to be representative it should represent a large number of entities whilst taking into account both temporal recency and distant references. We introduce new sampling techniques that take into account a notion of streaming discourse (current mentions depend on previous mentions). Using the proposed sampling techniques we are able to get a CEAFe score within 5% of a non-streaming system while using only 30% of the memory.

1 Introduction

Cross document coreference resolution (CDC) - identifying mentions that refer to the same entity across documents - is a prerequisite when combining entity specific information from multiple documents. Typically large scale CDC involves applying a scalable clustering algorithm to all the mentions. We consider *streaming* CDC, hence our system must conform to the streaming computational resource model (Muthukrishnan, 2005). Each mention is processed in bounded time and only a constant amount of memory is used. Honoring these constraints ensures our system can be applied to infinite streams such as newswire or social media.

Storing all the mentions in memory is clearly infeasible, hence we need to either compress mentions or store a *sample*. Compression is more computationally expensive as it involves merging/forgetting mention components (for example: components of a vector) whereas sampling decides to store or forget whole mentions. We investigate sampling techniques due to their computational efficiency. We explore which mentions should be stored while performing streaming CDC. A sample should represent a diverse set of entities while taking into account both temporal recency and distant mentions. We show that using a notion of streaming discourse, where what is currently being mentioned depends on what was previously mentioned significantly improves performance on a new CDC annotated Twitter corpus.

2 Related Work

There are many existing approaches to CDC (Bagga and Baldwin, 1998; Lee et al., 2012; Andrews et al., 2014). Few of them scale to large datasets. Singh et al. (2011) proposed a distributed hierarchical factor graph approach. While it can process large datasets, the scalability comes from distributing the problem. Wick et al. (2012) proposed a similar approach based on compressing mentions, while scalable it does not conform to the streaming resource model. The only prior work that addressed online/streaming CDC (Rao et al., 2010) was also not constrained to the streaming model. None of these approaches operate over an unbounded stream processing mentions in constant time/memory.

3 Entities in Streams

Streams like Twitter are well known as being real-time and highly bursty. Some entities are continually mentioned throughout the stream (eg: President Obama) whereas others burst, suddenly peak in popularity then decay (eg: Phillip Hughes, a cricketer who died following a bowling injury).

Capturing the information required to perform streaming CDC in constant space requires us to *sample* from the stream. For example we may consider only the most recent information (eg: the previous 24 hours worth of mentions). This may not be ideal as it would result in a sample biased towards bursting entities, neglecting the continually mentioned entities. We propose three properties that are important when sampling mentions from a stream of tweets:

- **Recency:** There should be some bias towards recent mentions to take into account the real-time nature of the stream. The set of entities mentioned one day is likely to be similar to the set of entities mentioned on the following day.
- **Distant Reference:** The temporal gap between mentions of the same entity can vary drastically, recency captures the small gaps though to capture the larger gaps older mentions should be stored. A mention should be correctly resolved if the last mention of the entity was either a day or a week ago.
- **Entity Diversity:** The sample should contain mentions of many entities instead of storing lots of mentions about a few entities. If the sample only contains mentions of the most tweeted about entity (the one that is bursting) it is impossible to resolve references to other entities.

These properties suggest we should take into account a notion of streaming discourse when sampling: mentions sampled should depend on the previous mentions (informed sampling).

4 Approach

We implemented a representative pairwise streaming CDC system using single link clustering. Mention similarity is a linear combination of mention text and contextual similarity (weighted 0.8 and 0.2 respectively) similar to Rao et al. (2010). Mention text similarity is measured using cosine similarity of character skip bigram indicator vectors and contextual similarity is measured using tf-idf weighted cosine similarity of tweet terms. The stream is processed sequentially: we resolve each mention by finding its nearest neighbor in the sample, linking the two mentions if the similarity is above the linking threshold.

5 Sampling Techniques

The sampling techniques we investigate are summarized below. Each technique has an insertion and removal policy that are followed each time a mention is processed. New sampling techniques are indicated by a star (*). The new sampling techniques require the nearest neighbor to be identified. As this is already computed during resolution hence the overhead of these new techniques is very low. Parameters particular to each sampling technique are noted in square brackets and are set using a standard grid search on a training dataset.

- **Exact:** To provide an upper bound on performance we forgo the constraints of the streaming resource model and store all previously seen mentions:

  Insertion: Add current mention to sample. **Removal:** Do nothing.

- **Window:** We sample a moving window of the most recent mentions (first in, first out). For example this technique assumes that if we are processing mentions on Monday with a window of approximately 24 hours all relevant entities were mentioned since Sunday.

  Insertion: Add current mention to sample. **Removal:** Remove oldest mention.

- **Uniform Reservoir Sampling (Uniform-R):** A uniform sample of previously seen mentions will capture a diverse set of entities from the entire stream - taking into account diversity and distant references. This can be achieved using a reservoir sample (Vitter, 1985). We assume each previously seen mention is equally likely to help resolve the current mention.

Insertion: Add current mention with probability p_i. **Removal:** If a mention was inserted choose a mention uniformly at random to remove.

Setting $p_i = k/N$ where k is the sample size and N is the number of items seen ensures the sample is uniform (Vitter, 1985).

- **Biased Reservoir Sampling (Biased-R):** To resolve both distant and recent references we should store recent mentions and some older mentions. An uninformed approach from randomized algorithms is to use an exponentially biased reservoir sample (Aggarwal, 2006; Osborne et al., 2014). It will store mostly recent mentions but will probabilistically allow older mentions to stay in the sample. For example this technique will sample lots of mentions from yesterday and less from the day before yesterday.

  Insertion: Add current mention with probability p_i **Removal:** If a mention was inserted choose a mention uniformly at random to remove.

  Unlike uniform reservoir sampling p_i is constant. A higher value puts more emphasis on the recent past. [p_i]

- **Cache*:** We should keep past mentions critical to resolving current references (an informed implementation of recency) and allow mentions to stay in the sample for an arbitrary period of time to help resolve distance references. For example if the same mention is used to resolve a reference on Saturday and Sunday it should be in the sample on Monday.

  Insertion: Add current mention to sample. **Removal:** Choose a mention that was not recently used to resolve a reference uniformly at random and remove it.

  When a mention is resolved we find its most similar mention in the sample, recording its use in a first in, first out cache of size n. The mention to be removed is chosen from the set of mentions not in the cache. We set n equal to a proportion of the sample size. [Proportion of mentions to keep]

- **Diversity*:** If we store fewer mentions about each distinct entity we can represent more entities in the sample. For example if news breaks that a famous person died yesterday the sample should not be full of mentions about that entity at the expense of other entities mentioned today.

  Insertion: Add current mention to sample. **Removal:** If there is a sufficiently similar mention in the sample remove it else choose uniformly at random to be removed.

  We remove the past mention most similar to the current mention, but only if the similarity exceeds a threshold. [Replacement Threshold]

- **Diversity-Cache (D-C)*:** We combine Diversity and Cache sampling.

  Insertion: Add current mention to sample. **Removal:** If there is a sufficiently similar mention in the sample remove it else remove a mention that has not recently been used to resolve a reference chosen uniformly at random.

  For this technique we first choose the replacement threshold then the proportion of mentions to keep. [Replacement threshold and proportion of mentions to keep]

6 Dataset

We collected 52 million English tweets from the 1% sample of all tweets sent over a 77 day period. We performed named entity recognition using Ritter et al. (2011). It is clearly infeasible for us to annotate all the mentions in the dataset. Hence we annotated a sample of the entities. As with most prior work we focused on person named entity mentions (of which there is approximately 6 million in the dataset).

To select the entities we first sampled two names based on how frequently they occur in the dataset: 'Roger' was chosen randomly from the low frequency names (between 1,000 and 10,000 occurrences) and 'Jessica' was chosen similarly from medium frequency names (10,000 to 100,0000 occurrences). We first annotated all mentions of the names 'Roger' and 'Jessica' discarding entities mentioned once. For the remaining entities we annotated all their mentions (not restricting to mentions that contained the words 'Roger' or 'Jessica').

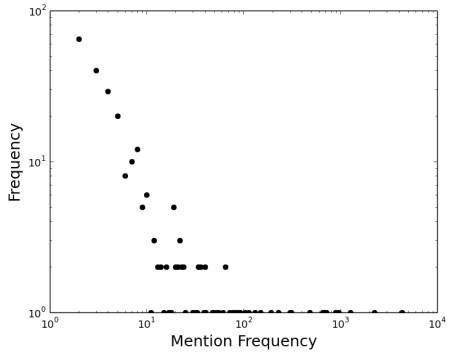

Figure 1: Mention Frequency Distribution.

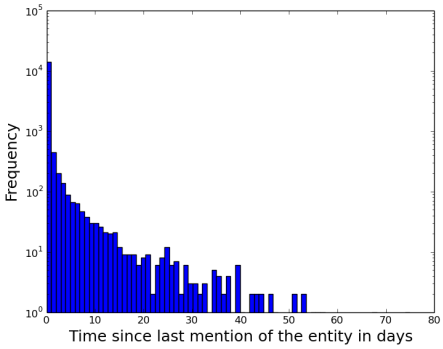

Figure 2: Distribution of time since previous mention of the same entity (gap). Each bar represents 24 hours.

This covers a diverse selection of people including: 'Roger Federer' (tennis player) and 'Jessie J' (the singer whose real name is 'Jessica Cornish') as well as less popular entities such as porn stars and journalists[1].

Some statistics of the dataset are summarized in table 1. We also plot the mention frequency (how often each entity was mentioned) distribution in figure 1 which shows a clear power law distribution similar to what Rao et al. (2010) reported on the New York Times annotated corpus. We show that recency and distant reference are important aspects by plotting the time since previous mention of the same entity (gap) for each mention in figure 2. The gap is often less than 24 hours demonstrating the importance of recency. There are also plenty of mentions with much larger gaps, demonstrating the need to be able to resolve distant references.

Source	Mentions	Entities	Wiki Page Exists
Roger	5,794	137	69%
Jessica	10,543	129	46%
All	16,337	266	58%

Table 1: Mention/entity counts and percentage of entities that have a Wikipedia page.

7 Experiments

As we are processing a stream we use a rolling evaluation protocol. Our corpus is split up into 11 constant sized temporally adjacent blocks each lasting approximately one week. Parameters are set using a standard grid search on one block then we progress to the next block to evaluate. The first block is reserved for setting the linking threshold prior to our rolling evaluation. We report the average over the remaining blocks. For all sampling techniques that have a randomized component we report an average over 10 runs.

As the sample size will have a large effect on performance we evaluate using various sample sizes. We base our sample size on the average amount of mentions per day (78,450) and evaluate our system with sample sizes of 0.25,0.5,1,2 times the average amount of mentions per day.

We evaluate using CEAFe (Luo, 2005), it is the only coreference evaluation metric that can be trivially adapted to datasets with a sample of annotated entities. With no adaption it measures how well a small amount of entities align with a system output over a large amount. To make the evaluation more representative we only use response clusters that contain an annotated mention. This scales precision and maintains interpretability. We determine if observed differences are significant by using a Wilcoxon signed-rank test with a p value of 5% over the 9 testing points. Results are shown in table 2.

- **Window:** This shows the performance that can be achieved by only considering recency.
- **Uniform Reservoir Sampling (Uniform-R):** This shows the performance achieved by using an uninformed technique to store a diverse set of older mentions.

[1]The annotations, including links to Wikipedia pages when available, can be downloaded from `https://sites.google.com/site/lukeshr/`.

Sample Size	Sampling Technique	CEAFe P	CEAFe R	CEAFe F

Mentions	Diversity ∗	55.2	75.2	63.7
	D-C ∗	**55.5**	**75.3**	**63.9**
≈600,000 Mentions	Exact	59.7	75.4	66.6

Table 2: CEAFe performance for various sample sizes and sampling techniques. ∗ indicates significant improvement over Window sampling. † indicates significant improvement over Diversity sampling

- **Biased Reservoir Sampling (Biased-R):** Uninformed sampling of older mentions is not sufficient to significantly improve performance.

- **Cache:** By using an informed model of recency we keep mentions critical to resolving references currently being tweeted resulting in a significant performance improvement.

- **Diversity:** By using an informed technique to increase the amount of distinct entities represented in the sample we significantly improve performance.

- **Diversity-Cache (D-C):** By combining the new sampling techniques we significantly improve performance. Once we have increased the amount of entities represented in the sample we are still able to benefit from an informed model of recency.

Using uninformed sampling techniques (reservoir sampling) does not result in a significant performance improvement over Window sampling, only informed sampling techniques show a significant improvement. As the sample size increases the performance difference decreases. With larger samples there is space to represent more entities and it is less likely to remove a useful mention at random.

8 Conclusion

We presented the first truly streaming CDC system, showing that significantly better performance is achieved by using an informed sampling technique that takes into account a notion of streaming discourse. We are able to get to within 5% of an exact system's performance while using only 30% of the memory required. Instead of improving performance by using an uninformed sampling technique and doubling the memory available, similar performance can be achieved by using the same amount of memory and a informed sampling technique. Further work could look at improving the similarity metric used, applying these sampling techniques to other streaming problems or adding a mention compression component.

Abstract

This paper describes a simple and principled approach to automatically construct sentiment lexicons using distant supervision. We induce the sentiment association scores for the lexicon items from a model trained on a weakly supervised corpora. Our empirical findings show that features extracted from such a machine-learned lexicon outperform models using manual or other automatically constructed sentiment lexicons. Finally, our system achieves the state-of-the-art in Twitter Sentiment Analysis tasks from Semeval-2013 and ranks 2nd best in Semeval-2014 according to the average rank.

1 Introduction

One of the early and rather successful models for sentiment analysis (Pang and Lee, 2004; Pang and Lee, 2008) relied on manually constructed lexicons that map words to their sentiment, e.g., *positive*, *negative* or *neutral*. The document-level polarity is then assigned by performing some form of averaging, e.g., majority voting, of individual word polarities found in the document. These systems show an acceptable level of accuracy, they are easy to build and are highly computationally efficient as the only operation required to assign a polarity label are the word lookups and averaging. However, the information about word polarities in a document are best exploited when using machine learning models to train a sentiment classifier.

In fact, most successful sentiment classification systems rely on supervised learning. Interestingly, a simple bag of words model using just unigrams and bigrams with an SVM has shown excellent results (Wang and Manning, 2012) performing on par or beating more complicated models, e.g., using neural networks (Socher et al., 2011).

Regarding Twitter sentiment analysis, the top performing system (Mohammad et al., 2013) from Semeval-2013 Twittter Sentiment Analysis task (Nakov et al., 2013) follows this recipe by training an SVM on various surface form, sentiment and semantic features. Perhaps, the most valuable finding is that sentiment lexicons appear to be the most useful source of features accounting for over 8 point gains in the F-measure on top of the standard feature sets.

Sentiment lexicons are mappings from words to scores capturing the degree of the sentiment expressed by a given word. While several manually constructed lexicons are made available, e.g., the MPQA (Wilson et al., 2005), the Bing and Liu (Hu and Liu, 2004) and NRC Emoticon (Mohammad and Turney, 2013) lexicons, providing high quality word-sentiment associations compiled by humans, still their main drawback is low recall.

For example, the largest NRC Emoticon lexicon contains only 14k items, whereas tweets with extremely sparse surface forms are known to form very large vocabularies. Hence, using larger lexicons with better recall has the potential of learning more accurate models. Extracting such lexicons automatically is a challenging and interesting problem (Lau et al., 2011; Bro and Ehrig, 2013; Liu et al., 2013; Tai and Kao, 2013; Yang et al., 2014; Huang et al., 2014). However, different from previous work our goal is not to extract human-interpretable lexicons but to use them as a source of features to improve the classifier accuracy.

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1397–1402,
Denver, Colorado, May 31 – June 5, 2015.

Following this idea, the authors in (Mohammad et al., 2013) use features derived from the lexicons to build a state-of-the-art sentiment classifier for Twitter. They construct automatic lexicons using noisy labels automatically inferred from emoticons and hashtags present in the tweets. The word-sentiment association scores are estimated using pointwise mutual information (PMI) computed between a word and a tweet label.

While the idea to model statistical correlations between the words and tweet labels using PMI or any other metric is rather intuitive, we believe there is a more effective way to exploit noisy labels for estimating the word-sentiment association scores. Our method relies on the idea of distant supervision (Marchetti-Bowick and Chambers, 2012). We use a large distantly supervised Twitter corpus, which contains noisy opinion labels (positive or negative) to learn a supervised polarity classifier. We encode tweets using words and multi-word expressions as features (which are also entries in our lexicon). The weights from the learned model are then used to define which lexicon items to keep, i.e., items that constitute a good sentiment lexicon. The scores for the lexicon items can be then directly used to encode new tweets or used to derive more advanced features. Using machine learning to induce the scores for the lexicon items has an advantage of learning the scores that are directly optimized for the classification task, where lexicon items with higher discriminative power tend to receive higher weights.

To assess the effectiveness of our approach, we reimplemented the state-of-the-art system ranking 1st in Semeval-2013 Twitter Sentiment Analysis challenge and used it as our baseline. We show that adding features from our machine-learned sentiment lexicon yields better results than any of the automatic PMI lexicons used in the baseline and all of them combined together. Our system obtains new state-of-the-art results on the SemEval-2013 message level task with an F-score of 71.32 – a 2% of absolute improvement over the previous best system in SemEval-2013. We also evaluate the utility of the ML lexicon on the five test sets from a recent Semeval-2014 task showing significant improvement over a strong baseline. Finally, our system shows high accuracy among the 42 systems participating in the Semeval-2014 challenge ranking 2nd best according to the average rank across all test sets.

2 Our model

We treat the task of sentiment analysis as a supervised learning problem, where we are given labeled data $\{(\mathbf{x}_i, \mathbf{y}_i)\}_{i=1}^{n}$ and the goal is to estimate a decision function $f(\mathbf{x}) \rightarrow \mathbf{y}$ that maps input examples to labels. In particular, we use a linear SVM model with the prediction function of the following form: $f = sign(\mathbf{w}^T\mathbf{x} + b)$, where the model weights $\mathbf{w}$ are estimated from the training set.

In the following we describe our approach to construct sentiment lexicons by learning an SVM model on the the distant supervised dataset. Finally, we describe our baseline model.

2.1 Distant Supervision for Automatic Lexicon Construction

Our sentiment lexicon consists of words and word sequences (we only use word unigrams and bigrams). To select lexicon items from a set of all unigrams and bigrams, we propose the following process:

1. Collect a large unlabelled corpus of tweets C.
2. For each tweet $t_i \in C$ use cues (hashtags or emoticons) to automatically infer its label (positive or negative): $y_i \in \{-1, +1\}$. For example, positive or negative emoticons, such as '**:**$-$)' or '**:** (' are good indicators of the general sentiment expressed by a tweet.
3. Extract unigram and bigram features to encode a tweet t_i into a feature vector $\mathbf{x}_i \in \mathbb{R}^{|L|}$, where the lexicon L is a set of unigrams and bigrams.
5. Train an SVM model $\mathbf{w} = \sum_{i=1..N} \alpha_i y_i \mathbf{x}_i$ on the encoded corpus $C = \{(\mathbf{x}_i, y_i)\}_{i=1}^{N}$. The model $\mathbf{w} \in \mathbb{R}^{|L|}$ is a dense vector whose components are obtained from a weighted combination of training examples $\mathbf{x}_i$ (support vectors) and their labels y_i (only those instances with $\alpha_i > 0$ contribute to the components of $\mathbf{w}$).
6. Given that the each component w^j of the model $\mathbf{w}$ directly corresponds to the lexicon entry $l_j \in L$ its raw score is used as a sentiment association score.

Different from manually constructed lexicons compiled by humans where each item is assigned

with an interpretable sentiment score, the scores in the automatic lexicon are learned automatically on a weakly supervised task. We use the weights from an SVM model whose weights are formed by the support vectors, i.e., the most difficult instances close to the decision boundary, hence most useful for the classification task. Additionally, due to its regularisation properties, SVM is known to select only the most robust features, which is important in the case of noisy labeled data. Hence, our method is a more principled way grounded in the statistical learning theory to exploit the noisy labels for estimating the word-sentiment association scores for the lexicon entries. Moreover, feature engineering with our lexicon appears to be more helpful (see Sec. 3) on a supervised task.

2.2 Baseline model

We re-implement the state-of-the-art NRC model from (Mohammad et al., 2013), which ranked 1st in the Semeval-2013, and use it as our baseline. This system relies on various n-gram, surface form and lexicon features. Briefly, we engineered the following feature sets:[1]

- **Word and character grams**: we use 1,2,3 n-grams for words and 3,4,5 n-grams for character sequences;
- **Negation**: the number of negated contexts – a span of words between a negation word (*not, never*), and a punctuation mark.
- **Lexicons**: given a word, we lookup its sentiment polarity score in the lexicon: $score(w)$. The following *aggregate* features are produced for the lexicon items found in a tweet: the total count, the total sum, the maximal score and the score of the last token. These features are produced for unigrams, bigrams, each part-of-speech tag, hashtags and all-caps tokens.
- **Other**: number of hashtags, capitalized words, elongated words, positive and negative emoticons, punctuation.

3 Experiments

In the following experiments our goal is to assess the value of our distant supervision method to automatically extract sentiment lexicons. We compare its performance with other automatically constructed lexicons extracted from large Twitter corpora, e.g., auto lexicons built using the PMI approach from (Mohammad et al., 2013).

Negative	Positive
(disappointing,)	(no, problem)
(depressing,)	(not, bad)
(bummer,)	(not, sad)
(sadly,)	(cannot, wait)
(passed, away)	(no, prob)

Table 1: Lexicon items learned from Emoticon140 corpus with top negative and positive scores.

3.1 Lexicon learning

We extract our lexicon from a freely available Emoticon140 Twitter corpus (Go et al., 2009), where the sentiment labels are automatically inferred from emoticons contained in a tweet[2]. The major advantage of such corpora is that it is easy to build as emoticons serve as fairly good cues for the general sentiment expressed in a tweet, thus they can be used as noisy labels. Hence, large datasets can be collected without incurring any annotation costs.

Tweets with positive emoticons, like '`:)`', are assumed to be positive, and tweets with negative emoticons, like '`:(`', are labeled as negative. The corpus contains 1.6 million tweets with equal distribution between positive and negative tweets. We use a tokeniser from the CMU Twitter tagger (Gimpel et al., 2011) extracting only unigrams and bigrams[3] to encode training instances. To make the extraction of word-sentiment association weights from the model straight-forward, we ignore neutral labels thus converting the task to a binary classification task. We use LibLinear (Fan et al., 2008) with L2 regularization and default parameters to learn a model. Preprocessing, feature extraction and learning is very fast taking only a few minutes. As the number of unique unigrams and bigrams can be very large and we would like to keep our sentiment lexicon rea-

[1] our baseline system, lexicon and the code to construct it are freely available at: `https://github.com/yyy`

[2] unfortunately, the corpus to build the NRC Hashtag lexicon (Mohammad et al., 2013) is not freely available due to Twitter data distribution policies.

[3] Adding tri-grams yielded a very minor improvement, yet the size of the dictionary exploded, so to keep the size of the dictionary relatively small we use only uni- and bi-grams.

Dataset	Size	Pos	Neg.	Neu.
Train'13	9,728	38%	15%	47%
Dev'13	1,654	35%	21%	45%
Twitter'13	3,813	41%	16%	43%
SMS'13	2093	24%	19%	58%
Twitter'14	1,853	53%	11%	36%
Sarcasm'14	86	38%	47%	15%
LiveJournal'14	1,142	37%	27%	36%

Table 2: Datasets.

sonably small, we filter entries with small weights. In particular, we found that selecting items with a weight greater than $1e-6$ did not cause any drop in accuracy, while the resulting lexicon is reasonably compact — it contains about 3 million entries.

Table 1 gives an example of top 10 lexicon entries with highest positive and negative scores. Interestingly, one would expect to find words such as *amazing*, *cool*, etc. as having the highest positive sentiment score. However, an SVM model assigns higher scores to bigrams containing negative words *problem, bad, worries*, to outweigh their negative impact. This helps to handle the inversion of the sentiment due to negations.

It is important to note that our goal is different from constructing sentiment lexicons that are interpretable by humans, e.g., manually built lexicons, but, similar to (Mohammad et al., 2013), we build automatic lexicons to derive highly discriminative features improving the accuracy of our sentiment prediction models.

3.2 Setup

Task. We focused on the Twitter Sentiment Analysis (Task 2) from Semeval-2013 (Nakov et al., 2013) and its rerun (Task 9) from Semeval-2014 (Rosenthal et al., 2014). Both tasks include two subtasks: an expression-level and a message-level subtasks. Being more general, we focus only on predicting the sentiment of tweets at the message level, where given a tweet, the goal is to classify whether it expresses *positive*, *negative*, or *neutral* sentiment.

Evaluation. We used the official scorers from the Semeval 2013 & 2014, which compute the average between F-measures for the positive and negative classes.

Data. We evaluated our models on both Semeval-2013 and Semeval-2014 tasks with 44 and 42 participating systems correspondingly. The Semeval-2013 task released the training set containing 9,728 tweets, dev and two test sets: *Twitter'13* and *SMS'13*. We train our model on a combined train and dev sets[4]. The Semeval-2014 re-uses the same training data and systems are evaluated on 5 test sets: two test sets from Semeval-2013 and three new test sets: *LiveJournal'14*, *Twitter'14* and *Sarcasm'14*. The datasets are summarized in Table 3.1.

n-grams	Manual			PMI		ML		Twitter'13
	M	B	N	hash	s140	raw	agg	
•								63.53
•	•							64.96 (+1.43)
•		•						66.74 (+3.21)
•			•					64.21 (+0.68)
•	•	•	•					67.44 (+3.91)
•	•	•	•	•				68.47 (+4.94)
•	•	•	•		•			69.08 (+5.55)
•	•	•	•	•	•			70.06 (+6.53)
•	•	•	•			•		69.47 (+5.94)
•	•	•	•				•	69.89 (+6.36)
•	•	•	•			•	•	70.93 (+7.40)
•	•	•	•	•	•	•	•	**71.32** (+7.79)
best Semeval'13 system								69.06

Table 3: Results on Semeval-2013 test set. Used feature sets: n-grams; features from *Manual* lexicons using MPQA (M), BingLiu (B) and NRCEmoticon (N) lexicons; PMI lexicon extracted from NRC-hashtag and Emoticon140 (s140) datasets; our ML lexicon using *raw* and aggregate (*agg*) features. The numbers in parenthesis indicate absolute improvement w.r.t. baseline *n-grams* model.

3.3 Results

We report the results on two runs of the Twitter Sentiment Analysis challenge organized by Semeval from 2013 and 2014.

3.3.1 Semeval-2013

The *n-grams* model includes word and character n-grams, negation and various surface form features as described in Section 2. We use this feature set as a yardstick to assess the value of adding features

[4]While in the real setting it is also possible to include additional weakly labeled data, e.g. Emoticon140, for training a model, we stick to the **constrained** setting of the Semeval tasks, where training is allowed only on the train and dev sets.

from various lexicons. Firstly, we note that using three manual lexicons: MPQA (M), BingLiu (B), and NRC (N) results in almost 4 points of absolute improvement. Notably, among all manual lexicons the *BingLiu* lexicon accounts for the largest improvement. Next, we explore the value of automatically generated lexicons using PMI scoring extracted from two large Twitter datasets: Emoticon140 (s140) and hashtag (hash). Both lexicons rely on PMI scoring formula to derive word-sentiment association scores. Adding features from these automatically generated lexicons results in further improvement over the *n-grams* feature set and yields F-score: 70.06.

Next, we explore the value of features derived from our ML based lexicon. We use the lexicon in two modalities: (i) including the raw scores (raw) of each lexicon entry (unigrams and bigrams) found in the given tweet; (ii) deriving aggregate features (*agg*) from the *raw* scores as described in Sec. 2; and (iii) using both. We note that the features from our ML-based lexicon yield superior performance to any of the PMI lexicons providing at least 2% gains and is even better when the two PMI lexicons are combined. Finally, adding the ML-based lexicon on top of the models including manual and auto lexicons provides the new state-of-the-art result on Semeval-2013 with an improvement of almost 8 points w.r.t. to the *basic* model. Our model achieves the score of 71.32 vs. 69.06 for the previous best system.

3.3.2 Semeval-2014

Table 4 shows that adding features from our ML-based vocabulary provides a substantial improvement over the previous best NRC system on 4 out of 5 test sets. Interestingly, we observe a strong drop on the Sarcasm'14 test set. One possible reason is that the labels for Emoticon140 corpus are inferred automatically using emoticons, which may strongly bias our model to incorrectly predict sentiment for those tweets containing sarcasm. With more than 40 systems participating in Semeval-2014 challenge, we note that the majority of systems perform well only on few test sets at once while failing on the others[5]. The performance of our system is rather high across all the test sets with an average rank of 3.4, which is the second best result in Semeval-2014 message-level task (the best system is from the NRC team with an ave-rank 2.4, whereas the closest follow up system has an ave-rank 6).

[5] http://alt.qcri.org/semeval2014/task9/

Table 4: Semeval-2014. Numbers in parenthesis is the absolute rank of a system on a given test set. Bold scores compares using our ML lexicon on top of the NRC system. Results marked with † are statistically significant at $p > 0.05$ (via the paired t-test).

System	NRC	NRC + ML lex.	best score
LJournal'14	75.28 (1)	**76.54**† (1)	74.84
SMS'13	66.86 (5)	**67.20** (5)	70.28
Twitter'13	70.06 (5)	**71.32**† (2)	72.12
Twitter'14	68.71 (6)	**70.51**† (2)	70.96
Sarcasm'14	**59.20** (1)	55.08 (7)	58.16
ave-rank	3.8	3.4 (2)	2.4 (1)

4 Conclusions

We demonstrated a simple and principled approach grounded in machine learning to construct sentiment lexicons. We show that using off-the-shelf machine learning tools to automatically extract lexicons greatly outperforms other automatically constructed lexicons that use pointwise mutual information to estimate sentiment scores for the lexicon items.

We have shown that combining our machine-learned lexicon with the previous best system yields state-of-the-art results in Semeval-2013 gaining over 2 points in F-score and ranking our system 2nd according to the average rank over the five test sets of Semeval-2014. Finally, our ML-based lexicon shows excellent results when added on top of the current state-of-the-art NRC system. While our experimental study is focused on Twitter, our method is general enough to be applied to sentiment classification tasks on other domains. In the future, we plan to experiment with constructing ML lexicons from larger Twitter corpora also using hashtags.

Recently, deep convolutional neural networks for sentence modelling (Kalchbrenner et al., 2014; Kim, 2014) have shown promising results on several NLP tasks. In particular, (Tang et al., 2014) showed that learning sentiment-specific word embeddings and using them as features can boost the accuracy of existing sentiment classifiers. In the future work we plan to explore such approaches.

Abstract

We present a large-scale Native Language Identification (NLI) experiment on new data, with a focus on cross-corpus evaluation to identify corpus- and genre-independent language transfer features. We test a new corpus and show it is comparable to other NLI corpora and suitable for this task. Cross-corpus evaluation on two large corpora achieves good accuracy and evidences the existence of reliable language transfer features, but lower performance also suggests that NLI models are not completely portable across corpora. Finally, we present a brief case study of features distinguishing Japanese learners' English writing, demonstrating the presence of cross-corpus and cross-genre language transfer features that are highly applicable to SLA and ESL research.

1 Introduction

Native Language Identification, the task of determining the native language (L1) of an author based on a second language (L2) text, has received much attention recently. Much of this is motivated by Second Language Acquisition (SLA) as NLI, often accomplished via machine learning methods, can be used to study language transfer effects.

Most NLI research hitherto has focused on identifying linguistic phenomena that can capture transfer effects, with little effort towards interpreting discriminant features. Some researchers have now shifted their focus to developing data-driven methods for the automatic extraction and ranking of linguistic features that distinguish specific L1s (Swanson and Charniak, 2014).

Such methods could be used not only to confirm existing SLA hypotheses, but also to create new ones. This hypothesis formulation is an inherently difficult problem requiring copious amounts of data. Contrary to this requirement, researchers have long noted the paucity of suitable corpora[1] for this task (Brooke and Hirst, 2011). This is one of the research issues addressed by this work.

Furthermore, deriving SLA hypotheses from a single corpus may not be entirely useful for SLA research. Many variables like genre and topic are constant within a corpus, restricting the validity of such cross-validation studies to those dimensions.

An alternative, potentially more helpful approach, is to identify transfer features that reliably distinguish an L1 across multiple corpora of differing genres and domains. A cross-corpus methodology may be a more promising avenue to finding features that generalize to diverse text sources, but requires additional large corpora. It is also a more realistic approach, and one we pursue in this work.

Accordingly, the aims of the present work are to: (1) test a large new corpus suitable for NLI, (2) perform within-corpus evaluation with a comparative analysis against equivalent corpora, (3) perform cross-corpus evaluation to determine the efficiency of corpus independent features and (4) analyze the features' utility for SLA & ESL research.

2 Background and Motivation

NLI work has been growing in recent years, using a wide range of syntactic and more recently, lexical features to distinguish the L1. A detailed review of NLI methods is omitted here for reasons of space, but a thorough exposition is presented in the report from the very first NLI Shared Task that was held in 2013 (Tetreault et al., 2013).

Most English NLI work has been done using two corpora. The *International Corpus of Learner En-*

[1] An ideal NLI corpus should have multiple L1s, be balanced by topic, proficiency, texts per L1 and be large in size.

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1403–1409,
Denver, Colorado, May 31 – June 5, 2015.

glish (Granger et al., 2009) was widely used until recently, despite its shortcomings[2] being widely noted (Brooke and Hirst, 2012a). More recently, TOEFL11, the first corpus designed for NLI was released (Blanchard et al., 2013). While it is the largest NLI dataset available, it only contains argumentative essays, limiting analyses to this genre.

Research has also expanded to use non-English learner corpora (Malmasi and Dras, 2014a; Malmasi and Dras, 2014c). Recently, Malmasi and Dras (2014b) introduced the Chinese Learner Corpus for NLI and their results indicate that feature performance may be similar across corpora and even L1-L2 pairs. This is a claim that we will test here.

NLI is now also moving towards using features to generate SLA hypotheses. Swanson and Charniak (2014) approach this by using both L1 and L2 data to identify features exhibiting non-uniform usage in both datasets, creating lists of candidate transfer features. Malmasi and Dras (2014d) propose a different method, using linear SVM weights to extract lists of overused and underused linguistic features for each L1 group.

Cross-corpus studies have been conducted for various data-driven NLP tasks, including parsing (Gildea, 2001), WSD (Escudero et al., 2000) and NER (Nothman et al., 2009). While most such experiments show a drop in performance, the effect varies widely across tasks, making it hard to predict the expected drop for NLI. We aim to address this question using large training and testing data.

3 EFCamDat: A new corpus for NLI

The EF Cambridge Open Language Database (EFCAMDAT) is an English L2 corpus that was released recently (Geertzen et al., 2013). It is composed of texts submitted to *Englishtown*, an online school used by thousands of learners daily.

This corpus is notable for its size, containing some 550k texts from numerous nationalities, making it an ideal candidate for NLI research. While the TOEFL11 is made of argumentative essays, EFCAMDAT has a much wider range of genres including writing emails, descriptions, letters, reviews, instructions and more.

In this work we present an application of NLI to this new data. As some of the texts can be short, we use the methodology of Brooke and Hirst (2011) to concatenate and create texts with at least 300 tokens, much like the TOEFL11.

[2]The issues exist as the corpus was not designed for NLI.

Common	Arabic, Chinese, French, German, Italian, Japanese, Korean, Spanish, Turkish
EFCAMDAT	Portuguese, Russian
TOEFL11	Hindi, Telugu

Table 1: The 11 L1 classes extracted from the EFCAMDAT corpus, compared to the TOEFL11 corpus. The first 9 classes are common between both.

From the data we choose 850 texts from each of the top 11 nationalities. This subset of EFCAMDAT thus consists of 9,350 documents totalling approximately 3.2m tokens. This is an average of 337 tokens per text, close to the 348 tokens per text in TOEFL11.

This also provides us with the same number of classes as the TOEFL11, as shown in Table 1, facilitating direct performance comparisons. The table also indicates the 9 classes common to both corpora. This subset of common classes enables us to perform large-scale cross-corpus validation experiments that have not been possible until now.

4 Methodology

We use the standard NLI classification approach. A linear Support Vector Machine is used for classification and feature vectors are created using relative frequency values. We also combine features with a mean probability ensemble classifier (Polikar, 2006, §4.2) using the probabilities assigned to each class. We compare results with a random baseline and the oracle baseline used by Malmasi et al. (2015). The oracle correctly classifies a text if any ensemble member correctly predicts its label and defines an upper-bound for classification accuracy. We avoid using lexical features as EFCAMDAT is not topic balanced. We extract the following topic-independent feature types:

Function words are topic-independent grammatical words such as prepositions which indicate the relations between other words. They are known to be useful for NLI. Frequencies of 400 English function words[3] are extracted as features. We also apply function word bigrams as described in Malmasi et al. (2013).

Context-free Grammar Production Rules are extracted after parsing each sentence. Each rule is a classification feature (Wong and Dras, 2011) and captures global syntactic patterns.

[3]Like previous work, this also includes stop words, which we sourced from the Onix Text Retrieval Toolkit: http://www.lextek.com/manuals/onix/stopwords1.html

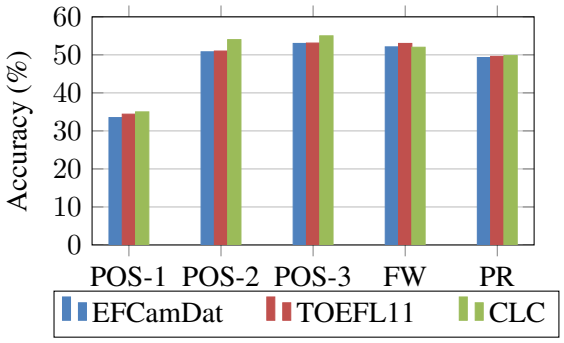

Figure 1: Comparing EFCAMDAT feature performance with the TOEFL11 and Chinese Learner Corpus (CLC). POS-1/2/3: POS uni/bi/trigrams, FW: Function Words, PR: CFG Productions

Part-of-Speech (POS) n-grams of size 1–3 are extracted as features. They capture preferences for word classes and their localized ordering patterns.

5 Within-Corpus Evaluation

Our first experiment applies 10-fold cross-validation within the corpus to assess feature efficacy. The results are shown in the first column of Table 2.

All features perform substantially higher than the 9% baseline. POS trigrams are the best single feature (53%), suggesting there exist significant inter-class syntactic differences. Next, we also combined all features using a classifier ensemble, which has been shown to be helpful for NLI (Tetreault et al., 2012). This yields the best accuracy of 65% against an upper-bound of 87% set by the oracle.

We also compare these results to those from the TOEFL11 and Chinese Learner Corpus (CLC). As shown in Figure 1, we find that feature performance is nearly identical across corpora. Consistent with the results in Malmasi and Dras (2014b), this seems to suggest an invariant degree of transfer across different learners and L1-L2 pairs.

Figure 2 shows the confusion matrix. German is the most correctly classified L1, while the highest confusion is between Japanese–Korean, followed by Spanish–Portuguese and French–Italian. This is not surprising given their syntactic similarity as well as being typologically related in case of the latter two.

6 Large-scale Cross-Corpus Evaluation

Our second experiment tests the cross-corpus efficacy of the features by training on EFCAMDAT and testing on TOEFL11,[4] and *vice versa*. As the corpus texts are from different genres, this approach enables us to test the cross-corpus and cross-genre generalizability of our features.

[4]The 9 common classes discussed in §3 are used.

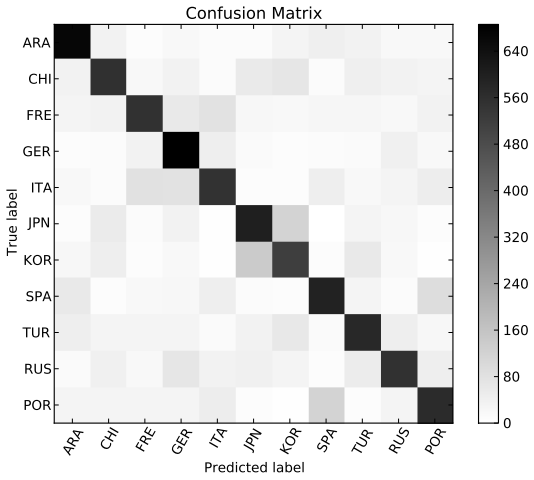

Figure 2: EFCAMDAT 11-class confusion matrix.

Arabic	German	Japanese
Saudi	Germany	Japan
Arabia	Berlin	Tokyo
Arabic	Hamburg	Osaka
Mohammed	Frankfurt	Nagoya
Ali	Munich	Yen

Table 3: Selected items from the top 15 most discriminative words for Arabic/German/Japanese.

Results are shown in the second and third column of Table 2. While lower than the cross-validation results which were on 11 classes *vs* 9 here, the results are far greater than the baseline. The accuracy for training on EFCAMDAT and testing on TOEFL11 is higher (33.45%) than the other way around (28.42%), even though TOEFL11 is the larger corpus. This is possibly because EFCAMDAT has numerous genres while TOEFL11 does not. The cross-corpus oracle is also over 20% lower, despite an increase in the random baseline, showing some features are not portable across corpora. Training on TOEFL11 yields a lower oracle.

Although a performance drop was expected due to the big genre differences, results suggest the presence of some corpus-independent features that capture cross-linguistic influence. However, they also suggest that a large portion of the features helpful for NLI are genre-dependent.

Previously, word n-grams have been applied in small-scale cross-corpus studies and found to be the best feature (Brooke and Hirst, 2012b). Word n-grams have been previously used in NLI and are believed to capture lexical transfer effects which have been previously noted by researchers and linguists

Classification Feature	EFCAMDAT 10-fold CV	Train EFCAMDAT Test TOEFL11	Train TOEFL11 Test EFCAMDAT
Random Baseline	9.09	11.11	11.11
Oracle Baseline	86.84	64.92	62.43
Function Word unigrams	52.01	27.14	21.77
Function Word bigrams	47.92	29.21	22.63
Production Rules	49.12	30.73	23.91
Part-of-Speech unigrams	33.21	23.42	16.71
Part-of-Speech bigrams	50.43	31.02	23.09
Part-of-Speech trigrams	53.05	32.38	25.55
Ensemble (All features)	**64.95**	**33.45**	**28.42**
Word unigrams	–	41.82	42.48

Table 2: Classification accuracy (%) for our within- and cross-corpus experiments.

(Odlin, 1989). The effects are mediated not only by cognates and word form similarities, but also semantics and meanings. Other NLI studies have also provided empirical evidence for this hypothesis (Malmasi and Cahill, 2015).

However, issues stemming from topic bias[5] have also limited their use in NLI (Brooke and Hirst, 2012a), although use could be justified in cross-corpus scenarios due to the lower risk of topic-bias across corpora. We applied word unigrams to our cross-corpus experiment, achieving an accuracy of 41.8% for training on the EFCAMDAT and testing on TOEFL11 and 42.5% for the reverse setting. These are the best results in this setup.

To check for any topic-bias effects, we inspected the most discriminative features for each L1 class using the method proposed by Malmasi and Dras (2014d). This analysis revealed that the top features were mostly cultural and geographic references related to the author's country. Table 3 contains words selected from the top 15 most discriminative features found in the cross-corpus experiment for three L1s. We observe that most of these are toponyms or culture-specific terms such as names and currencies. These results reveal another potential issue with using lexical features. Although this isn't topic-bias, the features do not represent genuine linguistic differences or lexical transfer effects between L1 groups. In practical scenarios, this could also make NLI systems vulnerable to content-based manipulation. The exclusion of proper nouns is one way to combat this.

7 A Case Study of Japanese Learners

To demonstrate the utility of this cross-corpus approach we present a brief case study of features that characterize English writings of Japanese learners. We extracted the most discriminative cross-corpus features of Japanese learner texts using the method of Malmasi and Dras (2014d).

Table 4 contains the top production rule features. The first rule shows a preference for having a subordinate clause before the main clause. The next two rules show that Japanese learners tend to begin their sentences with adverbs and conjunctions. This preference for placing information at the start of sentences is most likely rooted in the fact that Japanese is an SOV head-final language[6] where dependent clauses generally precede the main clause and relative clauses precede the noun they modify. The influence of this head-direction parameter on English acquisition has been previously investigated (Flynn, 1989).

In contrast, it is quite common for the main clause to precede the subordinate clause in English. Other research has also noted that Japanese speakers have a "long before short" preference[7] (Yamashita and Chang, 2001). This is also evidence by another highly discriminative rule for this L1: `S → S , CC S .`

Japanese writers also seem more likely to split longer arguments into multiple shorter sentences, as suggested by our third production rule. It has also been noted that Japanese and Korean sentences in the TOEFL11 have the shortest mean length (Cimino et al., 2013, p. 211).

Turning to POS trigrams, the POS tag sequence `VBZ JJ NN` is strongly linked to Japanese learn-

[5] Due to correlations between text topics and L1 classes.

[6] Contrasted with English which is SVO.

[7] This refers to how conjuncts are ordered: short-before-long in English, long-before-short in Japanese. Our findings suggest that Japanese writers transfer this internal order-preference into their L2 English writing.

Production Rule	Example Sentence
S → SBAR , NP VP .	If you have spare time, you'll think of shopping.
S → ADVP , NP VP .	Therefore, the online studying system is really convenient for me.
S → CC NP VP .	But I'm not good at English. / But it wasn't comfortable and cosy.

Table 4: The top 3 cross-corpus production rule features for Japanese L1 with example lexicalizations.

Overuse	Underuse
however	perhaps
though	somebody
cannot	everything
therefore	behind
such	upon
into	between

Table 5: English function words overused and underused by Japanese learners in their writing.

ers. It represents a third person verb, such as *is* or *has* followed by an adjective and a noun. A brief analysis reveals that this is commonly observed in Japanese learner texts because the sequence is missing a determiner before the noun phrase.[8] This likely stems from the fact that Japanese learners have difficulty with English articles, often failing to use them (Butler, 2002; Thomas, 1989). Its prominence in the ranked list shows that it is a common issue across distinct learners and genres.

The top overused and underused function words are listed in Table 5. The words *however* and *therefore* are highly relevant; Japanese writers often use these to start sentences, possibly due to the above-mentioned production rules. The word *into* is also predictive and seems to be used in places where *in* is more appropriate. This may be due to the Japanese words for *in*, *to* and *into* being similar.[9] In the underuse list, *perhaps* is never used by Japanese learners. Other words here are low-frequency in Japanese L1 texts in both corpora.

8 Discussion

In this work we presented the first application of one of the largest and newest publicly available learner corpora to NLI. Cross-validation experiments mirrored the performance of other corpora and demonstrated its utility for the task. We believe this will motivate future work by equipping researchers with a large-scale corpus that is highly suitable for NLI.

Next, results from the largest cross-corpus NLI evaluation to date were presented, providing strong evidence for the presence of transfer features that generalize across learners, corpora, topics and genres. However, the fact that the cross-corpus accuracy is lower than within-corpus cross-validation highlights that a large portion of the features are highly corpus-specific. This suggests that NLI models are not entirely portable across corpora. Practical applications of NLI to forensic linguistics or SLA must be robust to input from numerous sources and their associated variations, and this finding highlights the need for a cross-corpus approach.

To demonstrate how this methodology could be used for SLA, an examination of the cross-corpus features effective in classifying texts of Japanese learners was conducted. Through feature analysis, we were able to link these patterns of syntactic productions, article use and lexical choices to L1-based SLA hypotheses.

Our output lists hundreds of features, not included or examined here due to space limitations, whose analysis would allow SLA researchers to explore and generate new hypotheses, specially by combining multiple syntactic feature types.

A shortcoming here is that we did not balance texts by proficiency to match the TOEFL11. We expect that a more even sampling of proficiency or using proficiency-segregated models will yield higher accuracy and features more representative of students at each proficiency level.

Directions for future work are manifold. The next phase of this research will focus on developing tools to derive and browse ranked lists of the most discriminative cross-corpus features, which will then be used to formulate SLA hypotheses. Subject to availability of data, this could be expanded to a multiple cross-corpus methodology, using three or more corpora. Its application to other languages besides English is also of interest.

NLI is a young but rapidly growing field of research and this study is but a first step in shifting efforts towards a more interpretive approach to the task. We hope that the new dataset and directions presented here will galvanize future work.

[8] Example lexicalizations from EFCAMDAT include "She *wears black top*" and "This area *is famous park*."

Unediting: Detecting Disfluencies Without Careful Transcripts

Victoria Zayats, Mari Ostendorf and Hannaneh Hajishirzi
Electrical Engineering Department
University of Washington
Seattle, WA, USA
[vzayats, ostendor, hannaneh]@u.washington.edu

Abstract

Speech transcripts often only capture semantic content, omitting disfluencies that can be useful for analyzing social dynamics of a discussion. This work describes steps in building a model that can recover a large fraction of locations where disfluencies were present, by transforming carefully annotated text to match the standard transcription style, introducing a two-stage model for handling different types of disfluencies, and applying semi-supervised learning. Experiments show improvement in disfluency detection on Supreme Court oral arguments, nearly 23% improvement in F1.

1 Introduction

Many hearings, lectures, news broadcasts and other spoken proceedings are hand-transcribed and made available online for easier searching and increased accessability. For speed and cost reasons, standard transcription services aim at representing semantic content only; thus, filled pauses (uh, um) and many disfluencies (repetitions and self corrections) are omitted, though not all. Careful transcripts represent all the words (and word fragments spoken), as shown below with disfluent regions underlined.

Careful: *It is it is a we submit*
Where there used to be um um um uh the decision
Standard: *It is, it is, we submit*
Where there used to be the decision

These phenomena are quite common in spontaneous speech, even in formal settings such as Supreme Court oral arguments and congressional hearings (Zayats et al., 2014).

While disfluencies may not be important for analyzing the topic of a discussion, the rate and type of disfluencies provide an indication of other factors of interest in spoken language analysis, including cognitive load, emotion, and social cues (Shriberg, 2001). Further, predicting locations of disfluencies in standard transcripts would help to improve time alignments of transcripts to the audio signal, and to provide more useful text data for training language models for speech recognition. Since careful annotation of transcripts with this information is costly, this paper tackles the problem of recovering the disfluencies from clues in the standard orthographic transcripts, or "unediting" the transcripts.[1]

Here, unediting is treated as detection of the reparandum of the disfluencies. Following the structural representation of (Shriberg, 1994), as in:

[we would + which we would]
[would + [who + who] wouldn't]

the task is to detect the words in the brackets preceding the '+' which marks the self-interruption point. Of course, here, some of the words in those regions may not be in the transcript, so location is more important than extent. In addition, some cues used (i.e. filled pauses and word fragments) are not available in standard transcripts.

Three developments are combined to address the problem of unediting with the constraint of limited hand-annotated training data in the target domain: oral arguments from the Supreme Court of the United States (SCOTUS) available from the Oyez Project archive (oyez.org). First, we identify mechanisms for transforming the careful transcripts of the Switchboard corpus (Godfrey et al., 1992) to be

[1] Thanks to Mark Liberman for the term "unediting."

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1410–1415,
Denver, Colorado, May 31 – June 5, 2015.

more similar to the Oyez transcripts. Second, we introduce a multi-stage model that accounts for differences in the rates of repetitions and self-corrections in standard vs. careful transcripts. Lastly, we apply semi-supervised learning to take advantage of the large amount of original Oyez transcripts. The system combining all these techniques, referred to here as UNEDITOR, leads to an improvement in F1 of nearly 23% compared to a baseline of training from the original disfluency-annotated Switchboard corpus.

2 Related work

This paper builds on prior work using conditional random field (CRF) models (Liu et al., 2006; Georgila, 2009; Ostendorf and Hahn, 2013; Zayats et al., 2014). More recent work has shown a benefit from Markov networks (Qian and Liu, 2013; Wang et al., 2014). Since our work is on the transcription style mismatch, this work adopts the simpler CRF approach, but can be easily extended to other classification techniques.

In this work, we use only text features. While prosodic features have been shown to be useful (Shriberg, 1999; Kahn et al., 2005; Liu et al., 2006; Wang et al., 2014), the fact that the Oyez transcripts do not capture all the words means that forced time alignments are unreliable and the associated prosodic features are too noisy to be useful. Other studies integrate disfluency detection with parsing, e.g. (Charniak and Johnson, 2001; Johnson and Charniak, 2004; Lease et al., 2006; Hale et al., 2006; Miller, 2009; Miller et al., 2009; Zwarts et al., 2010; Rasooli and Tetreault, 2013; Honnibal and Johnson, 2014), but parsers trained on standard treebank data sets are not effective on the very long and complex sentences in SCOTUS; parser adaptation is left for future work.

There are a few studies that have investigated disfluency detection using cross-domain training data (Georgila et al., 2010; Ostendorf and Hahn, 2013; Zayats et al., 2014), and many more that have used multi-domain data for other language processing tasks. What is different about the task addressed here is that both the domain (topic and speaking style) and the transcription protocol differ between the target and source domain. There have been some attempts to transform written text to a more conversational style for training language models, e.g. Bulyko et al. (2007) inserted pause fillers and word repetitions, which led to reductions in perplexity though not word error rate. The work here differs in that the transformation is in the reverse direction (removing fillers from conversational text) and punctuation cues are emphasized.

3 Transforming training data

Here we describe methods for generating training data for use with standard transcripts: i) transferring labels from a small amount of carefully annotated data to corresponding standard transcripts, and ii) transforming the existing Switchboard training set to make it more similar to the target domain.

3.1 SCOTUS corpora

The Oyez Project at Chicago-Kent is a multimedia archive containing audio and transcripts of the Supreme Court hearings since 1955. While OYEZ transcripts are consistent with the audio in general, they are not accurate when it comes to disfluencies. We notice that most simple disfluencies such as repetitions have been omitted by OYEZ annotators, while more complex ones are often present and annotators have used the '...' symbol at locations of filled pauses or repetitions. Having those explicit cues indicating interruption points in disfluencies makes it possible to consider recovering the untranscribed disfluencies.

For CAREFUL SCOTUS annotation, we use the data provided by (Zayats et al., 2014), which includes seven cases with carefully transcribed audio and hand-annotated disfluencies, with separately marked repetitions. We develop ANNOTATED OYEZ transcripts, by transferring disfluency labels for those seven cases from CAREFUL SCOTUS to the corresponding files in OYEZ and dropping the deletion markers. As a result, those transcripts are identical to the original OYEZ transcripts, but in addition contain disfluency annotation derived from CAREFUL SCOTUS.

In order to align the CAREFUL SCOTUS and ORIGINAL OYEZ transcripts, we use a dynamic programming algorithm for sequence alignment with matching scores as given in Table 1 and a deletion

CAREFUL SCOTUS	OYEZ	Score
exact match	exact match	4
'+'	'...'	3
punctuation	punctuation	2
end of sentence	'...'	2
word/punct	'...'	1
word	other word	-1
word	punct	-1

Table 1: Matching scores used in dynamic programming transcript alignment.

cost of 1. Some examples of CAREFUL SCOTUS, OYEZ, ALIGNED OYEZ (with deletions marked) and ANNOTATED OYEZ transcripts are shown below. The full corpus is available at `https://ssli.ee.washington.edu/tial/data/oyez`.

CAREFUL SCOTUS: *[[S It is + it is] a +] we submit*
Where there used to be um um um uh the decision
OYEZ: *It is, it is, we submit*
Where there used to be the decision
ALIGNED OYEZ: *[[S It is, + it is], __ +] we submit*
Where there used to be __ __ __ __ the decision
ANNOTATED OYEZ: *[[S It is, + it is], +] we submit*
Where there used to be the decision

3.2 Switchboard transformation

The ANNOTATED OYEZ training set is a very small dataset, and other work has shown that Switchboard (SWBD) is useful for cross-domain training for SCOTUS (Zayats et al., 2014). However, prior work has been with careful transcripts. SWBD transcripts do not include '...' symbols, and SWBD has many more commas and other punctuation symbols. In order to make best use of the SWBD data, we transform it to be more similar to the OYEZ transcripts in two steps. First, we add '...' after interruption points in SWBD. Second, we remove all punctuations except '...' in the middle of the sentence in both of the corpora.

4 Detecting disfluencies

In this section we describe the UNEDITOR system, which is a two-stage CRF model trained on transformed training data and takes advantage of a large pool of unlabeled data with a self-training technique.

Baseline: CRF We use a conditional random field (CRF) model that labels each word in a sentence, following a tagging approach with separate repetition and non-repetition reparandum states, as in (Ostendorf and Hahn, 2013). The feature set includes identity and pattern match features widely used in disfluency detection tasks, as well as distance-based and disfluency language model features from (Zayats et al., 2014).

4.1 Two-stage model

Using the same features as in the baseline, we introduce a two-stage CRF model motivated by our observation that many repetitions are omitted from the standard transcriptions. Thus, while 62% of disfluencies in CAREFUL SCOTUS are repetitions, only 22% of all disfluencies in ANNOTATED OYEZ are repetitions. We find that training at two separate stages helps to overcome the difference in distributions of two disfluency types between source and target domains, and hence results in a better model for adaptation. In the first stage, we train a model to detect repetitions by only considering repetition states in the training data. In the second stage, we train a model to detect non-repetitions by removing all repetitions from the training data. Similarly at test time, we use the first-stage model to detect repetitions, then remove all the detected repetitions, and apply the second-stage model to detect non-repetitions. In evaluation, we report the disfluencies detected in both stages.

4.2 Self-training

A benefit of OYEZ transcripts is that there is a huge amount of unlabeled data available, which makes it natural to use semi-supervised learning. In this work, we use a simple self-training approach. First we apply a CRF model trained on the labeled data to the unlabeled data. Then we augment the training data with automatically labeled sentences that have been detected to contain a disfluency with a confidence score greater than 0.5, and retrain the model with the new augmented training set.

5 Experiments and discussion

We evaluate the different sources/transformations of training data, self-training and the two-stage detection model on ANNOTATED OYEZ transcripts from three cases (∼30k words).

Training set	Prec	Rec	F1
CAREFUL SCOTUS	66.1	16.7	26.7
ANNOT OYEZ	**86.7**	20.4	33.0
ORIG SWBD	62.2	29.1	39.7
CAREFUL SCOTUS + ORIG SWBD	63.7	27.8	38.7
ANNOT OYEZ + TRANSF SWBD	70.9	**49.0**	**57.9**

Table 2: Disfluency detection of ANNOT OYEZ with different training sets.

Training set: ANNOT OYEZ+	Prec	Rec	F1
ORIGSWBD	67.8	29.3	40.9
SWBD WITH ...	63.1	46.8	53.7
TRANSF SWBD	**70.9**	**49.0**	**57.9**

Table 3: The combination of ANNOT OYEZ and SWBD with different SWBD transformation steps.

Training set	Prec	Rec	F1
CAREFUL SCOTUS	57.8	21.2	31.0
ANNOT OYEZ	**81.7**	27.3	41.0
ORIG SWBD	59.0	31.7	41.2
CAREFUL SCOTUS + ORIG SWBD	64.6	33.7	44.3
ANNOT OYEZ + TRANSF SWBD	71.7	**52.8**	**60.8**

Table 4: Self-training performance using different initial models.

5.1 Transforming training data

First, we assess the utility of different training sources and training data transformation using the baseline model. Note that the two SCOTUS sets are quite small (four cases, ∼64k words) compared to Switchboard (1.3M words). Because of the difference in punctuation style between the original Oyez transcripts and the careful transcripts of both corpora, all sentence-internal punctuation is removed in the CAREFUL SCOTUS and ORIG SWBD data.

Table 2 reports results on training the CRF model with the different sources and their combinations. As expected, detection with in-domain training data and transformed SWBD (ANNOT OYEZ+TRANSF SWBD) outperforms training on all other dataset combinations. Training on ANNOT OYEZ alone significantly outperforms detection (especially precision) when only trained on the carefully annotated data because of the matching transcription style. Training with ORIG SWBD outperforms training with ANNOT OYEZ alone mainly due to the availability of more training data in the SWBD dataset, consistent with results in (Ostendorf and Hahn, 2013). Surprisingly, the CAREFUL SCOTUS data did not provide any benefit when added to the ORIG SWBD.

Next, we study the impact of adding '...' symbols and removing punctuation for transforming the SWBD data. Table 3 reports results for training the CRF model with the combination of ANNOT OYEZ and SWBD with different transformation steps. We observe that roughly 30% of the interruption points in CAREFUL SCOTUS are associated with the '...' symbol in the OYEZ transcripts; therefore, we add '...' symbols after $1/3$ of the interruption points in the SWBD. As expected, disfluency detection is improved by transforming SWBD with adding '...'. The largest gain is obtained when we also remove punctuation (the row TRANSF SWBD). All further experiments use this setting for training the models.

5.2 Self-training

Here we study the contribution of semi-supervised learning when applied on the baseline model (Table 5). For self-training, we use 1,765 OYEZ transcripts dated 1990 - 2011 as our unlabeled data (∼17.5M words), with a confidence threshold of 0.5 for augmenting the training data, as described previously. We use each one of the baseline models in Table 2 as an initial model for the self-training for comparison to the results in Table 4. While adding a lot of in-domain data definitely helps, the quality of the initial model plays a major role in the overall performance.

5.3 Two-stage model

Finally, we assess the impact of the two-stage model with and without self-training (Table 5). For the two-stage semi-supervised model, self-training was only used for the second stage (non-repetition detection). As expected, both two-stage and self-training models improve the baseline CRF model, and the combination performs the best. The two-stage model helps to adapt the differences in distribution of repetitions and non-repetitions between the two domains by factoring the different problems to improve the match of the more difficult non-repetition cases. Overall, we obtain nearly 23% im-

Model	Prec	Rec	F1
1-stage	70.9	49.0	57.9
1-stage semi	71.7	**52.8**	60.8
2-stage	**83.3**	47.6	60.6
UNEDITOR: 2-stage semi	76.8	52.2	**62.2**

Table 5: Baseline, two-stages and self-training methods, comparison: baseline self-training method is trained on ...., all the rest methods are trained on ANNOT OYEZ and TRANSF SWBD. Our method, UNEDITOR combines self-training and two-stage models.

provement using the full UNEDITOR system comparing to the model trained on the ORIG SWBD dataset.

6 Conclusion

In this paper we present a framework for disfluency detection in non-careful transcripts. Experiments are based on the OYEZ archive of transcriptions of Supreme Court oral arguments. To address the problem of lack of annotated data, we first transfer disfluency annotations from careful transcripts of a few cases to the less precise OYEZ transcripts. Next, we transform Switchboard transcripts to make them more similar to the target domain. In addition, we introduce a two-stage model and self-training to further improve performance.

Experiments show improvement in disfluency detection on Supreme Court oral arguments. Starting from baselines of training from carefully annotated in-domain data (F1=26.1) or Switchboard data (F1=39.7), we achieve a substantial improvement to (F1=62.2) with our best case system UNEDITOR, which corresponds to an improvement of nearly 23% over the stronger baseline.

Possible extensions of this work include exploring graph-based semi-supervised approaches (e.g., (Subramanya et al., 2010)) and combining the text-based approach with flexible ASR forced alignment allowing optional insertion of filled pauses and words that are common as repetitions. In addition, the availability of the automatically annotated disfluencies makes it possible to study the variation in rates for different cases and speakers over an extended time period.

Acknowledgments

Abstract

Semantic parsing has made significant progress, but most current semantic parsers are extremely slow (CKY-based) and rather primitive in representation. We introduce three new techniques to tackle these problems. First, we design the first linear-time incremental shift-reduce-style semantic parsing algorithm which is more efficient than conventional cubic-time bottom-up semantic parsers. Second, our parser, being type-driven instead of syntax-driven, uses type-checking to decide the direction of reduction, which eliminates the need for a syntactic grammar such as CCG. Third, to fully exploit the power of type-driven semantic parsing beyond simple types (such as entities and truth values), we borrow from programming language theory the concepts of subtype polymorphism and parametric polymorphism to enrich the type system in order to better guide the parsing. Our system learns very accurate parses in GEOQUERY, JOBS and ATIS domains.

1 Introduction

Most existing semantic parsing efforts employ a CKY-style bottom-up parsing strategy to generate a meaning representation in simply typed lambda calculus (Zettlemoyer and Collins, 2005; Lu and Ng, 2011) or its variants (Wong and Mooney, 2007; Liang et al., 2011). Although these works led to fairly accurate semantic parsers, there are two major drawbacks: efficiency and expressiveness.

First, as many researches in syntactic parsing (Nivre, 2008; Zhang and Clark, 2011) have shown, compared to cubic-time CKY-style parsing, incremental parsing can achieve comparable accuracies while being linear-time, and orders of magnitude faster in practice. We therefore introduce the first incremental parsing algorithm for semantic parsing. More interestingly, unlike syntactic parsing, our incremental semantic parsing algorithm, being strictly **type-driven**, directly employs type checking to automatically determine the direction of function application on-the-fly, thus reducing the search space and eliminating the need for a syntactic grammar such as CCG to explicitly encode the direction of function application.

However, to fully exploit the power of type-driven incremental parsing, we need a more sophisticated type system than simply typed lambda calculus. Compare the following two phrases:

(1) the governor of New York

(2) the mayor of New York

If we know that *governor* is a function from state to person, then the first *New York* can only be of type *state*; similarly knowing *mayor* maps city to person disambiguates the second *New York* to be of type *city*. This can not be done using a simple type system with just entities and booleans.

Now let us consider a more complex question which will be our running example in this paper:

(3) What is the capital of the largest state by area?

Since we know *capital* takes a state as input, we expect *the largest state by area* to return a state. But does *largest* always return a state type? Notice that it is polymorphic, for example, *largest city by population*, or *largest lake by perimeter*. So there is no unique type for *largest*: its return type should depend on the type of its first argument (*city*, *state*, or *lake*). This observation motivates us to introduce the powerful mechanism of parametric polymorphism from programming languages into natural language semantics for the first time.

For example, we can define the type of *largest* to be a template

$$\textbf{largest} : (\texttt{'a} \to \texttt{t}) \to (\texttt{'a} \to \texttt{i}) \to \texttt{'a}$$

where 'a is a *type variable* that can match any type (for formal details see §3). Just like in functional programming languages such as ML or Haskell, type variables can be bound to a real type (or a range of types) during function application, using the technique of type inference. In the above example, when *largest* is applied to *city*, we know that type variable 'a is bound to type city (or its subtype), so *largest* would eventually return a city.

We make the following contributions:

- We design the first linear-time incremental semantic parsing algorithm (§2), which is much more efficient than the existing semantic parsers that are cubic-time and CKY-based.

*We thank the reviewers for helpful suggestions. We are also grateful to Luke Zettelmoyer, Yoav Artzi, and Tom Kwiatkowski for providing data. This research is supported by DARPA FA8750-13-2-0041 (DEFT), NSF IIS-1449278, and a Google Faculty Research Award.

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1416–1421,
Denver, Colorado, May 31 – June 5, 2015.

- In line with classical Montague theory (Heim and Kratzer, 1998), our parser is type-driven instead of syntax-driven as in CCG-based efforts (Zettlemoyer and Collins, 2005; Kwiatkowski et al., 2011; Krishnamurthy and Mitchell, 2014) (§2.3).
- We introduce parametric polymorphism into natural language semantics (§3), along with proper treatment of subtype polymorphism, and implement Hindley-Milner style type inference (Pierce, 2005, Chap. 10) during parsing (§3.3).[1]
- We adapt the latent-variable max-violation perceptron training from machine translation (Yu et al., 2013), which is a perfect fit for semantic parsing due to its huge search space (§4).

2 Type-Driven Incremental Parsing

We start with the simplest meaning representation (MR), *untyped lambda calculus*, and introduce typing and the incremental parsing algorithm for it. Later in §3, we add subtyping and type polymorphism to enrich the system.

2.1 Meaning Representation with Types

The untyped MR for the running example is:

Q: What is the capital of the largest state by area?

MR: (**capital** (**argmax** **state** **size**))

Note the binary function **argmax**$(\cdot,\cdot)$ is a higher-order function that takes two other functions as input: the first argument is a "domain" function that defines the set to search for, and second argument is an "evaluation" function that returns a integer for an element in that domain.

The simply typed lambda calculus (Heim and Kratzer, 1998; Lu and Ng, 2011) augments the system with types, including base types (entities e, truth values t, or numbers i), and function types (e.g., $\mathsf{e}\to\mathsf{t}$). So **capital** is of type $\mathsf{e}\to\mathsf{e}$, **state** is of type $\mathsf{e}\to\mathsf{t}$, and **size** is of type $\mathsf{e}\to\mathsf{i}$. The **argmax** function is of type $(\mathsf{e}\to\mathsf{t})\to(\mathsf{e}\to\mathsf{i})\to\mathsf{e}$.[2] The simply typed MR is now written as

$$(\textbf{capital}:\mathsf{e}\to\mathsf{e}\quad(\textbf{argmax}:(\mathsf{e}\to\mathsf{t})\to(\mathsf{e}\to\mathsf{i})\to\mathsf{e}\quad \textbf{state}:\mathsf{e}\to\mathsf{t}\quad \textbf{size}:\mathsf{e}\to\mathsf{i}))).$$

2.2 Incremental Semantic Parsing: An Example

Similar to a standard shift-reduce parser, we maintain a *stack* and a *queue*. The queue contains words to be parsed, while the stack contains subexpressions of the final MR, each of which is a valid typed lambda expression. At each step, the parser choose to **shift** or **reduce**, but unlike standard shift-reduce parser, there is also a third possible action, **skip**, skipping a semantically vacuous word (e.g., "the", "of", "is", etc.). For example, the first three words of the example question *"What is the ..."* are all skipped (**steps 1–3** in Figure 1 (left)).

pattern	λ-expression templates, simple types (§2.2)
JJS	$\lambda P:(\mathsf{e}\to\mathsf{t})\to(\mathsf{e}\to\mathsf{i})\to\mathsf{e}\ .\ P$
NN	$\lambda P:\mathsf{e}\to\mathsf{e}\ .\ P;\quad \lambda P:\mathsf{e}\to\mathsf{t}\ .\ P;\quad \lambda P:\mathsf{e}\to\mathsf{i}\ .\ P$
pattern	**λ-expression templates, polymorphic types (§3.3)**
JJS	$\lambda P:(\mathtt{'a}\to\mathsf{t})\to(\mathtt{'a}\to\mathsf{i})\to\mathtt{'a}\ .\ P$
NN	$\lambda P:\mathtt{'b}\to\mathtt{'c}\ .\ P$

Table 1: POS-based meaning representation templates used in the running example (see Figure 1). The polymorphic types greatly simplifies the representation for common nouns (NN).

The parser then **shifts** the next word, *"capital"*, from the queue to the stack. But unlike incremental syntactic parsing where the word itself is moved onto the stack, here we need to find a **grounded** predicate in the GeoQuery domain for the current word. Triggered by the POS tag NN of word "capital", the template $\lambda P:\mathsf{e}\to\mathsf{e}\ .\ P$ is fetched from a predefined MR templates set like Table 1. In its outermost lambda abstraction, variable P needs to be grounded on-the-fly before we push the expression onto the stack. We find a predicate **capital**$:\mathsf{e}\to\mathsf{e}$ in the GEOQUERY domain applicable to the MR template. After the application, we push the result onto the stack (**step 4**).

Next, words *"of the"* are skipped (steps 5–6). For the next word *"largest"*, **argmax**$:(\mathsf{e}\to\mathsf{t})\to(\mathsf{e}\to\mathsf{i})\to\mathsf{e}$ is applied to the MR template triggered by its POS tag JJS in Table 1, and the stack becomes (**step 7**)

$$\textbf{capital}:\mathsf{e}\to\mathsf{e}\quad \textbf{argmax}:(\mathsf{e}\to\mathsf{t})\to(\mathsf{e}\to\mathsf{i})\to\mathsf{e}.$$

At this step we have two expressions on the stack and we could attempt to reduce. But type checking fails because for left reduce, **argmax** expects an argument (its "domain" function) of type $(\mathsf{e}\to\mathsf{t})$ which is different from **capital**'s type $(\mathsf{e}\to\mathsf{e})$, so is the case for right reduce. So we have to shift again. This time for word *"state"*: **state**$:\mathsf{e}\to\mathsf{t}$. The stack becomes:

$$\textbf{capital}:\mathsf{e}\to\mathsf{e}\quad \textbf{argmax}:(\mathsf{e}\to\mathsf{t})\to(\mathsf{e}\to\mathsf{i})\to\mathsf{e}\quad \textbf{state}:\mathsf{e}\to\mathsf{t}.$$

2.3 Type-Driven Reduce

At this step we can finally perform a **reduce** action, since the top two expressions on the stack pass the type-checking for rightward function application (a partial application): **argmax** expects an $(\mathsf{e}\to\mathsf{t})$ argument, which is exactly the type of **state**. So we conduct a right-reduce, applying **argmax** on **state**, which results in

$$(\textbf{argmax}\quad \textbf{state}):(\mathsf{e}\to\mathsf{i})\to\mathsf{e}$$

[1] There are three kinds of polymorphisms in programming languages: parametric (e.g., C++ templates), subtyping, and ad-hoc (e.g., operator overloading). See Pierce (2002, Chap. 15) for details.

[2] Note that the type notation is always *curried*, i.e., we represent a binary function as a unary function that returns another unary function. Also the type notation is always *right-associative*, so $(\mathsf{e}\to\mathsf{t})\to((\mathsf{e}\to\mathsf{i})\to\mathsf{e})$ is also written as $(\mathsf{e}\to\mathsf{t})\to(\mathsf{e}\to\mathsf{i})\to\mathsf{e}$.

step	action	stack after action (simple type)	stack after action (subtyping+polymorphism)
0	-	ϕ	ϕ
1–3	skip	ϕ	ϕ
4	$\text{sh}_{\text{capital}}$	**capital**:e→e	**capital**:st→ct
7	$\text{sh}_{\text{largest}}$	**capital**:e→e **argmax**:(e→t)→(e→i)→e	**capital**:st→ct **argmax**:('a→t)→('a→i)→'a
8	sh_{state}	**capital**:e→e **argmax**:(e→t)→(e→i)→e **state**:e→t	**capital**:st→ct **argmax**:('a→t)→('a→i)→'a **state**:st→t
9	$\text{re}_{\curvearrowright}$	**capital**:e→e (**argmax state**):(e→i)→e	**capital**:st→ct (**argmax state**):(st→i)→st †
11	sh_{area}	**capital**:e→e (**argmax state**):(e→i)→e **size**:e→i	**capital**:st→ct (**argmax state**):(st→i)→st **size**:lo→i
12	$\text{re}_{\curvearrowright}$	**capital**:e→e (**argmax state size**):e	**capital**:st→ct (**argmax state size**):st ‡
13	$\text{re}_{\curvearrowright}$	(**capital** (**argmax state size**)):e	(**capital** (**argmax state size**)):ct

Figure 1: Type-driven Incremental Semantic Parsing (TISP) with (a) simple types and (b) subtyping+polymorphism on the example question: "what is the capital of the largest state by area?". Steps 5–6 and 10 are skip actions and thus omitted. The stack and queue in each row are the results *after* each action. †: Type variable 'a is binded to st. ‡: From Eq. 4, st <: lo ⇒ (lo→i) <: (st→i).

while the stack becomes (**step 9**)

capital:e→e (**argmax state**):(e→i)→e

Now if we want to continue reduction, it does not type check for either left or right reduction, so we have to shift again. So we move on to shift the final word *"area"* with predicate: **size**:e→i and the stack becomes (**step 11**):

capital:e→e (**argmax state**):(e→i)→e **size**:e→i.

Now we can do two consecutive right reduces supported by type checking (**step 12, 13**) and get the final result:

(**capital** (**argmax state size**)):e.

Here we can see the novelty of our shift-reduce parser: its decisions are largely driven by the type system. When we attempt a reduce, **at most** one of the two reduce actions (left, right) is possible thanks to type checking, and when neither is allowed, we have to shift (or skip). This observation suggests that our incremental parser is more deterministic than those syntactic incremental parsers where each step always faces a three-way decision (shift, left-reduce, right-reduce). We also note that this type-checking mechanism, inspired by the classical type-driven theory in linguistics (Heim and Kratzer, 1998), eliminates the need for an *explicit* encoding of direction as in CCG, which makes our formalism much simpler than the synchronous syntactic-semantic ones in most other semantic parsing efforts (Zettlemoyer and Collins, 2005; Zettlemoyer and Collins, 2007; Wong and Mooney, 2007).[3]

3 Subtype and Parametric Polymorphisms

Currently in simply typed lambda calculus representation function **capital** can apply to any entity type, for example **capital**(**boston**), which should have been disallowed by the type checker. So we need a more sophisticated system that helps ground with refined types, which will in turn help type-driven parsing.

[3]We need to distinguish between two concepts: a) "direction of reduction": $f(g)$ or $g(f)$. Obviously at any given time, between the top two (unarized) functions f and g on the stack, at most one reduction is possible. b) "order of arguments": $f(x, y)$ or $f(y, x)$. For predicates such as **loc** : lo→lo→t the order does matter. Our parser can not distinguish this purely via types, nor can CCG via its syntactic categories. In practice, it is decided by features such as the voice of the verb.

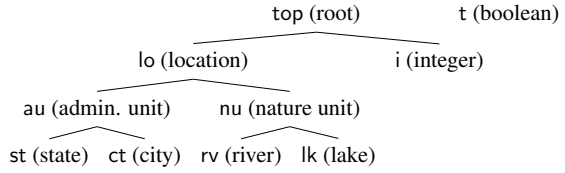

Figure 2: Type hierarchy for GEOQUERY (slightly simplified).

3.1 Semantics with Subtype Polymorphism

We first augment the meaning representation with a domain specific type hierarchy. For example Figure 2 shows a (slightly simplified) version of the type hierarchy for GEOQUERY domain. We use <: to denote the (transitive, reflexive, and antisymmetric) **subtyping relation** between types; for example in GEOQUERY, st <: lo.

Each constant in the GEOQUERY domain is well typed. For example, there are states (**michigan**:st), cities (**nyc**:ct), rivers (**mississippi**:rv), and lakes (**tahoe**:lk).

Similarly each predicate is also typed. For example, we can query the length of a river, **len**:rv→i, or the population of some administrative unit, **population**:au→i. Notice that **population**$(\cdot)$ can be applied to both states and cities, since they are subtypes of administrative unit, i.e., st <: au and ct <: au. This is because, as in Java and C++, a function that expects a certain type can always take an argument of a subtype. For example, we can query whether two locations are adjacent, using **next_to**:lo→(lo→t), as the **next_to**$(\cdot, \cdot)$ function can be applied to two states, or to a river and a city, etc.

Before we move on, there is an important consequence of polymorphism worth mentioning here. For the types of unary predicates such as **city**$(\cdot)$ and **state**$(\cdot)$ that *characterize* its argument, we define theirs argument types to be the required type, i.e., **city**:ct→t, and **state**:st→t. This might look a little weird since everything in the domain of those functions are always mapped to true; i.e., $f(x)$ is either undefined or true, and never false for such f's. This is different from classical simply-typed Montague semantics (Heim and Kratzer, 1998) which defines such predicates as type top→t so that **city**(**mississippi**:st) returns false. The reason for our design is, again, due to

subtyping and polymorphism: **capital** takes a state type as input, so **argmax** must returns a state, and therefore its first argument, the **state** function, must have type st→t so that the matched type variable 'a will be bound to st. This more refined design will also help prune unnecessary argument matching using type checking.

3.2 Semantics with Parametric Polymorphism

The above type system works smoothly for first-order functions (i.e., predicates taking atomic type arguments), but the situation with higher-order functions (i.e., predicates that take functions as input) is more involved. What is the type of **argmax** in the context "the capital of largest state ..."? One possibility is to define it to be as general as possible, as in the simply typed version (and many conventional semantic parsers):

$$\textbf{argmax}:(\mathsf{top}\to\mathsf{t})\to(\mathsf{top}\to\mathsf{i})\to\mathsf{top}.$$

But this actually no longer works for our sophisticated type system for the following reason.

Intuitively, remember that **capital**:st→ct is a function that takes a state as input, so the return type of **argmax** must be a state or its subtype, rather than top which is a supertype of st. But we can not simply replace top by st, since **argmax** can also be applied in other scenarios such as "the largest city". In other words, **argmax** is a *polymorphic* function, and to assign a correct type for it we have to introduce *type variables*:

$$\textbf{argmax}:(\,\mathsf{'a}\to\mathsf{t})\to(\,\mathsf{'a}\to\mathsf{i})\to\mathsf{'a},$$

where type variable 'a is a place-holder for "any type".

3.3 Parsing with Subtype Polymorphism and Parametric Polymorphism

We modify the previous parsing algorithm to accommodate subtyping and polymorphic types. Figure 1 (right) shows the derivation of the running example using the new parsing algorithm. Below we focus on the differences brought by the new algorithm.

Note that we also modified the MR templates as in Table 1. The new MR templates are more general due to the polymorphism from type variables. For example, now we use only one MR template $\lambda P:\mathsf{'b}\to\mathsf{'c}\ .\ P$ to replace the three NN MR templates for simple types.

In step 4, unlike **capital** : e→e, we shift the predicate **capital** : st→ct; in step 7, we shift the polymorphic expression for *"largest"*: **argmax**:('a→t)→('a→i)→ 'a. And after the shift in step 8, the stack becomes

capital:st→ct **argmax**:('a→t)→('a→i)→ 'a **state**:st→t

At **step 9**, in order to apply **argmax** onto **state**:st→t, we simply **bind** type variable 'a to type st, results in (**argmax state**) : (st→i)→st.

After the shift in **step 11**, the stack becomes:

capital:st→ct (**argmax state**):(st→i)→st **size**:lo→i.

Can we still apply right reduce here? According to subtyping requirement (§3.1), we want lo→i <: st→i to hold, knowing that st <: lo. Luckily, there is a rule about function types in type theory that exactly fits here:

$$\frac{\mathsf{A}<:\mathsf{B}}{\mathsf{B}\to\mathsf{C}<:\mathsf{A}\to\mathsf{C}} \tag{4}$$

which states the input side is reversed (contravariant). This might look counterintuitive, but the intuition is that, it is safe to allow the function **size**:lo→i to be used in the context where another type st→i is expected, since in that context the argument passed to **size** will be state type (st), which is a subtype of location type (lo) that **size** expects, which in turn will not surprise **size**. See the classical type theory textbook (Pierce, 2002, Chap. 15.2) for details.

Several works in literature (Zettlemoyer and Collins, 2005; Zettlemoyer and Collins, 2007; Wong and Mooney, 2007; Kwiatkowski et al., 2013) employ some primitive type hierarchies and parse with typed lambda calculus. However, simply introducing subtyped predicates without polymorphism will cause type checking failures in handling high-order functions, as we discussed above.

4 Training: Latent Variable Perceptron

We follow the latent variable max-violation perceptron algorithm of Yu et al. (2013) for training. This algorithm is based on the "violation-fixing" framework of Huang et al. (2012) which is tailored to structured learning problems with abundant search errors such as parsing or machine translation.

The key challenge in the training is that, for each question, there might be many different unknown derivations that lead to its annotated MR, which is known as the *spurious ambiguity*. In our task, the spurious ambiguity is caused by how the MR templates are chosen and grounded during the shift step, and the different reduce orders that lead to the same result. We treat this unknown information as latent variable.

More formally, we denote $D(x)$ to be the set of *all* partial and full parsing derivations for an input sentence x, and $mr(d)$ to be the MR yielded by a full derivation d. Then we define the sets of (partial and full) reference derivations as:

$$good_i(x,y) \triangleq \{d \in D(x) \mid |d| = i, \exists \text{full derivation } d' \text{ s.t. } d \text{ is a prefix of } d', mr(d') = y\},$$

Those "bad" partial and full derivations that do not lead to the annotated MR can be defined as:

$$bad_i(x,y) \triangleq \{d \in D(x) \mid d \notin good_i(x,y), |d| = i\}.$$

At step i, the best reference partial derivation is

$$d_i^+(x,y) \triangleq \underset{d \in good_i(x,y)}{\textbf{argmax}}\ \mathbf{w}\cdot\mathbf{\Phi}(x,d), \tag{5}$$

System	GEOQUERY			JOBS			ATIS		
	P	R	F1	P	R	F1	P	R	F1
Z&C'05	**96.3**	79.3	87.0	**97.3**	79.3	87.4	-	-	-
Z&C'07	91.6	86.1	88.8	-	-	-	**85.8**	**84.6**	**85.2**
UBL	94.1	85.0	89.3	-	-	-	72.1	71.4	71.7
FUBL	88.6	88.6	88.6	-	-	-	82.8	82.8	82.8
TISP (st)	89.7	86.8	88.2	76.4	76.4	76.4	-	-	-
TISP	92.9	**88.9**	**90.9**	85.0	**85.0**	**85.0**	84.7	84.2	84.4

Table 2: Performances (precision, recall, and F1) of various parsing algorithms on GEOQUERY, JOBS, and ATIS datasets. TISP with simple types are marked "st".

while the Viterbi partial derivation is

$$d_i^-(x,y) \triangleq \underset{d \in bad_i(x,y)}{\mathbf{argmax}}\ \mathbf{w} \cdot \mathbf{\Phi}(x,d), \qquad (6)$$

where $\mathbf{\Phi}(x,d)$ is the defined feature set for derivation d. In practice, to compute Eq. 6 exactly is intractable, and we resort to beam search. Following Yu et al. (2013), we then find the step i^* with the maximal score difference between the best reference partial derivation and the Viterbi partial derivation:

$$i^* \triangleq \underset{i}{\mathbf{argmax}}\, \mathbf{w} \cdot \Delta\mathbf{\Phi}(x, d_i^+(x,y), d_i^-(x,y)),$$

and do update $\mathbf{w} \leftarrow \mathbf{w} + \Delta\mathbf{\Phi}(x, d_{i^*}^+(x,y), d_{i^*}^-(x,y))$ where $\Delta\mathbf{\Phi}(x,d,d') \triangleq \mathbf{\Phi}(x,d) - \mathbf{\Phi}(x,d')$.

We also use minibatch parallelization of Zhao and Huang (2013); in practice we use 24 cores.

5 Experiments

We implement our type-driven incremental semantic parser (TISP) using `Python`, and evaluate its performance on GEOQUERY, JOBS, and ATIS datasets.

Our feature design is inspired by the very effective Word-Edge features in syntactic parsing (Charniak and Johnson, 2005) and MT (He et al., 2008). From each parsing state, we collect atomic features including the types and the leftmost and rightmost words of the span of the top 3 MR expressions on the stack, the top 3 words on the queue, the grounded predicate names and the ID of the MR template used in the shift action. We use budget scheme similar to (Yu et al., 2013) to alleviate the overfitting problem caused by feature sparsity. We get 84 combined feature templates in total. Our final system contains 62 MR expression templates, of which 33 are triggered by POS tags, and 29 are triggered by specific phrases.

In the experiments, we use the same training, development, and testing data splits as Zettlemoyer and Collins (2005) and Zettlemoyer and Collins (2007).

For evaluation, we follow Zettlemoyer and Collins (2005) to use *precision* and *recall*:

$$\text{Precision} = \frac{\#\text{ of correctly parsed questions}}{\#\text{ of successfully parsed questions}},$$

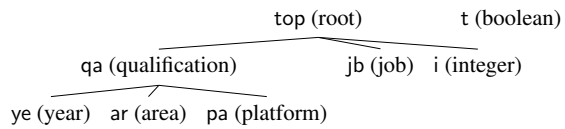

Figure 3: Type hierarchy for JOBS domain (slightly simplified).

$$\text{Recall} = \frac{\#\text{ of correctly parsed questions}}{\#\text{ of questions}}.$$

5.1 Evaluation on GEOQUERY Dataset

We first evaluate TISP on GEOQUERY dataset.

In the training and evaluating time, we use a very small beam size of 16, which gives us very fast decoding. In serial mode, our parser takes $\sim$ 83s to decode the 280 sentences (2,147 words) in the testing set, which means $\sim$0.3s per sentence, or $\sim$0.04s per word.

We compare the our accuracy performance with existing methods (Zettlemoyer and Collins, 2005; Zettlemoyer and Collins, 2007; Kwiatkowski et al., 2010; Kwiatkowski et al., 2011) in Table 2. Given that all other methods use CKY-style parsing, our method is well balanced between accuracy and speed.

In addition, to unveil the helpfulness of our type system, we train a parser with only simple types. (Table 2) In this setting, the predicates only have primitive types of location lo, integer i, and boolean t, while the constants still keep their types. It still has the type system, but it is weaker than the polymorphic one. Its accuracy is lower than the standard one, mostly caused by that the type system can not help pruning the wrong applications like (**population**:au→i **mississippi**:rv).

5.2 Evaluations on JOBS and ATIS Datasets

We also evaluate the performance of our parser on JOBS and ATIS datasets. Figure 3 shows the type hierarchy for JOBS. We omit the type hierarchy for ATIS due to space constraint. Note that ATIS contains more than 5,000 examples and is a lot larger than GEOQUERY and JOBS.

We show the results in Table 2. In JOBS, we achieves very good recall, but the precision is not as good as Zettlemoyer and Collins (2005), which is actually because we parsed a lot more sentences. Also, TISP with simple types is still weaker than the one with subtyping and parametric polymorphisms. For ATIS, our performance is very close to the state-of-the-art.

6 Conclusion

We have presented an incremental semantic parser that is guided by a powerful type system of subtyping and polymorphism. This polymorphism greatly reduced the number of templates and effectively pruned search space during the parsing. Our parser is competitive with state-of-the-art accuracies, but, being linear-time, is faster than CKY-based parsers in theory and in practice.

Abstract

A common approach to dependency parsing is scoring a parse via a linear function of a set of indicator features. These features are typically manually constructed from templates that are applied to parts of the parse tree. The templates define which properties of a part should combine to create features. Existing approaches consider only a small subset of the possible combinations, due to statistical and computational efficiency considerations. In this work we present a novel kernel which facilitates efficient parsing with feature representations corresponding to a much larger set of combinations. We integrate the kernel into a parse reranking system and demonstrate its effectiveness on four languages from the CoNLL-X shared task.[1]

1 Introduction

Dependency parsing is the task of labeling a sentence x with a syntactic dependency tree $y \in \mathcal{Y}(x)$, where $\mathcal{Y}(x)$ denotes the space of valid trees over x. Each word in x is represented as a list of linguistic properties (e.g. word form, part of speech, base form, gender, number, etc.). In the graph based approach (McDonald et al., 2005b) parsing is cast as a structured linear prediction problem:

$$h_{\mathbf{v}}(x) = \underset{y \in \mathcal{Y}(x)}{\operatorname{argmax}} \ \mathbf{v}^T \cdot \Phi(x, y) \qquad (1)$$

where $\Phi(x, y) \in \mathbb{R}^d$ is a feature representation defined over a sentence and its parse tree, and $\mathbf{v} \in \mathbb{R}^d$ is a vector of parameters.

To construct an effective representation, $\Phi(x, y)$ is typically decomposed into local representations over parts p of the tree y:

$$\Phi(x, y) = \sum_{p \in y} \phi(x, p)$$

Standard decompositions include different types of parts: *arcs*, *sibling arcs*, *grandparent arcs*, etc. Feature templates are then applied to the parts to construct the local representations. The templates determine how the linguistic properties of the words in each part should combine to create features (see Section 2).

Substantial effort has been dedicated to the manual construction of feature templates (McDonald et al., 2005b; Carreras, 2007; Koo and Collins, 2010). Still, for both computational and statistical reasons, existing templates consider only a small subset of the possible combinations of properties. From a computational perspective, solving Eq. 1 involves applying the templates to y and calculating a dot product in the effective dimension of Φ. The use of many templates thus quickly leads to computational infeasibility (the dimensionality of $\mathbf{v}$, as well as the number of non-zero features in Φ, become very large). From a statistical perspective, the use of a large number of feature templates can lead to overfitting.

Several recent works have proposed solutions to the above problem. Lei et al., (2014) represented the space of all possible property combinations in an arc-factored model as a third order tensor and learned the parameter matrix for the tensor under a low rank assumption. In the context of transition parsers, Chen and Manning (2014) have implemented a neural network that uses dense representations of words and parts of speech as its input and implicitly considers combinations in its inner layers. Earlier work on transition-based dependency parsing used SVM classifiers with 2nd order polynomial kernels to achieve similar effects (Hall

[1] See https://bitbucket.org/hillel/templatekernels for implementation.

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1422–1427,
Denver, Colorado, May 31 – June 5, 2015.

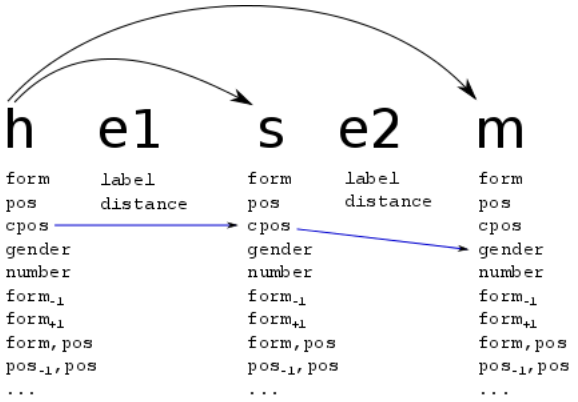

Figure 1: Feature template over the second order consecutive siblings part type. The part type contains slots for the head (h), sibling (s) and modifier (m) words, as well as for the two edges (e1 and e2). Each slot is associated with a set of properties. The directed path skips over the edge properties and defines the partial template <h-cpos=?; s-cpos=?; m-gender=?>.

et al., 2006). While training greedy transition-based parsers such as the ones used in (Chen and Manning, 2014) and (Hall et al., 2006) amounts to training a multiclass classifier, the graph-based parsing framework explored in (Lei et al., 2014) and in the present work is a more involved structured-learning task.

In this paper we present a kernel based approach to automated feature generation in the context of graph-based parsing. Compared to tensors and neural networks, kernel methods have the attractive properties of a convex objective and well understood generalization bounds (Shawe-Taylor and Cristianini, 2004). We introduce a kernel that allows us to learn the parameters for a representation similar to the tensor representation in (Lei et al., 2014) but without the low rank assumption, and without explicitly instantiating the exponentially many possible features.

In contrast to previous works on parsing with kernels (Collins and Duffy, 2002), in which the kernels are defined over trees and count the number of shared subtrees, our focus is on feature combinations. In that sense our work is more closely related to work on tree kernels for relation extraction (Zelenko et al., 2003; Culotta and Sorensen, 2004; Reichartz et al., 2010; Sun and Han, 2014), but the kernel we propose is designed to generate combinations of properties within selected part types and does not involve the all-subtrees representation.

2 Template Kernels

For simplicity, we begin with the case where parts p correspond to head modifier pairs (h, m) (i.e. all parts belong to the "arc" part type). The features in $\phi(x, p)$ can then depend on any property of h, m and the sentence x. We denote properties related to h using the prefix h- (e.g., h-pos corresponds to the part-of-speech of the head), and similarly for m-. We also use e- to denote properties related to the triplets h, m, x (e.g., the surface distance between h, m in x is denoted by e-$dist$).

Templates defined over the "arc" part type will then combine different properties of h, m and e, to create features. e.g. the template <h-form=?; e-dist=?; m-form=?,m-pos=?>, when applied to a dependency arc, may yield the feature: <h-form=dog;e-dist=1;m-form=black,m-pos=JJ>.

More generally, a parse tree *part* can be seen as ordered lists of slots that contain properties (different part types will contain different lists of slots). The feature templates defined over them select one property from each slot (possibly skipping some slots to produce partial templates). A template can thus be thought of as a directed path between the properties it selects in the different slots. Clearly, the number of possible templates in a given part type is exponential in the number of its slots. Figure 1 depicts the process for sibling parts.

As discussed in Section 1, manually constructed feature templates consider only a small subset of the combinations of properties (i.e. a small number of "good" paths is manually identified and selected). Our goal is to introduce a kernel that allows us to represent all possible paths for a part type in polynomial time.

Formally, let $\Phi(x, y) = \sum_{p \in y} \phi(x, p)$ be a feature representation which associates a feature with any distinct combination of properties in any of the tree parts in the training set. For a given part p, the effective dimensionality of $\phi(x, p)$ is thus $O(m^s)$ where s is the number of slots in p, and m is the maximal number of properties in a slot.

Explicitly representing $\Phi(x, y)$ is therefore often impractical. However, the well known "kernel trick" (Shawe-Taylor and Cristianini, 2004) implies that linear classifiers depend only on dot products between feature vectors and not on the feature vectors

themselves. In the context of reranking (see Section 3), it means we can learn classifiers if we can calculate dot products $K(y_1, y_2) = \Phi^T(x_1, y_1) \cdot \Phi(x_2, y_2)$ for two sentences and candidate parses.[2]

We first note that such dot products can be expressed as sum of dot products over parts:

$$K(y_1, y_2) = \sum_{p \in y_1} \sum_{p' \in y_2} k(p, p')$$

where $k(p, p') = \phi(x_1, p) \cdot \phi(x_2, p)$.

To calculate $k(p, p')$ we'll assume for simplicity that p and p' are of the same type (otherwise $k(p, p') = 0$). Let p_{ij} and p'_{ij} be the values of the i'th property in the j'th slot in p, p' (e.g., for a second order sibling part as in Figure 1, $p_{1,4}$ will correspond to the label of the edge e2 in p) , and let $C_{p \leftrightarrow p'} \in \{0, 1\}^{m \times s}$ be a binary matrix comparing p and p' such that $\left[C_{p \leftrightarrow p'}\right]_{ij} = 1$ when $p_{ij} = p'_{ij}$ and 0 otherwise. Simple algebra yields that:

$$k(p, p') = \prod_j \vec{1}^T \cdot \left[C_{p \leftrightarrow p'}\right]_{:,j}$$

That is, calculating $k(p, p')$ amounts to multiplying the sums of the columns in C.[3] The runtime of $k(p, p')$ is then $O(m \times s)$ which means the overall runtime of $K(y_1, y_2)$ is $O(|y_1| \times |y_2| \times |s| \times |m|)$, where $|y_1|, |y_2|$ are the number of parts in y_1 and y_2.

Finally, note that adding 1 to one of the column counts of C corresponds to a slot that can be skipped to produce a partial template (this simulates a wild card property that is always on).

3 Kernel Reranker

We next show how to use the template kernels within a reranker. In the reranking approach (Collins and Koo, 2005; Charniak and Johnson, 2005), a base parser produces a list of k-best candidate parses for an input sentence and a separately trained reranking model is used to select the best one.

Features: Our feature vector will have two parts. One, $\Phi_g(x, y) \in \mathbb{R}^{d_1}$, consists of features obtained from manually constructed templates. The other, $\Phi_k(x, y) \in \mathbb{R}^{d_2}$, corresponds to our kernel features. We will not evaluate or store it, but rather use the kernel trick for implicitly learning with it, as explained below. The score of a candidate parse y for sentence x is calculated via the following linear function:

$$\begin{aligned} \Phi(x, y) &= [\Phi_g(x, y), \Phi_k(x, y)] \\ h_{\mathbf{v}}(x, y) &= \mathbf{v} \cdot \Phi(x, y) \end{aligned} \quad (2)$$

Learning For learning we use the passive-aggressive algorithm (Crammer et al., 2006; McDonald et al., 2005a), and adapt it to use with kernels. Formally, let $S = \{(x_i, \mathcal{K}(x_i))\}_{i=1}^n$ be a training set of size n such that $\mathcal{K}(x_i) = \{y_{i1}, \ldots, y_{ik}\}$ is the set of k-best candidate trees produced for the sentence x_i. Assume that y_{i1} is the optimal tree in terms of Hamming distance to the gold tree.

A key observation to make is that the $\mathbf{v}$ generated by the PA algorithm will depend on two parameters. One is a weight vector $\mathbf{w} \in \mathbb{R}^{d_1}$, in the manually constructed Φ_g feature space. The other is a set of weights α_{ij} with $i = 1, \ldots, n$ and $j = 1, \ldots, k$ corresponding to the j^{th} candidate for the i^{th} sample.[4] The score is then given by:

$$f_{\mathbf{w},\alpha}(x, y) = \mathbf{v} \cdot \Phi(x, y) = \mathbf{w} \cdot \Phi_g(x, y) + f_\alpha(x, y)$$

where:

$$f_\alpha(x, y) = \sum_{i,j} \alpha_{ij} \cdot (K(y_{i1}, y) - K(y_{ij}, y))$$

We can now rewrite the updates of the PA algorithm using $\mathbf{w}, \alpha$, as described in Alg 1.[5]

4 Implementation

The classifier depends on parameters α_{ij}, which are updated using the PA algorithm. In the worst case, all nk of these may be non-zero. For large datasets, this may slow down both learning and prediction.

[2] For brevity we'll omit x from the kernel parameters and use $K(y_1, y_2)$ instead of $K((x_1, y_1), (x_2, y_2))$.

[3] We omit the proof, but intuitively, the product of column sums is equal to the number of 1 valued paths between elements in the different columns of C. Each such path corresponds to a path in p and p' where all the properties have identical values. i.e. it corresponds to a feature that is active in both $\phi(x_1, p)$ and $\phi(x_2, p')$ and thus contributes 1 towards the dot product.

[4] This follows from tracing the steps of PA and noting their dependence on dot products.

[5] The denominator in line 5 is equal to $\|\Phi_g(x_i, y_{ij}) - \Phi_g(x_i, y_{i1})\|^2 + K(y_{ij}, y_{ij}) - 2K(y_{ij}, y_{i1}) + K(y_{i1}, y_{i1})$ so it can be calculated efficiently using the kernel. $\|y_{i1} - y_{ij}\|_1$ is the hamming distance between y_{i1} and y_{ij}. The updates for $\bar{\alpha}$ are equivalent to averaging over all alphas in iterations $1, ..., T$. We use this form to save space.

Below we discuss implementation techniques to mitigate this problem. To facilitate the discussion we rewrite the dot-product computation as follows:

$$f_\alpha(x,y) = \sum_{p' \in y} \hat{f}_\alpha(x,p') \quad (3)$$

where:

$$\hat{f}_\alpha(x,p') = \sum_{i,j} \alpha_{ij} \left(\sum_{p \in y_{i1}} k(p,p') - \sum_{p \in y_{ij}} k(p,p') \right)$$

Reducing Prediction Runtime From Equation 3 we note several facts. First, prediction involves calculating $k(p,p')$ for every combination of a part p from the support instances (i.e., those for which $\alpha_{ij} > 0$) and part p' from the instances in the k-best list. Our implementation thus maintains its support as a set of parts rather than a set of instances.

Second, parts that appear in both y_{i1} and y_{ij} do not affect the result of $f_\alpha(x,y)$ since they cancel each other out. Our implementation thus only updates the support set with parts that belong exclusively to either y_{i1} or y_{ij}. This improves performance significantly since the number of non-overlapping parts in y_{i1} and y_{ij} is typically much smaller than the total number of parts therein.

Another important performance gain is obtained by caching the results of $\hat{f}_\alpha(x,p')$ when calculating $f_\alpha(x,y)$ for the different instances in the k-best list. This avoids recalculating the summation for parts that occur multiple times in the k-best list. Once again, this amounts to a considerable gain, as the number of distinct parts in the k-best list is much smaller than the total number of parts therein.

Reducing Training Runtime We greatly improve training speed by caching the results of $f_\alpha(x_i, y_{ij})$ between training iterations so that on each repeating invocation of the function, only the support parts added since the previous iteration need to be considered. Since the predictions of the learning algorithm become increasingly more accurate, the number of added support parts decreases sharply between iterations[6], and so does the runtime. In practice, all iterations from the 3rd onwards have negligible runtime compared to the first and second iterations. This technique allows us to comfortably train the kernel predictor on large datasets.

Algorithm 1 PA Algorithm for Template Kernels

Input: $S = \{(x_i, \mathcal{K}(x_i))\}_{i=1}^n$, $NumIters$, Aggressiveness parameter C

1: $\forall i,j\ \alpha_{ij} \leftarrow 0,\ \bar{\alpha}_{ij} \leftarrow 0; T \leftarrow n \times NumIters$
2: **for** $t = 1$ to T **do**
3: $\quad i \leftarrow t \mod n$
4: $\quad j \leftarrow \underset{j:\ y_{ij} \in \mathcal{K}(x_i)}{\text{argmax}}\ f_{\mathbf{w},\alpha}(x_i, y_{ij})$
5: $\quad \tau_t \leftarrow \min\left\{C, \frac{f_{\mathbf{w},\alpha}(x,y_{ij}) - f_{\mathbf{w},\alpha}(x,y_{i1}) + \|y_{i1} - y_{ij}\|_1}{\|\Phi(x_i,y_{ij}) - \Phi(x_i,y_{i1})\|^2}\right\}$
6: $\quad \alpha_{ij} \leftarrow \alpha_{ij} + \tau_t$
7: $\quad \bar{\alpha}_{ij} \leftarrow \bar{\alpha}_{ij} + \tau_t (T - t + 1)$
8: $\quad \mathbf{w}^{(t+1)} \leftarrow \mathbf{w}^{(t)} + \tau_t (\Phi_g(x_i, y_{i1}) - \Phi_g(x_i, y_{ij}))$
9: **end for**
10: $\forall i,j,\ \bar{\alpha}_{ij} \leftarrow \frac{\bar{\alpha}_{ij}}{T},\ \bar{\mathbf{w}} = \frac{1}{T}\sum_{t=1}^{T} \mathbf{w}^{(t)}$

Output: predictor: $\underset{y \in \mathcal{K}(x)}{\text{argmax}}\ (f_{\bar{\mathbf{w}},\bar{\alpha}}(x,y))$

5 Experimental Setup

Datasets We test our system on 4 languages from the CoNLL 2006 shared task, all with rich morphological features.[7] The properties provided for each word in these datasets are its *form*, part of speech (*pos*), coarse part of speech (*cpos*), *lemma* and *morph* features (number, gender, person, etc. around 10-20 feats in total). We use 20-fold jackknifing to create the k-best lists for the reranker (Collins and Duffy, 2002).

Base Parser The base parser used in experiments was the sampling parser of Lei et al. (2014), augmented to produce the k-best trees encountered during sampling. The parser was set to use feature templates over third order part types, but its tensor component and global templates were deactivated.

Features The manual features Φ_g were based on first to third order templates from Lei et al. (2014). For the kernel features Φ_k we annotated the nodes and edges in each tree with the properties in Table 1. We used a first order template kernel to train a model using all the the possible combinations of head, edge and modifier properties. Our kernel also produces all the property combinations of the head and modifier words (disregarding the edge properties).

[6] On correct predictions, τ_t at line 5 of Alg 1 is 0, so no update is taking place and no support parts are added.

[7] Our property combination approach is less relevant for treebanks that do not specify morphological properties. This is the

Node Unigram properties:		
form	form_{-1}	form_{+1}
pos	pos_{-1}	pos_{+1}
cpos	cpos_{-1}	cpos_{+1}
$\forall i$ morph_i		
Node Bigram properties:		**Edge prop:**
pos_{-1}, pos		label
pos, pos_{+1}		len, dist
pos, form		always on

Table 1: Linguistic properties for nodes and edges.

Results For each language we train a *Kernel Reranker* by running Alg 1 for 10 iterations over the training set, using k-best lists of size 25 and C set to infinity. As baseline, we train a *Base Reranker* in the same setup but with kernel features turned off. Table 2 shows the results for the two systems. Even though they use the same feature set, the base-reranker lags behind the base-parser. We attribute this to the fact that the reranker explores a much smaller fraction of the search space, and that the gold parse tree may not be available to it in either train or test time. However, the kernel-reranker significantly improves over the base-reranker. In Bulgarian and Danish, the kernel-reranker outperforms the base-parser. This is not the case for Slovene and Arabic, which we attribute to the low oracle accuracy of the k-best lists in these languages. As is common in reranking (Jagarlamudi and Daumé III, 2012), our final system incorporates the scores assigned to sentences by the base parser: i.e. $score_{final}(x, y) = \beta score_{base}(x, y) + score_{reranker}(x, y)$. β is tuned per language on a development set.[8] Our final system outperforms the base parser, as well as TurboParser (Martins et al., 2013), a parser based on manually constructed feature templates over up to third order parts. The system lags slightly behind the sampling parser of Zhang et al. (2014) which additionally uses global features (not used by our system) and a tensor component for property combinations. Another important difference between the systems is that our search is severely restricted by the use of a reranker. It is likely that using our kernel in a graph-based parser will further improve its accuracy.

reason we did not select the English treebank.

[8]To obtain a development set we further split the reranker training sets into tuning training and a development sets (90/10). We then tune β per language on the respective development sets by selecting the best value from a list of $\{0,\ 0.05, \ldots, 3\}$

Table 3: Runtime statistics, measured on a standard Macbook Pro 2.8 GHz Core i7 using 8 threads.

Performance Table 3 lists the performance metrics of our system on the four evaluation treebanks. While training times are reasonable even for large datasets, the increase in support size causes prediction to become slow for medium and large training sets. The number of support instances is a general problem with kernel methods. It has been addressed using techniques like feature maps (Rahimi and Recht, 2007; Lu et al., 2014) and bounded online algorithms (Dekel et al., 2008; Zhao et al., 2012). The application of these techniques to template kernels is a topic for future research.

6 Conclusions

We present a kernel approach to graph based dependency parsing. The proposed method facilitates globally optimal parameter estimation in a high dimensional feature space, corresponding to the full set of property combinations. We implemented our solution as part of a parse reranking system, demonstrating state of the art results. Future work will focus on performance improvements, using the kernel on higher order parts, and integrating the kernel directly into a graph based dependency parser.

Embedding a Semantic Network in a Word Space

Richard Johansson and **Luis Nieto Piña**

Abstract

We present a framework for using continuous-space vector representations of word meaning to derive new vectors representing the meaning of *senses* listed in a semantic network. It is a post-processing approach that can be applied to several types of word vector representations. It uses two ideas: first, that vectors for polysemous words can be decomposed into a convex combination of sense vectors; secondly, that the vector for a sense is kept similar to those of its neighbors in the network. This leads to a constrained optimization problem, and we present an approximation for the case when the distance function is the squared Euclidean.

We applied this algorithm on a Swedish semantic network, and we evaluate the quality of the resulting sense representations extrinsically by showing that they give large improvements when used in a classifier that creates lexical units for FrameNet frames.

1 Introduction

Representing word meaning computationally is central in natural language processing. Manual, knowledge-based approaches to meaning representation maps word strings to symbolic concepts, which can be described using any knowledge representation framework; using the relations between concepts defined in the knowledge base, we can infer implicit facts from the information stated in a text: a *mouse* is a *rodent*, so it has prominent *teeth*.

Conversely, data-driven meaning representation approaches rely on cooccurrence patterns to derive a vector representation (Turney and Pantel, 2010). There are two classes of methods that compute word vectors: context-counting and context-predicting; while the latter has seen much interest lately, their respective strengths and weaknesses are still being debated (Baroni et al., 2014; Levy and Goldberg, 2014). The most important relation defined in a vector space between the meaning of two words is *similarity*: a *mouse* is something quite similar to a *rat*. Similarity of meaning is operationalized in terms of geometry, by defining a distance metric.

Symbolic representations seem to have an advantage in describing *word sense ambiguity*: when a surface form corresponds to more than one concept. For instance, the word *mouse* can refer to a *rodent* or an *electronic device*. Vector-space representations typically represent surface forms only, which makes it hard to search e.g. for a group of words similar to the rodent sense of *mouse* or to reliably use the vectors in classifiers that rely on the semantics of the word. There have been several attempts to create vectors representing senses, most of them based on some variant of the idea first proposed by Schütze (1998): that senses can be seen as clusters of similar contexts. Recent examples in this tradition include the work by Huang et al. (2012) and Neelakantan et al. (2014). However, because sense distributions are often highly imbalanced, it is not clear that context clusters can be reliably created for senses that occur rarely. These approaches also lack interpretability: if we are interested in the rodent sense of *mouse*, which of the vectors should we use?

In this work, we instead derive sense vectors by embedding the graph structure of a semantic network in the word space. By combining two complementary sources of information – corpus statistics and network structure – we derive useful vectors also for concepts that occur rarely. The method, which can be applied to context-counting as well as context-predicting spaces, works by decompos-

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1428–1433,
Denver, Colorado, May 31 – June 5, 2015.

ing word vectors as linear combinations of sense vectors, and by pushing the sense vectors towards their neighbors in the semantic network. This intuition leads to a constrained optimization problem, for which we present an approximate algorithm.

We applied the algorithm to derive vectors for the senses in a Swedish semantic network, and we evaluated their quality extrinsically by using them as features in a semantic classification task – mapping senses to their corresponding FrameNet frames. When using the sense vectors in this task, we saw a large improvement over using word vectors.

2 Embedding a Semantic Network

The goal of the algorithm is to *embed* the semantic network in a geometric space: that is, to associate each sense s_{ij} with a *sense embedding*, a vector $E(s_{ij})$ of real numbers, in a way that reflects the topology of the semantic network but also that the vectors representing the lemmas are related to those corresponding to the senses. We now formalize this intuition, and we start by introducing some notation.

For each lemma l_i, there is a set of possible senses $s_{i1}, \ldots, s_{im_i}$ for which l_i is a surface realization. Furthermore, for each sense s_{ij}, there is a *neighborhood* consisting of senses semantically related to s_{ij}. Each neighbor n_{ijk} of s_{ij} is associated with a weight w_{ijk} representing the degree of semantic relatedness between s_{ij} and n_{ijk}. How we define the neighborhood, i.e. our notion of semantical relatedness, will obviously have an impact on the result. In this work, we simply assume that it can be computed from the network, e.g. by picking a number of hypernyms and hyponyms in a lexicon such as WordNet. We then assume that for each lemma l_i, we have a D-dimensional vector $F(l_i)$ of real numbers; this can be computed using any method described in Section 1. Finally, we assume a *distance function* $\Delta(x, y)$ that returns a non-negative real number for each pair of vectors in $\mathbb{R}^D$.

The algorithm maps each sense s_{ij} to a sense embedding, a real-valued vector $E(s_{ij})$ in the same vector space as the lemma embeddings. The lemma and sense embeddings are related through a *mix constraint*: $F(l_i)$ is decomposed as a convex combination $\sum_j p_{ij} E(s_{ij})$, where the $\{p_{ij}\}$ are picked from the probability simplex. Intuitively, the mix variables correspond to the occurrence probabilities of the senses, but strictly speaking this is only the case when the vectors are built using simple context counting. Since the mix gives an estimate of which sense is the most frequent in the corpus, we get a strong baseline for word sense disambiguation (McCarthy et al., 2007) as a bonus; see our followup paper (Johansson and Nieto Piña, 2015) for a discussion of this.

We can now formalize the intuition above: the weighted sum of distances between each sense and its neighbors is minimized, while satisfying the mix constraint for each lemma. We get the following constrained optimization program:

$$\begin{aligned} \underset{E,p}{\text{minimize}} \quad & \sum_{i,j,k} w_{ijk} \Delta(E(s_{ij}), E(n_{ijk})) \\ \text{subject to} \quad & \sum_j p_{ij} E(s_{ij}) = F(l_i) \qquad \forall i \\ & \sum_j p_{ij} = 1 \qquad \forall i \\ & p_{ij} \geq 0 \qquad \forall i, j \end{aligned} \tag{1}$$

The mix constraints make sure that the solution is nontrivial. In particular, a very large number of words are monosemous, and the procedure will leave the embeddings of these words unchanged.

2.1 An Approximate Algorithm

The difficulty of solving the problem stated in Equation (1) obviously depends on the distance function Δ. Henceforth, we focus on the case where Δ is the squared Euclidean distance. This is an important special case that is related to a number of other distances or similarities, e.g. cosine similarity and Hellinger distance. In this case, (1) is a quadratically constrained quadratic problem, which is NP-hard in general and difficult to handle with off-the-shelf optimization tools. We therefore resort to an approximation; we show empirically in Sections 3 and 4 that it works well in practice.

The approximate algorithm works in an online fashion by considering one lemma at a time. It adjusts the embeddings of the senses as well as their mix in order to minimize the loss function

$$L_i = \sum_{jk} w_{ijk} \|E(s_{ij}) - E(n_{ijk})\|^2. \tag{2}$$

The embeddings of the neighbors n_{ijk} of the sense are kept fixed at each such step. We iterate through the whole set of lemmas for a fixed number of epochs or until the objective is unchanged.

Furthermore, instead of directly optimizing with respect to the sense embeddings (which involves $m_i \cdot D$ scalars), the sense embeddings (and therefore also the loss L_i) can be computed analytically if the mix variables $p_{i1}, \ldots, p_{im_i}$ are given, so we have reduced the optimization problem to one involving $m_i - 1$ scalars, i.e. it is univariate in most cases.

Given a sense s_{ij} of a lemma l_i, we define the *weighted centroid* of the set of neighbors of s_{ij} as

$$c_{ij} = \frac{\sum_k w_{ijk} E(n_{ijk})}{\sum_k w_{ijk}}. \quad (3)$$

If the mix constraints were removed, c_{ij} would be the solution to the optimization problem: they minimize the weighted sum of squared Euclidean distances to the neighbors. Then, given the mix, the *residual* is defined

$$r_i = \frac{1}{\sum_j \frac{p_{ij}^2}{\sum_k w_{ijk}}} \left(\sum_j p_{ij} c_{ij} - F(l_i) \right). \quad (4)$$

The vector r_i represents the difference between the linear combination of the weighted centroids and the lemma embedding. Finally, we the sense embeddings for the lemma l_i become

$$E(s_{ij}) = c_{ij} - \frac{p_{ij}}{\sum_k w_{ijk}} r_i. \quad (5)$$

Equations (4) and (5) show the role of the mix variables: if $p_{ij} = 0$, then the sense embedding $E(s_{ij})$ is completely determined by the neighbors of the sense (that is, it is equal to the weighted centroid). On the other hand, if $p_{ij} = 1$, then the sense embedding becomes equal to the embedding of the lemma, $F(l_i)$. To optimize the mix variables $p_{i1}, \ldots, p_{im_i}$ with respect to the loss L_i, basically any search procedure could be used; we found it easiest to use a variant of a simple randomized gradient-free search method (Matyas, 1965).

3 Application to Swedish Data

The algorithm described in Section 2 was applied to Swedish data: we started with lemma embeddings computed from a corpus, and then created sense embeddings by using the SALDO semantic network (Borin et al., 2013). The algorithm was run for a few epochs, which seemed to be enough for reaching a plateau in performance; the total runtime of the algorithm was a few minutes.

3.1 Creating Lemma Embeddings

We created a corpus of 1 billion words downloaded from Språkbanken, the Swedish language bank.[1] The corpora are distributed in a format where the text has been tokenized, part-of-speech-tagged and lemmatized. Compounds have been segmented automatically and when a lemma was not listed in SALDO, we used the parts of the compounds instead. The input to the software computing the lemma embedding consisted of lemma forms with concatenated part-of-speech tags, e.g. *dricka..vb* for the verb 'to drink' and *dricka..nn* for the noun 'drink'. We used the `word2vec` tool[2] to build the lemma embeddings. All the default settings were used, except the vector space dimensionality which was set to 512.

3.2 SALDO, a Swedish Semantic Network

SALDO (Borin et al., 2013) is the largest freely available lexical resource for Swedish. We used a version from May 2014, which contains 125,781 entries organized into a single semantic network. Compared to WordNet (Fellbaum, 1998), there are similarities but also significant differences. Most significantly, SALDO is organized according to the lexical-semantic relation of *association*, not *is-a* as in WordNet. In SALDO, when we go up in the hierarchy we move from specialized vocabulary to the most central vocabulary of the language (e.g. 'move', 'want', 'who'); in WordNet we move from specific to abstract (e.g. 'entity'). Another difference is that sense distinctions in SALDO tend to be more coarse-grained than in WordNet.

Each entry except a special root is connected to other entries, its *semantic descriptors*. One of the

[1] `http://spraakbanken.gu.se`

[2] `https://code.google.com/p/word2vec`

semantic descriptors is called the *primary* descriptor: this is the semantic neighbor that is conceptually most central. Primary descriptors are most often hypernyms or synonyms, but they can also be e.g. antonyms or meronyms, or be in an argument–predicate relationship with the entry. To exemplify, we consider the word *rock*, which has two senses: a long coat and rock music, respectively. Its first sense has the primary descriptor *kappa* 'coat', while for the second sense it is *musik* 'music'.

When embedding the SALDO network using the algorithm in Section 2, the neighbors n_{ijk} of a SALDO sense s_{ij} are its primary descriptor and inverse primaries (the senses for which s_{ij} is the primary descriptor). We did not use any descriptors beside the primary. The neighborhood weights were set so that the primary descriptor and the set of inverse primaries were balanced, and so that all weights sum to 1. If there were N inverse primaries, we set the weight of the primary descriptor to $\frac{1}{2}$ and of each inverse primary to $\frac{1}{2N}$. We did not see any measurable effect of using a larger set of neighbors (e.g. adding connections to second-order neighbors).

3.3 Inspection of Sense Embeddings

Table 1 shows a list of the nearest neighbors of the two senses of *rock*; as we can see, both lists make sense semantically. (A similar query among the lemma embeddings returns a list almost identical to that of the second sense.)

rock-1 'coat'	*rock*-2 'rock music'
syrtut-1 'overcoat'	*punk*-1 'punk music'
kåpa-2 'cloak'	*pop*-1 'pop music'
kappa-1 'coat'	*soul*-1 'soul music'
kavaj-1 'blazer'	*hårdrock*-1 'hard rock'
jacka-1 'jacket'	*hot*-2 'hot jazz'

Table 1: The senses closest to the two senses of *rock*.

A more difficult and interesting use case, where corpus-based methods clearly have an advantage over knowledge-based methods, is to search among the lemmas that have occurred in the corpus but which are not listed in SALDO. Table 2 shows the result of this search, and again the result is very useful. We stress that the list for the first sense would have been hard to derive in a standard word vector space, due to the dominance of the music sense.

rock-1 'coat'	*rock*-2 'rock music'
midjekort 'doublet'	*indie* 'indie'
trekvartsärm '3/4 sleeve'	*indierock* 'indie rock'
spetsbh 'lace bra'	*doo-wop* 'doo-wop'
blåjeans 'blue jeans'	*psykedelia* 'psychedelia'
treggings 'treggings'	*R&B* 'R&B'

Table 2: The unlisted lemmas closest to the two senses of *rock*.

4 Evaluation

Evaluating intrinsically using e.g. a correlation between a graph-based similarity measure and geometric similarity would be problematic, since this is in some sense what our algorithm optimizes. We therefore evaluate extrinsically, by using the sense vectors in a classifier that maps senses to semantic classes defined by FrameNet (Fillmore and Baker, 2009). FrameNet is a semantic database consisting of two parts: first, an ontology of *semantic frames* – the classes – and secondly a lexicon that maps word senses to frames. In standard FrameNet terminology, the senses assigned to a frame are called its *lexical units* (LUs). Coverage is often a problem in frame-semantic lexicons, and this has a negative impact on the quality of NLP systems using FrameNet (Palmer and Sporleder, 2010). The task of finding LUs for frames is thus a useful testbed for evaluating lemma and sense vectors.

To evaluate, we used 567 frames from the Swedish FrameNet (Friberg Heppin and Toporowska Gronostaj, 2012); in total we had 28,842 verb, noun, adjective, and adverb LUs, which we split into training (67%) and test sets (33%). For each frame, we trained a SVM with LIBLINEAR (Fan et al., 2008), using the LUs in that frame as positive training instances, and all other LUs as negative instances. Each LU was represented as a vector: its lemma or sense embedding normalized to unit length.

Table 3 shows the precision, recall, and F-measure for the classifiers for the five frames with most LUs, and finally the micro-average over all frames. In the overall evaluation as well as in four

out of the five largest frames, the classifiers using sense vectors clearly outperform those using lemma vectors. The frame where we do not see any improvement by introducing sense distinctions, PEOPLE_BY_VOCATION, contains terms for professions such as *painter* and *builder*; since SALDO derives such terms from their corresponding verbs rather than from a common hypernym (e.g. *worker*), they do not form a coherent subnetwork in SALDO or subregion in the embedding space.

5 Conclusion

We have presented a new method to embed a semantic network consisting of linked word senses into a continuous-vector word space; the method is agnostic about whether the original word space was produced using a context-counting or context-predicting method. Unlike previous approaches for creating sense vectors, since we rely on the network structure, we can create representations for senses that occur rarely in corpora. While the experiments described in this paper have been carried out using a Swedish corpus and semantic network, the algorithm we have described is generally applicable and the software[3] can be applied to other languages and semantic networks.

The algorithm takes word vectors and uses them and the network structure to induce the sense vectors. It is based on two separate ideas: first, sense embeddings should preserve the structure of the semantic network as much as possible, so two senses should be close if they are neighbors in the graph; secondly, the word vectors are a probablistic mix of sense vectors. These two ideas are stated as an optimization problem where the first becomes the objective and the second a constraint. While this is hard to solve in the general case, we presented an approximation that can be applied when using the squared Euclidean distance.

We implemented the algorithm and used it to embed the senses of a Swedish semantic network into a word space produced using the skip-gram model. While a qualitative inspection of nearest-neighbor lists of a few senses gives very appealing results, our main evaluation was extrinsic: a FrameNet lexical unit classifier saw a large performance boost when using sense vectors instead of word vectors.

In a followup paper (Johansson and Nieto Piña, 2015), we have shown that sense embeddings can be used to build an efficient word sense disambiguation system that is much faster than graph-based systems with a similar accuracy, and that the mix variables can be used to predict the predominant sense of a word. In future work, we plan to investigate whether the sense vectors are useful for retrieving rarely occurring senses in corpora. Furthermore, since we now evaluated extrinsically, it would be useful to devise intrinsic sense-based evaluation schemes, e.g. a sense analogy task similar to the word analogy task used by Mikolov et al. (2013).

Abstract

Random walks over large knowledge bases like WordNet have been successfully used in word similarity, relatedness and disambiguation tasks. Unfortunately, those algorithms are relatively slow for large repositories, with significant memory footprints. In this paper we present a novel algorithm which encodes the structure of a knowledge base in a continuous vector space, combining random walks and neural net language models in order to produce novel word representations. Evaluation in word relatedness and similarity datasets yields equal or better results than those of a random walk algorithm, using a dense representation (300 dimensions instead of 117K). Furthermore, the word representations are complementary to those of the random walk algorithm and to corpus-based continuous representations, improving the state-of-the-art in the similarity dataset. Our technique opens up exciting opportunities to combine distributional and knowledge-based word representations.

1 Introduction

Graph-based techniques over Knowledge Bases (KB) like WordNet (Fellbaum, 1998) have been widely used in NLP tasks, including word sense disambiguation (Agirre et al., 2014; Moro et al., 2014), semantic similarity and semantic relatedness between terms (Agirre et al., 2009; Agirre et al., 2010; Pilehvar et al., 2013). For instance, Agirre et al. (2009; 2010) apply a random walk algorithm based on Personalized PageRank to WordNet, presenting the best results to date among WordNet-based methods for the well-known WS353 word-similarity dataset (Finkelstein et al., 2001). For each target word, the method performs a personalized random walk on the WordNet graph. At convergence, the target word is represented as a vector in a multi-dimensional conceptual space, with one dimension for each concept in the KB. The good results of the algorithm contrast with the large dimensionality of the vectors that it needs to produce, 117K dimensions (one per synset) for WordNet.

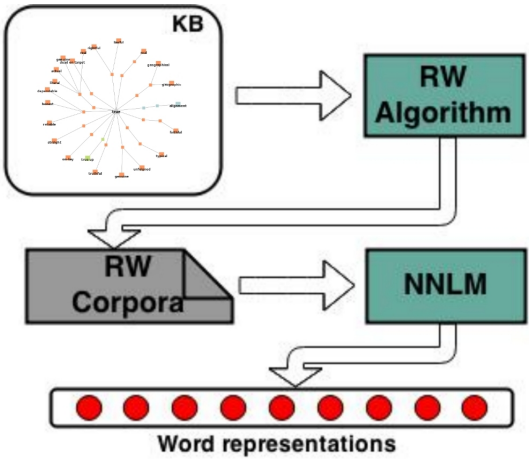

Figure 1: Main architecture for generating KB word embeddings. A random walk algorithm over the KB produces a synthetic corpus, which is fed into a NNLM to produce continuous word representations.

In recent years a wide variety of Neural Network Language Models (NNLM) have been successfully employed in several tasks, including word similarity (Collobert and Weston, 2008; Socher et al., 2011;

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1434–1439,
Denver, Colorado, May 31 – June 5, 2015.

Turian et al., 2010). NNLM extract meaning from unlabeled corpora following the distributional hypothesis (Harris, 1954), where semantic features of a word are related to its co-occurrence patterns. NNLM learn word representations in the form of dense scalar vectors in n-dimensional spaces (e.g. 300 dimensions), in which each dimension is a latent semantic feature. The representations are obtained by optimizing the likelihood of existing unlabeled text. More recently, Mikolov et al. have developed simpler NNLM architectures (Mikolov et al., 2013a; Mikolov et al., 2013b; Mikolov et al., 2013c), which drastically reduced computational complexity by deleting the hidden layer, enabling to compute accurate word representations from very large corpora. The representations obtained by these methods are compact, taking 1.5G for 3M words on 300-dimensional space, and have been shown to outperform other distributional corpus-based methods on several tasks, including the WS353 word similarity dataset (Baroni et al., 2014).

In this work we propose to encode the meaning of words using the structural information in knowledge bases. That is, instead of modeling the meaning based on the co-occurrences of words in corpora, we model the meaning based on random walks over the knowledge base. Each random walk is seen as a context for words in the vocabulary, and fed into the NNLM architecture, which optimizes the likelihood of those contexts (cf. Fig. 1). The resulting word representations are more compact than those produced by regular random walk algorithms (300 vs. tens of thousands), and produce very good results on two well-known benchmarks on word relatedness and similarity: WS353 (Finkelstein et al., 2001) and SL999 (Hill et al., 2014b), respectively. We also show that the obtained representations are complementary to those of random walks alone and to distributional representations obtained by the same NNLM algorithm, improving the results.

Some recent work has explored embedding KBs in low-dimensional continous vector spaces, representing each entity in a k-dimensional vector and characterizing typed relations between entities in the KB (e.g. born-in-city in Freebase or part-of in WordNet) as operations in the k-dimensional space (Wang et al., 2014). The model estimates the parameters which maximize the likelihood of the triples, which can then be used to infer new typed relations which are missing in the KB. In contrast, we use the relations to explicitly model the context of words, in two complementary approaches to embed information in KBs into continuous spaces.

2 NNLM

Neural Network Language Models have become a useful tool in NLP on the last years, specially in semantics. We have used the two models proposed in (Mikolov et al., 2013c) due to their simplicity and effectiveness in word similarity and relatedness tasks (Baroni et al., 2014): Continuous Bag of Words (CBOW) and Skip-gram. The first one is quite similar to the feedforward Neural Network Language Model, but instead of a hidden layer it has a projection layer, and thus all the words are projected in the same position. Word order has thus no influence in the projection. The training criterion is as follows: knowing previous and subsequent words in context, the model maximizes the probability of the predicting the word in the middle. The Skip-gram model uses each current word as an input to a log-linear classifier with a continuous projection layer, and predicts the previous and subsequent words in a context window.

Although the Skip-gram model seems to be more accurate in most of the semantic tasks, we have used both variants in our experiments. We used a publicly available implementation[1].

3 Random Walks and NNLM

Our method performs random walks over KB graphs to create synthetic contexts which are fed into the NNLM architecture, creating novel word representations. The algorithm used for creating the contexts is a Monte Carlo method for computing the PageRank algorithm (Avrachenkov et al., 2007).

We consider a KB as undirected graph $G = (V, E)$, where V is the set of concepts and E represents links among concepts. We also need a dictionary, an association from words to KB concepts. We construct an inverse dictionary that maps graph vertices with the words than can be linked to it.

The inputs of the algorithm are: 1) the graph $G = (V, E)$, 2) the inverse dictionary and 3) the damp-

[1] https://code.google.com/p/word2vec/

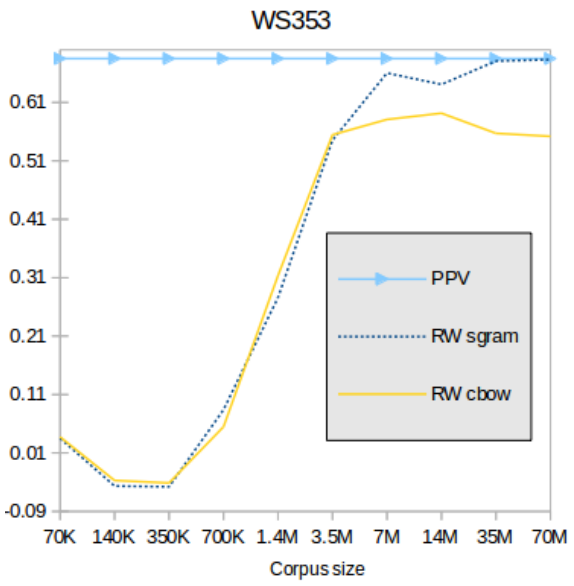

Figure 2: Spearman results on relatedness (WS353) for different corpus sizes (in sentences).

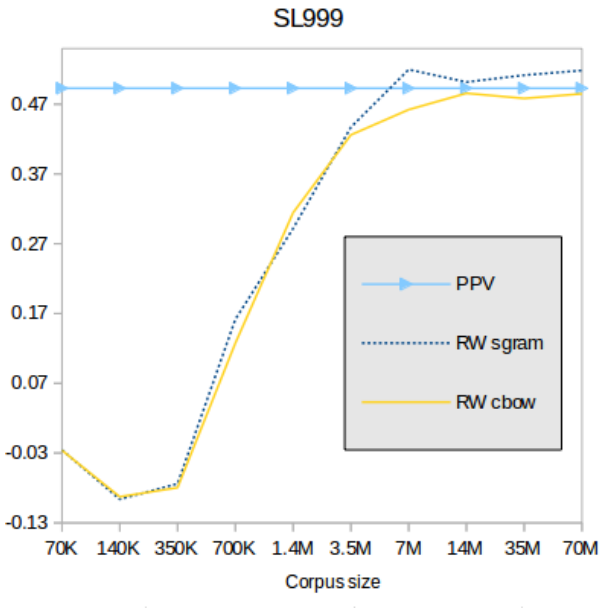

Figure 3: Spearman results on similarity (SL999) for different corpus sizes (in sentences).

ing factor α[2]. In our experiments we used WordNet 3.0 with gloss relations[3], which has 117.522 nodes (synsets) and 525.356 edges (semantic relations). Regarding the dictionary, WordNet already contains links from words to concepts. The dictionary includes the probability of a concept being lexicalized by a specific word, as estimated by the WordNet team from their hand-annotated corpora. Both dictionary and graph are freely available[4].

The method first chooses a vertex at random from the vertex set V, and performs a random walk starting from it. At each step, the random walk might terminate with probability $(1-\alpha)$ or choose a neighbor vertex at random with probability α. Each time the random walk reaches a vertex, a word is emitted at random using the probabilities in the inverse dictionary. When the random walk terminates, the sequence of emitted words forms the pseudo sentence which is fed to the NNLM architecture, and the process starts again choosing a vertex at random until a maximum number of pseudo sentences have been generated.

Our method creates pseudo sentences like the following:

(1) *amphora wine nebuchadnezzar bear retain long*

(2) *graphology writer write scribble scrawler heedlessly in_haste jot note notebook*

These examples give us clues of the kind of the implicit semantic information that is encoded in the generated pseudo-corpus. Example 1 starts with *amphora* following with *wine* (with which amphoras are usually filled with), *nebuchadnezzar* (a particular bottle size) and finishing with words that are related to wine storage, like *bear*,*retain* and *long*. Example 2 shows a similar phenomenom; it starts with *graphology*, follows with the closely related *writer*, then *writer*, finishing with names and adjectives of different variants of writing, such as *scribble*, *scrawler*, *heedlessly*, *in_haste* and *jot*; finally, the context ends with *note* and *notebook*. Note that our method also produces multiword terms like *in_haste*.

4 Experiments

We have trained two Neural Network models, CBOW and Skip-gram, with several iterations of random walks over WordNet. We trained both models with default parameters (Mikolov et al., 2013a): vector size 300, 3 iterations, 5 negative samples, and

[2]The damping factor is the only parameter of PageRank.

(c) Skip-gram	0.442	0.686
(a+b)	0.535	0.700
(a+c)	0.533	0.748
(a+b+c)	**0.552**	0.759
Best	0.520	**0.800**

Table 2: Combinations and best published results: SL999 (Hill et al., 2014a), WS353 (Radinsky et al., 2011).

window size 5. In order to check how many iterations of the random walk algorithm are needed to learn good word representations, we produced up to $70 \cdot 10^6$ contexts. The the damping factor (α) of the random walk algorithm was set to 0.85, a usual value (Agirre et al., 2010). All parameters were thus set to default, and we only explored different corpus sizes.

The word representations were evaluated on WS353 (Finkelstein et al., 2001) and SL999 (Hill et al., 2014b), two datasets on word relatedness and word similarity, respectively. In order to compute the similarity of two words, it suffices to calculate the cosine between the respective word representations. The evaluation measure computes the rank correlation (Spearman) between the human judgments and the system values.

In order to contrast our results with the two related techniques, we used UKB[5], a publicly available implementation of Personalized PageRank (Agirre et al., 2014), and ran it over the same graph as our proposed methods. We used it out-of-the-box with a damping value of 0.85. We also downloaded the embeddings learnt by (Mikolov et al., 2013a) using Skip-gram over a large text corpus [6]. We used the same cosine algorithm to compute similarity with all word representations. To distinguish one word representation from the other, we will call our models RWCBOW and RWSGRAM respectively (RW for random-walk), in contrast to the original Personalized PageRank algorithm (PPV) and the corpus-based embeddings learned using Skip-grams (Skip-gram).

Figures 2 and 3 show the learning curves on the WS353 and SL999 datasets relative to the number of contexts produced by the random walks on WordNet. The results show that WordNet representations grow quickly (around 7 million contexts), converging around 70M, obtaining practically the same results as PPV for WS353, and better results for SL999[7].

The results at convergence are shown in Table 1, together with those of PPV and Skip-gram. Regarding SL999, we can see that the best results are obtained with RWSGRAM, improving over PPV and Skip-gram. Regarding WS353, all methods except RWSGRAM obtain similar results. The results show that our methods are able to effectively capture the information in WordNet, performing on par to the original PPV algorithm, and better than the corpus-based Skip-gram on the SL999 dataset. Note that the best published results for WS353 using WordNet are those of (Agirre et al., 2010) using PPV, which report 0.685.

In order to see if the word representations that we learn are complementary to those of PPV and Skip-gram, we combined the scores produced by each word representation. Given the potentially different scales of the similarity values, we assigned to each item the average of the ranks of the pair in each output. The top part of Table 2 repeats the three relevant systems. The (a+b) row reports an improvement in both datasets, showing that RWSGRAM on WordNet is complementary to PPV in WordNet, and is thus a different representation, even if both use the same knowledge base. The (a+b) and (a+b+c) show that corpus-based Skip-grams are also complemen-

[5] http://ixa2.si.ehu.eus

[6] https://code.google.com/p/word2vec/

[7] We tried larger context sizes, up to 700M confirming that convergence was around 70M.

tary, yielding incremental improvements. In fact, the combination of all three improves over the best published results on SL999, and approaches the best results for WS353, as shown in the last row of the Table. The state of the art on SL999 corresponds to (Hill et al., 2014a), who training a Recurrent Neural Net model on bilingual text. The best results on WS353 correspond to (Radinsky et al., 2011), who combine a Wikipedia-based algorithm with a corpus-based method which uses date-related information from news to learn word representations.

Note that we have only performed some simple combination to show the complementarity of each information source. More sophisticated combinations (e.g. learning a regression model) could further improve results.

We have performed some qualitative analysis, which indicates that there is a slight tendency for corpus embeddings (with the window size used in the experiments) to group related words (e.g. physics - proton), and not so much similar words (e.g. vodka - gin), while our KB embeddings include both. This analysis agrees with the results in Table 1, where all KB results are better than corpus-based Skip-gram for the semantic similarity dataset (SL999). In passing, note that the best published results to date on similarity (Hill et al., 2014a) use embeddings learnt from bilingual text which suggests that bilingual corpora are better suited to learn embeddings capturing semantic similarity.

5 Conclusions

We have presented a novel algorithm which encodes the structure of a knowledge base in a continuous vector space, combining random walks and neural net language models to produce new word representations. Our evaluation in word relatedness and similarity datasets has shown that these new word representations attain similar results to those of the original random walk algorithm, using 300 dimensions instead of tens of thousands. Furthermore, the word representations are complementary to those of the random walk algorithm and to corpus-based continuous representations, producing better results when combined, and improving the state-of-the-art in the similarity dataset. Hand inspection reinforces the observation that WordNet-based

A promising direction of this research is to leverage multilingual Wordnets to produce cross-lingual embeddings.

On another direction, one of the main limitations of KB approaches is that they produce a relatively small number of embeddings, limited by the size of the dictionary. In the future we want to overcome this sparsity problem by combining both textual and KB based embeddings into a unified model. In fact, we think that our technique opens up exciting opportunities to combine distributional and knowledge-based word representations.

It would also be interesting to investigate the influence of the different semantic relations in WordNet, either by removing certain relations or by assigning different weights to them. This investigation could give us deeper insights about the way our knowledge-based approach codes meaning in vector spaces.

Identification and Characterization of Newsworthy Verbs in World News

Benjamin Nye
University of Pennsylvania
bepnye@gmail.com

Ani Nenkova
University of Pennsylvania
nenkova@seas.upenn.edu

Abstract

We present a data-driven technique for acquiring domain-level importance of verbs from the analysis of abstract/article pairs of world news articles. We show that existing lexical resources capture some the semantic characteristics for important words in the domain. We develop a novel characterization of the association between verbs and personal story narratives, which is descriptive of verbs avoided in summaries for this domain.

1 Introduction

Summarization, either by people or machine, calls for the ability to identify important content. Computational approaches to identifying important content fall into the two extremes of a possible spectrum. On one end, the types of important information for a given domain and topic are predefined as information extraction templates defined by experts, as in the earliest approaches to multi-document summarization (Radev and McKeown, 1998) and the recently introduced guided summarization (Owczarzak and Dang, 2011). On the other extreme, traditional systems work only with indicators of importance coming solely from the input to be summarized, or possibly also from the context of the input, i.e . analyzing the anchor text of links to a webpage, or comments on a blog post or citations to a scientific article (Nenkova and McKeown, 2012).

Here we explore the feasibility of data-driven identification of important information in the world news domain. We specifically focus on the analysis of verbs, which is the first step of identifying event types of special interest. The goal is to collect evidence of verb importance globally, without regard to a particular input or its context. Such ideas have been explored in the past as subcomponents of extractive summarizers (Schiffman et al., 2002; Hong and Nenkova, 2014) or as features derived from small datasets for sentence compression (Woodsend and Lapata, 2012). In contrast, in our work we rely on large corpora and exclusively focus on the task of acquiring input independent indicators of importance. We also constrain our analysis to a single domain, which allows us to examine the semantic aspects of the verbs that may contribute to their perceived importance.

We leverage a dataset of human-written summaries of news articles to objectively ground the definition of word importance. Summaries are intended to convey important information while omitting the less important pieces, so words that are important in a newsworthy sense will occur more frequently in summaries. The same data and intuition was used recently to develop a large corpus for determining entity salience (Dunietz and Gillick, 2014).

We derive a list of over one thousand verbs that have statistically significant bias to appear in the summaries (important verbs) and verbs with higher rate of occurrence in the original articles (unimportant). This resource of verbs and their domain-level importance may be fruitfully exploited in models of summarization that do not use pre-defined templates but are richer than approaches that rely solely on analysis of the article text.

We furthermore seek to characterize the properties of words that are biased to occur more often

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1440–1445,
Denver, Colorado, May 31 – June 5, 2015.

in either summaries or in articles. We noticed that verbs that tended to be dis-preferred in the summaries related to personal narratives, in which people are described as private entities rather than public personas. We applied the same measures that we used to analyze domain-level importance in world news to a collection of labeled personal and nonpersonal blog entries. Characterizing verbs on the personal vs. nonpersonal dimension indeed turned out to beneficial for explaining domain-level importance of verbs in world news: personal narratives are not considered important in this domain and verbs that tended to get excluded from summaries also tended to appear more frequently in personal blog entries. This characterization offered broad coverage of the article vocabulary and additional explanatory power compared to a characterization derived from General Inquirer categories.[1]

The derived lexical resources may serve as shallow semantics for a range of language processing tasks such as summarization, news filtering and search.[2]

2 Determining domain-level importance

To determine domain-level importance, we use summaries and articles from the New York Times Annotated Corpus[3], a collection of NYT articles that includes genre tags and summaries written by library scientists. We use articles published in the world news section between 1996 and 2005 for a total of 36,69 article-summary pairs.

All of the documents were parsed with the Stanford Parser to obtain lemmatized forms of the words and part of speech tags. There are 2,634,850 tokens in the summaries and 32,587,740 tokens in the respective articles.

The overall verb frequency is very similar in the summaries (14.5%) and the articles (14.6%). In our analysis we reduce the corpus of summaries and original articles to only the verbs that occur in them. Then we compare the rate of occurrence of each verb in the two types of writing. Verbs used proportionally more in summaries are likely to correspond to events that are important, while verbs that occur more frequently in the articles are less likely to be related to the key topics of an article. To generate two classes of verbs representing important and non-important verbs, we consider two measurements: the difference of a verb's usage frequency between summaries and articles, and the statistical significance of this bias.

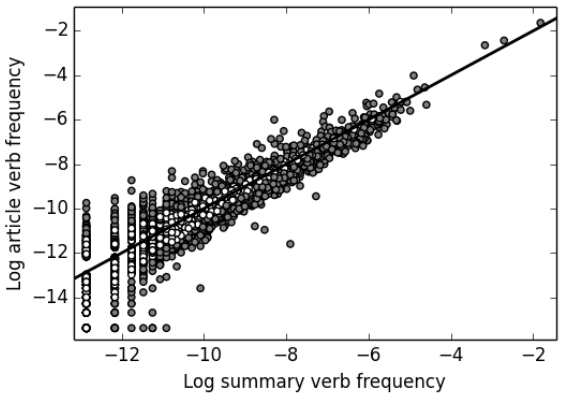

Figure 1: Word frequency in summaries vs. articles. The black line is where the frequencies are equal, and words plotted in grey have statistically significant differences in frequencies for the two classes.

Figure 1 shows the plot of each verb's probability in the summaries, $P_s(w_i)$ vs. in the articles, $P_a(w_i)$. Points above the line are verbs that occur more frequently in articles, while points below the line are more frequent in summaries. Dividing the points along this line produces two classes of verbs. We can further quantify how strongly a word is associated with its class using a variety of metrics (Monroe et al., 2008).

For this application, we chose to use the log odds ratio. To measure how much more likely a word w is to occur in a class c, we compute the odds of a word occurring in corpora type c, i.e summary (s) or original article (a):

$$Odds(w, c) = \frac{P(w \mid class = c)}{1 - P(w \mid class = c)}$$

The ratio of the odds with respect to the two different corpora is a measure of how much more frequently

[1]The two lists characterizing the domain-level importance and the personal–public dimension are available for download at `http://www.cis.upenn.edu/~nlp/software/importance.html`.

[2]Personal perspective verbs may not be important in reporting world news but may be excellent indicators of celebrity/gossip search for example.

[3]https://catalog.ldc.upenn.edu/LDC2008T19

a word is used in each case. To make the measure interpretable, we take the log of the odds ratio producing the final weight for a word:

$$\log\left(\frac{Odds(w,s)}{Odds(w,a)}\right) \simeq \log\left(\frac{P(w \mid class = s)}{P(w \mid class = a)}\right)$$

This metric gives an intuitive measure of the usage rate of words. For example, if a word occurs 3 times more often in the summaries it will be given a weight of $\log(3)$, and if it occurs three times more often in the articles it will be given a weight of $-\log(3)$.

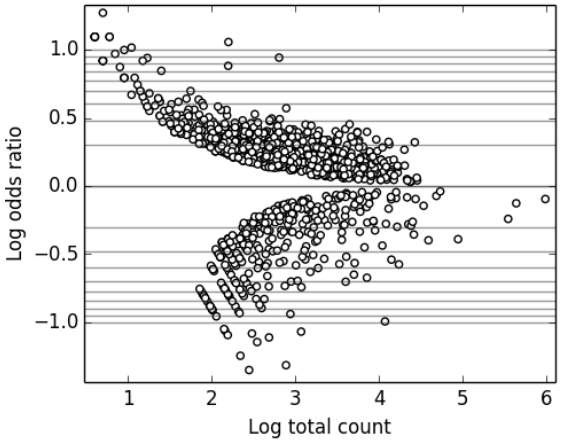

Figure 2: Frequency vs. log odds ratio for each word. Positive odds ratios correspond to summary-biased words and negative correspond to article-biased. The lines indicate integer usage ratios (1:3, 1:2, 1:1, 2:1, 3:1, etc).

However, this metric is unreliable for verbs with low counts in either class of texts. If a verb occurs five times in summaries and only once in articles, it is difficult to say if there is true signal for importance. As the number of counts of a verb in the two classes increases, so does our certainty about the significance of any observed differences in usage rates. To obtain a measure of the statistical significance of the domain-level importance weight of a verb, we treat the set of observed tokens as a Bernoulli trial where each token occurs either in a summary (success) or in an article (failure). We apply a binomial test to compute the probability of the observed distribution of tokens in the two types of text under the null hypothesis that the word has equal frequency in summaries and articles. The p-value from the test gives a measure of the certainty that a word is important and not. We can filter out words with p-values above a certain threshold. Moving the threshold closer to 0 enforces more and more certainty about the classification, reducing vocabulary size but also decreasing noise. Discarding verbs with a p-value of less than 0.05 reduces the vocabulary size from 3,924 words to 1,210.

Table 1: Words with highest weights, drawn from verbs with frequency greater than the median verb frequency.

In Figure 2, the log odds ratio is plotted against the overall frequency for each verb after discarding unreliable verbs. The most extreme weights occur mostly for the infrequent words, even after filtering out low p-value words. Although these words have extremely high bias weights, they tend to be uncommon and not particularly informative. Examples include verbs such as "hostage-take", "muckrake", and "blaspheme." To get a clearer picture of trends in the verbs in each category, we show in Table 1 the verbs with the 30 highest and 30 lowest weights among the verbs in the 50th percentile of total counts across all documents.

In the following two sections, we turn to analyzing *why* certain verbs may be more important in the domain than others. First we examine the relationship between the summary- or article-bias of a word and categories in the General Inquirer lexicon. Then we develop a new characterization of verbs showing their association with person-centered perspective of the narrative.

3 General Inquirer

The General Inquirer lexicon provides a list of words manually annotated with a variety of tags (Stone et al., 1966). We considered eight of these tags that were relevant to our task and could explain why

Tag	Summ.	Article	Examples
none	0.58	0.77	
Negative	0.21	0.05	counterfeit avert, weep wail
Active	0.26	0.15	intensify overhaul, grasp hop
Strong	0.16	0.03	oust devestate, roar promote
Hostile	0.13	0.01	kidnap ravage, shrug crush
Power	0.08	0.01	curb reclaim, persuade overcome
Positive	0.07	0.03	reinstate mend, reassure hug
Passive	0.05	0.05	deplore mourn, gaze huddle
Weak	0.04	0.03	flounder sag, abandon hesitate

Table 2: Percentage of words in each class covered by different GI tags. The first two example words come from the summary-biased class and last two come from the article-biased class.

a verb has domain-level importance: NEGATIVE, POSITIVE, ACTIVE, PASSIVE, STRONG, WEAK, HOSTILE, and POWER.

Table 2 shows some randomly selected words from each of the eight GI tags. The first two words come from the summary-biased class and last two come from the article-biased class. Table 2 also shows the fraction of verbs in each class that occur in the GI with a given tag, as well as the fraction of verbs that do not have any of the eight tags. It becomes immediately clear that the GI categories do have explanatory power but that it has a major problem with coverage, with the majority of verbs in the summary and article corpora not appearing in the GI at all as shown on the first line. Notably, the coverage is considerably better for the summary-biased verbs. Verbs from several GI categories appeared notably more often in summaries than in articles. For example, verbs with the NEGATIVE tag account for 21% of verbs in summaries, but only 5% of verbs in articles. Other such categories include verbs that imply an active physical engagement (ACTIVE), imply that the actor is in a position of power (STRONG), imply that hostility exists between the entities involved (HOSTILE) or that imply that the actor has the influence to affect the policies of others (POWER). POSITIVE, PASSIVE, and WEAK verbs had more similar appearance rates in both classes, but the absolute number of words covered by these tags was low.

Increasing the strictness of the p-value cutoff for pruning the vocabulary as described in the previous section reduces the size of the vocabulary but increases the purity of the classes by only including verbs that have sufficiently different usage ratios. As shown in Table 3, as we restrict the vocabulary to increasingly certain verbs, the proportion of verbs in the summary class that are tagged by the GI remains almost constant while the proportion of untagged verbs in the article class steadily increases. This indicates that the summary-biased verbs have a consistent distribution of GI tags across all usage ratios, while verbs tended to be tagged less often as the bias towards the articles increased. Although the GI gives good indicators for which words are likely to be important summary words but no indicators for which words are likely to be of no interest in summarizing world news.

p-value	0.01	0.001	0.0001	0.00001
Summary	0.54	0.53	0.54	0.54
Article	0.80	0.86	0.88	0.91

Table 3: Percentage of words with zero GI tags for increasing p-value cutoff strictness

3.1 Personal Stories

To get a sense for what aspects of the verb semantics causes a word to be excluded from the summary, we examined the contexts for the verbs with the highest bias weights in each class. To define the context for each verb, we used the dependency relations produced by the Stanford Parser. Any verb, noun, or adverb placed in a dependency relation with a given verb is considered to co-occur with it. For each of the ten most highly weighted verbs in each class, Table 4 shows the lemmas that co-occurred most frequently with it.

The verbs that are biased towards the articles (not important) seem to capture human element of the news reports, corresponding to passages narrating personal stories of ordinary people involved in the larger political situation discussed in the news. The summary-biased verbs are clearly evocative of the NEGATIVE, ACTIVE, STRONG, HOSTILE, and POWER tags given by the GI and the common usages suggested by their contexts tend to be official, non-personal or that of people in public roles.

No existing resources provide descriptions of this personal vs. non-personal dimension of lexical meaning and we decided to derive such a characterization from data unrelated to the NYT.

Table 5: Top weighted words derived from personal and non-personal blog entries

For this purpose, we used a subset of the ICWSM 2009 Spinn3r Blog Dataset that has been annotated with a semi-supervised classifier trained to identify personal stories (Gordon and Swanson, 2009). We took 56,048 blog entries that had been tagged as being a personal story and 2,196,162 blog entries that were not identified as personal.

We then applied the same procedure that we used for the NYT articles to produce two classes of words: those biased towards blogs describing personal stories and those biased towards non-personal blogs. After restricting the vocabulary to only verbs with a binomial test p-value of at most 0.05, we obtained log odds ratio weights for 3,143 verbs. Of the 1,210 verbs in the NYT classes, 937 were also present in the restricted blog vocabulary. The 20 most and least personal verbs are shown in Table 5.

p-value	GI	GI+blog
0.05	0.134	0.098
0.01	0.130	0.087

Table 6: 10-fold cross-validation mean squared error of a linear regression for increasingly biased vocabularies.

The Pearson correlation between the NYT log odds ratio and the blog log odds ratio is negative and rather high, -0.54, indicating a strong relationship between personal and article-biased words. Restricting the significance to p-value cutoff of 0.01 reduces the vocabulary from 937 to 675 verbs, but strengthens the correlation to -0.61. Of the top 100 summary-biased words, only 18 were personal. Of the top 100 article-biased words, 90 were personal.

Not only do the personal/non-personal classes map on to the summary/article classes well, but they supply explanatory information about words that the GI did not cover. In order to measure this effect, we trained a linear regression to predict the NYT log-odds ratio of a word using a binary feature for each GI tag, as well as a binary feature indicating no tags. We were interested in the reduction of error when the personal-biased information was added. Adding the blog log-odds ratio for each word as a feature improved our results in 10-fold cross-validation, reducing the prediction error by almost 30%. The detailed results are shown in Table 6, for experiments performed for two different p-value cut-offs.

4 Conclusion

We presented a method for data-driven acquisition of domain-level importance of verbs in reports of world news events. Analysis of the acquired verbs reveals that summary-biased words tend to be more negative, active, and hostile, while the article-biased words mostly describe personal actions. This lexicon provides a useful notion of global importance in a domain and can serve as resource for semantic characterization of words in a variety of tasks, including sentence selection in summarization, flagging articles as newsworthy or filtering uninteresting documents. Additionally, we provide a lexicon for personal and non-personal verbs that also captures some of the newsworthiness of the article and summary classes.

Enhancing Sumerian Lemmatization by Unsupervised Named-Entity Recognition

Yudong Liu, Clinton Burkhart, James Hearne and **Liang Luo**

Abstract

Lemmatization for the Sumerian language, compared to the modern languages, is much more challenging due to that it is a long dead language, highly skilled language experts are extremely scarce and more and more Sumerian texts are coming out. This paper describes how our unsupervised Sumerian named-entity recognition (NER) system helps to improve the lemmatization of the Cuneiform Digital Library Initiative (CDLI), a specialist database of cuneiform texts, from the Ur III period. Experiments show that a promising improvement in personal name annotation in such texts and a substantial reduction in expert annotation effort can be achieved by leveraging our system with minimal seed annotation.

1 Introduction

Because the Sumerian cuneiform writing system is historically the earliest, Sumerian culture is the earliest recorded civilization. The large number of clay tablets that have been recovered from Mesopotamia reveal "an almost obsessive concern for the preservation of daily events of the time: the digging of ditches, the care of livestock, the storage of grain, and so on. Their survival allows insight into the lives of the city dwellers of remote antiquity" (Garfinkle, 2012). Today, most cuneiform texts are held in public institutions, but the texts are widely separated both from each other and often from scholars by great distances and expensive journeys. Current projects like the Digital Library Initiative (CDLI, 2014) and the Database of Neo-Sumerian Texts (BDTNS, 2014) aim to provide scholars immediate access to virtual collections of tens of thousands of texts.

The Ur III period (2112-2004 BCE) is particularly abundant in surviving texts. Because this era was the specialty of our principle informant, an Assyriologist at our home university, we focus on the tablets that are from this era. The vast majority of these tablets record financial transactions, such as records of cattle deliveries, receipt of metals, repayment of loans, and so forth.

Figure 1 shows a tablet from the CDLI repository. For expository purposes, we arranged the original cuneiform drawings on the left (which are not input to our computations), with its transliteration (a one-to-one transcription of signs in a cuneiform text to computer readable text) in the middle, and the modern English translation on the right. The original CDLI data includes transliterations in ASCII format and inline lemmatization markup. More detail about CDLI data will be introduced in Section 2.

As we can see in Figure 1, in addition to the provider and recipient of transference, tablets consistently enumerate lists of witnesses ("sealed by"). This fact makes the tablet an invaluable resource for the social history of the time since they record, implicitly, on each tablet, lists of persons who knew one another and enjoyed professional relations (Widell, 2008). The recovery of personal names on the tablets suggests the possibility of reconstructing social networks of actors in the mercantile class and also, given the overlap, their social network connections to royalty.

Motivated by this perspective, we built an unsupervised Sumerian named-entity recognition (NER) system, also to accommodate the facts of 1) Sumerian is a dead language; 2) the corpus is of a size too large for even a community of scholars to master; 3) the tablets come in many cases damaged by time and

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1446–1451,
Denver, Colorado, May 31 – June 5, 2015.

the circumstances of their recovery which was, in many cases, looting; 4) new tablets are still being uncovered. More detail on our Decision List Co-Train method (Collins and Singer, 1999) can be found in Section 3. In the process of evaluating our NER sys-

Figure 1: Tablet with ID of P105955 from CDLI.

tem, we noticed that a major inconsistency between our result and the lemmata in CDLI lies in the annotation of personal names with missing signs in damaged tablets. For example, "szu-[x]-lum" is not labeled as a name in the lemmata, but our system does so with a high confidence score. As shown this word contains a damaged sign (indicated by "[x]"). Inconsistencies of this kind account for around 50% of the total false positives in our result. With the help of the Sumerologist at our home university, around 40% of such damaged occurrences have been easily verified as personal names. This suggests that the original lemmatization is performed by a more critical and conservative approach. Our work offers a promising automation tool for the annotation task on this corpus by making good recommendations on name candidates to the annotators.

2 CDLI and the Annotations

The CDLI is a collaborative project with cuneiform text capturing and processing efforts underway in North America, Europe and the Middle East. It aims to provide an open access to electronic documentation of ancient cuneiform, consisting of texts, images, transliterations and glossaries of 3500 years of human history. Adhering to the open-source policy, any contribution to the collection by providing electronic catalogues, transliterations, or images of cuneiform artifacts is welcomed (CDLIwiki, 2014).

When represented in Roman script in transliterations, the syllable signs that make up a Sumerian word are written joined together with dashes. As there is no concept of upper- or lowercase in cuneiform writing, signs in transliterations typically occur in lowercase. However, signs rendered in uppercase do occur when the phonetic equivalent of the sign is unclear, tentative or fairly new (Sahala, 2012). One important property of Cuneiform is a high degree of homophony (referred to in the literature on Cuneiform as 'polyvalence'). This phenomenon is conventionally handled by numerical subscripts. For example, "du" means "to go", "du_3" means "to build" (Tablan et al., 2006).

Royal epithets notwithstanding, Sumerian personal names are exclusively comprised of a single word, almost always consisting of at least two signs. In cases where disambiguation is required, a patronymic may added (for example, szu-esz4-tar2 dumu zu-zu, "Su-Estar, son of Zuzu"). This disambiguation is frequent in practice due to the relatively shallow pool of personal names used (Limet, 1960).

In the lemmatization information exposed by CDLI that we make use of in our NER task, when the word is a noun or verbal form, the two types of information included in the lemmata are 1) the *citation form*, rendered as the Sumerian stem; 2) the *guide word*, which functions as a disambiguator and is generally the English translation of the stem; otherwise, the lemma contains only the part of speech, as is the case with proper names and numbers. For example, in the following excerpt (CDLI No: P100032), wherein text is presented with interlinear lemmata (English translation: *Egi-zi-mah received 2 oxen from runner.*), we see both types of lemmatization.

```
1. 2(disz) gu4
#lem: n; gud[ox]
2. ki kas4-ta
#lem: ki[place]; kasz[runner]
3. egi-zi-mah i3-dab5
#lem: PN; dab[seize]
```

On line 3, the verbal form i3-dab5, indicating the receipt of an animate object, is lemmatized with the citation form dab, which is the Sumerian root for this form, and guide word "seize", the best English translation of the citation form. On lines 1 and 3, we have a number lemmatized with the part of speech n and the personal name egi-zi-mah with the part of speech PN, respectively. These annotated

PNs are used as gold standard labels to evaluate our NER system.

In the study of the Ur III corpus, the most exhaustive infrastructure and documentation for lemmatization is that provided for "the Open Richly Annotated Cuneiform Corpus (Oracc)" (ORACC, 2014). The lemmatizer for the Oracc system is accessed via an Emacs interface designed to encourage simultaneous transliteration and lemmatization by a human expert. The process begins with the human expert submitting an unlemmatized transliteration in a format called ATF (ASCII Transliteration Format). This format is the standard interchange format for transliteration across many projects dealing in and exchanging Assyriological textual representations (such as CDLI, BDTNS, the Pennsylvania Sumerian Dictionary (PSD, 2006), and Digital Corpus of Cuneiform Lexical Texts (DCCLT, 2014)). Via the Emacs interface, the transliteration is submitted to the linguistic annotatation system, which identifies an existing project-specific glossary based on directives provided by the human expert in the transliteration, and returns a preliminary lemmatization whose completeness and content depends on the referenced project glossary. The transliterator may then modify any automatically-generated lemmata, or, in the case of new words or new senses in which existing words used, manually lemmatize the word to allow the lemmatizer to "harvest" the new lemma and add it to the glossary. Oracc's lemmatizer also performs normalization and morphological analysis in order to automatically and consistently identify words in the text. The lemmatizer is not designed to "learn" new insights or induce new rules regarding Sumerian morphology on the basis of new lemmata harvested from submissions, but rather serves as a mechanism to consistently apply rules that have been harvested.

Based on our statistics, 53,146 tablets (about 60%) of the CDLI repository are accompanied by the in-line annotations described above. That is the amount of the tablets we used for the NER System.

3 Sumerian Personal Name Recognition

3.1 Related Work

To our knowledge, no previous empirical research exists directly addressing the question of how to recognize named entities from the Sumerian text. Our very preliminary work on this task (Brewer et al., 2014) uses an existent name list to recognize existing names, and applies simple heuristics and a similarity measure to recognize unseen personal names and dates. And at the time, no comprehensive evaluation and analysis could be done due to the unavailability of the language expert.

The investigation most closely related to ours is found in (Jaworski, 2008), which describes a system for processing Sumerian economic documents. Even though we borrowed 3 rules from their work as our seed rules (more details can be found in Section 3.2), and we are dealing with the same language in the same domain, there are a few important differences between our work and theirs. 1) Their goal is to model the content of the text by using an ontology driven method, whereas our goal is to extract named entities from the text by using some statistical method. 2) Their data set is strictly smaller than ours. The corpus used in their work was restricted to $\sim$12,000 tablets containing transactions involving animals, with the contents of these transactions being extracted via an a priori ontology. Our work is addressed to almost the entire corpus where the lemmatization is available, $\sim$53,000 tablets. 3) Their work involved no learning but rather the application of pre-defined Finite State Methods for entity recognition.

Supervised named entity recognition has achieved excellent performance (Bikel et al., 2002) (Zhou and Su, 2002) (McNamee and Mayfield, 2002) (MaCallum and Li, 2003) (Oliver et al., 2003). Semi-supervised approaches and unsupervised approaches have also achieved notable success on this task. Although our research also has a fairly large amount of data, unlike the previous unsupervised methods (Etzioni et al., 2005) (Nadeau et al., 2006) (Li et al., 2012), we do not have extremely large external corpora such as Wikipedia to retrieve very precise, but sparse features. Our work adopted the DL-Cotrain method proposed in (Collins and Singer, 1999). However, all their features are at the word sequence level, instead of at the token level. As noted in Section 2, there is no concept of upper- or lowercase in cuneiform writing, features on capitalization are not relevant here. Another important observation is that Sumerian personal names are exclusively comprised

of a single word, thus our spelling features are on the token level. In addition, unlike their work where POS and parsing information is used for named entity candidate selection, we do not have the candidate selection component given that no Sumerian POS tagger or parser available. In fact, further complicating factors in determining syntactic features include the lack of standardization in spelling and inconsistent scribal quality.

3.2 Our System

Our NER system has three components: the preprocessing component, the Decision List Co-Train (DL-CoTrain) (Collins and Singer, 1999) component and the post-processing component.

When the Sumerologists transliterate the tablets, they use metacharacters such as "[...]" and "#" to indicate damage to the text, and "!", "?", "*", and "<...>" to represent correction, querying or collation (Tinney and Robson, 2014). For "[...]" and "<...>" cases, the Sumerologists put their "best guess" within the brackets. For example, in the word "[nu]-su", the first sign was originally damaged but restored by the Sumerologists as the "best guess". Our system removes the metacharacters as noise, and treats the resulting text as if it were otherwise unannotated.

To utilize the pre-knowledge from the language experts and (Weibull, 2004), we apply a tag set of 13 tags to pre-annotate the corpus. The 13 tags in the tag set {"GN", "FN", "TN", "WN", "MN", "n", "TITLE", "UNIT", "GOODS", "OCCUPATION", "YEAR", "MONTH", "DAY"} represent geographical names, field names, temple names, watercourse names, month names, numbers, title names, unit names, trade goods names, occupation names and indicators for year, month and day, respectively.

After the above pre-processing step, we applied the DL-CoTrain method by utilizing contextual and spelling rules to create a decision list.

A contextual rule specifies the context for a named-entity with the window size of 1 or -1 (the right word or the left word). For example, according to the contextual rule "right_context = TITLE → Person", "nam-zi" is recognized as a personal name in "nam-zi simug" given that "simug" is pre-tagged as "TITLE" (Smith) in the pre-processing phase.

A spelling rule specifies the spelling of a named-entity. It is a sign sequence that can be either the full string of an entity or is contained as a substring of the entity. For example, "contains(ab-ba) → Person" is a spelling rule. By applying the rule, the word "ab-ba-sab-ga-ta" is recognized as a personal name. With the spelling rule "full-string = ur-{d}szul-pa-e3 → Person", the word "ur-{d}szul-pa-e3" is recognized as a personal name.

We use the following three contextual rules (Jaworski, 2008) as the seed rules for the system 1) left_context = giri3 → Person 2) left_context = kiszib3 → Person 3) left_context = mu-DU → Person.

The first rule indicates that a person is acting as an intermediary in the transaction. The second rule indicates that the tablet was sealed by the named individual, and usually appears in administrative records. The last rule indicates that a delivery was made to the named individual. Since these seed rules have a high specificity to personal names, each of them is given a strength of 0.99999.

The major task of the system is to learn a decision list to classify a word as a personal name. Initialized with the 3 contextual seed rules, the decision list is applied to label the training data to get spelling rules. In the next iteration, the newly obtained spelling rules are applied to label the training data to get new contextual rules. In this alternating process, each iteration produces a new set of rules which are ranked by their strength.

In our NER system, we experimentally settled on a ranking criterion that made use of frequency of some feature x, instead of (smoothed) relative frequency as used in (Collins and Singer, 1999), in order to avoid the problem of some context feature occurs once only as the cue of a personal name, and reverting to the relative frequency formula in the case of ties.

The two post-processing rules are applied to eliminate false positives 1) A word that starts with a number should not be a name; 2) A word following the word "iti" (month indicator) should not be a name. The application of these 2 rules improved the performance by 0.5%.

4 Experiments and Evaluation

We used a 5-fold cross-validation model to train and test our NER system. In each fold, we randomly picked 85% of the tablets from the corpus for training and the remaining 15% of the tablets for testing. With the top 20 new rules from each iteration being added to the decision list, the system produces a decision list of over 2000 rules and approximately 17,000 personal names in these Sumerian texts, after 150 iterations.

When the lemmata is used as the gold standard data set in this experiment, the system achieved 91.4% recall and 39.6% precision score on average from the 5-fold cross-validation. The low precision motivated us to take a closer look at the cause of the false positives from our system.

Using fold-2 as an example, the system reported 16,657 personal names, and there are 7,406 annotated names in the lemmata. Among all these 7,406 names, 91.4% has been correctly identified by the system. However, 60.6% of the names reported by our system are not labeled as names in the lemmata. Through error analysis, we found that nearly 50% of these false positive names contain"missing" or "damaged" signs in the transliteration (i.e., annotated as [x] or [u] in the lemmata). They were therefore not annotated at all in the lemmata, even though their linguistic context clearly shows that they are personal names. For example, "`szu-x-lum`" in "`giri3 szu-x-lum`" is a word in the testing data labeled as a name by our system after applying one of the seed rules. However, owing to physical damage to the word in the original tablet (flagged by "`x`" in the lemmata), it is unannotated. As a result, it's reported as a false positive in the evaluation.

Based on this observation, we asked the Sumeriologist at our home university to verify the "false positives" that contain "missing" or "damaged" signs (marked in the lemmata as either "unknown" (part of speech `X`) or "unlemmatizable" (part of speech `u`)), restricting our concern to damaged signs to limit the imposition on his time. It turns out that over 40% of such names should have been labeled as a name in the first place. This elevates the precision to 55.8% from 39.4% without sacrificing the recall, for fold-2 testing data. Similar performance gain is obtained for other folds.

Due to the large number of "false positives" and time constraints, we cannot impose on our Assyriologist informant the task of verifying all of the system reported names for us at the moment. However, the current evaluation result reveals that the systematic lemmatization on CDLI, as discussed in Section 2, follows an extremely conservative approach. We suspect that the reason for this is to avoid labeling damaged personal names as such is to prevent partial or potentially incorrect sign information from being reused by the morphological analyzer in future runs of the lemmatizer. Our result suggests that the existing lemmata has its own limitation and should not be fully relied on for evaluation for our NER task. It also suggests that our NER system can be used for automatic annotation task given that it performs well in recovering names based on the context and spelling features, even with the minimal prior knowledge. More details of the algorithms and result can be found in (Liu et al., 2015).

5 Conclusions and Future Work

We have shown that a DL-CoTrain based name tagger, with only three initial seed rules and unlabeled data, performs well in recovering personal names from Sumerian texts. This work can potentially make the annotation job much less costly, especially when the expert resource is extremely scarce.

Our results show that the existing lemmatization on CDLI corpus was generated by a, perhaps, excessively conservative policy, especially when one or more signs in the name have sustained damage. As a result, we consider that the existing lemmata cannot be fully relied on, especially for damaged names, for our NER evaluation. Our system is able to make good guesses on such damaged occurrences, based on the context and the spelling features. Confirmed by the language expert, such a high-recall, not-so-high-precision system can be particularly useful for the corpus annotators because they can simply focus on and verify the system's recommended names. Furthermore, we would expect that by applying supervised learning or combining with gazetteer-based method, and by extending the current method to recognizing other types of names in the texts, our system can work even better as an automation tool for such an annotation task.

Abstract

Our research aims to extract information about medication use from veterinary discussion forums. We introduce the task of categorizing information about medication use to determine whether a doctor has *prescribed* medication, *changed protocols*, *observed effects*, or *stopped* use of a medication. First, we create a medication detector for informal veterinary texts and show that features derived from the Web can be very powerful. Second, we create classifiers to categorize each medication mention with respect to six categories. We demonstrate that this task benefits from a rich linguistic feature set, domain-specific semantic features produced by a weakly supervised semantic tagger, and balanced self-training.

1 Introduction

Natural language processing holds great promise for automatically extracting empirical data about medications, from the perspective of both doctors and patients. A wealth of information about the administration and effectiveness of medications lies within unstructured text, including medical records created by health care professionals (e.g., discharge summaries) as well as informal texts written by medical practitioners and patients (e.g., Web forums).

Previous work has been done on detecting medication terms and recognizing relations between medications and other medical concepts, such as diseases and symptoms. Our research explores a new problem: identifying and categorizing contexts involving the administration of medications, which we call *medication use categorization*. For each mentioned medication, we want to know whether it was used in a patient's care, and if so, what actions or observations are being reported. Our task aims to distinguish between contexts where a doctor *prescribed* a medication, *changed* the protocol of a medication (e.g., dosage or frequency), *stopped* use of a medication, *observed effects* produced by the medication, or *is asking a question* about a medication. Distinguishing these contexts is an important step toward being able to extract empirical data about medication use, such as effectiveness, success under different protocols, and adverse events.

Our research studies veterinary discussion forums, which often contain informal vocabulary such as shortened and abbreviated medication terms (e.g. *"pred"* instead of *"prednisone"*, or *"abx"* for *"antibiotics"*). The first part of our research addresses the problem of medication detection from informal text. We create an effective medication detector using supervised learning with linguistic features as well as contextual features acquired from the Web. We show that the Web context features substantially improve recall, and yield an effective medication detector even with small amounts of training data.

Second, we design supervised classifiers for medication use categorization. We incorporate a rich set of contextual, syntactic, and sentential features as well as a semantic tagger trained for the veterinary domain with bootstrapped learning over a large set of unannotated veterinary texts. We demonstrate additional performance gains by using balanced self-training with the unannotated texts.

2 Related Work

Previous work on extracting medication information from text has primarily focused on clinical medical text, such as discharge summaries (e.g., (Doan and Xu, 2010; Halgrim et al., 2010; Doan et al., 2012; Tang et al., 2013; Segura-Bedmar et al.,

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1452–1458,
Denver, Colorado, May 31 – June 5, 2015.

2013)). The Third and Fourth i2b2 Shared Tasks included medication detection from clinical texts (Uzuner et al., 2010; Uzuner et al., 2011), and the Fourth i2b2 Shared Task also included relation classification between treatments (including medications), problems, and tests. Recently, there has been growing interest in extracting medication information from other types of text, such as Twitter, online health forums, and drug review sites (e.g., (Leaman et al., 2010; Bian et al., 2012; Liu et al., 2013; Liu and Chen, 2013; Yates and Goharian, 2013; Segura-Bedmar et al., 2014)). Much of this research is geared toward identifying adverse drug events or drug-drug interactions.

Many methods have been used for medication extraction, including rule based approaches (Levin et al., 2007; Xu et al., 2010), machine learning (Patrick and Li, 2010; Doan and Xu, 2010; Tang et al., 2013), and hybrid methods (Halgrim et al., 2010; Meystre et al., 2010). Rule based and hybrid approaches typically rely on manually created lexicons and rules. RxNorm (Nelson et al., 2011; Liu et al., 2005) is a large knowledge base containing generic and brand names of drugs and it is often used as a component in these systems. We compare our results with the MedEx system (Xu et al., 2010), which uses RxNorm coupled with manually defined rules.

To our knowledge, classifying medication mentions with respect to administration use categories has not yet been studied. A novel aspect of our work is also the use of Web Context features for medication detection. Similar Web features have been exploited for fine-grained person classification (Giuliano, 2009), while we demonstrate that they can be highly beneficial for medical concept extraction.

3 Task Description and Data Set

We divide our task into two subproblems: (1) *Medication Detection* aims to identify words corresponding to non-food substances used to treat patients (e.g., drugs, potassium supplements), and (2) *Medication Use Categorization* aims to classify medication mentions based on actions and observations related to their administration and to identify question contexts. We assign each medication mention to one of the six categories below.

Rx: The text indicates that a doctor prescribed the medication for a patient, or that a patient is taking (or has previously taken) the medication.
Example: "*I started the dog on abx.*"
Change: A change in the administration of the medication was made (e.g., dosage, route, frequency).
Example: "*I increased the pred to 5mg.*"
Stop: Use of the medication was discontinued.
Example: "*We took the cat off metacam.*"
Effect: The text reports a positive or negative effect from the medication on a patient.
Example: "*The dog responded well to Vetsulin.*"
Question: A question is asked about the medication.
Example: "*Do you think we should consider lasix?*"
Other: None of the above. This category primarily covers contexts not describing patient use.
Example: "*Aranesp is expensive.*"

Our data consists of discussion forums from the Veterinary Information Network (VIN), which is a web portal (www.vin.com) that hosts message boards for veterinary professionals to discuss cases and issues in their practice. To produce gold standard annotations, we collected the initial post of 500 randomly selected threads from VIN forums about cardiology/pulmonology, endocrinology, and feline internal medicine. We defined annotation guidelines to identify the minimum span of medication mentions.[1] Two people independently annotated 50 texts, and we measured their inter-annotator agreement (IAA) using Cohen's kappa (κ) statistic. For medication detection, their IAA score was κ = .96.

For the medication use categories, we measured IAA in two ways. First, we measured agreement on all of the words labeled as a medication by at least one annotator, yielding $\kappa = 0.80$. Second, we measured agreement only on the words labeled as a medication by both annotators (to more directly assess agreement on the six categories), yielding $\kappa = .92$. Finally, the annotators labeled an additional 450 texts, producing a gold standard set of 500 labeled texts. Of the annotated medication mentions, 93% have one word and 6% have two words. The frequency of each category is shown below.

Rx	Question	Effect	Change	Stop	Other
908	289	181	52	53	470

[1] Dosage and duration terms were not included.

4 Medication Detection

Detecting medication terms in discussion forums is challenging because of their informal nature. As we will show in Section 4.1, dictionary look-up from lexicons is not sufficient. Therefore the first part of our research aims to create an effective medication detector for these informal veterinary texts. We used the Stanford CoreNLP tools (Manning et al., 2014) for lemmatization, POS tagging and parsing, and created a SVM classifier with a linear kernel using SVMlin (Sindhwani and Keerthi, 2006). The classifier labels each token as a medication term or not a medication term. Adjacent medication tokens are then combined into a single medication mention. We designed three types of features:

Word Features include the medication word's string, lemma, and part-of-speech tag. Since drugs often have common affixes (e.g., *"-sone"* is a common suffix for corticosteroids), we also defined features for character sequences of length 2-4 at the beginning and end of a word.

Local Context Features represent the word preceding and the word following each medication term. We replace numbers with the symbol "CD". We also defined features to represent the syntactic dependency relations linked to the medication word using the Stanford Parser (De Marneffe et al., 2006).

Web Context Features capture information from web sites that mention a term, which provides external context beyond the information available in the training texts. During training, we issued a Google query for each unique word in our training data and collected the title and text snippets of the top 10 retrieved documents. We then defined binary-valued features to represent all of the words in the retrieved texts.[2] We store the results of each query so that additional queries are needed only for previously unseen words.

4.1 Medication Detection Results

We conducted 10-fold cross-validation experiments on our data set to evaluate our medication detector.

First, we created three baselines to assess the difficulty of medication detection for this data. The first row of Table 1 shows the performance of a veterinary thesaurus manually created by the VIN.[3] We extracted all of the words in the entries categorized as *Pharmacologic Substance* and label all instances of those words as medication terms. The VIN thesaurus achieved high precision but only 51% recall. Some reasons for the low coverage include abbreviations, misspellings, general terms (e.g., *"drug"*), and pronouns that refer to medications (which are annotated in our data). The second row shows the results of MedEx (Xu et al., 2010), which uses the RxNorm drug lexicon and ranked in second place for the 2009 i2b2 Medication Extraction challenge. MedEx's low precision is primarily due to labeling chemical substances (e.g., *"glucose"*) as medications, but in our data they are often test results (e.g., *"the cat's glucose level..."*). The third row shows the results of creating a Training Lexicon by collecting all nouns annotated as medications in the training data. We labeled all instances of these nouns as medication terms in the test data, which produced slightly higher recall and precision than MedEx.

Method	Precision	Recall	F
VIN thesaurus	**90.9**	51.3	65.6
MedEX	52.5	73.8	61.4
Training Lexicon	59.4	76.9	67.0
SVM Classifier			
Word Features	88.2	79.9	83.9
+ Local Context	89.7	81.2	85.3
+ Web Context	89.2	**86.1**	**87.6**

Table 1: Medication Detection Results

The last three rows in Table 1 show the results for our classifier. With only Word Features, the classifier produced an 83.9% F score, outperforming the baselines. Adding the Local Context Features yielded small gains in recall and precision. The Web Context Features further increased recall from 81% to 86%, raising the F score to 87.6%. We tried adding features for the VIN thesaurus and MedEx system, but they did not improve upon the results obtained with the Web Context features.

We observed that the Web Context Features can compensate for small amounts of training data. To demonstrate how powerful they are, we randomly selected 100 gold standard texts to use as a test

[2] We also tried different context windows but found that using the title and entire snippet achieved the best results.

[3] We used a version provided to us in 2013.

set, and trained classifiers using different amounts of training data. Figure 1 shows the results for classifiers using only the Word Features, Word and Local Context Features, and all features. The classifier with Web Context Features achieved an F score $> 70\%$ using only 10 training texts, and approached its best performance with just 100 training texts.

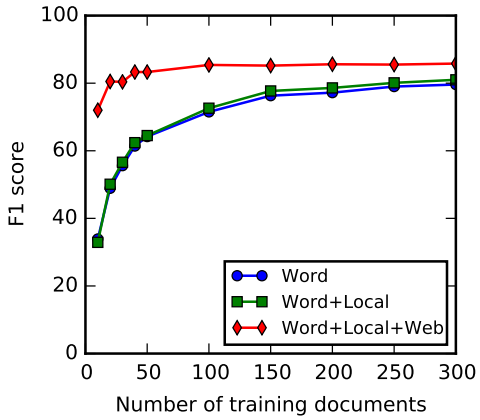

Figure 1: Learning curves with different feature sets

5 Medication Use Categorization

We tackled this problem by designing a supervised classifier with linguistic features, and incorporated a semantic tagger trained by bootstrapping on a large collection of veterinary text. We also used a balanced self-training method on unannotated veterinary texts to further improve performance.

First, we created a one-vs-the-rest binary SVM classifier for each category using scikit-learn (Pedregosa et al., 2011).[4] If an instance is labeled with multiple categories, we select the most confident one using the distance from the hyperplane. We designed three sets of features. **N-gram Features** represent a context window of size eight (+/-4) around the medication mention. We define features for lexical unigrams, lexical bigrams, lemma unigrams, and lemma bigrams. **Syntactic Features** capture verb phrases that participate in a dependency relation with the medication, using the Stanford parser. The third set of **Sentential Features** are for the *Question* and *Other* categories to recognize sentences that do not describe use of the medication on a patient, but ask questions, request guidance, describe hypothetical scenarios, etc. The sentential features consist of clause initial part-of-speech (POS) and lemma bigrams; whether the sentence ends with a question mark; whether the word "question" occurs in the same NP as the medication; whether the sentence contains the POS sequence <MD PRP>[5]; and whether the medication is separated by a comma from the ending question mark (for lists).

Semantic Tagging. We hypothesized that identifying semantic concepts might be beneficial. For example, the presence of an ANIMAL term suggests a patient, and a SYMPTOM term may indicate the reason for a prescription or an effect of medication use. First, we used WordNet (Miller, 1995) and identified synsets for 4 semantic classes: ANIMAL, DRUG, DISEASE/SYMPTOM, and HUMAN. We assigned any noun phrase with a head in these synsets to the corresponding semantic type. Next, we used a bootstrapping method (Huang and Riloff, 2010) to build domain-specific semantic taggers (**SemTaggers**) for the same four semantic classes as well as TEST, TREATMENT and OTHER. We used 10 seed words[6] for each category and 10,000 unlabeled veterinary forum texts for bootstrapping. Finally, we created **Semantic Features** for our medication use classifier. Each noun phrase tagged with a semantic class was replaced by a semantic type. Then we constructed features from pairs of adjacent terms in a context window of size eight (+/-4) around each medication mention. For example, the word sequence *"for a Boston terrier with diabetes"* would be transformed into *"for* ANIMAL *with* DISSYM*"* and the features for this context would be: <for ANIMAL>, <ANIMAL with>, and <with DISSYM>.

5.1 Medication Use Categorization Results

Table 2 shows the results for medication use classification, applied to the mentions identified by our medication detector (from Section 4). The N-gram

[4]Note that for medication detection we used SVMlin, but we switched to scikit-learn for the medication categorization because it supported additional types of classifiers that we wanted to try. Ultimately, however, the SVM performed best. We confirmed that SVM results from both toolkits were very similar.

[5]For question phrases such as "would he".

[6]We used the same seeds as (Huang and Riloff, 2010). However we added one semantic class, TREATMENT, so for this category we manually identified the 10 most frequent words in the unannotated texts that describe treatments.

Method	Rx			Question			Effect			Change			Stop			Other			Average

Table 3: Medication Use Categorization Results on gold medications (each cell shows Precision, Recall, and F)

features alone yield an average F score of 55.9%. Both the Sentential features and Syntactic features (added cumulatively) further improve performance, raising the average F score to 61.8%. The next two rows show the effect of adding the semantic features. WordNet improves performance for **Effect** and **Change** but recall is lower for **Stop** and **Other**. In contrast, the SemTaggers improve performance across all categories, raising the F score to 64.2%. Our ablation studies show the ANIMAL class contributed most to the improvement.

In addition, we explored self-training to exploit unannotated texts. We applied the classifiers to 2,000 unlabeled veterinary texts, and used the newly labeled instances as additional training data. This did not improve performance, presumably because the most common categories dominated the new instances. We then explored a balanced self-training method that enforces an even distribution of the six categories in the new training instances. For this approach, we added exactly k new instances[7] for each class, where k was selected to be the size of the smallest set of newly labeled instances among the six categories. The last row of Table 2 shows that this balanced self-training approach improved the average F score from 64.2% to 66.6%.

[7]The most confident new instances were selected based on the differences between the scores for the winning class and the other classes.

Table 3 shows the results for medication use classification applied to gold standard medication mentions. The same trends hold: the *sentential* and *syntactic* features improve over n-grams, the *SemTagger* semantic features add value and outperform WordNet, and balanced self-training further improves performance. Overall performance increases from 66.6% to 75.1% F score with gold medications.

6 Conclusion

This research introduced a new task for classifying medication mentions with respect to their use in patient care. We created an effective medication detector for informal veterinary texts that exploits features derived from Web pages, and we created classifiers to recognize six medication use categories. These classifiers achieved precision $\geq$ 75% for all categories except Other, with recall ranging from 54% for Effects to 86% for Questions. This research is a first step toward NLP systems that can acquire empirical data about the administration and effectiveness of medications from unstructured text.

Acknowledgments

This material is based upon work supported by the National Science Foundation under grant IIS-1018314. We are very grateful to the Veterinary Information Network for providing samples of their data, and Ashequl Qadir for help annotating the data.

Abstract

This paper presents CROWN, an automatically constructed extension of WordNet that augments its taxonomy with novel lemmas from Wiktionary. CROWN fills the important gap in WordNet's lexicon for slang, technical, and rare lemmas, and more than doubles its current size. In two evaluations, we demonstrate that the construction procedure is accurate and has a significant impact on a WordNet-based algorithm encountering novel lemmas.

1 Introduction

Semantic knowledge bases are an essential, enabling component of many NLP applications. A notable example is WordNet (Fellbaum, 1998), which encodes a taxonomy of concepts and semantic relations between them. As a result, WordNet has enabled a wide variety of NLP techniques such as Word Sense Disambiguation (Agirre et al., 2014), information retrieval (Varelas et al., 2005), semantic similarity (Pedersen et al., 2004; Bär et al., 2013), and sentiment analysis (Baccianella et al., 2010). However, semantic knowledge bases such as WordNet are expensive to produce; as a result, their scope and domain are often constrained by the resources available and may omit highly-specific concepts or lemmas, as well as new terminology that emerges after their construction. For example, WordNet does not contain the nouns "stepmom," "broadband," and "prequel."

Because of the coverage limitations of WordNet, several approaches have attempted to enrich WordNet with new relations and concepts. One group of approaches has enriched WordNet by aligning its structure with that of other resources such as Wikipedia or Wiktionary (Ruiz-Casado et al., 2005; Navigli and Ponzetto, 2012; Miller and Gurevych, 2014; Pilehvar and Navigli, 2014). However, because these approaches identify corresponding lemmas with identical lexicalizations, they are often unable to directly add novel lemmas to the existing taxonomic structure. The second group of approaches performs taxonomy induction to learn hypernymy relationships between words (Moro and Navigli, 2012; Meyer and Gurevych, 2012). However, these approaches often produce separate taxonomies from WordNet, which are also generally not readily accessible as resources.

We introduce a new resource CROWN (**C**ommunity-en**R**iched **O**pen **W**ord**N**et) that extends the existing WordNet taxonomy, more than doubling the existing number of synsets, and attaches these novel synsets to their appropriate hypernyms in WordNet. Novel sense data is extracted from Wiktionary, a large-scale collaboratively-constructed dictionary, and attached using multiple heuristics. CROWN fills an important gap in WordNet's limited coverage of both domain-specific lemmas and slang terminology and idioms.[1] In two experiments, we demonstrate that (1) our construction process accurately associates a novel sense with its correct hypernym and (2) the resulting resource has an immediate benefit for existing WordNet-based applications. Importantly, CROWN v1.0 is publicly available and released in WordNet format, making it seamlessly integratable with all existing WordNet libraries and tools.

2 Wiktionary

Wiktionary is a multilingual online dictionary that, as of May 2014, contains more than 470K English gloss definitions. Thanks to its collaboratively-constructed nature, Wiktionary provides a high coverage of novel domain-specific, idiomatic and slang terms or meanings, across all parts of speech, while featuring a wide variety of linguistic information such as morphology, etymology, pronunciation and alternative lexicalizations of a lemma. Given these characteristics, Wiktionary is an ideal resource for improving the coverage of hand-crafted lexicons, such as WordNet.

In addition to definitions, Wiktionary contains two sources of semantic relations. First, the Wiktionary entry

[1] For example, "reserate" is correctly included in CROWN as a hypernym of `unlock%2:35:00::` (to open the lock of) and "awesometastic" as a synonym of `fantastic%3:00:00:extraordinary:00` (extraordinarily good or great).

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1459–1465,
Denver, Colorado, May 31 – June 5, 2015.

for a lemma may contain a note stating its relationship with another lemma. Second, Wiktionary includes a separate thesaurus, Wikisaurus, which specifies (1) a lemma and its gloss and (2) all other lemmas sharing a relation with that sense. However, these Wiktionary relations cannot directly be used to enrich WordNet for two reasons. First, Wiktionary entries are defined in terms of lemmas, rather than senses. As a result, directly ontologizing the resource or integrating its semantic relations requires disambiguating each relation's lemmas, which is not always possible due to the limited context. Second, semantic relations in Wiktionary are infrequent, with 19.8% of all words having any specified relation and only 0.3% having a hypernym relation. As a result of this sparsity, structure alignment-based approaches for extending WordNet cannot be directly applied.

3 Extending WordNet

CROWN is created by identifying lemmas that are out of vocabulary (OOV) in WordNet but have one or more associated glosses in Wiktionary. A new synset is created for that lemma and a hypernym relation is added to the appropriate WordNet synset. The CROWN attachment process rates hypernym candidates using two methods. First, where possible, we exploit structural or morphological information to identify highly-probable candidates. Second, following previous work on resource alignment showing that lexical overlap accurately measures gloss semantic similarity (Meyer and Gurevych, 2011; Navigli and Ponzetto, 2012), candidates are found by measuring the similarity of the Wiktionary gloss with the glosses of synsets found by a constrained search of the WordNet graph. We note that attaching OOV lemmas by first aligning WordNet and Wiktionary is not possible due to relation sparsity within Wiktionary, where most OOV words would not be connected to the aligned network. Following, we first describe the Wiktionary preprocessing steps and then detail both OOV attachment methods.

3.1 Preprocessing

Wiktionary was parsed using JWKTL (Zesch et al., 2008) to extract the text associated with each Wiktionary definition and remove Wiktionary markup. The extracted texts were then partitioned into two sets: (1) those expressing a lexicalization, e.g., "1337" is an alternative spelling of "elite" and (2) those indicating a definition. Novel lexicalizations that are not already handled by the WordNet morphological analyzer (Morphy) were added to the lexicalization exception lists in CROWN.

Definitions are processed using two methods to identify a set of candidate lemmas whose senses might be identical or near to the appropriate hypernym synset. First, candidates are obtained by parsing the gloss with Stanford CoreNLP (Manning et al., 2014) and extracting the head word and all other words joined to it by a conjunction. Second, additional candidates are collected from the first hyperlinked term or phrase in the gloss, which is similar to the approach of Navigli and Velardi (2010) for hypernym extraction in Wikipedia. Candidates are then filtered to ensure that (1) they have the same part of speech as the definition's term and (2) they are defined in WordNet, which is necessary for the attachment.

3.2 Structural and Lexical Attachment

Three types of structural or lexical heuristics were used to attach OOV lemmas when the appropriate data was available. First, Wikisaurus or Wiktionary synonym relations create sets of mutually-synonymous lemmas, which may contain OOV lemmas. The common hypernym of these lemmas is estimated by computing the most frequent hypernym synset for all the senses of the set's lemmas that are in WordNet. Any OOV lemma also in the set is then attached to this estimated hypernym.

Second, some Wiktionary glosses follow regular patterns that identify a particular meaning. Two pattern heuristics were used: (1) a group of *Person* patterns and (2) a *Genus* pattern. The *Person* patterns match glosses that start with phrases such as "somebody who." Senses with such glosses have their set of candidate attachments restricted to descendants of the human sense of the noun *person*; the sense is then attached to a descendant using the gloss ranking procedure for lexical attachment (described below). The *Genus* pattern matches glosses that start with "Any member of the" and later contain a proper noun matching a scientific genus in WordNet; in such cases the OOV lemma is attached to the same hypernym as the synsets with a holonymy relation to the genus's synset.

Third, an *Antonymy* heuristic is used to identify OOV lemmas with an antonym relation to lemmas already in WordNet. OOV lemmas are tested for having a prefix indicating it could be an antonym, e.g., "anti." If the lemma formed from the remainder after prefix is in WordNet, then the OOV lemma is treated as its antonym and attached to the antonym's hypernym. Furthermore, the two synsets are marked as antonyms in CROWN.

3.3 Gloss-based Attachment

Each OOV lemma is associated with one or more Wiktionary senses, $s_{1...n}$, where each sense s_i is associated with a set of lemmas l_i, one of whose senses may be its hypernym. The gloss-based attachment method analyzes each sense separately, first generating a set of candidate hypernym synsets and then ranking each synset according to its gloss similarity, both defined next. Ultimately the OOV lemma is attached to the highest-scoring synset across all of its Wiktionary senses. This procedure is intended to maximize precision by attaching only the

Wikipedia	admin, verifiability, bio, sockpuppetry, same-sex

Table 1: Examples of high-frequency lemmas in CROWN but not in WordNet, from three corpora.

lemma's dominant sense, though we note that most OOV lemmas are monosemous.

The initial set C of candidate hypernym synsets for Wiktionary sense s_i is generated from the union of the synsets of the lemmas in l_i. Then, C is expanded by including all WordNet synsets reachable from each synset $c_i \in C$ by a path of hypernym or hyponym edges, where a path (1) has at most three edges and (2) contains at most one hypernym edge. The second constraint is designed to avoid including overly-general concepts.

The glosses of the synsets in C are then compared with the Wiktionary sense's gloss. Directly comparing glosses with string similarity measures omits the important detail that certain lemmas can be highly-specific and most strongly indicate that two glosses refer to the same concept. Therefore, prior to comparison, the lemmas occurring in all glosses are assigned a weight $-\log\frac{1}{f(w)}$, where $f(w)$ denotes the number of glosses in which lemma w appeared. Glosses' similarity is measured by (1) lemmatizing their texts and computing the lemmas in common, and then (2) summing the weights of the in-common lemmas. This similarity function assigns higher scores to glosses sharing more specific concepts.

3.4 Resource Creation

The resulting attachments are converted into WordNet lexicography files and then integrated with the existing WordNet taxonomy using the GRIND program. Table 2 shows the resulting statistics for CROWN in comparison to WordNet. The attachment process more than doubles the number of synsets and adds a significant number of new lexicalizations which are essential for capturing common spelling variants that are not reflected in WordNet. Additionally, 4739 new antonym relations were added. Of the OOV lemmas, 87.8% were attached using the lexical attachment procedure. Of the remaining, the *Person* and *Antonymy* heuristics were the most frequently used, accounting for 4.2% and 2.7% of cases respectively. The infrequent use of the structural and lexical heuristics underscores the sparsity of the available data in Wiktionary for straight-forward attachments.

As an initial test of additional content present in CROWN but not in WordNet, all lemmas unique to CROWN were extracted and their occurrences counted in three corpora: (1) all of the English Wikipedia, (2) the web-gathered ukWaC corpus (Ferraresi et al., 2008), and (3) a sample of 50M microtext message from Twitter. Table 1 shows five example high-frequency lemmas from each corpus that are only present in CROWN , highlighting the types of commonly-recognized terms not in WordNet due to their technical, informal, or recently-created nature. Indeed, "selfie" was only recently included in the Merriam Webster dictionary as of 2014,[2] demonstrating the potential for quickly integrating new terminology into CROWN from the frequently-updated entries of Wiktionary.

PoS	WordNet synsets	new CROWN synsets	new CROWN lex. variants
Noun	82115	124967	29563
Verb	13767	16199	43318
Adj.	18156	25534	6902
Adv.	3621	2031	481

Table 2: The number of synsets in WordNet and new synsets and lexicalizations added by CROWN.

4 Evaluation

Two evaluations were performed. The first estimates attachment accuracy by simulating OOV attachment with lemmas that are already in WordNet. The second calculates the benefit of using CROWN in an example application using a WordNet-based algorithm to measure similarity.

4.1 WordNet Replication

No standard dataset exists for where OOV lemmas should be attached to WordNet; therefore in the first evaluation, we assess construction accuracy by simulating the inclusion of OOV lemmas using those already in WordNet, which allows testing on tens of thousands of lemmas. Specifically, the CROWN attachment approach is used to reattach all monosemous lemmas in WordNet. We opted for monosemous terms as they can have only one valid location in the taxonomy.

4.1.1 Methodology

Glosses were extracted for 36,605 of the 101,863 nouns that were monosemous in WordNet and also present in Wiktionary, and for 4668 of the 6277 verbs matching the same condition. These glosses were then provided as input to the CROWN attachment process. We note that these lemmas are not necessarily monosemous in Wiktionary, with nouns and verbs having on average 1.40 and 1.76 senses, respectively; however, the construction process will attach only the highest-scoring of these senses. Once a lemma is attached, accuracy is measured as the number of hyponym or hypernym edges away that CROWN placed the lemma from its original position.

[2] http://www.merriam-webster.com/new-words/2014-update.htm

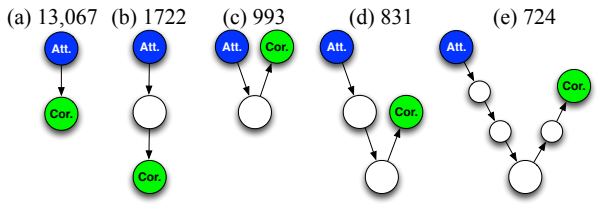

Figure 1: The five most-frequent error patterns and their frequencies seen in the results of monosemous lemma evaluation. Graphs show the attachment point (Att.) and correct hypernym synset (Cor.), with downward edges indicating hypernym relations and upward indicating hyponym. The overall error trend reveals that the vast majority of error was due to attaching a new sense to a more-specific concept than its actual hypernym.

4.1.2 Results

The CROWN construction process was able to attach 34,911 of the 36,605 monosemous noun lemmas (95.4%) and 4209 of the 4668 verb lemmas (90.2%). The median error for attaching monosemous nouns was three edges and for verbs was only one edge, indicating the attachment process is highly accurate for both. The most common form of error was attaching the OOV lemma to a hyponym of the correct hypernym, occurring in 13,067 of the erroneous attachments.

Figure 1 shows the five most common displacement patterns when incorrectly attaching a monosemous noun, revealing that the majority of incorrect placements were to a more-specific concept than what was actually the hypernym. Furthermore, examining the 50 furthest-away noun and verb placements, we find that 28% of nouns and 20% of verbs were attached using a novel sense of the lemma not in WordNet (but in Wiktionary) and the placement is in fact reasonable. As a result, the median error is likely an overestimate of the expected error for the CROWN construction process.

4.2 Application-based evaluation

Semantic similarity is one of the core features of many NLP applications. The second evaluation measures the performance improvement of using CROWN instead of WordNet for measuring semantic similarity when faced with slang or OOV lemmas. Notably, prior semantic similarity benchmarks such as SimLex-999 (Hill et al., 2014) and the ESL test questions (Turney, 2001) have largely omitted these types of words. However, the recent dataset of SemEval-2014 Task 3 (Jurgens et al., 2014) includes similarity judgments between a WordNet sense and a word not defined in WordNet's vocabulary or with a slang interpretation not present in WordNet.

	All	Regular	OOV	Slang
WordNet	0.195	0.463	0.0	-0.170
CROWN	0.248	0.452	0.448	0.138
GST Baseline	0.148	0.283	0.148	0.018
Best System	0.389	0.529	0.501	0.146

Table 3: The Pearson correlation performance of ADW when using the WordNet and CROWN semantic networks on the word-to-sense test dataset of SemEval-2014 Task 3. We also show results for the string-based baseline system (GST) and for the best participating system in the word-to-sense comparison type of Task 3.

4.2.1 Methodology

Semantic similarity was measured using the similarity algorithm of Pilehvar et al. (2013), ADW,[3] which first represents a given linguistic item (such as a word or a concept) using random walks over the WordNet semantic network, where random walks are initialized from the synsets associated with that item. The similarity between two linguistic items is accordingly computed in terms of the similarity of their corresponding representations. ADW is an ideal candidate for measuring the impact of CROWN for two reasons. First, the algorithm obtains state-of-the-art performance on both word-based and sense-based benchmarks using only WordNet as a knowledge source. Second, the method is both unsupervised and requires no parameter tuning, removing potential performance differences between WordNet and CROWN being due to these factors.

To perform the second experiment, the ADW algorithm was used to generate similarity judgments for the data of Task 3, changing only the underlying semantic network to be either (1) the WordNet 3.0 network, with additional edges from disambiguated glosses,[4] or (2) the same network with novel synsets from CROWN. As the ADW algorithm is unchanged between settings, any performance change is due only to the differences between the two networks. Performance is measured using Pearson correlation with the gold standard judgments.

4.2.2 Results

Of the 60 OOV lemmas and 38 OOV slang terms in the test data, 51 and 26 were contained in CROWN, respectively. Table 3 shows the Pearson correlation performance of ADW in the two settings for all lemmas in the dataset, and for three subsets of the dataset: OOV, slang, and regular lemmas, the latter of which are in WordNet; the bottom rows show the performance of the Task's best participating system for the word-to-sense comparison type (Kashyap et al., 2014) and the most competi-

[3] https://github.com/pilehvar/ADW
[4] http://wordnet.princeton.edu/glosstag.shtml

tive baseline, based on Greedy String Tiling (GST) (Wise, 1996).

ADW sees large performance improvements in the OOV and slang words when using CROWN instead of WordNet, which are both statistically significant at $p<0.01$. The overall improvement of ADW would place it as the fifth best system in this comparison type of Task 3. The performance on regular in-WordNet and OOV lemmas is approximately equal, indicating the high accuracy of OOV hypernym attachment in CROWN. Notably, on OOV and Slang, the unsupervised ADW, when coupled with the additional information in CROWN , produces competitive results with the best performing system, which is a multi-feature supervised system utilizing extensive external dictionaries and distributional methods.

5 Related Work

Most related is the work of Poprat et al. (2008), who attempted to automatically build an extension of WordNet with biomedical terminology; however, they were unsuccessful in constructing the resource. Other work has attempted to leverage distributional similarity techniques (Snow et al., 2006) or exploit the structured information in Wikipedia (Ruiz-Casado et al., 2005; Toral et al., 2008; Ponzetto and Navigli, 2009; Yamada et al., 2011) in order to extend WordNet with new synsets. However, structure-based approaches are limited only to the concepts appearing in Wikipedia article titles, which almost always correspond to noun concepts. Distributional and probabilistic approaches are also limited to OOV terms for which it is possible to gather enough statistics. As Wiktionary contains all parts of speech and our method is independent of word frequency, neither limitation applies to this work.

Other related work has attempted to tap resources such as Wikipedia for automatically constructing new ontologies (Suchanek et al., 2007; Dandala et al., 2012; Moro and Navigli, 2012; Meyer and Gurevych, 2012), extending existing ones through either alignment-based methods (Matuschek and Gurevych, 2013; Pilehvar and Navigli, 2014) or inferring the positions of new senses by their shared attributes which are extracted from text (Reisinger and Paşca, 2009). Extension and alignment approaches based on Wikipedia are limited mainly to noun concepts in Wikipedia; furthermore, these techniques cannot be directly applied to Wiktionary because its lack of taxonomic structure would prevent adding most OOV data to the existing WordNet taxonomy.

6 Conclusion

This work has introduced CROWN version 1.0, a new extension of WordNet that merges sense definitions from Wiktionary to add new hypernym and antonym relations. The resulting taxonomy has more than doubled the number of synsets in WordNet and includes many technical and slang terms, as well as non-standard lexicalizations. CROWN is released in the same format as WordNet[5] and therefore is fully compatible with all existing WordNet-based tools and libraries. Furthermore, the software for building CROWN has been opened-sourced and will be updated with future versions. In two experiments we demonstrated that the CROWN construction process is accurate and that the resulting resource has a real benefit to WordNet-based applications.

Immediate future work will add support for including new lemmas as synonyms in existing synsets and linking newly-created synsets with all appropriate types of WordNet semantic relationship. Longer-term future work will pursue more sophisticated methods for taxonomy enrichment to improve the quality of integrated content and will aim to integrate additional dictionaries, with a special emphasis on adding domain-specific terminology.

Cross-lingual Text Classification Using Topic-Dependent Word Probabilities

Abstract

Cross-lingual text classification is a major challenge in natural language processing, since often training data is available in only one language (target language), but not available for the language of the document we want to classify (source language). Here, we propose a method that only requires a bilingual dictionary to bridge the language gap. Our proposed probabilistic model allows us to estimate translation probabilities that are conditioned on the whole source document. The assumption of our probabilistic model is that each document can be characterized by a distribution over topics that help to solve the translation ambiguity of single words. Using the derived translation probabilities, we then calculate the expected word frequency of each word type in the target language. Finally, these expected word frequencies can be used to classify the source text with any classifier that was trained using only target language documents. Our experiments confirm the usefulness of our proposed method.

1 Introduction

Text classification is ubiquitous in natural language processing. It's applications range from simple topic detection, like articles about sport vs articles about computers, to sentimental analysis, and subtle discrimination of Tweets that report the abuse of drugs or the metaphoric use of drugs ("love is like a drug"). Text classification hugely relies on manually annotated training data in one language.

However, creating training data for each language is expensive, and therefore, we are interested in using training data given in only one language (e.g. English, denoted as target language) to classify text written in a different language (e.g. Chinese, or Japanese, denoted as source language).

Our approach addresses this issue by using a simple bilingual dictionary. Bilingual dictionaries have the great advantage that they are available often for free[1], and have good coverage for major languages, like Chinese and Japanese. With the help of the dictionary, we calculate the expected frequency of each word in the target language. Finally, we create a feature vector in the target language that is used as input for the text classifier.

However, due to the translation ambiguity of a word in the source language, it is important to carefully choose the translation probability for calculating the expected frequencies of the target words. For example, consider a Japanese news article that contains the word 拘束 (restrict, restrain, in custody), and we want to find out whether the article is about "foreign policy" or not. The most simple method is to use all its English translations, and assume a uniform distribution over them, i.e. $\{0.33, 0.33$ and $0.33\}$. However, depending on the topic of the news article, the translation "in custody" is more appropriate. For example, if the article reports about a crime/crime suspect, the translation "in custody" is more likely than "restrict" and "restrain". Conversely, if the article is about "military", the translation "in custody" is less likely. Moreover, an article that is about the topic "military" is more likely to belong to the class "foreign policy". This example demonstrates the importance of estimating good translation probabilities in order to improve the clas-

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1466–1471,
Denver, Colorado, May 31 – June 5, 2015.

sification of the source text.

Therefore, we propose a probabilistic model that uses latent document topics to help improve the translation probabilities for a source document. Our experiments, on three different pairs of corpora, confirm that our probabilistic model for estimating word translation probabilities is helpful for cross-lingual text classification.

2 Related Work

The work in (Wu et al., 2008) and (Shi et al., 2010) uses a bilingual dictionary for cross-lingual text classification. The method described in (Wu et al., 2008) is motivated by transfer learning to adjust the class probability $p(c)$ to account for the differences in distributions between source and target language. Similar to our work, in the first step, they generate a probabilistic bilingual lexicon that contain word translation probabilities $p(e|f)$. However, one main difference to our work is that they translate each source word f in source text F independently, without considering any topic or context information of F.

Instead of translating the source text into the target language, the method in (Shi et al., 2010) suggests to translate the target classification model into the source language. They directly estimate the translation probabilities $p(f|e, c)$ using the source and target language data. One limitation of their method is that it assumes that the class of the document, that we want to translate, is given.

Our idea of learning word translation probabilities in context is related to the work in (Koehn and Knight, 2000). They describe an efficient method for learning word translation probabilities $p(f|e)$ using a bilingual dictionary and a pair of comparable corpora[2]. Like our approach, their method has the advantage that no parallel corpora are needed for translation. However, to solve the ambiguity of word-translation they considered only (local) bi-gram context. Moreover, their method assumes that the word order in the languages are the same. This is obviously not the case for language pairs like English and Japanese.

We note that the bilingual paired topic model, suggested in (Jagarlamudi and Gao, 2013), can also be used to disambiguate and select the appropriate word translations by using the topic associated with the given document. However, their model does not consider the use of a document class, and uses fixed word translation probabilities. In Section 3.2, we show that our model can also be used to learn the translation probabilities.

Alternatively, the multi-lingual topic model described in (Ni et al., 2011), and the use of a common low-dimensional projection described in (Platt et al., 2010) have also been applied to the cross-lingual text classification problem. However, both models require for training that cross-lingually aligned documents are available.

3 Proposed Method

Our proposed method does not use one translation of F, but implicitly generates all translations and weights them by the probability of each translation. More formally, let E be one translation of source text F. Moreover, let $count_E(e)$ denote the frequency of word e in E. Instead of using $count_E(e)$, we use the expected number of word occurrences denoted by $\mathbb{E}[count_E(e)|F]$ as features. When we use a simple uni-gram language model in the source language we get:

$$\mathbb{E}[count_E(e)|F] = \sum_{j=1}^{k} p(e_j = e|f_j) \qquad (1)$$

where we might write F as $(f_1, f_2, f_3, ...f_k)$, where f_j is the j-th word in F, and k is the number of words in source text F.[3] The random variable e_j denotes the translation of the j-th word in F. However, such a simple model translates each source word independently and ignores the context of the word.

In the following, we describe a probabilistic model that allows us to consider the whole document context F into account for translating one word f_j. The generative story is as follows:

1. For each document, we generate a class label c with probability υ_c. Here we consider only the binary classification task with class label "positive", or "negative".

[2]Two corpora written in different languages which do not need to be translations of each other

[3]Here "word" refers to a word occurrence (and not unique word). Therefore, k is the length of the source text F.

2. For each document, we generate a topic z with probability $\pi_{z|c}$.

3. Given topic z, we generate each word e in the target language document independently from a categorical distribution with probability $\vartheta_{e|z}$.

4. For each word e in the target language, we generate a word f in the source language independently from a categorical distribution with probability $\theta_{f|e}$.[4]

Under this model, for one target document $(e_1, ..., e_k)$ and its corresponding source document $(f_1, ..., f_k)$, the joint probability $p(z, c, e_1, ..., e_k, f_1, ..., f_k)$ is

$$\upsilon_c \pi_{z|c} \prod_{j=1}^{k} \vartheta_{e_j|z} \cdot \theta_{f_j|e_j} \,.$$

The parameter vector $\boldsymbol{\vartheta}_z$ specifies the target word probabilities $\vartheta_{e|z}$ that can be learned from the target language training data as described in Section 3.1. The parameter vector $\boldsymbol{\theta}_e$ specifies the word translation probability $\theta_{f|e}$ for a target word e into a source language word f. These word translation probabilities are determined with the help of the bilingual dictionary as described in Section 3.2.

Our goal is to estimate the translation probability $p(e|f_j, F)$, since this allows us to calculate

$$\mathbb{E}[count_E(e)|F] = \sum_{j=1}^{k} p(e_j = e|f_j, F) \,. \qquad (2)$$

Note, that under our proposed probabilistic model, it holds that

$$p(e_j|f_j, F) \;=\; \sum_z p(e_j|f_j, z) \cdot p(z|F) \,.$$

This can be interpreted as follows. First, the model determines a probability distribution over the latent topics, conditioned on the given input source document, i.e. $p(z|F)$. And then, second, the model uses the conditional probability $p(z|F)$ to determine the translation probability for each word in the source document, i.e. $p(e_j|f_j, z)$.

The actual calculation of $p(e_j = e|f_j, F)$ can be derived as follows.[5]

$$\begin{aligned} p(e_j|f_j, F) &= p(e_j|f_1, ..., f_k) \\ &\propto p(e_j, f_1, ..., f_k) \\ &= \sum_c \sum_z p(e_j, f_1, ..., f_k|z) p(z|c) p(c) \,, \end{aligned}$$

where the probability $p(e_j, f_1, ..., f_k|z)$ can be efficiently calculated using

$$\begin{aligned} & \sum_{e_{l_1} \in V} ... \sum_{e_{l_{k-1}} \in V} p(e_1, \ldots, e_k, f_1, \ldots, f_k|z) \\ = & \sum_{e_{l_1} \in V} ... \sum_{e_{l_{k-1}} \in V} \prod_{j'=1}^{k} \theta_{f_{j'}|e_{j'}} \cdot \vartheta_{e_{j'}|z} \\ = & \; \theta_{f_j|e_j} \cdot \vartheta_{e_j|z} \prod_{j' \in \{l_1 ... l_{k-1}\}} \sum_{e_{j'} \in V} \theta_{f_{j'}|e_{j'}} \cdot \vartheta_{e_{j'}|z} \,, \end{aligned}$$

where the indexes $l_1 \ldots l_{k-1}$ correspond to $1, \ldots, j-1, j+1, \ldots k$.

3.1 Learning υ_c, $\pi_{z|c}$, and $\vartheta_{e|z}$

Note that under our model, class c and topic z are independent from $f_1, ..., f_k$ given document $e_1, ..., e_k$ in the target language. Therefore, the parameters υ_c, $\pi_{z|c}$, and $\vartheta_{e|z}$ can be learned solely using the training documents in the target language. Given a collection of training documents with known classes $D = \{(E_1, c_1)..., (E_n, c_n)\}$, we can estimate the parameters as follows.

Parameter υ_c is estimated using the maximum-likelihood (ML), which is

$$\upsilon_c^* = \frac{\sum_{i=1}^{n} 1_c(c_i)}{n} \,, \qquad (3)$$

where $1_x(y)$ is the indicator function which is 1, if $x = y$, otherwise 0.

The optimal ML-estimate of $\vartheta_{e|z}$ and $\pi_{z|c}$ can be found by maximizing $\log p(D|\vartheta, \pi)$, for which, however, an analytic solution cannot be derived. Therefore, instead, we use the EM-algorithm

[4] It might seem that we need cross-lingually aligned documents, or documents of same length in both languages. However, both is not the case, since in our experiments the translations will always be unobserved, and therefore sum over all possible translations.

[5] When it is clear from the context, we write $p(e_j)$ instead of $p(e_j = e)$.

(Dempster et al., 1977), deriving for the E-step: setting the probability distribution q to

$$p(z_i|D,\vartheta,\pi) \propto \pi_{z_i|c_i} \prod_{j=1}^{k_i} \sum_{e_j} \vartheta_{e_j|z_i}\,, \tag{4}$$

and in the M-step:

$$\vartheta^*_{e|z} = \frac{\sum_{i=1}^{n}\sum_{j=1}^{k_i} 1_e(e_j)\cdot q(z_i=z)}{\sum_{i=1}^{n}\sum_{j=1}^{k_i} q(z_i=z)} \tag{5}$$

and

$$\pi^*_{z|c} = \frac{\sum_{i=1}^{n} 1_c(c_i)\cdot q(z_i=z)}{\sum_{i=1}^{n} q(z_i=z)}\,. \tag{6}$$

3.2 Learning $\theta_{f|e}$

Here we propose to chose the translation probabilities $\theta_{f|e}$ with highest probability, under our current model, and such that the probability of observing the source documents (without labels) is maximized. Formally, given a collection of source documents $D' := F_1, ..., F_m$, the optimal translation probability $\theta^*_{f|e}$ is

$$\underset{\theta_{f|e}}{\operatorname{argmax}}\, p(D'|\theta_{f|e}, \upsilon^*_c, \pi^*_{z|c}, \vartheta^*_{e|z})\,,$$

where $\upsilon^*_c, \pi^*_{z|c}, \vartheta^*_{e|z}$ are the parameters learned in the previous section. Unfortunately, the exact optimization is intractable, and therefore, we resort again to an EM-approximation, analogously to before.

The E-step corresponds to setting for each source document i, the probability $q(e_{i,1}, ..., e_{i,k_i})$ to

$$\begin{aligned} & p(e_{i,1}, ..., e_{i,k_i}|f_{i,1}, \ldots f_{i,k}, \theta_{f|e}) \\ \propto & \sum_{c_i}\sum_{z_i} p(c_i)p(z_i|c_i) \prod_{j=1}^{k} p(e_{i,j}|z_i)\theta_{f_{i,j}|e_{i,j}}\,. \end{aligned}$$

In the M-step, we update $\theta_{f|e}$ to

$$\theta^*_{f|e} \;=\; \frac{\sum_{i=1}^{m}\sum_{j=1}^{k_i} 1_f(f_{j,i})\cdot q(e_{i,j}=e)}{\sum_{i=1}^{m}\sum_{j=1}^{k_i} q(e_{i,j}=e)}\,.$$

4 Experiments

For our experiments we use three pair of corpora denoted by NEWS, WEB, and TWEETS. The corpora NEWS contains news articles in English and Japanese crawled from Internet news sites during 2012-2013, and were annotated as being related to "foreign policy" or not related. The corpora WEB contains web pages in English and Chinese that are categorized either as "sport" or "computer" in the Open Directory Project (ODP)[6] crawled in 2013. TWEETS contains tweets in English and Chinese gathered during 2013, classified as related to "violence", or not related.[7]

Method	NEWS	WEB	TWEETS
Co	**0.687** (0.68)	0.842 (0.84)	**0.430** (0.18)
Co (freq)	0.668 (0.68)	0.849 (0.83)	0.424 (0.20)
Co (uni)	0.666 (0.68)	0.842 (0.83)	0.426 (0.22)
Wu et al.	0.632 (0.56)	0.849 (0.74)	0.391 (0.13)
Freq	0.635 (0.58)	0.842 (0.76)	0.376 (0.13)
Uniform	0.628 (0.53)	**0.856** (0.76)	0.407 (0.13)
CN/JA only	0.816 (0.81)	0.893 (0.90)	0.894 (0.89)
EN only	0.718 (0.67)	0.967 (0.97)	0.682 (0.67)

Table 1: Shows the break-even point (f1-score) of the proposed method Co and three baselines for each pair of corpora. Co (freq) and Co (uni) denote the proposed method without estimation of dictionary probabilities, but instead using word frequency and uniform distribution, respectively.

We tokenize and stem the words in the English corpora using Senna (Collobert et al., 2011). For Chinese and Japanese we use the morphological analyzers described in (Qiu et al., 2013), and an in-house analyzer, respectively. The Chinese to English dictionary, and the Japanese to English dictionary contains translations for 94351 and 1483440 words, respectively.

For the classification we use LIBSVM (Chang and Lin, 2011) with linear kernel, and the feature representation as suggested in (Rennie et al., 2003).

For the parameter estimation of our proposed model we use EM, as described in Section 3.1 and 3.2.[8] The number of topics was determined by optimizing the f1-measure using only the English training data when applying the probabilistic model to monolingual text classification. In order to prevent non-zero probabilities, we use a symmetric Dirichlet

[6] www.dmoz.com

[7] The number of documents in the corpora pairs for source/target language are 2472/2289, 1302/6294, and 2005/1499 for NEWS, WEB and TWEETS, respectively.

[8] We observed convergence for less than 50 iterations.

prior.

We compare our proposed method "Co" to four different baselines that also use solely a bilingual dictionary. For all methods (baselines and proposed), we use Equation (2) to estimate the expected word frequencies. The baseline "Wu et al." refers to the method proposed in (Wu et al., 2008). The baseline "Freq" sets the probability $p(e|f)$ to be proportional to the word frequency in the training data. Analogously, the baseline "Uniform" assumes a uniform probability over all translations of f.

For measuring the performance of each text classifier we use precision and recall. The break-even point[9] and the f1-measure of our proposed method and all baselines are shown in Table 1. As can be seen, our method performs favorable for the NEWS and TWEETS corpora. For the WEB corpora pair and our proposed method is at par with the baseline "Wu et al.", and looses slightly to the "Uniform" baseline. For reference, we also show the upper bounds "CN/JA only" and "EN only" that train and test in the same source and target language, respectively.[10]

We also analyzed the contribution of using the word translation probabilities learned in Section 3.2. The method "Co (freq)" is the same as our proposed method, except that the translation probabilities $p(f|e)$ are not estimated using the method described in Section 3.2, but instead simply uses the word-frequency distribution. Analogously, the method "Co (uni)" is the same as our proposed method, except that $p(f|e)$ is set to the uniform probability for all translations of e. Limiting the discussion to break-even points, we see, in Table 1, an improvement of around 2 percent points for NEWS, but only minor changes in performance for the other two corpora (WEB and TWEETS).

Finally, we give an example which shows the translation probabilities for the word 拘束 (restrict, restrain, custody) for two different source documents in NEWS. The first source document F_1 reports a military action, and is labeled as "foreign policy". The second document F_2 is a news article about terror, and is labeled as "not foreign policy". The results shown in Table 2, confirm our intuition, that the translation "custody" is more likely in documents related to crime.

	e = restrict	**e = restrain**	**e = custody**
$p(e\|f, F_1)$	0.33	0.10	0.57
$p(e\|f, F_2)$	0.02	0.00	0.98

Table 2: Shows the translation probabilities for the source word f = 拘束, within document F_1 (military related, class is "foreign policy") and document F_2 (terror related, class is not "foreign policy").

5 Conclusions

In contrast, to most previous work, we focused on the word translation problem, rather than the domain-adaptation problem for cross-lingual text classification. We have proposed a probabilistic model that allows us to estimate word-translation probabilities that are conditioned on the whole source document. Our experiments on three different pairs of corpora, show that our estimated translation probabilities can improve text classification accuracy, and that our estimated word translation probabilities are able to reflect the topic of a text.

Testing and Comparing Computational Approaches for Identifying the Language of Framing in Political News

Abstract

The subconscious influence of framing on perceptions of political issues is well-document in political science and communication research. A related line of work suggests that drawing attention to framing may help reduce such framing effects by enabling frame reflection, critical examination of the framing underlying an issue. However, definite guidance on how to identify framing does not exist. This paper presents a technique for identifying frame-invoking language. The paper first describes a human subjects pilot study that explores how individuals identify framing and informs the design of our technique. The paper then describes our data collection and annotation approach. Results show that the best performing classifiers achieve performance comparable to that of human annotators, and they indicate which aspects of language most pertain to framing. Both technical and theoretical implications are discussed.

1 Introduction

Contentious political issues are rarely understood *per se* but rather through the lens of framing. Terms such as "tax relief," "death taxes," "racial quotas," "death panels," and others have famously rallied citizens around fairly complex causes. More generally, research has shown that the way an issue is framed (Entman, 1993) – how a problem is defined, to what other problems and people it is linked, etc. – has a significant impact on both perceptions of the issue and prescriptions for action. A variety of work has shown that minor changes in language – "global warming" vs. "climate change" (Schuldt et al., 2011), "gay civil unions" vs. "homosexual marriage" (Price et al., 2005), "not allow" vs. "forbid" (Rugg, 1941) – can significantly impact opinions.

A related but less explored line of research suggests that "frame reflection" (Schön and Rein, 1994), i.e., critical thinking about an issue's framing, can play an important role in understanding issues and reconciling conflicts. Indeed, some recent work suggests that drawing attention to framing may help mitigate framing effects (Baumer et al., 2015). However, such reflection is no mean feat. "Various observers have noted how subtly and unconsciously [framing] operates" (Gamson and Modigliani, 1989, p. 7), making it difficult to acknowledge that an issue is being framed at all, let alone examine that framing critically or consider alternatives. Furthermore, "straightforward guidelines on how to identify [...] a frame in communication do not exist" (Chong and Druckman, 2007, p. 106).

To address this challenge, this paper compares different computational approaches for identifying the language of framing, specifically in political news coverage. The best performing classifiers achieve accuracy around 61% and F1 scores of 0.45 to 0.46, outperforming a dummy baseline and approaching or matching human performance of 73% accuracy and F1 score of 0.46. This work makes two key contributions. First, compares different techniques for identifying language invoking conceptual framing, a novel yet important task. Second, it offers evidence about what language is perceived as related to framing, helping to addressing the gap identified by (Chong and Druckman, 2007).

2 Related Work

2.1 Conceptual Framing

Generally speaking, in order to make sense of their interactions, people frame their experiences (Goffman, 1974). Facts "take on their meaning by being embedded in a frame [...] that organizes them and gives them coherence" (Gamson, 1989, p. 157). Frames help people "locate, perceive, identify, and label," i.e., organize and give meaning to, information about experiences in the world. A frame consists of a variety of components, including "keywords, stock phrases, stereotype images, sources of information" (Entman, 1993, p. 52), "metaphors, exemplars, catchphrases, depictions, [...] visual images" (Gamson and Modigliani, 1989, p. 3), and other devices that provide an interpretive lens or "package." Frames define what counts as a problem, diagnose what is causing the problem, make moral judgments about those involved, and suggest remedies for resolving the problem (Entman, 1993). Framing can significantly impact the perception of a variety of political issues. (Schuldt et al., 2011) found that belief in "global warming" was significantly lower than in "climate change," specifically among Republicans. Gamson and Modigliani (1989) show how nuclear power is framed by such phrases as "atoms for peace," "we have created a Frankenstein," and "the war being waged against the environment and our health."

Crucially, framing differs from subjectivity, sentiment, bias, and related constructs. Subjectivity detection may not effectively identify well-established, codified frames (e.g., "tax relief" or "racial quotas"). Sentiment analysis focuses on assessing the valence (e.g., positive, neutral, or negative) of an entity's description. Bias involves a clear, often intentional, preference shown in writing for one position or opinion on an issue. In contrast, there does not exist a one-to-one mapping between framing and opinions (Gamson and Modigliani, 1989). For example, in late 2013, the international community was considering what actions should be taken against Syrian president Bashar al-Assad for using chemical weapons against rebelling citizens. Some viewed the situation as a humanitarian crisis and argued for military intervention. Others argued that al-Assad's actions were a threat to regional security, also arguing for military action. Here, different framings are used to support the same position on an issue.

In contrast, framing involves an ensemble of rhetorical elements to create an "interpretive package" (Gamson and Modigliani, 1989) that functions by altering the relative salience or importance of different aspects of an issue (Chong and Druckman, 2007). In the humanitarian crisis framing vs. regional security framing example above, a regional security framing does not negatively valence human suffering; rather, it shifts the emphasis to make other concerns more apparent. Thus, while we can draw on subjectivity, bias, and sentiment detection, identifying framing requires features and techniques that go beyond any one of these related concepts.

2.2 Related Computational Approaches

Some computational work explored concepts related to conceptual framing. For example, Choi et al. (2012) identify hedging in discussion of GMOs using an SVM trained on n-grams from annotated cue phrases. Greene and Resnik (2009) showed how examining grammatical construction (i.e., syntax) can reveal implicit sentiment; for example, passive and active voice imply different degrees of agency and causality. Recasens et al. (2013) used edits from Wikipedia intended to enforce a neutral point of view to identify biased sentences and the terms indicative of that bias.

Relatively little work has been done on identifying frames per se. Lind and Salo (2002) used co-occurrence frequencies to examine the framing of feminism in news media. Matthes and Kohring (2008) take a mixed methods approach, asking human coders to annotate the occurrence of certain features in a text problem definition, attribution of causation, moral evaluation, etc. then cluster the text using that coding to identify high-level frames. Boydstun et al. (2013) suggest that approaches based on hierarchical topic modeling may be an effective means of identifying both issue-specific and generic frames.

Such techniques, while useful from an analytic standpoint, are not as directly relevant here. The work described in this paper does not aim to identify the framing in a text. Rather, it seeks to determine what language is perceived as being most related to framing, especially by lay-persons, as a means of

supporting reflection on that framing.

3 Exploratory Pilot Study

While the framing literature provides some guidance (Entman, 1993; Chong and Druckman, 2007), little work has explored how exactly non-elites go about identifying framing (Chong and Druckman, 2007). Thus, we conducted a pilot investigating to explore laypersons' understandings and identification of framing.

3.1 Methods

We recruited undergraduate students at two major US universities. Participants were asked to read an article that framed the issue of health care in terms of equality (as opposed to cost). Previous work showed that reading this article was associated with stronger support for a national healthcare system (Druckman et al., 2012). Participants were then asked to re-read the article and highlight any words or phrases they believed were related to framing. Specifically, participants were given the following prompt and instructions:

Political issues can often be complex, contentious, and difficult to understand. One way of making sense of these issues, and the different positions that one can take on an issue, is to think about the frames that structure debate about the issue. Frames help organize facts and information. They help define what counts as a problem, diagnose the problem's causes, and suggest remedies for solving the problem. These ways of thinking have lots of different parts, including stereotypes, metaphors, images, catchphrases, and other elements.

These different frames are often associated with a particular way of talking about or communicating about an issue. Certain words or phrases might suggest that one or another frame.

Please use the tool at the link below to highlight the words or phrases that help you identify the framings used in the article you just read.

After a student finished highlighting the article, s/he also participated in a debriefing interview where a researcher asked her or him about what s/he highlighted and why.

We recruited total of 47 students; 20 completed the task in person, who completed the debriefing interview immediately, and 27 used an online annotation tool, who completed the debriefing over the phone within 24 hours.

3.2 Results

First, we sought to determine the extent to which study participants' annotations agreed with one another. Do different people see the same words and phrases as being related to framing? An intraclass correlation (ICC) among participants' annotations of 0.757 indicated that the annotators demonstrated a moderately high degree of agreement as to which words and phrases were most related to framing.

As an example, one article about health care contained the sentence: "A good doctor might recognize the regenerative powers of the body politic and come up with a comprehensive treatment plan that also attacks root causesincluding the twin cancers of racism and poverty." Three students highlighted the entire sentence, another three highlighted only the phrase "twin cancers of racism and poverty," and one more highlighted "twinpoverty," "regenerative powers," and "body politic."

Several important insights were also derived from the debriefing interviews. Participants drew a distinction between facts and opinions, the later being more relevant to framing. For example, statistics were rarely seen as related to framing. Also, framing often dealt not only with a word itself but also with aspects of its context and its relationships with other terms in the article. For example, a participant might highlight just the word "but" because it indicates an important rhetorical shift and, implicitly, the article's take on the issue. Similarly, latent relationships between an individual word and the article's main argument also played an important role. For example, the article participants read emphasized "disparities" between healthcare available to the wealthy and to the working class. Many participants indicated that they would highlight any words or phrases that drew attention to such disparities. These insights, in conjunction with the theoretical literature on conceptual framing, were used to guide feature selection.

4 Data

We sought to develop a classifier that could automatically identify the language in a text that most related to framing. We chose to focus on news coverage rather than, say, opinion and editorial columns. Framing likely occurs in a more apparent, poten-

tially obvious fashion in opinion articles. In ostensibly "straight" news, though, framing may be harder to identify. Thus, this context would benefit more from a classifier that could automatically draw attention to frame-invoking language.

For training data, we wanted political texts where lay readers had indicated the words and phrases they perceived as most related to framing. Lay annonators were used instead of experts because the classifier's purpose is to support frame reflection among the lay public. Thus, the words and phrases the classifier highlights should align with that population's perception of framing. To our knowledge, no such data set exists. So, we used Mechanical Turk (Snow et al., 2008) and university students to build an annotated dataset that could be used for training and testing.

4.1 Collection

We began by collecting political news articles from top 15 online sources of news, as determined by Alexa rankings (http://www.alexa.com/topsites/category/Top/News). We excluded sources outside the US (e.g., BBC), news aggregators (e.g., Yahoo News, Google News), blogs (Huffington Post), and sites without a dedicated politics feed (e.g., USA Today, weather.com). Doing so left eight sources CNN, NYT, Fox, NBC, Washington Post, ABC, LA Times, Reuters.

For each source, we collected all items on their politics-specific RSS feed on two separate days roughly six months apart to provide content about diverse issues and events: Tuesday November 12, 2013, and Thursday May 15, 2014. We manually removed duplicate posts, "round-up" style posts that simply summarized and linked to other stories, video-only posts, and other non-textual content, resulting in a total of 205 documents. Of these, we randomly selected 75 to be annotated.

4.2 Annotation

Each article was annotated by five to 13 annotators, who were either Mechanical Turk (MTurk) workers or students at one of two major US universities. The task first asked the annotator to read the article, then gave the same directions from the framing prompt described above.

To encourage MTurk workers to pay attention to the task and complete high-quality work, we provided a scheme for bonus payments. Every word a worker annotated that was also annotated by at least two others (i.e., a majority of the 5 workers annotating each document) would earn the worker a $0.02 bonus (two cents). Each word s/he annotated that was annotated by no other work would reduce the bonus by $0.005 (half a cent). Workers were then linked to our web tool where they could complete and submit their annotations. Student annotators received no agreement-based incentive but were granted extra course credit.

4.3 Quality Assurance

Crowd workers do not always provide reliable annotations (Snow et al., 2008). For example, we noted multiple instances where annotators had only annotated about a dozen words in an article of several hundred words. These seemed likely to be cases in which the annotator was completing the task as quickly as possible without paying much attention. By comparing the annotations with those collected during our pilot study, in which participants' justifications during the debriefing ensured higher attention and quality, we developed the following criteria for identifying questionable annotations. Those that did not pass at least three of these five requirements were removed from the analysis.

1. All Annotations Short — While some annotations of short words, such as conjunctions, could be meaningful (see example above), we encountered a number of annotations where every annotated phrase consisted of only one or two words at a time. Thus, we required that the average annotated contiguous segment be at least 3 words long.

2. Few Words Annotated — When very few words in a document are annotated, we suspect the annotator may have been completing the task as quickly as possible and paying little attention. Thus, we required that each annotator's work include enough annotated words to total more than 5% of the document's length.

3. Large Contiguous Passages without Annotation — While pilot study participants pointed out portions of a text that consisted of "facts and figures," these were generally relatively short. Thus, we require the longest block of text without any annotations to be no more than one third the length of

the entire document.

4. Large Contiguous Passages Entirely Annotated — Large, unbroken annotations rarely occurred in our pilot study. Such annotations may also have indicated that the annotator was not attending to the entire content being annotated. Thus, we require that the longest contiguous annotation be no more than 120 words long.

5. Annotating Solely Stop Words — A number of annotations include only very common words, such as articles, prepositions, forms of the verb "to be," etc. Single words such as "but," "all," or "not" could arguably be related to framing. However, accounts from our pilot study participants made us less likely to believe that other single words, such as "an," "of," or "that," instantiated framing. Thus, we require that no more than 3 annotated passages consistent entirely of such stop words1.

We also encountered two situations in which pairs of MTurk workers submitted virtually identical annotations for multiple documents. Following up with the workers, we discovered that in one situation a husband and wife team had actually been working together. Based on our pilot study, we would expect annotators to agree to some degree, but we would not want such agreement to arise because annotators were collaborating. Thus, we also exclude these annotations where we suspect the possibility of collaboration.

We only include in our dataset documents with at least three valid annotations. In total, the resulting data set includes 74 articles containing 53,878 total words (M=728.1 words per particle), each with three to 11 valid annotations (Mdn=6). The data set includes 59,948 annotated words across 507 annotations from 372 annotators (M=122.8 annotated words per article). The full data set is available at http://hdl.handle.net/1813/39216.

5 Classifier Design and Implementation

As argued above, drawing attention to framing-related language may both mitigate frame effects (Baumer et al., 2015) and facilitate frame reflection (Schön and Rein, 1994). This section describes the features used to train a classifier to identify framing along with justifications for each, different subsets of features that were tested, our classifier selection, and the training and testing methods.

5.1 Features and Subsets

We treat each word as a data point to be classified as framing-related or not. Feature extraction began with splitting each article into sentences with NLTK (Bird et al., 2009) then using Stanford CoreNLP (Klein and Manning, 2003; De Marneffe et al., 2006) to parse each sentence, obtain POSs and lemmatized forms for each word, etc. We then construct a feature vector for each non-stop word. Table 1 lists all features used. The remainder of this subsection describes the justificaton for each feature, as well as several subsets of features.

Framing is often instantiated by specific "keywords, stock phrases," (Entman, 1993, p. 52) or "catchphrases" (Gamson and Modigliani, 1989, p. 3). Therefore, we include lexical features that capture the specific words used. Furthermore, many of our pilot study participants pointed out that a given word might be seen as related to framing because of the other words near which it appears. Therefore, each of these features includes a contextual window of up to two words before and after the word being classified (Recasens et al., 2013).

Participants in our pilot study said physical locations, such as the names of states, were often not related to framing. However, they sometimes saw names of political figures or experts as indicating framing. Thus, we include the named entity type as a feature, both of the word itself and of its context.

Pilot study participants also mentioned that a word's relationship to the remainder of a document and its overall thesis played important roles. A number of similar structural aspects of the document, both explicit and latent, may help draw out these relationships.

Several specific types of terms may be indicative of framing. For example, "depictions," "visual images," and figurative language such as metahpor (Gamson and Modigliani, 1989) often invoke frames. For imagery, we use previously established imagery ratings for 1818 common words (Paivio et al., 1968; van der Veur, 1975). Words that appear in this list are given an imagery rating, either low (first quantile), medium (second and third quantile), or high (fourth quantile) imagery. The context feature represents the average imagery of the

Feature	Description	Feature Subset(s)
Token ±1, ±2	The word token itself and the tokens in its context.	Lexical, Theoretical
Lemma ±1, ±2	The lemmatized word and the lemmas in its context.	Lexical, Theoretical
Bigrams and trigrams	All bigrams and trigrams of which the word is a part.	Lexical, Theoretical
POS ±1, ±2	The word's and its context's part(s) of speech.	Grammatical
Root	Whether the word is the sentence's parse tree's root.	Grammatical
Relation and Role	The grammatical relations in which the word is involved and its role in those relations, e.g., passive subject of a verb.	Grammatical
Named Entity ±1, ±2	Named entity type of the word and its context.	Grammatical
In Title	Whether the word appears in the article's title.	Document
Sentence Lengeth	The number of words in the sentence.	Document
Sentence Position	Whether the word appears in the first third of the sentence, the middle third, or the last third.	Document
TFIDF	The word's tf-idf score, grouped into 8 bins of increasing size.	Document
Imagery & Context	Imagery rating of the word and average imagery rating of its context (Paivio et al., 1968; van der Veur, 1975).	Theoretical, Dictionaries
Figurativeness & Context	Figurativeness rating of the word and average figurativeness rating of its context (Gamson and Modigliani, 1989; Turney et al., 2011).	Theoretical, Dictionaries
Abstractness & Context	Abstractness rating of the word and average abstractness rating of its context (Gamson and Modigliani, 1989; Turney et al., 2011).	Theoretical, Dictionaries
Dictionaries & Context	One feature each for whether word or context is a subjective word (Riloff and Wiebe, 2003), a report verb (Recasens et al., 2013), a hedge (Hyland, 2005), a factive verb (Hooper, 1975), an entailment (Berant et al., 2012), an assertive word (Hooper, 1975), a bias word (Recasens et al., 2013), a negative word (Liu et al., 2005), or a positive word (Liu et al., 2005).	Theoretical, Dictionaries

Table 1: Name and description of all features for each word, as well as the set(s) to which each feature belongs.

word's context. For figurative language, we used Turney et al.'s (Turney et al., 2011) approach of measuring figurativeness based on the absolute difference in the concreteness of two terms that are grammatically related. The figurativeness score for a given word is the average absolute difference between its concreteness and the concreteness of every word with which it is in some grammatical relationship. We also used Turney et al.'s (Turney et al., 2011) approach to rate the individual abstractness of each word and its context. Lastly, subjective words, hedges, entailments, and other terms that perform specific psycholinguistic functions (Recasens et al., 2013) may also be useful in identifying framing. For each, we include one feature for the word itself and one feature for the two-word context around the word.

The features used here are informed by a combination of theoretical literature on framing, our own pilot studies, and prior work in computational linguistics. However, we have little means of knowing a priori which of these features will be most important or even necessary. Therefore, in the interest of developing the most perspicacious model, we test several feature subsets, as noted in Table 1. Lexical features involve only words that actually occur in the text. Grammatical features use only aspects of grammatical structure. Document features use various ex-

plicit and latent aspects of the document's structure. Theoretical features are those specifically mentioned in the theoretical literature on framing. Finally, the Dictionaries feature set tests whether there might be specific terms that invoke framing.

5.2 Training and Testing

We implemented and tested a variety of different classifiers, including Stochastic Gradient Descent (SGD), Multinomial Naïve Bayes, Perceptron, Nearest Neighbor, Logistic Regression, and Passive Aggressive classifiers. In several tests, the Naïve Bayes classifier performed best, so we used a Naïve Bayes classifier throughout.

As described above, our data include three to 11 annotators' annotations for each word in the corpus. To create training data, we aggregated these annotations such that any word highlighted by at least one fourth of the annotators was treated as framing-related (i.e., true positive) for training and testing purposes, and the remaining words were treated as not frame-related (i.e., true negative).

These data, in the combinations of features described above, were used to train our ensemble classifier using scikit-learn (Pedregosa et al., 2011) using ten-fold random shuffle cross-validation, as well as a random dummy classifier based on class distributions in the training set. Performance in terms of f-score, accuracy, precision, and recall was averaged across the ten folds.

6 Results

This section summarizes results, highlighting some important aspects thereof, while the subsequent Discussion section considers interpretation and broader implications. Figure 1 presents a summary of results for each feature set, including comparison with the dummy baseline and the aggregate human performance. The Document Structure feature set performed very poorly, identifying 0 true positives, so we exclude it from the detailed results report.

Since overall accuracy does not vary drastically, we focus on other performance metrics. Except for the Dictionaries, all feature sets perform statistically significantly better than the dummy (ANOVA with Tukey's posthoc $p < 0.001$). F1 scores among the top three performers (Lexical, Theoretical, and All features) are statistically indistinguishable. Furthermore, each of these three top performers matches aggregate human annotator performance.

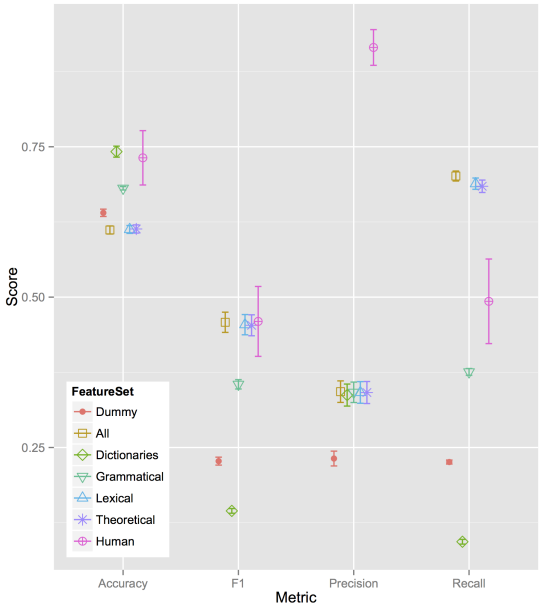

Figure 1: Performance of each feature set, as well as the dummy baseline and human annotators, on accuracy, F1, precision, and recall. Three feature sets (Lexical, Theoretical, and All features) match human annotators on F1 and outperform human recall, but humans demonstrate higher precision.

Looking at precision and recall, we can see that the classifiers and the human annotators make different trade offs. Precision for all feature sets is around 34% (all statisticially significantly better than the dummy and significantly indistinguishable from one another), while human average precision is 91.5%. On the other hand, the three top performing feature sets (All, Lexical, and Theoretical) all achieve recall around 70%, while average recall for the human annotators is only 49.3%.

It is also important to note that human performance is calculated by comparing each individual annotator to the aggregate of all the annotators. Because each individual is part of that aggregate, precision scores for the humans are fairly high. We consider comparison with human performance further in the discussion below.

We also examine the most influential features for classifiers using each of the three top performing

feature sets. For the Lexical feature set, the most informative features for negative cases are bigrams that begin with quotation marks. Since we manually assign all punctuation, including quotation marks, as true negatives, this is perhaps unsurprising. For positive cases, many of the "offset" style features emerge as informative. For example, words that appear one or two words before a comma or period are more likely to involve framing. Similarly, words that occur just before or just after prepositions or conjunctions — to, and, in, of, etc. — are more likely classified as framing (i.e., positive). This result aligns with some of our pilot study findings about the relationships between such function terms the words surrounding them. Interestingly, though, these features do not resemble the catchphrases and keywords described in the framing literature (Entman, 1993; Gamson and Modigliani, 1989).

For the Theoretically Informed feature set, which adds in imagery, figurativeness, and other dictionary-based features, roughly the same kinds of lexical features are most important in identifying negative cases. For positive cases, constructs such as descriptiveness and abstractness play important roles, but mostly when words in the context do *not* appear in these dictionaries, calling into question the importance of imagery, metaphor, and other figurative language (Gamson and Modigliani, 1989). Other dictionary-based features, such as being an entailment word, having an entailment in context, having a bias term in context, or having a subjective term in context, become important in identifying positive cases. Some of the lexical features, such as proximity to a comma or period, also remain informative.

With All features, which adds features for document structure and grammatical structure, two major differences occur. First, some elements of document structure become important features for positive cases, including sentence length and TFIDF. Second, various part of speech tags, mostly NN and NNP, become important to identifying framing. These findings suggest that the choice of terms used to label concepts or entities can indicate framing. Indeed, entity type, both of the word and its context, also emerges as an informative feature.

7 Discussion

Chiefly important among the results, three of our feature sets were able to achieve F1 scores on par with those of human annotators. This result provides encouraging evidence that a machine classifier can effectively accomplish the task of identifying the language that invokes framing in political news coverage.

That said, examining the results more closely exposes that, in order to achieve this level of performance, the classifier makes a trade-off. Specifically, the classifier is far more aggressive than humans, resulting in significantly higher recall but lower precision. We did experiment with different post-hoc decision thresholds to make the classifier less aggressive. However, as we the decision threshold rose, recall fell much more quickly than precision increased, resulting in lower overall F1 scores. Moreover, this precision-recall trade off may have different ramifications in different applications. For example, in terms of supporting frame reflection, would it be harmful or distracting for a machine classifier to mark too many words as frame-invoking, thereby potentially overwhelming a potential user? Or would it be worse if the classifier were too sparse, missing certain important key words or phrases? These are questions for later empirical work that incorporates the results of this classifier into interactive systems to support frame reflection.

Also, our results above identifying important features within the classifier contribute to and build on prior computational work. For example, Recasens et al. (Recasens et al., 2013) find entailment (Berant et al., 2012), implicature (Karttunen, 1971), subjectivity (Riloff and Wiebe, 2003), and other related constructs helpful in identifying bias. The results above suggest that, when included, such features also emerge as important for identifying the language of framing. However, the feature sets that include dictionaries of these terms do not perform statistically significantly better than those feature sets without them. This result supports our initial assertion that bias and framing, while conceptually related, are separate constructs that are each perceived and instantiated via different linguistic cues.

These findings also relate to recent efforts at identifying which frame(s) are operating in a text (e.g.,

Boydstun et al., 2013). On the one hand, the performance of the Lexical feature set suggests that topic modeling, especially including certain n-grams, may prove an effective approach. That said, Boydstun et al. are more interested in determining *which* frames are at work in a text as a whole, whereas this paper focuses more on determining *where* within a text frames are invoked. Thus, different computational approaches and features may prove effective for each task.

Interestingly, the grammatical structure feature set is not one of the top performers. Given our expectations, including the importance that pilot study participants placed on structural relationships within the sentence, the role of grammatical construction both in metaphors (Turney et al., 2011) in framing more broadly (Fairclough, 1999), and prior computational work on implicit sentiment (Greene and Resnik, 2009), this result appears fairly surprising. It could be that grammatical structure alone is not sufficient to identify framing, but even combining grammatical structure with other features does not significnatly improve performance. Perhaps, then, grammatical construction matters less than the specific words chosen. On the other hand, lexical features may be topic-specific, such that even obtaining two samples six months apart still resulted in the same buzzwords invoking framing. Future work should examine more closely the role that structural features play, or perhaps do not play, in invoking framing.

This point also draws attention to some practical implications. Performing a full grammatical parse can be computationally intensive. If using other features that do not require a full parse can achieve comparable performance, then perhaps real time applications, such as analyzing live speeches as they happen, could employ only features that are relatively quicker and easier to extract.

Finally, we note that the annotated data analyzed here come from political news stories in US mainstream media. Since these sources ostensibly strive for impartiality, framing in these data may occur implicitly or unconsciously. Future work should compare these results with similar analyses of texts containing more explicit framing, such as opinion columns, campaign speeches, or political advertisements. Differences in how framing is identified may give important clues to how framing operates in different contexts. Similarly informative insights could be gained by comparing lay-persons' annotations with framing experts'.

8 Conclusion

"Facts have no intrinsic meaning. They take on their meaning by being embedded in a frame" (Gamson, 1989, p. 157). Given framing's pervasive influence, this paper argues for the importance of computational techniques that can identify and draw attention to the language of framing. Doing so can help support frame reflection (Schön and Rein, 1994) and, thereby, deeper understanding of and engagement with political issues.

This paper both develops a computational approach to identifying framing and tests how well different linguistic features indicate frame-invoking language. Results suggest grammatical structure alone as the most important indicator of framing. However, other data less computationally demanding to extract, such as lexical features (e.g., tokens and n-grams), can prove almost as effective.

In sum, the paper makes two main contributions. First, it provides a technical contribution by identifying a task of importance and demonstrating a technique that performs close to as well as humans. Second, the paper makes a theoretical contribution, helping to provide "guidelines on how to identify [] a frame in communication" (Chong and Druckman, 2007, p. 106). The data set of annotations released with this paper may also prove a valuable resource for future analyses of framing.

Abstract

While the effect of various lexical, syntactic, semantic and stylistic features have been addressed in persuasive language from a computational point of view, the persuasive effect of phonetics has received little attention. By modeling a notion of euphony and analyzing four datasets comprising persuasive and non-persuasive sentences in different domains (political speeches, movie quotes, slogans and tweets), we explore the impact of sounds on different forms of persuasiveness. We conduct a series of analyses and prediction experiments within and across datasets. Our results highlight the positive role of phonetic devices on persuasion.

1 Hocus Pocus

Historically, in human sciences, several definitions of persuasion have been proposed – see for example (Toulmin, 1958; Walton, 1996; Chaiken, 1980; Cialdini, 1993; Petty and Cacioppo, 1986). Most of them have a common core addressing: *methodologies aiming to change the mental state of the receiver by means of communication in view of a possible action to be performed by her/him.* (Perelman and Olbrechts-Tyteca, 1969; Moulin et al., 2002).

These methodologies might take into account the overall structure of a text such as the ordering of the arguments or simply single word choices. For a successful text both of them are often required. The focus of persuasion may vary according to the goal of the communication and it can take different forms according to the domain: from memorability (e.g., making people remember a statement or a product) to diffusion (e.g., making people pass on a content in social networks by sharing it), from behavioral change (e.g., political communication) to influencing purchasing decisions (e.g., slogans to convince people to try or buy a product) – see for example (Heath and Heath, 2007). While many techniques such as resorting to expert opinion, utilizing the framing effect, emotive language or exaggeration can be used to obtain such persuasive effects, we devote this study to explore particular techniques pertaining to euphony.

Euphony refers to the inherent pleasantness of the sounds of words, phrases and sentences, and it is utilized to achieve pleasant, rhythmical and harmonious effects. The idea that the pleasantness of the sounds in a sentence can foster its effectiveness is rooted in our culture, and is connected to the concepts of rhythm and music. The fact that language and music interact in our brain has been shown by localizing low-level syntactic processes of music and language in the temporal lobe (Sammler et al., 2013). It has also been shown that changes in the cardiovascular and respiratory systems can be induced by music – specifically tempo, rhythm, melodic structure (Bernardi et al., 2006). The importance of euphony has its roots also in ancient human psychology. As Julian Jaynes suggests (Jaynes, 2000), poetry used to be divine knowledge. It was the sound and tenor of authorization and it commanded where plain prose could only ask. A paradigmatic example of this conception is the act of casting a spell. Spells (incantations) are special linguistic objects that are meant not only to change how

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1483–1493,
Denver, Colorado, May 31 – June 5, 2015.

people think or behave but they are also so powerful that they can – allegedly – change reality. Spells are often very euphonic (and meaningless) sentences, e.g. "Hocus Pocus".

Various psycholinguistic studies addressed the effects of phonetics on the audience in different aspects such as memorability (Wales, 2001; Benczes, 2013) or more specifically advertisement (Leech, 1966; Bergh et al., 1984). There are also computational studies that address the problem of recognizing persuasive sentences according to various syntactic, lexical and semantic features (Danescu-Niculescu-Mizil et al., 2012; Tan et al., 2014). However, to the best of our knowledge, the direct impact of phonetic elements on persuasiveness has not been explored in computational settings yet.

In this paper, we fill in this gap by conducting a series of analyses and prediction experiments on four datasets representing different aspects of persuasive language to evaluate the importance of a set of phonetic devices (i.e. rhyme, alliteration, homogeneity and plosives) on various forms of persuasiveness. Our experiments show that phonetic features play an important role in the detection of persuasiveness and encode a notion of "melodious language" that operates both within and across datasets.

2 Related Work

In the following, we first revise some NLP studies addressing linguistic features of successful communication. Then, we summarize a selection of studies devoted to the effects of phonetics on persuasion.

2.1 NLP studies on persuasion

Berger and Milkman (2009) focus on a particular form of persuasion by using New York Times articles to examine the relationship between virality (i.e., the tendency of a content to be circulated on the Web) and emotions evoked by the content. They conduct semi-automated sentiment analysis to quantify the affectivity and emotionality of each article. Results suggest a strong relationship between affect and virality, in this case measured as the count of how many people emailed each article. As suggested by the authors, this metric represents a form of "narrowcasting", as opposed to other "broadcasting" actions such as sharing on Twitter.

Another line of research investigates the impact of various textual features on audience reactions. The work by Guerini et al. (2011) correlates several viral phenomena with the wording of a post, while Guerini et al. (2012) show that features such as the readability level of an abstract influence the number of downloads, bookmarking and citations.

A particular approach to content virality is presented by Simmons et al. (2011), who explore the impact of different types of modification on memes spreading from one person to another.

Danescu-Niculescu-Mizil et al. (2012) measure a different ingredient of persuasion by analyzing the features of a movie quote that make it "memorable". They compile a corpus consisting of memorable and non-memorable movie quote pairs and conduct a detailed analysis to investigate the lexical and syntactic differences between these pairs.

Louis and Nenkova (2013) focus on influential science articles in newspapers by considering characteristics such as readability, description vividness, use of unusual words and affective content. High quality articles (NYT articles appearing in "The Best American Science Writing" anthology) are compared against typical NYT articles.

Borghol et al. (2012) investigate how differences in textual description affect the spread of content-controlled videos. Lakkaraju et al. (2013) focus on the act of resubmissions (i.e., content that is submitted multiple times with multiple titles to multiple different communities) to understand the extent to which each factor influences the success of a content. Tan et al. (2014) consider how content spreads in an on-line community by pinpointing the effect of wording in terms of content informativeness, generality and affect. Althoff et al. (2014) develop a model that can predict the success of requests for a free pizza gifted from the Reddit community. The authors consider high-level textual features such as politeness, reciprocity, narrative and gratitude.

2.2 Studies on the effects of phonetics

Benczes (2013) states that alliteration and rhyme can be considered as attention-seeking devices as they enhance emphasis. The author also suggests that they are useful for acceptability and long-term retention of original expressions, decrypting their meanings, indicating informality, and breaking the ice be-

tween an audience and a speaker. Therefore, these devices are commonly used in original metaphorical and metonymical compounds.

According to Leech (1966), phonetic devices such as rhyme and alliteration are systematically exploited by advertisers to achieve memorability. Similarly, Wales (2001) underlines the effectiveness of alliteration and rhyme on emphasis and memorability of an expression.

The relation between the usage of plosives (i.e., consonants in which the vocal tract is blocked so that all airflow ceases, such as "p", "t" or "k") and memorability has also been investigated. According to the study carried out by Bergh et al. (1984) brand names starting with plosive sounds are recalled and recognized more than the ones starting with other sounds. Özbal et al. (2012) carry out an analysis of brand names and discover that plosives are very commonly used.

Danescu-Niculescu-Mizil et al. (2012), whom we previously mentioned, carry out an auxiliary analysis and observe the differences in letter and sound distribution (e.g. usage of labials or front vowels, back sounds, coordinating conjunctions) of memorable and non-memorable quotes.

Özbal et al. (2013) propose a phonetic scorer for creative sentence generation such that generated sentences can contain various phonetic features including alliteration, rhyme and plosive sounds. The authors evaluate the proposed model on automatic slogan generation. In a more recent work (Özbal et al., 2014), they enforce the existence of these features in the sentences that are automatically generated for second language learning to introduce hooks to echoic memory.

3 Phonetic Scorer

For the design of the phonetic features, we were mostly inspired by the work of Özbal et al. (2013), who built and used three phonetic scorers for creative sentence generation. Similarly to this work, all the phonetic features that we used are based on the phonetic representation of English words of the Carnegie Mellon University pronouncing dictionary[1]. We selected four classes of phonetic devices, namely plosives, alliteration, rhyme and homogeneity, which can easily be modeled by observing the distribution of specific classes of phonemes within the sentence. The *plosive* score is calculated as the ratio of the number of plosive sounds in a sentence to the overall number of phonemes. For both *alliteration* and *rhyme* scorers, we provide a naïve implementation that does not consider stresses or syllables, but only counts the number of repeated sounds at the beginning or end of words in the sentence. The alliteration score is calculated as the number of repeated phonetic prefixes in a sentence normalized by the total number of phonemes. Similarly, the *rhyme* score is calculated as the ratio of the number of repeated phonetic endings in a sentence to the total number of phonemes. Lastly, the homogeneity scorer simply calculates the degree of homogeneity in terms of phonemes used in a sentence independently from their positions. If we let d_{ph} be the count of distinct phonemes and t_{ph} be the total count of phonemes in a sentence, then the homogeneity score is calculated as $1 - (d_{\text{ph}}/t_{\text{ph}})$.

4 Dataset

In this section, we describe the four datasets we used to conduct our analyses and experiments. As we mentioned previously, the definition of persuasion is a debated topic and it can comprise distinct strategies or facets. For this reason, we experimented with datasets where at least one ingredient is clearly in the equation. To explore the effects of wording and euphonics on persuasion, the datasets were built in a controlled setting (topic, author, sentence length) to avoid confounding factors such as author or topic popularity, by following the procedure described in (Danescu-Niculescu-Mizil et al., 2012; Tan et al., 2014). In addition, these datasets comprise short texts (mostly single sentences) to focus on surface realization of persuasion, where strategic planning – which might act as a confounding factor – plays a minor role. The idea of using controlled experiments (usually in an A/B test setting) to study persuasive communication can be traced back at least to Hovland et al. (1953). While two of these datasets (Twitter and Movies) were already available, the other two (CORPS and Slogans) were collected by following the methodology proposed in the first two as

[1]The CMU pronunciation dictionary is freely available at `http://www.speech.cs.cmu.edu/cgi-bin/cmudict`. We have used version 0.7a in our implementation.

closely as possible[2].

All datasets are built around the core idea of collecting pairs consisting of a persuasive sentence (P) and a non-persuasive counterpart ($\neg P$), where P and $\neg P$ are structurally very similar and controlled for the above mentioned confounding factors.

Twitter. A set of 11,404 tweet pairs, where each pair comes from the same user (author control) and contains the same URL (topic control). P and $\neg P$ are determined based on their retweet counts (Tan et al., 2014). It is worth noting that in our experiments we were able to collect only 11,019 of such tweet pairs since some of them were deleted in the meanwhile.

Movie. A set of 2,198 single-sentence memorable movie quotes (P) paired with non-memorable quotes ($\neg P$). For each P, the dataset contains a contrasting quote $\neg P$ from the same movie such that (i) P and $\neg P$ are uttered by the same speaker, (ii) P and $\neg P$ have the same number of words, (iii) $\neg P$ does not occur in the IMDb list of memorable quotes and (iv) P and $\neg P$ are as close as possible to each other in the script (Danescu-Niculescu-Mizil et al., 2012).

CORPS. A set of 2,600 sentence pairs uttered by various politicians. We collected these pairs from CORPS, a freely available corpus of political speeches tagged with audience reactions (Guerini et al., 2013). The methodology that we used to build the pairs is very similar to Danescu-Niculescu-Mizil et al. (2012): for each P, where P is the sentence preceding an audience reaction (e.g. `APPLAUSE`, `LAUGHTER`), we selected a contrasting single-sentence $\neg P$ from the same speech. We required $\neg P$ to be close to P in the speech transcription, subject to the conditions that (i) P and $\neg P$ are uttered by the same speaker - which is trivial since these are monologues, where a single speaker is addressing the audience - (ii) P and $\neg P$ have the same number of words, and (iii) $\neg P$ is 5 to 15 sentences away from P. This last condition had to be imposed since, differently from movie quotes, we do not have the evidence of which fragment of the speech exactly provoked the audience reaction (i.e. it could be the combination of more than one sentence).

Slogan. A set of 1,533 slogans taken from online resources paired with non-slogans that are similar in content. We collected the non-slogans from the subset of the New York Times articles in English GigaWord – 5th Edition – released by Linguistic Data Consortium (LDC)[3]. For each slogan, we picked the most similar sentence in the New York Times articles having the same length and the highest LSA similarity (Deerwester et al., 1990) with the slogan. The LSA similarity approach that we used to collect the non-slogans is very similar to the approach used by Louis and Nenkova (2013) to collect the non-persuasive counterparts of successful news articles.

In Table 1, we sum up the criteria used in the construction of each dataset. As can be observed from the table, each dataset satisfies at least two of the three criteria described above. In the last two columns of the table, we also provide the average token length of the persuasive and non-persuasive sentences in each dataset. Finally, in Table 2 we provide examples of euphonic and persuasive sentences for each dataset together with their phonetic scores.

	Criterion			Length	
DATASET	Author	Length	Topic	P	$\neg P$
CORPS	✓	✓	✗	14.0	14.0
Movie	✓	✓	✗	9.7	9.7
Slogan	✗	✓	✓	5.0	5.0
Twitter	✓	✗	✓	16.2	15.4

Table 1: Criteria used in the construction of each dataset and average token length of persuasive and non-persuasive pairs

5 Data Analysis

To provide a first insight on the data, in Table 3 we report the average phonetic scores for each data set (Mann-Whitney U Test is used for statistical significance between P and $\neg P$ samples, with Bonferroni correction to ameliorate issues with multiple comparisons). The results are partially in line with our expectations of the euphony phenomena being more relevant in the persuasive sentences across the datasets.

As can be observed from the table, the average rhyme scores are higher in persuasive sentences and

Table 3: Average phonetic scores for our datasets - ***, $p < .001$; **, $p < .01$; *, $p < .05$; †, not significant

the difference is highly significant for Slogan and Twitter ($p < .001$), slightly significant for Movie quotes ($p < .05$), but not significant for CORPS. The average alliteration scores are again higher in persuasive sentences and all the differences are highly significant in all datasets (apart from CORPS with $p < .01$). Plosives seem not to correlate well with our intuition of persuasiveness and euphony: either there is no significance (movie quotes) or the averages of euphonic scores are higher in the non-persuasive sentences (the difference is highly significant in slogans, and significant in Twitter). The only dataset that meets our expectation is CORPS with a highly significant difference in favor of persuasive sentences. Finally, the average homogeneity scores are significantly ($p < .001$) higher in persuasive sentences in all datasets except CORPS, where the scores of non-persuasive sentences are significantly higher ($p < .01$) than persuasive ones.

Without going into details of cross-dataset comparisons we would like to note that CORPS seems a very peculiar dataset in terms of average scores, as compared to the others. In terms of rhyme and alliteration, the average scores of non-persuasive sentences ($\neg P$) in CORPS are always higher than the persuasive sentences (P) in the other datasets ($p < .001$ in all cases), while for homogeneity the same holds apart from Twitter. These results may derive from the fact that a political speech is a carefully crafted text – aimed at influencing the audience – in its entirety, so also "non-persuasive" sentences in CORPS are on average more persuasive than in other datasets.

As a next step, we conducted another analysis on the distribution of "extreme cases", i.e. sentences that have a very high phonetic score at least in one feature. This analysis derives from the intuition that a euphonic sentence might be recognized as such by humans only if its phonetic scores are above a certain threshold. In fact, sound repetition in a sentence may occur by chance, as in "I saw **the** knife in **the** drawer", and the longer the sentence is, the higher the probability that phonetic scores will be non-zero even in absence of a euphonic effect. Therefore, the average scores for each phonetic device, as reported in Table 3, are only partially informative.

Given this premise, to evaluate the "persuasive power" of the phonetic devices taken into account,

Dataset	$\hat{F}_{rh}(t)$	$\hat{F}_{al}(t)$	$\hat{F}_{pl}(t)$	$\hat{F}_{ho}(t)$
CORPS$_{\neg P}$	0.025	0.012	0.362	0.394
CORPS$_P$	0.033**	0.023**	0.415***	0.363†
Movie$_{\neg P}$	0.018	0.011	0.397	0.092
Movie$_P$	0.041***	0.025***	0.363†	0.173***
Slogan$_{\neg P}$	0.005	0.003	0.460	0.011
Slogan$_P$	0.055***	0.043***	0.410***	0.018***
Twitter$_{\neg P}$	0.006	0.003	0.385	0.377
Twitter$_P$	0.012***	0.008***	0.364**	0.449***

Table 4: Probability of examples above threshold, - ***, $p < .001$; **, $p < .01$; *, $p < .05$; †, not significant

we compare them in terms of empirical Complementary Cumulative Distribution Functions (CCDFs) of the persuasive/non-persuasive pairs in various datasets. These functions are commonly used to analyze online social networks in terms of growth in size and activity (see for example (Ahn et al., 2007; Jiang et al., 2010; Leskovec, 2008)) and also for measuring content diffusion, e.g. the number of retweets of a given content (Kwak et al., 2010). Here, we use CCDFs to account for the probability P that the score of a phonetic device d will be greater than n indicating it with $\hat{F}_d(n)$. For example, the probability of having a text with more than .75 rhyme score is indicated with $\hat{F}_{rh}(.75) = \mathrm{P}(\#\mathrm{rhyme} > .75)$. To assess whether the CCDFs of the several types of texts we take into account show significant differences, we use the Kolmogorov-Smirnov goodness-of-fit test, which specifically targets cumulative distribution functions. In particular, for each phonetic device and dataset, we use a two-tailed Kolmogorov-Smirnov test (again with Bonferroni correction) to test whether the number of examples above the threshold is higher in the persuasive sentences than in their non-persuasive counterparts for that device.

Since we do not have a theoretical way to define such thresholds, we resort to empirically define them by using a specific dataset of euphonic sentences. Even if it might seem reasonable to consider poems as paradigmatic examples of "euphonic" writing, we discard them as the phonetic devices used in poems may span across sentences. Instead, we resort to tongue twisters as a gold reference of how a euphonic sentence should be. Accordingly, we collected a set of 534 tongue twisters from various online resources. Then, for each phonetic index we defined our thresholds as the average of the phonetic scores in this data, in particular: $t_{rh} = 0.55$ for rhyme, $t_{al} = 0.58$ for alliteration, $t_{pl} = 0.20$ for plosives and $t_{ho} = 0.68$ for homogeneity.

In Table 4, we report the results of our CCDF analysis. After analyzing the "extreme cases", where euphony is granted, we see that the trends found in Table 3 on the correlation between persuasiveness and euphony are confirmed and strengthened. The number of persuasive sentences with a rhyme score above threshold is 30% more than the non-persuasive ones in CORPS, while the difference is 90% in Twitter[4]. The ratio of persuasive sentences above threshold to non-persuasive ones is very high in movies and slogans (more than 2 and 10 respectively). All results are either highly significant or significant. For comparison, in Table 3 these differences are not significant for CORPS and only slightly significant ($p < .05$) for movies. Concerning alliteration, there are 85% more cases above threshold in the persuasive sentences of CORPS than the non-persuasive ones. For movie quotes and Twitter, the persuasive sentences above threshold are more than two times as many as the non-persuasive ones, while the ratio is more than 13 for slogans. All results are either highly significant or significant in line with the results of Table 3. Instead, for plosive scores we observe a negative or no correlation with persuasiveness, the only exception being CORPS. Regarding homogeneity, for CORPS the difference between persuasive and non-persuasive sentences is not significant (in Table 3 it was significantly in favor of non-persuasive sentences), while for the other datasets there is a highly significant difference in favor of persuasive sentences (between 20% and 80%). As a whole, these results confirm our intuition that phonetic features play a significant role with respect to persuasiveness. In the next section we will validate this claim by means of prediction experiments.

6 Prediction Experiments

In this section, we describe the prediction tasks (both within and across datasets) that we carried out to in-

[4]In the following the ratios are computed on the real values while Table 4 presents the rounded values.

vestigate the impact of the phonetic features on the detection of various forms of persuasiveness. We compare three different sets of features, namely phonetic, n-grams and their combination to understand whether phonetic information can improve the performance of standard lexical approaches. Similarly to Danescu-Niculescu-Mizil et al. (2012) and Tan et al. (2014), we formulate a pairwise classification problem such that given a pair (s_1, s_2) consisting of sentences s_1 and s_2, the goal is to determine the more persuasive one (i.e., the one on the *left* or *right*). We can consider this as a binary classification task where for each instance (i.e., pair) the possible labels are *left* or *right*.

6.1 Dataset and preprocessing

For the prediction experiments, we used the four datasets described in Section 4 (i.e., CORPS, Twitter, Slogan and Movie), all of which consist of a persuasive sentence P and its non-persuasive counterpart ($\neg P$) labeled as either *left* or *right*. To make the positions of the sentences in a pair irrelevant (i.e. to provide symmetry), for each instance occurring in the original datasets (e.g., (s_1, s_2) with label *left*), we added another instance including the same sentence pair in reverse order (i.e., (s_2, s_1) with label *right*). As a preprocessing step, all the sentences were tokenized by using Stanford CoreNLP (Manning et al., 2014).

6.2 Classifier and features

We performed a 10-fold cross-validation on each dataset and experimented with three feature sets by using a Support Vector Machine (SVM) classifier (Cortes and Vapnik, 1995). We preferred SVM as a classifier due to its characteristic property to especially perform well on high-dimensional data (Weichselbraun et al., 2011).

The first feature set consists of the phonetic features (i.e. plosive, alliteration, rhyme and homogeneity scores as detailed in Section 3). The second feature set is a standard bag of word n-grams including unigrams, bigrams and trigrams. All the non-ascii characters, punctuations and numbers were ignored. The URLs and mentions in Twitter data were replaced with tags (i.e. *_URL_* and *_MENTION_* respectively). In addition, for the unigram features, stop words were filtered out. We did not apply this filtering for bigrams and trigrams to capture longer-range usage patterns such as propositional phrases. The third feature set is simply the union of both phonetic and n-gram features.

To find the best configuration for each dataset and feature set, we conducted a grid search over the degree of the polynomial kernel (1 or 2) and the number of features to be used (in the range between 1,000 and 20,000). Due to the low dimensionality of the phonetic feature set, feature selection was performed only for the feature sets including n-grams. The selection was performed based on the information gain of each feature.

Dataset	*Phonetic*	*N-Gram*	*All*
CORPS	0.589 (-, 1)	0.733^{***} (4k, 1)	$0.736^{\dagger}$ (2k, 1)
Movie	0.600 (-, 2)	0.694^{***} (1k, 1)	0.722^{***} (1k, 1)
Slogan	0.700 (-, 2)	0.826^{***} (3k, 1)	0.883^{***} (5k, 1)
Twitter	0.563 (-, 2)	0.732^{***} (5k, 1)	0.745^{***} (4k, 1)

Table 5: Results of the within-dataset experiments.

6.3 Within-dataset experiments

For this set of experiments, we conducted a 10-fold cross validation on each dataset separately. In Table 5, for each dataset listed in the first column, in the subsequent columns we report the performance of the best model obtained with 10-fold cross validation using i) only phonetic features (*Phonetic*), ii) only n-grams (*N-Gram*), iii) both phonetic and n-gram features (*All*). As mentioned previously, for each pair (s_1, s_2) consisting of sentences s_1 and s_2, our dataset contains another pair including the same sentences in reverse order (i.e., (s_2, s_1)), resulting in a symmetric and balanced dataset. Therefore, classification performance is measured in terms of accuracy (i.e., the percentage of pairs of which labels were correctly predicted). For each accuracy value, we also report in parenthesis the number of features selected and the kernel degree of the corresponding model. While the kernel degree did not make a big difference in the performance, the number of selected features had an important effect on the accuracy of the models. As can be observed from these values, the best performance on all the datasets is achieved with a relatively small number of features.

Among the values reported in the table, the ones followed by *** are significantly different ($p < .001$)

Dataset	*N-Gram*	*N-Gram+Rhyme*	*N-Gram+Plosive*	*N-Gram+Homogeneity*	*N-Gram+Alliteration*
CORPS	0.733	$0.738^{\dagger}$ (3k, 1)	$0.740^{\dagger}$ (2k, 1)	$0.738^{\dagger}$ (3k, 1)	$0.738^{\dagger}$ (2k, 1)
Movie	0.694	$0.694^{\dagger}$ (1k, 1)	$0.692^{\dagger}$ (1k, 1)	0.721^{***} (1k, 1)	0.709^{**} (1k, 1)
Slogan	0.826	0.864^{***} (2k, 1)	$0.824^{\dagger}$ (2k, 1)	0.867^{***} (3k, 1)	0.859^{***} (3k, 1)
Twitter	0.732	0.740^{**} (4k, 1)	$0.733^{\dagger}$ (4k, 1)	0.746^{***} (4k, 1)	0.742^{***} (4k, 1)

Table 7: Results of the cross-dataset prediction experiments optimized on the training set.

from the ones to their left, while † represents no significance, as calculated according to McNemar's test (McNemar, 1947). For each dataset, the weakest models (i.e. the ones using only the phonetic features in all cases) are still significantly ($p < .001$) more accurate than a random baseline (accuracy = 50%). As can be observed from the table, the models using only n-grams significantly outperform the ones only based on phonetic features in all datasets. However, while the phonetic features are not very strong by themselves, their combination with n-grams results in models outperforming the n-gram based models in all cases. The difference is highly significant for all datasets except CORPS, where n-grams alone are sufficient to achieve a good performance. We speculate that the kind of persuasiveness used in political speeches is more dependent on the lexical choices of the speaker and on the use of a specific set of semantically loaded words such as *bless*, *victory*, *God* and *justice* or *military*. This is in line with the work of Guerini et al. (2008), who built a domain specific lexicon to study the persuasive impact of words in political speeches.

We also conducted an additional set of experiments to investigate if some phonetic features stand out among the others, and to find out the contribution and importance of each phonetic feature in isolation. To achieve that, for each dataset we conducted a 10-fold cross validation to obtain the best four models containing a single phonetic feature on top of n-gram features (i.e. *N-Gram+Rhyme*, *N-Gram+Plosive*, *N-Gram+Homogeneity* and *N-Gram+Alliteration*). In Table 6, we report the accuracy of the n-gram model and these four models for each dataset. Similarly to Table 5, for each accuracy value, we also report in parenthesis the number of features selected and the kernel degree of the corresponding model obtained with grid search. The results demonstrate that homegeneity is the most effective feature when added on top of n-grams, resulting in highly significant improvement against the basic n-gram models in three out of four datasets. Alliteration and rhyme closely follow homogeneity by yielding models that significantly outperform the n-gram models in three and two datasets respectively. Finally, the models containing plosives do not improve over the n-gram models in any of the four datasets. It is worth noting that in CORPS none of the n-gram models enriched with phonetic features improves over the basic n-gram models as in line with the results of the within-dataset experiments reported in Table 5.

6.4 Cross-dataset experiments

After observing that the combination of phonetic and n-gram features can be effective in the within-dataset prediction experiments, we took a further step and investigated the interaction of the three feature sets across datasets. More specifically, we classified each dataset with the best models (one for each feature set) trained on the other datasets. With these experiments, we investigated the ability of phonetic

features to generalize across the different lexicons of the datasets. As we discussed previously, the four datasets represent different forms of persuasiveness. In this respect, the results of the cross-dataset experiments can also be interpreted as a measure of the degree of compatibility among these kinds of persuasiveness.

In Table 7, we present the results of the cross-dataset prediction experiments. For each training and test set pair, we report the accuracy of the best models, one for each feature set, based on cross-validation on the training set. As can be observed from the table, the figures are generally low and various domain adaptation techniques could be employed to improve the results. However, the objective of this evaluation is not to train an optimized cross-domain classifier, but to assess the potential of the feature sets to model different kinds of persuasiveness.

As expected, n-gram features show poor performance due to the lexical and stylistic differences among the datasets. In many cases, the phonetic models outperform the n-gram models, and in several cases the combination of the two feature sets deteriorates the performance of the phonetic features alone. These findings support our hypothesis that phonetic features, due to their generality, have better correlation with different forms of persuasiveness than lexical features. The experiments involving the CORPS dataset, both for training and testing, do not share this behavior. Indeed, when CORPS is used as a training or test dataset, the performance of the models is quite low (very close to or worse than the baseline in many cases) independently from the feature sets. These results suggest that the notion of persuasiveness encoded in this dataset is remarkably different from the others, as previously discussed in the data analysis in Section 5. As seen in the within dataset experiments (see Table 5), CORPS is the only dataset in which the combination of lexical and phonetic features do not improve the classification accuracy. This explains the inability of the phonetic features to improve the accuracy in cross-dataset experiments when this dataset is employed.

7 Conclusion

In this paper, we focused on the impact of a set of phonetic features – namely rhyme, alliteration, homogeneity and plosives – on various forms of persuasiveness including memorability of slogans and movie quotes, re-tweet counts of tweets, and effectiveness of political speeches. We conducted our analysis and experiments on four datasets comprising pairs of a persuasive sentence and a non-persuasive counterpart.

Our data analysis shows that persuasive sentences are generally euphonic. This finding is confirmed by the prediction experiments, in which we observed that phonetic features consistently help in the detection of persuasiveness. When combined with lexical features, they help improving classification performance on three of the four datasets that we considered. The key role played by phonetic features is further underlined by the cross-dataset experiments, in which we observed that phonetic features alone generally outperform the lexical features. To the best of our knowledge, this is the first systematic analysis of the impact of phonetic features on several types of persuasiveness. Our results should encourage researchers dealing with different aspects of persuasiveness to consider the inclusion of phonetic attributes in their models.

As future work, we will investigate the impact of other phonetic devices such as assonance, consonance and rhythm on persuasiveness. It would also be interesting to focus on the connection between sound symbolism and persuasiveness, and investigate how the context or domain of persuasive statements interacts with the sounds in those statements.

We would like to conclude this paper with the most favorite and retweeted tweet of @NAACL2015 (the Twitter account of the conference whose proceedings comprise this paper), which is a good example of the positive effect of euphony in persuasiveness:

The deadline for @NAACL2015 paper submissions is approaching: Remember, remember, the 4th of December!

Abstract

Solving the visual symbol grounding problem has long been a goal of artificial intelligence. The field appears to be advancing closer to this goal with recent breakthroughs in deep learning for natural language grounding in static images. In this paper, we propose to translate videos directly to sentences using a unified deep neural network with both convolutional and recurrent structure. Described video datasets are scarce, and most existing methods have been applied to toy domains with a small vocabulary of possible words. By transferring knowledge from 1.2M+ images with category labels and 100,000+ images with captions, our method is able to create sentence descriptions of open-domain videos with large vocabularies. We compare our approach with recent work using language generation metrics, subject, verb, and object prediction accuracy, and a human evaluation.

1 Introduction

For most people, watching a brief video and describing what happened (in words) is an easy task. For machines, extracting the meaning from video pixels and generating natural-sounding language is a very complex problem. Solutions have been proposed for narrow domains with a small set of known actions and objects, e.g., (Barbu et al., 2012; Rohrbach et al., 2013), but generating descriptions for "in-the-wild" videos such as the YouTube domain (Figure 1) remains an open challenge.

Progress in open-domain video description has been difficult in part due to large vocabularies and very limited training data consisting of videos with associated descriptive sentences. Another serious obstacle has been the lack of rich models that can capture the joint dependencies of a sequence of frames and a corresponding sequence of words. Previous work has simplified the problem by detecting a fixed set of semantic roles, such as subject, verb, and object (Guadarrama et al., 2013; Thomason et al., 2014), as an intermediate representation. This fixed representation is problematic for large vocabularies and also leads to oversimplified rigid sentence templates which are unable to model the complex structures of natural language.

Our output: *A cat is playing with a toy.*
Humans: *A Ferret and cat fighting with each other. / A cat and a ferret are playing. / A kitten is playing with a ferret. / A kitten and a ferret are playfully wrestling.*

Figure 1: Our system takes a short video as input and outputs a natural language description of the main activity in the video.

In this paper, we propose to translate from video pixels to natural language with a single deep neural network. Deep NNs can learn powerful features (Donahue et al., 2013; Zeiler and Fergus, 2014), but require a lot of supervised training data. We address the problem by transferring knowledge from auxiliary tasks. Each frame of the video is modeled by a convolutional (spatially-invariant) network pre-trained on 1.2M+ images with category labels (Krizhevsky et al., 2012). The meaning state

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1494–1504,
Denver, Colorado, May 31 – June 5, 2015.

and sequence of words is modeled by a recurrent (temporally invariant) deep network pre-trained on 100K+ Flickr (Hodosh and Hockenmaier, 2014) and COCO (Lin et al., 2014) images with associated sentence captions. We show that such knowledge transfer significantly improves performance on the video task.

Our approach is inspired by recent breakthroughs reported by several research groups in image-to-text generation, in particular, the work by Donahue et al. (2014). They applied a version of their model to video-to-text generation, but stopped short of proposing an end-to-end single network, using an intermediate role representation instead. Also, they showed results only on the narrow domain of cooking videos with a small set of pre-defined objects and actors. Inspired by their approach, we utilize a Long-Short Term Memory (LSTM) recurrent neural network (Hochreiter and Schmidhuber, 1997) to model sequence dynamics, but connect it directly to a deep convolutional neural network to process incoming video frames, avoiding supervised intermediate representations altogether. This model is similar to their image-to-text model, but we adapt it for video sequences.

Our proposed approach has several important advantages over existing video description work. The LSTM model, which has recently achieved state-of-the-art results on machine translation tasks (French and English (Sutskever et al., 2014)), effectively models the sequence generation task without requiring the use of fixed sentence templates as in previous work (Guadarrama et al., 2013). Pre-training on image and text data naturally exploits related data to supplement the limited amount of descriptive video currently available. Finally, the deep convnet, the winner of the ILSVRC2012 (Russakovsky et al., 2014) image classification competition, provides a strong visual representation of objects, actions and scenes depicted in the video.

Our main contributions are as follows:

- We present the first end-to-end deep model for video-to-text generation that simultaneously learns a latent "meaning" state, and a fluent grammatical model of the associated language.
- We leverage still image classification and caption data and transfer deep networks learned on such data to the video domain.
- We provide a detailed evaluation of our model on the popular YouTube corpus (Chen and Dolan, 2011) and demonstrate a significant improvement over the state of the art.

2 Related Work

Most of the existing research in video description has focused on narrow domains with limited vocabularies of objects and activities (Kojima et al., 2002; Lee et al., 2008; Khan and Gotoh, 2012; Barbu et al., 2012; Ding et al., 2012; Khan and Gotoh, 2012; Das et al., 2013b; Das et al., 2013a; Rohrbach et al., 2013; Yu and Siskind, 2013). For example, Rohrbach et al. (2013), Rohrbach et al. (2014) produce descriptions for videos of several people cooking in the same kitchen. These approaches generate sentences by first predicting a semantic role representation, e.g., modeled with a CRF, of high-level concepts such as the actor, action and object. Then they use a template or statistical machine translation to translate the semantic representation to a sentence.

Most work on "in-the-wild" online video has focused on retrieval and predicting event tags rather than generating descriptive sentences; examples are tagging YouTube (Aradhye et al., 2009) and retrieving online video in the TRECVID competition (Over et al., 2012). Work on TRECVID has also included clustering both video and text features for video retrieval, e.g., (Wei et al., 2010; Huang et al., 2013).

The previous work on the YouTube corpus we employ (Motwani and Mooney, 2012; Krishnamoorthy et al., 2013; Guadarrama et al., 2013; Thomason et al., 2014) used a two-step approach, first detecting a fixed tuple of role words, such as subject, verb, object, and scene, and then using a template to generate a grammatical sentence. They also utilize language models learned from large text corpora to aid visual interpretation as well as sentence generation. We compare our method to the best-performing method of Thomason et al. (2014). A recent paper by Xu et al. (2015) extracts deep features from video and a continuous vector from language, and projects both to a joint semantic space. They apply their joint embedding to SVO prediction and generation, but do not provide quantitative generation results. Our network learns a joint state vector implicitly, and additionally models sequence dynamics of the language.

Predicting natural language desriptions of still images has received considerable attention, with some of the earliest works by Aker and Gaizauskas (2010), Farhadi et al. (2010), Yao et al. (2010), and Kulkarni et al. (2011) amongst others. Propelled by successes of deep learning, several groups released record breaking results in just the past year (Donahue et al., 2014; Mao et al., 2014; Karpathy et al., 2014; Fang et al., 2014; Kiros et al., 2014; Vinyals et al., 2014; Kuznetsova et al., 2014).

In this work, we use deep recurrent nets (RNNs), which have recently demonstrated strong results for machine translation tasks using Long Short Term Memory (LSTM) RNNs (Sutskever et al., 2014; Cho et al., 2014). In contrast to traditional statistical MT (Koehn, 2010), RNNs naturally combine with vector-based representations, such as those for images and video. Donahue et al. (2014) and Vinyals et al. (2014) simultaneously proposed a multimodal analog of this model, with an architecture which uses a visual convnet to encode a deep state vector, and an LSTM to decode the vector into a sentence.

Our approach to video to text generation is inspired by the work of Donahue et al. (2014), who also applied a variant of their model to video-to-text generation, but stopped short of training an end-to-end model. Instead they converted the video to an intermediate role representation using a CRF, then decoded that representation into a sentence. In contrast, we bypass detection of high-level roles and use the output of a deep convolutional network directly as the state vector that is decoded into a sentence. This avoids the need for labeling semantic roles, which can be difficult to detect in the case of very large vocabularies. It also allows us to first pre-train the model on a large image and caption database, and transfer the knowledge to the video domain where the corpus size is smaller. While Donahue et al. (2014) only showed results on a narrow domain of cooking videos with a small set of pre-defined objects and actors, we generate sentences for open-domain YouTube videos with a vocabulary of thousands of words.

3 Approach

Figure 2 depicts our model for sentence generation from videos. Our framework is based on deep image description models in Donahue et al. (2014);Vinyals et al. (2014) and extends them to generate sentences describing events in videos. These models work by first applying a feature transformation on an image to generate a fixed dimensional vector representation. They then use a sequence model, specifically a Recurrent Neural Network (RNN), to "decode" the vector into a sentence (i.e. a sequence of words). In this work, we apply the same principle of "translating" a visual vector into an English sentence and show that it works well for describing dynamic videos as well as static images.

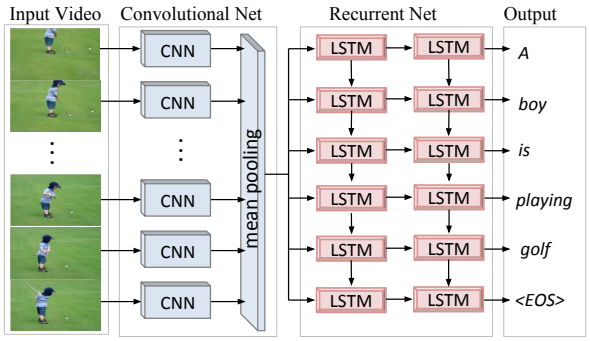

Figure 2: The structure of our video description network. We extract fc_7 features for each frame, mean pool the features across the entire video and input this at every time step to the LSTM network. The LSTM outputs one word at each time step, based on the video features (and the previous word) until it picks the end-of-sentence tag.

We identify the most likely description for a given video by training a model to maximize the log likelihood of the sentence S, given the corresponding video V and the model parameters θ,

$$\theta^* = \underset{\theta}{\operatorname{argmax}} \sum_{(V,S)} \log p(S|V;\theta) \qquad (1)$$

Assuming a generative model of S that produces each word in the sequence in order, the log probability of the sentence is given by the sum of the log probabilities over the words and can be expressed as:

$$\log p(S|V) = \sum_{t=0}^{N} \log p(S_{w_t}|V, S_{w_1}, \ldots, S_{w_{t-1}})$$

where S_{w_i} represents the i^{th} word in the sentence and N is the total number of words. Note that we have dropped θ for convenience.

A sequence model would be apt to model $p(S_{w_t}|V, S_{w_1}, \ldots, S_{w_{t-1}})$, and we choose an RNN. An RNN, parameterized by θ, maps an input x_t, and the previously seen words expressed as a hidden state or memory, h_{t-1} to an output z_t and an

updated state h_t using a non-linear function f:

$$h_t = f_\theta(x_t, h_{t-1}) \tag{2}$$

where $(h_0 = 0)$. In our work we use the highly successful Long Short-Term Memory (LSTM) net as the sequence model, since it has shown superior performance on tasks such as speech recognition (Graves and Jaitly, 2014), machine translation (Sutskever et al., 2014; Cho et al., 2014) and the more related task of generating sentence descriptions of images (Donahue et al., 2014; Vinyals et al., 2014). To be specific, we use two layers of LSTMs (one LSTM stacked atop another) as shown in Figure 2. We present details of the network in Section 3.1. To convert videos to a fixed length representation (input x_t), we use a Convolutional Neural Network (CNN). We present details of how we apply the CNN model to videos in Section 3.2.

3.1 LSTMs for sequence generation

A Recurrent Neural Network (RNN) is a generalization of feed forward neural networks to sequences. Standard RNNs learn to map a sequence of inputs $(x_1, \ldots, x_t)$ to a sequence of hidden states $(h_1, \ldots, h_t)$, and from the hidden states to a sequence of outputs $(z_1, \ldots, z_t)$ based on the following recurrences:

$$h_t = f(W_{xh}x_t + W_{hh}h_{t-1}) \tag{3}$$

$$z_t = g(W_{zh}h_t) \tag{4}$$

where f and g are element-wise non-linear functions such as a sigmoid or hyperbolic tangent, x_t is a fixed length vector representation of the input, $h_t \in \mathbb{R}^N$ is the hidden state with N units, W_{ij} are the weights connecting the layers of neurons, and z_t the output vector.

RNNs can learn to map sequences for which the alignment between the inputs and outputs is known ahead of time (Sutskever et al., 2014) however it's unclear if they can be applied to problems where the inputs (x_i) and outputs (z_i) are of varying lengths. This problem is solved by learning to map sequences of inputs to a fixed length vector using one RNN, and then map the vector to an output sequence using another RNN. Another known problem with RNNs is that, it can be difficult to train them to learn long-range dependencies (Hochreiter et al., 2001). However, LSTMs (Hochreiter and Schmidhuber, 1997),

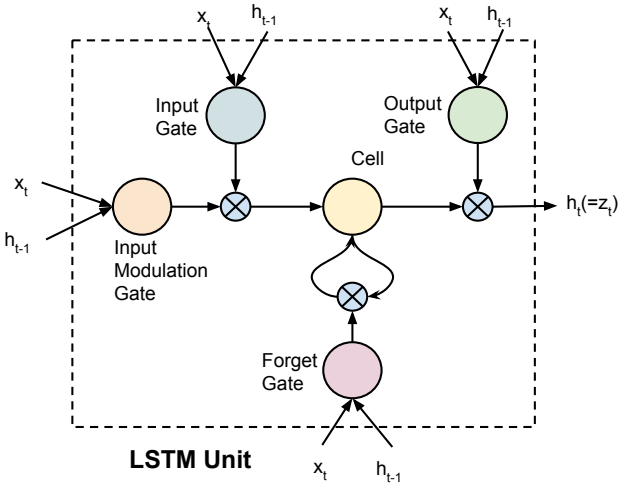

Figure 3: The LSTM unit replicated from (Donahue et al., 2014). The memory cell is at the core of the LSTM unit and it is modulated by the input, output and forget gates controlling how much knowledge is transferred at each time step.

which incorporate explicitly controllable memory units, are known to be able to learn long-range temporal dependencies. In our work we use the LSTM unit in Figure 3, described in Zaremba and Sutskever (2014), and Donahue et al. (2014).

At the core of the LSTM model is a memory cell c which encodes, at every time step, the knowledge of the inputs that have been observed up to that step. The cell is modulated by gates which are all sigmoidal, having range $[0, 1]$, and are applied multiplicatively. The gates determine whether the LSTM keeps the value from the gate (if the layer evaluates to 1) or discards it (if it evaluates to 0). The three gates – input gate (i) controlling whether the LSTM considers its current input (x_t), the forget gate (f) allowing the LSTM to forget its previous memory (c_{t-1}), and the output gate (o) deciding how much of the memory to transfer to the hidden state (h_t), all enable the LSTM to learn complex long-term dependencies. The recurrences for the LSTM are then defined as:

$$i_t = \sigma(W_{xi}x_t + W_{hi}h_{t-1}) \tag{5}$$

$$f_t = \sigma(W_{xf}x_t + W_{hf}h_{t-1}) \tag{6}$$

$$o_t = \sigma(W_{xo}x_t + W_{ho}h_{t-1}) \tag{7}$$

$$c_t = f_t \odot c_{t-1} + i_t \odot \phi(W_{xc}x_t + W_{hc}h_{t-1}) \tag{8}$$

$$h_t = o_t \odot \phi(c_t) \tag{9}$$

where σ is the sigmoidal non-linearity, ϕ is the hyperbolic tangent non-linearity, $\odot$ represents the

product with the gate value, and the weight matrices denoted by W_{ij} are the trained parameters.

3.2 CNN-LSTMs for video description

We use a two layer LSTM model for generating descriptions for videos based on experiments by Donahue et al. (2014) which suggest two LSTM layers are better than four and a single layer for image to text tasks. We employ the LSTM to "decode" a visual feature vector representing the video to generate textual output. The first step in this process is to generate a fixed-length visual input that effectively summarizes a short video. For this we use a CNN, specifically the publicly available *Caffe* (Jia et al., 2014) reference model, a minor variant of *AlexNet* (Krizhevsky et al., 2012). The net is pre-trained on the 1.2M image ILSVRC-2012 object classification subset of the ImageNet dataset (Russakovsky et al., 2014) and hence provides a robust initialization for recognizing objects and thereby expedites training. We sample frames in the video (1 in every 10 frames) and extract the output of the fc_7 layer and perform a mean pooling over the frames to generate a single 4,096 dimension vector for each video. The resulting visual feature vector forms the input to the first LSTM layer. We stack another LSTM layer on top as in Figure 2, and the hidden state of the LSTM in the first layer is the input to the LSTM unit in the second layer. A word from the sentence forms the target of the output LSTM unit. In this work, we represent words using "one-hot" vectors (i.e 1-of-N coding, where is N is the vocabulary size).

Training and Inference: The two-layer LSTM model is trained to predict the next word S_{w_t} in the sentence given the visual features and the previous $t-1$ words, $p(S_{w_t}|V, S_{w_1}, \ldots, S_{w_{t-1}})$. During training the visual feature, sentence pair (V, S) is provided to the model, which then optimizes the log-likelihood (Equation 1) over the entire training dataset using stochastic gradient descent. At each time step, the input x_t is fed to the LSTM along with the previous time step's hidden state h_{t-1} and the LSTM emits the next hidden state vector h_t (and a word). For the first layer of the LSTM x_t is the concatenation of the visual feature vector and the previous encoded word ($S_{w_{t-1}}$, the ground truth word during training and the predicted word during test time). For the second layer of the LSTM x_t is z_t of the first layer. Accordingly, inference must also be performed sequentially in the order $h_1 = f_W(x_1, 0)$, $h_2 = f_W(x_2, h_1)$, until the model emits the end-of-sentence (EOS) token at the final step T. In our model the output ($h_t = z_t$) of the second layer LSTM unit is used to obtain the emitted word. We apply the Softmax function, to get a probability distribution over the words w in the vocabulary D.

$$p(w|z_t) = \frac{\exp(W_w z_t)}{\sum_{w' \in D} \exp(W_{w'} z_t)} \tag{10}$$

where W_w is a learnt embedding vector for word w. At test time, we choose the word $\hat{w}$ with the maximum probability for each time step t until we obtain the EOS token.

3.3 Transfer Learning from Captioned Images

Since the training data available for video description is quite limited (described in Section 4.1), we also leverage much larger datasets available for image captioning to train our LSTM model and then fine tune it on the video dataset. Our LSTM model for images is the same as the one described above for single video frames (in Section 3.1, and 3.2). As with videos, we extract fc_7 layer features (4096 dimensional vector) from the network (Section 3.2) for the images. This forms the visual feature that is input to the 2-layer LSTM description model. The vocabulary is the combined set of words in the video and image datasets. After the model is trained on the image dataset, we use the weights of the trained model to initialize the LSTM model for the video description task. Additionally, we reduce the learning rate on our LSTM model to allow it to tune to the video dataset. This speeds up training and allows exploiting knowledge previously learned for image description.

4 Experiments

4.1 Datasets

Video dataset. We perform all our experiments on the Microsoft Research Video Description Corpus (Chen and Dolan, 2011). This video corpus is a collection of 1970 YouTube snippets. The duration of each clip is between 10 seconds to 25 seconds, typically depicting a single activity or a short

sequence. The dataset comes with several human generated descriptions in a number of languages; we use the roughly 40 available English descriptions per video. This dataset (or portions of it) have been used in several prior works (Motwani and Mooney, 2012; Krishnamoorthy et al., 2013; Guadarrama et al., 2013; Thomason et al., 2014; Xu et al., 2015) on action recognition and video description tasks. For our task we pick 1200 videos to be used as training data, 100 videos for validation and 670 videos for testing, as used by the prior works on video description (Guadarrama et al., 2013; Thomason et al., 2014; Xu et al., 2015).

Domain adaptation, image description datasets. Since the number of videos for the description task is quite small when compared to the size of the datasets used by LSTM models in other tasks such as translation (Sutskever et al., 2014) (12M sentences), we use data from the Flickr30k and COCO2014 datasets for training and learn to adapt to the video dataset by fine-tuning the image description models. The Flickr30k (Hodosh and Hockenmaier, 2014) dataset has about 30,000 images, each with 5 or more descriptions. We hold out 1000 images at random for validation and use the remaining for training. In addition to this, we use the recent COCO2014 (Lin et al., 2014) image description dataset consisting of 82,783 training images and 40,504 validation images, each with 5 or more sentence descriptions. We perform ablation experiments by training models on each dataset individually, and on the combination and report results on the YouTube video test dataset.

4.2 Models

HVC This is the Highest Vision Confidence model described in (Thomason et al., 2014). The model uses strong visual detectors to predict confidence over 45 subjects, 218 verbs and 241 objects.

FGM (Thomason et al., 2014) also propose a factor graph model (FGM) that combines knowledge mined from text corpora with visual confidences from the HVC model using a factor graph and performs probabilistic inference to determine the most likely subject, verb, object and scene tuple. They then use a simple template to generate a sentence from the tuple. In this work, we compare the output of our model to the subject, verb, object words predicted by the HVC and FGM models and the sentences generated from the SVO triple.

Our LSTM models We present four main models. LSTM-YT is our base two-layer LSTM model trained on the YouTube video dataset. LSTM-YT$_{flickr}$ is the model trained on the Flickr30k (Hodosh and Hockenmaier, 2014) dataset, and fine tuned on the YouTube dataset as descibed in Section 3.3. LSTM-YT$_{coco}$ is first trained on the COCO2014 (Lin et al., 2014) dataset and then fine-tuned on the video dataset. Our final model, LSTM-YT$_{cocoflickr}$ is trained on the combined data of both the Flickr and COCO models and is tuned on YouTube. To compare the overlap in content between the image dataset and YouTube dataset, we use the model trained on just the Flickr images (LSTM$_{flickr}$) and just the COCO images (LSTM$_{coco}$) and evaluate their performance on the test videos.

4.3 Evaluation Metrics and Results

SVO accuracy. Earlier works (Krishnamoorthy et al., 2013; Guadarrama et al., 2013) that reported results on the YouTube dataset compared their method based on how well their model could predict the subject, verb, and object (SVO) depicted in the video. Since these models first predicted the content (SVO triples) and then generated the sentences, the S,V,O accuracy captured the quality of the content generated by the models. However, in our case the sequential LSTM directly outputs the sentence, so we extract the S,V,O from the dependency parse of the generated sentence. We present, in Table 1 and Table 2, the accuracy of S,V,O words comparing the performance of our model against any valid ground truth triple and the most frequent triple found in human description for each video. The latter evaluation was also reported by (Xu et al., 2015), so we include it here for comparison.

Sentence Generation. To evaluate the generated sentences we use the BLEU (Papineni et al., 2002) and METEOR (Banerjee and Lavie, 2005) scores against all ground truth sentences. BLEU is the metric that is seen more commonly in image description literature, but a more recent study (Elliott and Keller, 2014) has shown METEOR to be a better evaluation metric. However, since both metrics have been shown to correlate well with human eval-

Model	S%	V%	O%
HVC (Thomason et al., 2014)	86.87	38.66	22.09
FGM (Thomason et al., 2014)	**88.27**	37.16	24.63
LSTM$_{flickr}$	79.95	15.47	13.94
LSTM$_{coco}$	56.30	06.90	14.86
LSTM-YT	79.40	35.52	20.59
LSTM-YT$_{flickr}$	84.92	38.66	21.64
LSTM-YT$_{coco}$	86.58	42.23	**26.69**
LSTM-YT$_{coco+flickr}$	87.27	**42.79**	24.23

Table 1: SVO accuracy: Binary SVO accuracy compared against any valid S,V,O triples in the ground truth descriptions. We extract S,V,O values from sentences output by our model using a dependency parser. The model is correct if it identifies S,V, or O mentioned in any one of the multiple human descriptions.

Model	S%	V%	O%
HVC (Thomason et al., 2014)	76.57	22.24	11.94
FGM (Thomason et al., 2014)	76.42	21.34	12.39
JointEmbed[1] (Xu et al., 2015)	**78.25**	24.45	11.95
LSTM$_{flickr}$	70.80	10.02	07.84
LSTM$_{coco}$	47.44	02.85	07.05
LSTM-YT	71.19	19.40	09.70
LSTM-YT$_{flickr}$	75.37	21.94	10.74
LSTM-YT$_{coco}$	76.01	23.38	**14.03**
LSTM-YT$_{coco+flickr}$	75.61	**25.31**	12.42

Table 2: SVO accuracy: Binary SVO accuracy compared against most frequent S,V,O triple in the ground truth descriptions. We extract S,V,O values from parses of sentences output by our model using a dependency parser. The model is correct only if it outputs the most frequently mentioned S, V, O among the human descriptions.

uations, we compare the generated sentences using both and present our results in Table 3.

Human Evaluation. We used Amazon Mechanical Turk to also collect human judgements. We created a task which employed three Turk workers to watch each video, and rank sentences generated by the different models from "Most Relevant" (5) to "Least Relevant" (1). No two sentences could have the same rank unless they were identical. We also evaluate sentences on grammatical correctness. We created a different task which required workers to rate sentences based on grammar. This task

[1]They evaluate against a filtered set of groundtruth SVO words which provides a tiny boost to their scores.

Model	BLEU	METEOR
FGM (Thomason et al., 2014)	13.68	23.90
LSTM-YT	31.19	26.87
LSTM-YT$_{flickr}$	32.03	27.87
LSTM-YT$_{coco}$	**33.29**	**29.07**
LSTM-YT$_{coco+flickr}$	**33.29**	28.88

Table 3: Scores for BLEU at 4 (combined n-gram 1-4), and METEOR scores from automated evaluation metrics comparing the quality of the generation. All values are reported as percentage (%).

Model	Relevance	Grammar
FGM (Thomason et al., 2014)	2.26	**3.99**
LSTM-YT	2.74	3.84
LSTM-YT$_{coco}$	**2.93**	3.46
LSTM-YT$_{coco+flickr}$	2.83	3.64
GroundTruth	4.65	4.61

Table 4: Human evaluation mean scores. Sentences were uniquely ranked between 1 to 5 based on their relevance to a given video. Sentences were rated between 1 to 5 for grammatical correctness. Higher values are better.

displayed only the sentences and did not show any video. Here, workers had to choose a rating between 1-5 for each sentence. Multiple sentences could have the same rating. We discard responses from workers who fail gold-standard items and report the mean ranking/rating for each of the evaluated models in Table 4.

Individual Frames. In order to evaluate the effectiveness of mean pooling, we performed experiments to train and test the model on individual frames from the video. Our first set of experiments involved testing how well the image description models performed on a randomly sampled frame in the video. Similar to Tables 1 and 2, the model trained on Flickr30k when tested on random frames from the video scored better on subjects and verbs with any valid accuracy of 75.16% and 11.65% respectively; and 9.01% on objects. The one trained on COCO did better on objects (12.54%, any valid accuracy) but very poorly on subjects and verbs. In our next experiment, we used image description models (trained on Flickr30k, COCO or a combination of both) and fine-tuned them on individual frames in the video by picking a different frame

Model (individual frames)	BLEU	METEOR
LSTM$_{flickr}$	08.62	18.56
LSTM$_{coco}$	11.39	20.03
LSTM-YT-frame$_{flickr}$	26.75	26.51
LSTM-YT-frame$_{coco}$	**30.77**	**27.66**
LSTM-YT-frame$_{coco+flickr}$	29.72	27.65

Table 5: Scores for BLEU at 4 (combined n-gram 1-4), and METEOR scores comparing the quality of sentence generation by the models trained on Flickr30k and COCO and tested on a random frame from the video. LSTM-YT-frame models were fine tuned on individual frames from the Youtube video dataset. All values are reported as percentage (%).

for each description in the YouTube dataset. These models were tested on a random frame from the test video. The overall trends in the results were similar to those seen in Tables 1 and 2. The model trained on COCO and fine-tuned on individual video frames performed best with any valid S,V,O accuracies $84.8\%, 38.98\%,$ and 22.34% respectively. The one trained on both COCO and Flickr30k had any valid S,V,O accuracies of $85.67\%, 38.83\%,$ and 19.72%. We report the generation results for these models in Table 5.

5 Discussion

Image only models. The models trained purely on the image description data LSTM$_{flickr}$ and LSTM$_{coco}$ achieve lower accuracy on the verbs and objects (Tables 1, 2) since the YouTube videos encompass a wider domain and a variety of actions not detectable from static images.

Base LSTM model. We note that in the SVO binary accuracy metrics (Tables 1 and 2), the base LSTM model (LSTM-YT) achieves a slightly lower accuracy compared to prior work. This is likely due to the fact that previous work explicitly optimizes to identify the best subject, verb and object for a video; whereas the LSTM model is trained on objects and actions jointly in a sentence and needs to learn to interpret these in different contexts. However, with regard to the generation metrics BLEU and METEOR, training based on the full sentence helps the LSTM model develop fluency and vocabulary similar to that seen in the training descriptions and allows it to outperform the template based generation.

Transferring helps. From our experiments, it is clear that learning from the image description data improves the performance of the model in all criteria of evaluation. We present a few examples demonstrating this in Figure 4. The model that was pre-trained on COCO2014 shows a larger performance improvement, indicating that our model can effectively leverage a large auxiliary source of training data to improve its object and verb predictions. The model pre-trained on the combined data of Flickr30k and COCO2014 shows only a marginal improvement, perhaps due to overfitting. Adding dropout as in (Vinyals et al., 2014) is likely to help prevent overfitting and improve performance.

From the automated evaluation in Table 3 it is clear that the fully deep video-to-text generation models outperform previous work. As mentioned previously, training on the full sentences is probably the main reason for the improvements.

Testing on individual frames. The experiments that evaluated models on individual frames (Section 4.3) from the video have trends similar to those seen on mean pooled frame features. Specifically, the model trained on Flickr30k, when directly evaluated on YouTube video frames performs better on subjects and verbs, whereas the one trained on COCO does better on objects. This is explained by the fact that Flickr30k images are more varied but COCO has more examples of a smaller collection of objects, thus increasing object accuracy. Amongst the models trained on images and individual video frames, the ones trained on COCO (and the combination of both) perform well, but are still a bit poorer compared to the models trained on mean-pooled features. One point to note however is that, these models were trained and evaluated on random frames from the video, and not necessarily a key-frame or most-representative frame. It's likely that choosing a representative frame from the video might result in a small improvement. But, on the whole, our experiments show that models trained on images alone do not directly perform well on video frames, and a better representation is required to learn from videos.

Mean pooling is significant. Our additional experiments that trained and tested on individual frames in the video, reported in section 4.3, suggest that mean pooling frame features gives significantly better results. This could potentially indicate that mean pooling features across all frames in the video

is a reasonable representation for short video clips at least for the task of generating simple sentential descriptions.

Human evaluation. We note that the sentences generated by our model have been ranked more relevant (Table 4) to the content in the video than previous models. However, there is still a significant gap between the human ground truth sentence and the ones generated by the LSTM models. Additionally, when we ask Turkers to rate only the sentences (they are not provided the video) on grammatical correctness, the template based FGM (Thomason et al., 2014) achieves the highest ratings. This can be explained by the fact that their work uses a template technique to generate sentences from content, and is hence grammatically well formed. Our model sometimes predicts prepositions and articles more frequently, resulting in duplicates and hence incorrect grammar.

6 Conclusion

In this paper we have proposed a model for video description which uses neural networks for the entire pipeline from pixels to sentences and can potentially allow for the training and tuning of the entire network. In an extensive experimental evaluation, we showed that our approach generates better sentences than related approaches. We also showed that exploiting image description data improves performance compared to relying only on video description data. However our approach falls short in better utilizing the temporal information in videos, which is a good direction for future work. We will release our *Caffe*-based implementation, as well as the model and generated sentences.

Acknowledgments

This research was partially supported by ONR ATL Grant N00014-11-1-010, NSF Awards IIS-1451244 and IIS-1212798.

Figure 4: Examples to demonstrate effectiveness of transferring from the image description domain. YT refer to the LSTM-YT, YTcoco to the LSTM-YT$_{coco}$, and YTcocoflickr to the LSTM-YT$_{coco+flickr}$ models. GT is a random human description in the ground truth. Sentences in **bold** highlight the most accurate description for the video amongst the models. Bottom two examples show how transfer can overfit. Thus, while base LSTM-YT model detects water and monkey, the LSTM-YT$_{coco}$ and LSTM-YT$_{cocoflickr}$ models fail to describe the event completely.

Learning to Interpret and Describe Abstract Scenes

Luis Gilberto Mateos Ortiz, Clemens Wolff and **Mirella Lapata**

Abstract

Given a (static) scene, a human can effortlessly describe what is going on (who is doing what to whom, how, and why). The process requires knowledge about the world, how it is perceived, and described. In this paper we study the problem of interpreting and verbalizing visual information using abstract scenes created from collections of clip art images. We propose a model inspired by machine translation operating over a large parallel corpus of visual relations and linguistic descriptions. We demonstrate that this approach produces human-like scene descriptions which are both fluent and relevant, outperforming a number of competitive alternatives based on templates, sentence-based retrieval, and a multimodal neural language model.

1 Introduction

What is going on in the scene in Figure 1? Is the boy trying to feed the dog or play with it? Why is the girl upset? Is it because the dog is wearing her glasses? Or perhaps she is just scared of the dog? Scene interpretation is effortless for humans, almost everyone can summarize Figure 1 in a few words, without probably paying too much attention to the fact the girl is wearing a pink dress, the sun is yellow or that there is a plane in the sky.

Discovering what an image means and relaying it in words is of theoretical importance raising questions about language and its grounding in the perceptual world but also has practical applications. Examples include sentence-based image search and tools that enhance the accessibility of the web for visually impaired (blind and partially sighted) individuals. Indeed, there has been a recent surge of interest in the development of models that automatically describe image content in natural language (see references in Section 2). Due to the complex nature of the problem, existing approaches resort to modeling simplifications, on the generation side (e.g., through the use of templates and sentence-based retrieval methods), or the image processing side (e.g., by avoiding object-detection), or both.

Figure 1: Given an image, humans do not simply see an arrangement of objects, they understand how they relate to each other as well as their attributes and the activities they are involved in.

In this paper we study the problem of interpreting visual scenes and rendering their content using natural language. We approach this problem within the methodology of Zitnick and Parikh (2013), who proposed the use of abstract scenes generated from clip art to model scene understanding (see Figure 1). The use of abstract scenes offers several advantages over real images. Firstly, it allows us to study the scene description problem in isolation, without the noise introduced by automatic object and attribute detectors in real images. Secondly, it is relatively easy to gather large amounts of data, allowing us to compare multiple models on an equal footing, study in more detail the problem of language grounding, and how to identify what is important in an image. Thirdly, information learned from abstract scenes will lead to better understanding of the challenges and data requirements arising when using real images.

We propose a model inspired by machine trans-

Denver, Colorado, May 31 – June 5, 2015.

lation, where the task is to transform a source sentence E into its target translation F. We argue that generating descriptions for scenes is quite similar, but with a twist: the translation process is very loose and selective; there will always be objects in a scene not worth mentioning, and words in a description that will have no visual counterpart. Our key insight is to represent scenes via visual dependency relations (Elliott and Keller, 2013) corresponding to sentential descriptions. This allows us to create a large parallel corpus for training a statistical machine translation system, which we interface with a content selection component guiding the translation toward interesting or important scene content. Advantageously, our model can be used in the reverse direction, i.e., to generate scenes, without additional engineering effort. Our approach outperforms a number of competitive alternatives, when evaluated both automatically and by humans.

2 Related Work

The task of image description generation has recently gained popularity in the natural language processing and computer vision communities. Several methods leverage recent advances in computer vision and generate novel sentences relying on object detectors, attribute predictors, action detectors, and pose estimators. Generation is performed using templates or syntactic rules which piece the description together while leveraging word-co-occurrence statistics (Kulkarni et al., 2011; Yang et al., 2011; Elliott and Keller, 2013; Mitchell et al., 2012). Recent advances in neural language models have led to approaches which generate captions by conditioning on feature vectors from the output of a deep convolutional neural network without the use of templates or syntactic trees (Kiros et al., 2014; Vinyals et al., 2014). Most methods assume no structural information on the image side either (images are represented as unstructured bags of regions or as feature vectors). A notable exception are Elliott and Keller (2013) who introduce visual dependency relations between objects and argue that such structured representations are beneficial for image description.

A large body of work has focused on the complementary problem of matching sentences (Ordonez et al., 2011; Farhadi et al., 2010; Hodosh et al., 2013; Feng and Lapata, 2013; Mason and Charniak, 2014) or phrases (Kuznetsova et al., 2012; Kuznetsova et al., 2014) to an image from existing human authored descriptions. Sentence-based approaches embed images and descriptions into the same multidimensional space, and retrieve descriptions from images most similar to a query image. Phrase-based approaches are more involved in that phrases need to be composed into a description and extraneous information optionally removed. A common modeling choice is the use of Integer Linear Programming (ILP) which naturally allows to encode various well-formedness constraints (e.g., grammaticality).

We are not aware of any previous work generating descriptions for abstract scenes, although the same dataset has been used to model sentence-to-scene generation (Zitnick et al., 2013) and predict object dynamics in scenes (Fouhey and Zitnick, 2014). Using the visual relations put forward in Elliott and Keller (2013), we convert the abstract scenes dataset into a parallel corpus of visual and linguistic descriptions, which allows us to train a statistical machine translation (SMT) model. In contrast to earlier work (Kuznetsova et al., 2014; Kuznetsova et al., 2012), which models the task as an optimization problem end-to-end, we employ ILP for content selection only, deferring the surface realization process entirely to an SMT engine.

3 The Abstract Scenes Dataset

The abstract scenes dataset[1] was created with the intent to represent real-world scenes that depict a diverse set of subtle relations. It contains 10,020 images of children playing outside and 60,396 descriptions (on average six per image). The data was collected in three stages. First, Amazon Mechanical Turk (AMT) workers were asked to created scenes for a collection of 80 pieces of clip art depicting a boy and a girl (in different poses and with different facial expressions), and several objects including trees, toys, hats, animals, and so on. Next, a new set of subjects were asked to describe the scenes using a one or two sentence description, finally, semantically similar scenes were generated by asking multiple subjects to create scenes depicting the same writ-

Figure 2: Example of a scene, its rendering information (right), and human-written descriptions (bottom).

ten description. By construction, the dataset encodes the objects in each scene, and their position.

An example is shown in Figure 2. The table on the right-hand side specifies how the image was rendered. The top row contains the scene identifier (i.e., 0) and the number of pieces of clip art in the image (i.e., 6). The remaining rows encode rendering information for each individual piece of clipart, i.e., its name (column 1), type (column 2), attribute (column 3), position (columns 4–6), and whether or not it is horizontally flipped (column 7). Six human authored descriptions are shown the bottom. AMT participants were instructed to write simple descriptions using basic words that would appear in a book for young children ages 4–6. Participants who wished to use proper names in their descriptions were provided with names "Mike" and "Jenny" for the boy and girl. The vocabulary consists of 2,705 words, and the average sentence length is 6.3 words. As can be seen in Figure 2, subjects choose to focus on different aspects of the image (e.g., Mike and his sunglasses, the fact that Jenny is chasing Mike). Also notice that even though by design we know which visual objects are present in the image and their spatial relationships (see the right hand-side in Figure 2), the alignment between pieces of clipart and linguistic expressions is hidden. In other words, we do not know which actions the objects depict (e.g., playing, holding) and which words can be used to describe them (e.g., that t_4s.png is called a ball).

4 Problem Formulation

We formulate scene description generation as a translation problem from the visual to the linguistic modality. Our approach follows the general paradigm of SMT with two important differences. Firstly, the source side (i.e., scene) is fundamentally different from the target (i.e., linguistic descriptions) both in terms of representation and structure. Secondly, the scene and its corresponding descriptions constitute a very loose parallel corpus: not all visual objects are verbalized (note that no participant chose to mention the sun in Figure 2) and there are multiple valid descriptions for a single scene focusing on different objects and their relations. In the following we first describe how we create a parallel corpus representing the arrangement of objects in a scene and their linguistic realization and then we move on to present our generation model.

4.1 Parallel Corpus Creation

As mentioned earlier, each scene in the dataset has six descriptions (on average). For each *linguistic* description we create its corresponding *visual* encoding. We initially ground words and phrases by aligning them to pieces of clipart. We parse the descriptions using a dependency parser, and identify expressions that function as arguments (e.g., subject, object). In our experiments we used the Stanford parser (Klein and Manning, 2003) but any parser with similar output could have been used instead. Next, we compute the mutual information (MI) between arguments and clip-art objects defined as:

$$MI(X,Y) = \sum_{x \in X} \sum_{y \in Y} p(x,y) \log \frac{p(x,y)}{p(x)p(y)} \quad (1)$$

where X is the set of clip-art objects and Y the set of arguments found in the dataset. We assume that the visual rendering of an argument is the clip-art object with which its MI value is highest. Figure 3 shows argument-clipart pairs with high MI values.

Having identified which objects in the scene are talked about, we move on to encode their spatial relations. We adopt the relations outlined in *Visual Dependency Grammar* (VDG; Elliott and Keller (2013)). The latter are defined for pairs of image regions but can also directly apply to clip-art objects. VDR Relations are specified according to

X on Y	More than 50% of X overlaps with Y
X surrounds Y	X overlaps entirely with Y
X above Y	The angle between X and Y is between 225°and 315°
X below Y	The angle between X and Y is between 45°and 135°.
X opposite Y	The angle between X and Y is between 315°and 45°or 135°and 225°. The Euclidean distance between X and Y is greater than $w \cdot 0.72$.
X near Y	Similar to *opposite* but the Euclidean distance between X and Y is greater than $w \cdot 0.36$.
X close Y	Similar to *opposite* but the Euclidean distance between X and Y is less or equal to $w \cdot 0.36$.
X infront Y	X is in front Y in the Z-plane
X behind Y	X is behind Y in the Z-plane
X same Y	X and Y are at the same depth

Table 1: VDG relations between pairs of clip art objects. All relations are considered with respect to the centroid of an object and the angle between those centroids. We follow the definition of the unit circle, in which 0°lies to the right and a turn around the circle is counter-clockwise. All regions are mutually exclusive. Parameter w refers to the width of the scene.

three geometric properties: pixel overlap, the angle between regions, and the distance between regions. Table 1 summarizes the relations used in our experiments most of which encode spatial object relations in the *x*-*y* space; the last three encode relative object position along the z axis. Our relations are broadly similar to those proposed in Elliott and Keller (2013) with the exception of *beside* which we break down into more fine-grained relations (namely *near* and *close*). We also add the *same* relation in the z axis. In cases where object X is facing object Y we subscript relations *opposite*, *near*, and *close* with the letter $\mathcal{F}$.

The procedure described above will generate a visual description for each linguistic description. It also assumes that visual relations hold between pairs of objects. The assumption is not unwarranted, 73.87% of the descriptions in the dataset involve

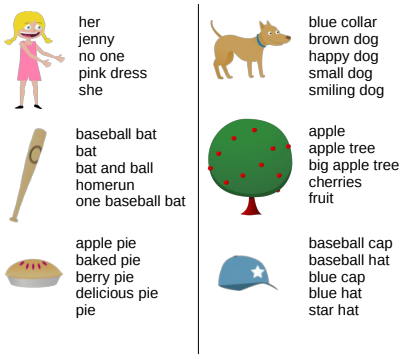

Figure 3: Examples of argument-clipart object pairs with high MI values (shown in descending order).

only two arguments. The parallel sentences corresponding to Figure 2 are illustrated in Table 2. In cases where the the original description involves three objects, ternary relations are decomposed into binary ones. We create as many visual representations as there are linguistic descriptions. If two humans generate identical descriptions, we produce identical visual encodings. In total, we were able to create 46,053 parallel descriptions[2] accounting for 79.5% of the sentences in the dataset.

4.2 Generation Model

It is straightforward to train a phrase-based SMT model on the parallel corpus outlined above. The model would learn to translate a visual description (see the source side in Table 2) into natural language. However, when generating linguistic descriptions for a scene at test time, we must first decide "what to say" (content selection) and then "how to say" it (surface realization). What is the most important content in the scene worth describing? Given that visual relations between objects are assumed to be binary (see the VDG grammar in Table 1), there are $n(n-1)$ combinations of pairs of objects in a scene (where n is the number of clipart pieces available) and as many corresponding visual expressions. However, many of these visual expressions will capture unimportant aspects of the scene, or even express atypical relations unattested in the training data. We develop below a content selection component based on the intuition that frequently

[2]Our parallel corpus can be downloaded from `http://homepages.inf.ed.ac.uk/mlap/index.php?page=resources`.

Table 2: Parallel corpus of visual expressions and linguistic descriptions corresponding to Figure 2.

mentioned object pairs probably express important scene content. In addition, it is reasonable to assume that the selected objects will be in close proximity, especially when actions are involved. One would expect the agent of the action to be near the object or person receiving it (e.g., *Mike is kicking the ball*, *Jenny is holding Mike's hand*). The same is true for instruments, which are typically held by the persons using them (e.g., *Jenny is digging with a shovel*).

Content Selection We cast the problem of finding suitable objects to talk about as an integer linear program (ILP). Our model selects clip art object pairs that best describe the content of a scene and ranks them based on their relevance. Indicator variable y_{stk} denotes whether two objects are being selected and how they are ranked (e.g, whether they should be mentioned first or last):

$$y_{stk} = \begin{cases} 1 & \text{if objects } s \text{ and } t \text{ are selected for rank } k \\ & \text{and } s \text{ is before } t \\ 0 & \text{otherwise} \end{cases} \quad (2)$$

where s and t index two clip art objects and $k = 1,..,S$ encodes their rank (based on relevance). Our objective function is given below:

$$Z = \sum_{s \in S, t \in S} F_{st} \cdot D_{st} \cdot \sum_{k \in S} ((card(S)+1)-k) \cdot y_{stk} \quad (3)$$

where F_{st} quantifies the normalized co-occurrence frequency of objects s and t (in the training set) and D_{st} specifies their relative distance. The term $((card(S)+1)-k)$ accounts for the ranking of pairs so that most relevant ones are ranked first. Here, $card(S)$ represents the cardinality of the set S denoting the number of clip art objects in the scene; k ranges over all available ranks (which is limited by the number of clip art objects available). The term

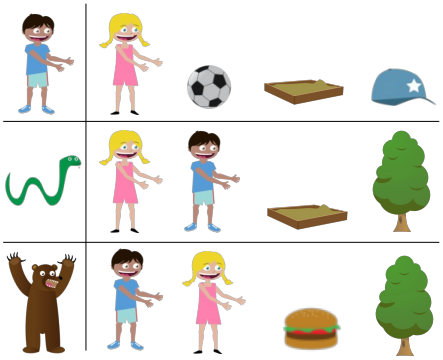

Figure 4: Example of three clip art objects and the most frequent objects they co-occur with.

$((card(S)+1)-k)$ is inversely proportional to k, so its highest value is when k is 1. In other words, the value of the term is maximum when the selected objects are ranked first. This way, we ensure that most relevant object pairs are given high ranks.

We compute F_{st} from our parallel corpus (see left-hand side in Table 2), simply by counting the number of times objects s and t co-occur. Figure 4 shows three clip art objects (Mike, a snake, and a bear) and their most frequent co-occurrences. We estimate term D_{st}, the distance between objects s and t, using function $\sqrt{\Delta x^2 + \Delta y^2 + \Delta z^2}$. Coordinate z has only three possible values (see Table 1). To increase the effect of Δz, we use a scaling factor. We normalize and invert D_{st} so that it ranges from 0 to 1. In addition, we transform it with a sigmoid function so as to maximize the effect of near and distant objects (distances of relatively close objects are set to 1 and distances of distant objects are set to 0).

The objective function in Equation (3) is too permissive, allowing repetitions of the same object within a pair and of the object pairs themselves. Constraints (4)–(10) avoid repetitions and ensure

that the selected objects are varied with the aim of generating logically consistent descriptions. Constraint (4) avoids empty descriptions, by enforcing that at least one clip art object pair is selected. Constraint (5) ensures that an object cannot appear in the same pair twice, whereas constraint (6) requires that at most one pair can be selected for a given rank k. We also enforce the selection of different pairs of objects (constraint (7)) at contiguous ranks (constraint (8)).

$$\sum_{s\in S,t\in S} y_{st1} = 1 \tag{4}$$

$$\forall_{stk,s==t},\ y_{stk} = 0 \tag{5}$$

$$\forall_k,\ \sum_{s\in S,t\in S} y_{stk} \leq 1; \tag{6}$$

$$\forall_{st},\ \sum_{k\in S}(y_{stk} + y_{tsk}) \leq 1 \tag{7}$$

$$\forall_{k=1,..,S-1},\ \sum_{s\in S,t\in S} y_{stk+1} \leq \sum_{s\in S,t\in S} y_{stk} \tag{8}$$

Finally, to instill some coherence in the descriptions, while avoiding overly repetitive discourse, we disallow objects to be selected more than four times:

$$\forall_s,\ sum_s = \sum_{t\in S,k\in S} y_{stk} \tag{9}$$

$$\forall_t,\ sum_t = \sum_{s\in S,k\in S} y_{stk} \tag{10}$$

$$\forall_{st,s==t},\ sum_s + sum_t \leq 4 \tag{11}$$

Auxiliary variables sum_s and sum_t represent the number of times objects s and t are selected to be the first and second object of a pair.

Given a new unseen scene, we obtain the F_{st} values for all pair-wise combinations of the objects in it and compute their distance D_{st}. We solve the ILP problem defined above and read the value of the variable y_{stk} which contains the selected clip art object pairs ranked by relevance. So, our model can in principle produce multiple descriptions for a given scene, highlighting potentially different aspects of the visually encoded information. We used GLPK[3] to maximize the objective function subject to the constraints introduced above.

[3] https://www.gnu.org/software/glpk/

Surface realization The ILP selects all description-worthy pairs of clip art objects for a scene. Using the rules presented in Table 1 we create visual encodings for them (see Table 2, source side), and finally translate them into natural language using a Phrase-based SMT engine (Koehn et al., 2003). Specifically, given a source visual expression $\mathbf{f}$, our aim is to find an equivalent target natural language description $\hat{\mathbf{e}}$ that maximizes the posterior probability:

$$\hat{\mathbf{e}} = \operatorname*{argmax}_{\mathbf{e}} P(\mathbf{e}|\mathbf{f}) \tag{12}$$

Most recent SMT work models the posterior $P(\mathbf{e}|\mathbf{f})$ directly (Och and Ney, 2002) using a log-linear combination of several models where:

$$P(\mathbf{e}|\mathbf{f}) = \frac{\exp\sum_{k=1}^{K}\lambda_k h_k(\mathbf{f},\mathbf{e})}{\sum_{e'}\exp\sum_{k=1}^{K}\lambda_k h_k(\mathbf{f},\mathbf{e}')} \tag{13}$$

and the decision decision rule is given by:

$$\hat{\mathbf{e}} = \operatorname*{argmax}_{\mathbf{e}} \sum_{k=1}^{K}\lambda_k h_k(\mathbf{f},\mathbf{e}) \tag{14}$$

where $h_k(\mathbf{f},\mathbf{e})$ is a scoring function representing important features for the translation of $\mathbf{f}$ into $\mathbf{e}$. Examples include the language model of the target language, a reordering model, or several translation models. K is the number of models (or features) and λ_k are the weights of the log-linear combination. Typically, the weights $\Lambda = [\lambda_1,\ldots,\lambda_K]^T$ are optimized on a development set, by means of Minimum Error Rate Training (MERT; Och (2003)).

One of the most popular instantiations of loglinear models in SMT are phrase-based (PB) models (Zens et al., 2002; Koehn et al., 2003). PB models allow to learn translations for entire phrases instead of individual words. The basic idea behind PB translation is to segment the source sentence into phrases, then to translate each source phrase into a target phrase, and finally reorder the translated target phrases in order to compose the target sentence. For this purpose, phrase-tables are produced, in which a source phrase is listed together with several target phrases and the probability of translating the former into the latter. Throughout our experiments, we obtained translation models using the PB SMT framework implemented in MOSES (Koehn et al., 2007).

Mike is kicking the ball	The plane is flying in the sky
nsubj,aux,verb,det,dobj	det,nsubj,aux,verb,prep, det,pobj

Table 3: Sample scenes with human-written descriptions and corresponding templates.

5 Model Comparison

We evaluated the model described above through comparison to four alternatives, representing different modeling paradigms in the literature. Our first comparison model is based on templates, which are commonly used to produce descriptions for images (Elliott and Keller, 2013; Kulkarni et al., 2011). Rather than manually creating template rules we induce them from dependency-parsed scene descriptions. We represent each description in the data as a sequence of typed dependencies. The scene descriptions are relatively simple, and many sentences have similar structure. Overall, 20 templates represent the syntactic structure of more than 44% of all scene descriptions. Examples of scenes, their descriptions, and corresponding templates are shown in Table 3 (template `nsubj,aux,verb,det,dobj` is the most frequent in the data).

We train a logistic regression classifier (Yu et al., 2011) on scene-template pairs, and learn to assign a template for a new unseen scene. The "template-predictor" uses variety of features based on the alignment between clip-art objects and POS-tags as well as objects and dependency roles. The alignments were computed using MI as described in Section 4.1. We also used visual features based on the absolute and relative distance between objects, their co-occurrence, spatial location, depth ordering, facial expression and poses (see Zitnick et al. (2013) for details). In order to transform the templates into natural language sentences we train a "word-predictor" which fills the most likely word for every grammatical function slot in a given template (again using logistic regression and the same feature space as for the template predictor). The word predictor uses a vocabulary of 70 frequently occurring words (attested no less than 150 times in the corpus). For a new scene, candidate templates are predicted and subsequently expanded to descriptions by predicting words for every function slot in the templates. Candidate descriptions are ranked using a trigram language model to ensure grammatical coherence.

We also implemented two sentence-based retrieval approaches. Our first system is conceptually similar to the model proposed by Farhadi et al. (2010). In their work, images and descriptions seen at training time are mapped into a shared meaning space M using a function f. Given an unseen image λ, the description closest to $f(\lambda)$ in M is retrieved and returned by the model. We used the word-predictor described above as a simple way of annotating an unseen scene λ with the words that most saliently describe it. These keywords then used as a TFIDF search query against the set H of human scene descriptions seen during training:

$$\begin{aligned} \text{TFIDF}(q,d) &= \sum_{w \in q} \text{TF}(w,d)\text{IDF}(w), \\ \text{TF}(w,q) &= \sqrt{\sum_{w' \in q} \mathbb{1}_{w=w'}}, \\ \text{IDF}(w) &= 1 + \log \frac{\|H\|}{1 + \sum_{d \in H} \sum_{w' \in d} \mathbb{1}_{w=w'}}. \end{aligned} \quad (15)$$

where H is the set of all human descriptions seen at training time, $\|\cdot\|$ is the set-norm, q is a search query, d is any description in H and $\mathbb{1}_{w=w'}$ an indicator variable set to 1 if w and w' are the same word and 0 otherwise. The human description maximizing the TFIDF similarity with the predicted keywords is returned as the description for the new scene.

Our third baseline exploits image similarity (Ordonez et al., 2011). Given an unseen scene λ, we retrieve from the training set λ', the scene most similar to it, and return one of λ''s human descriptions selected at random. We used locality sensitivity hashing to find the subset of candidate scenes similar to λ. Scenes were represented with the same visual features used for the word and template predictors and their similarity was computed with the cosine metric.

Finally, we also trained a multimodal log-bilinear model (Kiros et al., 2014) on the abstract scenes

System	BLEU	METEOR

dataset. The model essentially implements a feed-forward neural network to predict the next word given the image and previous words.[4] Images were associated with feature representations obtained from the output of a convolutional network, following the feature learning procedure outlined in Kiros et al. (2014).

6 Results

We evaluated system output automatically using (smoothed) BLUE and METEOR as calculated by NIST's MultEval software[5] using the human-written descriptions as reference. Elliott and Keller (2014) find that both metrics correlate well with human judgments. For a fair comparison, we force our model to output one description, i.e., the most relevant one.

Our results are summarized in Table 4. As can be seen, our model (SMT) performs best both in terms of BLEU and METEOR. The template-based generator (Template) obtains competitive performance which is not surprising, it incorporates some of the ingredients of the SMT system such as word-to-clipart alignments, a language model, and is guaranteed to produce grammatical output. The performance of the multimodal log-bilinear model (MLBL) keyword- and image-based retrieval systems is inferior. We conjecture that the image features, and similarity functions used in these models are not fine-grained enough to capture the subtle differences in scenes which humans detect and express in the descriptions. Finally, notice that visual information is critical in doing well on the description generation task. A log-bilinear language model (LBL) trained solely on the descriptions performs poorly (see the top row in Table 4).

Resp	1^{st}	2^{nd}	3^{rd}	4^{th}	5^{th}	6^{th}
YES	75.5	65.8	53.0	44.7	44.0	37.5

MAYBE	6.5	9.50	15.8	15.8	18.5	4.50

Table 6: Proportion of SMT descriptions deemed accurate and relevant. System output evaluated for rank placements 1...6.

We further evaluated system output eliciting human judgments for 100 randomly selected test scenes. Participants were presented with a scene and descriptions generated by our system, the template-based model, the best-performing sentence retrieval model, and a randomly selected human description. Subjects were asked to rank the four descriptions from best to worst (ties are allowed) in order of informativeness (does the description capture what is shown in the scene?) and fluency (is the description written in well-formed English?). We elicited rankings using Amazon's Mechanical Turk crowdsourcing platform. Participants (self-reported native English speakers) saw 10 scenes per session. We collected 5 responses per item.

The results of our human evaluation study are shown in Table 5. Specifically, we show, proportionally, how often our participants ranked each system 1st, 2nd and so on. Perhaps unsurprisingly, the human-written descriptions were considered best (and ranked 1st 57% of the time). Our model is ranked best 0.53% of the time, followed by the template and keyword-based retrieval systems which are only ranked first 25% of the time.[6] We further

"Mike and Jenny decide to make hot dogs on the grill.", "It's a rainstorm and Jenny runs away to stay dry.", "Mike stays beside the fire.", "Jenny is standing next to the tree.", "Mike is sitting next to the fire.", "The hot dog is on the pit."

Figure 6: Right scene is generated by SMT model (left scene is the original) given descriptions (bottom) as input.

converted the ranks to ratings on a scale of 1 to 4 (assigning ratings $4 \ldots 1$ to rank placements $1 \ldots 4$). This allowed us to perform Analysis of Variance (ANOVA) which revealed a reliable effect of system type. Specifically, post-hoc Tukey tests showed that our SMT model is significantly ($p < 0.01$) better than the other two comparison systems but does not differ significantly from the human goldstandard.

We also evaluated more thoroughly our content selection mechanism. Since our system can in principle generate multiple descriptions for a scene, we were interested to see how many of these are indeed relevant. We let the system generate the six best descriptions per scene and asked AMT participants to assess whether they were accurate (are the people, objects and actions mentioned in the description shown in the scene?) and appropriate (is the description relevant for the scene?). Participants answered with "yes", "no", or "maybe". Again we used 100 items from the test set, and elicited 5 responses per item. Table 6 shows the outcome of this study. The majority of first-best descriptions (75.5%) returned by our system are perceived as relevant and scene appropriate. The same is true for 2nd and 3rd best descriptions, whereas the quality of descriptions deteriorates with lower ranks. This suggests that we could generate short discourses describing different viewpoints in a scene.

Figure 5 illustrates the descriptions produced by our model for two scenes, whereas Figure 6 shows example output when the system is run in reverse, i.e., it takes descriptions as input and generates a scene. This can be done straightforwardly, without any additional effort, however note that the model is unaware of the absolute position of objects, it places the cloud next to Jenny.

7 Conclusions

In this paper we presented proof of concept that an SMT-based approach is successful at generating human-like scene descriptions provided that (a) there is a large enough parallel corpus to learn from and (b) a content selection component identifies important scene content. Our results further indicate that instilling some degree of structural information in visual scenes (via the VDG) is beneficial. It allows to describe visual content more accurately and facilitates its rendering in natural language (since the two modalities are structurally similar). The template-based, retrieval, and language modeling systems do not use this structural information, and even though their descriptions are largely grammatical, they are not as felicitous. Our results also point to difficulty of the task. Even when computer vision is taken out of the equation, and the description language is simple, human-written text is still preferable (see Table 5). In the future, we would like to develop better content selection models (e.g., identify surprising aspects in a scene) and more accurate grounding strategies (e.g., via discriminative alignment).

Abstract

This work presents a flexible and efficient discriminative training approach for statistical machine translation. We propose to use the RPROP algorithm for optimizing a maximum expected BLEU objective and experimentally compare it to several other updating schemes. It proves to be more efficient and effective than the previously proposed growth transformation technique and also yields better results than stochastic gradient descent and AdaGrad. We also report strong empirical results on two large scale tasks, namely BOLT Chinese→English and WMT German→English, where our final systems outperform results reported by Setiawan and Zhou (2013) and on matrix.statmt.org. On the WMT task, discriminative training is performed on the full training data of 4M sentence pairs, which is unsurpassed in the literature.

1 Introduction

The main advantage of learning parameters in a discriminative fashion is the possibility to directly optimize towards a quality or error measure on the task that is being performed. This stands in contrast to the generative approach, where parameters are chosen to maximize likelihood under a generative story, which often bears little correspondence with the actual application of the model.

In statistical machine translation (SMT), extending the generative noisy-channel formulation (Brown et al., 1993) as a discriminative, log-linear combination of multiple models (Och, 2003) has become the state of the art. However, most of the component models are still estimated by heuristics or generative training. In this paper, a flexible, efficient and easy to implement discriminative training scheme for SMT is presented. It can be applied to any kind and any number of features. We use the RPROP algorithm to optimize a maximum expected BLEU objective. n-best lists approximate the infeasibly large space of translation hypotheses. They are generated with the application of leave-one-out to make them more representative with respect to unseen data.

We make the following main contributions:

1. We propose to apply the RPROP algorithm for maximum expected BLEU training and perform an experimental comparison with growth transformation (GT) (He and Deng, 2012; Setiawan and Zhou, 2013), stochastic gradient descent (Auli et al., 2014) and AdaGrad (Green et al., 2013). RPROP yields superior performance, reaching a total improvement of 1.2 BLEU points over our IWSLT German→English baseline using 5.22M features.

2. In terms of time and memory efficiency, RPROP clearly outperforms GT. The latter needs to update a much larger number of features due to its renormalization component. On the IWSLT data, RPROP is 6.4 times faster than GT and requires a third of the memory.

3. On the WMT German→English task, we perform discriminative training on 4M sentence

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1516–1526,
Denver, Colorado, May 31 – June 5, 2015.

pairs, which, to the best of our knowledge, is 2.4 times the size of the largest training set reported in previous work (1.66M sentences in (Simianer et al., 2012)). This proves the scalability of our approach.

4. On two large scale tasks our experiments show good improvements over strong baselines which include recurrent language modeling components. On the Chinese→English DARPA BOLT task, we achieve nearly twice the improvement reported in (Setiawan and Zhou, 2013) on the same test sets which results in a superior final system. Finally, the best single system reported on matrix.statmt.org is outperformed by 0.8 BLEU points on the WMT German→English *newstest2013* set.

Our experiments also prove that leave-one-out impacts translation quality.

This paper is organized as follows. We review related work in Section 2 and present the translation system in Section 3. In Section 4 we describe the different discriminative update strategies applied in this work and Section 5 derives the complete maximum expected BLEU training algorithm. Finally, experimental results are given in Section 6 and we conclude with Section 7.

2 Related Work

Discriminative training is one of the most active research areas in SMT and it can be integrated into the pipeline at various stages.

Och (2003) proposed to apply minimum error rate training (MERT) to optimize the different feature weights in the log-linear model combination on a small development data set. This is still considered to be the state of the art, but is only capable of optimizing a handful of features. More recently, MIRA (Watanabe et al., 2007; Chiang et al., 2008) and PRO (Hopkins and May, 2011) have been presented as optimization procedures that can replace MERT and scale to thousands of parameters.

In a different line of work, Liang et al. (2006) describe a fully discriminative training pipeline, where more than one million features are tuned on the training data using a perceptron-style update algorithm. The Direct Translation Model 2 introduced by Ittycheriah and Roukos (2007) is similar in that it also trains millions of features on the training data. However, the weights are estimated based on a maximum entropy model and the underlying translation paradigm differs from the standard phrase-based model. Gao and He (2013) use gradient ascent to train Markov random field models for phrase translation. These models are interpreted as undirected phrase compatibility scores rather than translation probabilities. Thus, as in our work, they are not subject to a sum-to-one constraint. Simianer et al. (2012) propose a distributed setup for large-scale discriminative training with joint feature selection. The training corpus is divided into several shards, on which features are updated via perceptron-style gradient descent. The authors present results showing that training on large data sets improves results over just using a small development corpus. Another approach based on the AdaGrad method that scales to large numbers of sparse features is proposed in (Green et al., 2013; Green et al., 2014). Different from our work, the authors use either the tuning sets or a small subsample of the training data (15k sentences) for discriminative training.

A notably different idea is pursued by Yu et al. (2013), who present a large-scale training procedure that explicitly minimizes search errors. This is achieved by force-decoding the training data and updating at the point where the correct derivation drops off the beam.

In (Blunsom et al., 2008), conditional random fields (CRFs) are trained within a hierarchical phrase-based translation framework. The hierarchical phrase-based paradigm is used to model the search space in model estimation and search, leaving the hypothesis weighting to CRF features. They constrain search by a beam width for gradient estimation and update the model with the help of L-BFGS. In a similar way Lavergne et al. (2011) use the n-gram based approach (Casacuberta and Vidal, 2004; Mariño et al., 2006) to model the reordering, phrase alignment, and the language model. A CRF is applied to estimate the phrase weights. Model updates are carried out by the RPROP algorithm (Riedmiller and Braun, 1993). However, both approaches only improve over constrained baselines.

Our work is inspired by (He and Deng, 2012; Setiawan and Zhou, 2013), where the authors propose to

train the standard phrasal and lexical channel models with the growth transformation (GT) algorithm. They use n-best lists on the training data and optimize a maximum expected BLEU objective, that provides a clear training criterion, which is missing e.g. in MIRA estimation. Auli et al. (2014) report good results by applying the same objective function to reordering features, which are trained with stochastic gradient descent (SGD).

Our work differs in several key aspects: (i) We propose to apply the RPROP algorithm, which yields superior results to GT, SGD and AdaGrad in our experimental comparison. (ii) For the first time, we apply maximum expected BLEU training on a data set as large as four million sentence pairs. (iii) We apply a leave-one-out heuristic (Wuebker et al., 2010) to make better use of the training data. (iv) We apply phrasal, lexical, reordering and triplet features. (v) Finally, we do not run MERT after each training iteration, which is expensive for large translation systems.

3 Statistical Translation System

Our work can be applied to any statistical machine translation paradigm and we will present results on a standard phrase-based translation system (Koehn et al., 2003) and a hierarchical phrase-based translation system (Chiang, 2005). The translation process is implemented as a weighted log-linear combination of several models $h_{m,\Theta}(E, F)$, where $E = e_1, \ldots, e_I$ denotes the translation hypothesis, $F = f_1, \ldots, f_J$ the source sentence, m a model index, and Θ the model parameters. These models include the phrase translation and lexical smoothing scores in both directions, language model (LM) score, distortion penalty, word penalty and phrase penalty (Och and Ney, 2004). Given a source sentence F, the models $h_{m,\Theta}(E, F)$ and the corresponding log-linear feature weights λ_m, the translation decoder searches for the best scoring translation $\hat{E}$:

$$\hat{E} = \arg\max_{E} \{f_\Theta(E, F)\} \tag{1}$$

$$f_\Theta(E, F) = \sum_{m \in M} \lambda_m h_{m,\Theta}(E, F) \tag{2}$$

where $\ldots, \lambda_m, \ldots$ are the model weighting parameters. In practice, the Viterbi approximation is applied and for simplicity, in the following we will assume the particular derivation for a translation hypothesis to be included in the variable E. The log-linear feature weights are optimized with minimum error rate training (MERT) (Och, 2003).

4 Update Strategies

4.1 Previously Proposed Algorithms

The **Growth Transformation (GT)** or Extended Baum-Welch Algorithm was proposed by He and Deng (2012) for maximum expected BLEU training of the standard phrasal and lexical channel models. It is an algorithm to iteratively optimize polynomials of random variables that are subject to sum-to-one contraints and is therefore suitable for training probability distributions. The disadvantage is that each parameter update requires a renormalization step, which artificially blows up the number of features that need to be changed and has a significant impact on time and memory efficiency. The update formulas are derived in (He and Deng, 2012).

Stochastic Gradient Descent (SGD) is a well-known and frequently applied training scheme, which is used for maximum expected BLEU training of reordering models by (Auli et al., 2014). It performs the following update:

$$\vartheta^{(t+1)} = \vartheta^{(t)} + \eta \cdot \nabla_\vartheta^{(t)} \tag{3}$$

Here, the disadvantage is its high sensitivity to the fixed learning rate η. However, as it does not subject the features to sum-to-one-contraints, it is considerably more time and memory efficient than GT.

As an improvement to SGD, **AdaGrad** (Duchi et al., 2011) is designed for large, sparse feature sets and makes use of an adaptive learning rate. It was proposed for MT training by (Green et al., 2013). Although its main area of application are online algorithms, it is also applicable in our offline setting and is more robust than SGD due to the adaptive learning rate. Following (Green et al., 2013), we apply the approximation with a diagonal outer product matrix, which is computationally cheap. This results in the update equations

$$\vartheta^{(t+1)} = \vartheta^{(t)} + \eta \cdot G_t^{-\frac{1}{2}} \cdot \nabla_\vartheta^{(t)} \tag{4}$$

$$G_t = G_{t-1} + (\nabla_\vartheta^{(t)})^2 \tag{5}$$

4.2 RPROP

The resilient backpropagation algorithm (RPROP) proposed by Riedmiller and Braun (1993) is a gradient-based optimization algorithm that emprirically learns the step size without taking the slope into account, making it highly robust and avoiding the need for a learning rate. If the gradient switches algebraic sign compared to the previous iteration, the last step is reverted and the step size reduced. If the sign remains the same, the step size is increased. Formally, given a set of parameters Θ and an objective function $O(\Theta)$, in iteration t each parameter $\vartheta \in \Theta$ is updated according to

$$\vartheta^{(t+1)} = \begin{cases} \vartheta^{(t-1)} & \text{, if } \quad \nabla_\vartheta^{(t-1)} \cdot \nabla_\vartheta^{(t)} < 0 \\ \vartheta^{(t)} + \Delta\vartheta^{(t)} & \text{, else if } \quad \nabla_\vartheta^{(t)} > 0 \\ \vartheta^{(t)} - \Delta\vartheta^{(t)} & \text{, else if } \quad \nabla_\vartheta^{(t)} < 0 \\ \vartheta^{(t)} & \text{, else} \end{cases}$$

where $\nabla_\vartheta^{(t)} := \frac{\delta O(\Theta^{(t)})}{\delta \vartheta}$ denotes the derivative of the objective function. The step size $\Delta\vartheta^{(t)} > 0$ grows or decreases depending on the sign of the gradient:

$$\Delta\vartheta^{(t)} = \begin{cases} \eta^+ \cdot \Delta\vartheta^{(t-1)} & \text{, if } \quad \nabla_\vartheta^{(t-1)} \cdot \nabla_\vartheta^{(t)} > 0 \\ \eta^- \cdot \Delta\vartheta^{(t-1)} & \text{, if } \quad \nabla_\vartheta^{(t-1)} \cdot \nabla_\vartheta^{(t)} < 0 \\ \Delta\vartheta^{(t-1)} & \text{, else} \end{cases}$$

The strength parameters $0 < \eta^- < 1 \leq \eta^+$ usually have little impact and are fixed to $\eta^- = 0.5$ and $\eta^+ = 1.2$ throughout this work. The RPROP algorithm is simple and easy to implement. It has proven effective for a number of tasks, e.g. in (Wiesler et al., 2013; Heigold et al., 2011; Lavergne et al., 2011; Hahn et al., 2011). Different from growth transformation (cf. Sec. 4.1), it does not assume a probability distribution and performs its updates without a sum-to-one constraint.

Compared to SGD and AdaGrad, RPROP's practical advantage is the absence of a learning rate that needs to be tuned. Further, we see its theoretical advantage in the empirically learned step size. In the first iterations, RPROP's updates are considerably smaller than with the other strategies, resulting in a more careful exploration of the search space. In higher iterations, the update steps for good features keep growing and we observe an exponential increase of the objective function. In contrast, GT, SGD, and AdaGrad determine the size of their update step based on the slope of the gradient, which we believe to be misleading given the complex topology of the feature space in MT.

5 Training

5.1 Maximum Expected BLEU

Following (He and Deng, 2012), we want to optimize a maximum expected BLEU objective. We denote the universe of possible sentences in the source language as $\mathbb{F}$ and in the target language as $\mathbb{E}$. The expected BLEU score under parameter set Θ with respect to the joint probability distribution $p_\Theta(\cdot,\cdot)$ is defined as

$$\langle\beta\rangle_\Theta = \sum_{F\in\mathbb{F}} \sum_{E\in\mathbb{E}} p_\Theta(E,F)\beta(E) \qquad (6)$$

Here, $\beta(E)$ is the BLEU score for target sentence E (assuming the reference translation to be part of the mapping β) and we use the notation $\langle\cdot\rangle$ to denote the expectation. Enumerating all possible source and target sentences F, E is infeasible. Therefore, we estimate the empirical expectation on a corpus $\mathbb{C} \subset \mathbb{E} \times \mathbb{F}$. We denote the source sentences in $\mathbb{C}$ as $\mathbb{C}_F$ and the size of the corpus as $N = |\mathbb{C}|$. The joint probability $p_\Theta(E,F)$ is decomposed with the help of the Bayes Theorem, resulting in:

$$\langle\beta\rangle_\Theta = \sum_{F\in\mathbb{C}_F} p(F) \sum_{E\in\mathbb{E}_\Theta(F)} p_\Theta(E|F)\beta(E) \qquad (7)$$

For $p(F) = \frac{N_F}{N}$ we assume the empirical distribution within the training corpus, where N_F is the count of sentence F. The summation over all $E \in \mathbb{E}$ is sampled with a subset $\mathbb{E}_\Theta(F)$ of the most likely hypotheses with respect to the parameterized probability $p_\Theta(E,F)$, which in practice is an n-best list generated by the decoder. Iterating over the corpus $\mathbb{C} = \{(E_1,F_1),\ldots,(E_n,F_n),\ldots,(E_N,F_N)\}$ finally results in

$$\langle\beta\rangle_\Theta = \frac{1}{N}\sum_{n=1}^{N} \sum_{E\in\mathbb{E}_\Theta(F_n)} p_\Theta(E|F_n)\beta(E)$$

We use the same unclipped sentence-level BLEU-4 score with smoothed 3-gram and 4-gram precisions as in (He and Deng, 2012), which we denote as $\beta(E) = \text{BLEU}(E, E_n^*)$ with respect to the reference translation E_n^*.

The normalized posterior translation probability $p_\Theta(E|F)$ from source sentence F to target sentence E approximates a maximum entropy model normalized on sentence level:

$$p_\Theta(E|F) = \frac{e^{-f_\Theta(E,F)}}{\sum_{E' \in \mathbb{E}_\Theta(F)} e^{-f_\Theta(E',F)}} \quad (8)$$

The denominator of this probability does not depend on the output sentence. Thus, the $\arg\max$ of Equation 8 is equal to the $\arg\max$ of the translation score in Equation 1.

Maximum Entropy models tend to generalize poorly, which can be circumvented by regularization. He and Deng (2012) use Kullback-Leibler regularization, raising the need of having normalized models $h_{m,\Theta}(E,F)$. We employ the more general L_2-regularization and the objective function is defined as

$$O(\Theta) = log\langle\beta\rangle_\Theta - \tau \cdot \sum_{\vartheta \in \Theta} \vartheta^2 \quad (9)$$

including the hyper parameter τ controlling the degree of regularization. The derivative of the objective function, which is needed for the gradient-based training methods, directly follows:

$$\frac{\delta O(\Theta)}{\delta \vartheta} = -\tau \cdot 2\vartheta + \frac{1}{\langle\beta\rangle_\Theta} \cdot \frac{\delta\langle\beta\rangle_\Theta}{\delta\vartheta} \quad (10)$$

With $\frac{\partial h_{m,\Theta}(E,F)}{\partial \vartheta} = \#_\vartheta(E,F)$ the number of times feature ϑ fires in the derivation for translation hypothesis E given source sentence F, the derivative of $p_\Theta(E|F)$ is defined as (for ease of notation $\mathbb{E}_\Theta(F_n)$ is represented by $\mathbb{E}_n$)

$$\frac{\partial p_\Theta(E|F)}{\partial \vartheta} = -p_\Theta(E|F) \cdot \quad (11)$$
$$\left(\#_\vartheta(E,F) - \sum_{E' \in \mathbb{E}_n} p_\Theta(E'|F) \#_\vartheta(E',F) \right)$$

And the derivative of the expected BLEU is

$$\frac{\delta\langle\beta\rangle_\Theta}{\delta\vartheta} = \frac{1}{N} \sum_{n=1}^{N} \sum_{E \in \mathbb{E}_n} \beta(E) \frac{\partial p_\Theta(E|F_n)}{\partial \vartheta}$$
$$= -\frac{1}{N} \sum_{n=1}^{N} \Bigg(\sum_{E \in \mathbb{E}_n} p_\Theta(E|F)\beta(E)\#_\vartheta(E,F)$$
$$- \Big(\sum_{E \in \mathbb{E}_n} p_\Theta(E|F)\beta(E) \Big) \cdot$$
$$\Big(\sum_{E \in \mathbb{E}_n} p_\Theta(E|F)\#_\vartheta(E,F) \Big) \Bigg) \quad (12)$$

This can be more compactly expressed by local expectations $\langle\cdot\rangle_n$ of the BLEU score and the feature count $\#_\vartheta$:

$$\frac{\delta\langle\beta\rangle_\Theta}{\delta\vartheta} = -\frac{1}{N} \sum_{n=1}^{N} (\langle\beta\#_\vartheta\rangle_n - \langle\beta\rangle_n\langle\#_\vartheta\rangle_n)$$

In our implementation, $\#_\vartheta$ is moved to the front of the equation to obtain common factors that can be used by all parameter updates:

$$\frac{\delta\langle\beta\rangle_\Theta}{\delta\vartheta} = \frac{1}{N} \sum_{n=1}^{N} \sum_{E \in \mathbb{E}_n} \#_\vartheta(E,F) \cdot$$
$$p_\Theta(E|F)(\langle\beta\rangle_n - \beta(E)) \quad (13)$$

5.2 Leave-one-out

Although He and Deng (2012) claim that it is not necessary, we apply a leave-one-out heuristic similar to (Wuebker et al., 2010) when generating the n-best lists on the training data. The authors have shown this to effectively counteract over-fitting effects and we argue that it helps to bring out the full potential of our discriminative training procedure.

When we decode the training data of our translation model, very long and rare phrases can be used to translate the sentence. The translation probability for these phrases, which are often singletons, are generally over-estimated by the heuristic count model. When they are too dominant in the n-best lists they effectively render the training data useless, as they are unlikely to generalize to unseen data. The idea of leave-one-out is that for decoding each sentence, the global counts of the relative frequency estimates are reduced by the local counts extracted from the current sentence pair. This way, the

above mentioned rare phrases are penalized and the decoder is encouraged to use more general phrases taken from the remainder of the training data. Singleton phrases are given a fixed penalty. In this work, we apply leave-one-out with all update strategies.

5.3 Features

Maximum expected BLEU training facilitates training of arbitrary features. In this work we apply four types of features. (a) A discriminative phrase table, i.e. one feature for each phrase pair. (b) Lexical features, i.e. one feature for each source-target word pair that appear within the same phrase. (c) Source and target triplet features (Hasan et al., 2008), i.e. triples of one source and two target words or one target and two source words appearing within a single phrase pair. (d) The hierarchical lexicalized reordering model (Galley and Manning, 2008), i.e. one feature for each combination of phrase pair, orientation (monotone (M), swap (S) or discontinuous (D)) and orientation direction (forward or backward). GT is only applied with feature set (a), where we re-estimate the two phrasal channel models as was done in (He and Deng, 2012). With the other update algorithms we follow the approach taken in (Auli et al., 2014) and condense each feature type into a small number of models for the log-linear combination, which is afterwards tuned with MERT. (a) and (b) result in a single additional model, (c) in two models (source and target triplets) and (d) in six models ($\{$forward,backward$\}\times\{$M,S,D$\}$).

5.4 Efficient Implementation

The expected BLEU $\langle\beta\rangle_\Theta$ is efficiently computed in one iteration over the full n-best list. As can be seen from Equation 13, the derivative $\frac{\delta\langle\beta\rangle_\Theta}{\delta\vartheta}$ is additive with respect to each firing instance of feature ϑ in the n-best list. The additive factor only depends on the current sentence pair. Therefore, for each sentence of the training data we iterate through its n-best list once to compute the expectation of the sentence-level BLEU score $\langle\beta\rangle_n$ and then a second time to update the current derivative for each time the feature fires. The only thing that needs to be kept in memory is a list of the current derivatives for each parameter ϑ.

1. Create the baseline system and run MERT
2. Generate n-best list on training corpus
3. Compute sentence-level BLEU $\beta(E_n)$ for each hypothesis E_n in the list
4. Initialize parameters with $\vartheta = 0, \forall\vartheta \in \Theta$
5. Iterate:
   a) Compute the derivatives $\frac{\delta O(\Theta)}{\delta\vartheta}$
   b) Perform update and output $\Theta^{(t)}$
6. Run MERT on `dev` with each table $\Theta^{(t)}$
7. Select best $\Theta^{(t)}$ on `dev`
8. Evaluate on test sets

Figure 1: The complete training algorithm.

5.5 Complete Training Algorithm

The complete training and evaluation procedure is shown in Figure 1. We start by building a baseline translation system with MERT-optimized model weights λ. With the baseline system we generate n-best lists on the training data. Now, for each translation hypothesis E_n of the n-best list, we compute the sentence-level BLEU score $\beta(E_n)$ and initialize the parameter set for training with the count model. Next, we run the training algorithm for a fixed number of iterations[1] and output the updated feature values $\Theta^{(t)}$ after each iteration t. Finally, we run MERT with each $\Theta^{(t)}$, select the best table on `dev` and evaluate on our test sets.

6 Experiments

6.1 Setup

The experiments are carried out on the IWSLT 2013 German→English shared translation task.[2] For rapid experimentation, the translation model is trained on the in-domain TED portion of the bilingual data, which is also used for maximum expected BLEU training. However, we use a large 4-gram LM with modified Kneser-Ney smoothing (Kneser and Ney, 1995; Chen and Goodman, 1998), trained with the SRILM toolkit (Stolcke, 2002). As additional data sources for the LM we use the complete News Commentary, Europarl v7 and Common Crawl corpora as well as selected parts of the Shuffled News

[1] Note that we keep the λ weights fixed throughout all iterations of maximum expected BLEU training.

Table 1: Statistics for the bilingual training data of the IWSLT 2013 German→English, the DARPA BOLT Chinese→English and the WMT 2014 German→English tasks.

and LDC English Gigaword corpora. The selection is based on cross-entropy difference (Moore and Lewis, 2010). This makes for a total of 1.7 billion running words for LM training. The baseline further contains a hierarchical reordering model (HRM) (Galley and Manning, 2008) and a 7-gram word class language model (Wuebker et al., 2013). On IWSLT, all results are averages over three independent MERT runs, and we evaluate statistical significance with *MultEval* (Clark et al., 2011).

To confirm our findings, additional experiments are run on two large-scale tasks over strong baselines including recurrent neural language models. On the DARPA BOLT Chinese→English task we use our internal evaluation system as a baseline. It is a powerful hierarchical phrase-based SMT engine with 19 dense features, including an LSTM recurrent neural language model (Sundermeyer et al., 2012) and a hierarchical reordering model (Huck et al., 2013). The 5-gram backoff LM is in total trained on 2.9 billion running words. We use the same data for tuning and testing as Setiawan and Zhou (2013), namely 1275 (tune) and 1239[3] sentences of web data taken from LDC2010E30, the NIST MT06 evaluation set and an additional single-reference test set from the discussion forum (df) domain containing 1124 sentence pairs. Maximum expected BLEU training is performed on the discussion forum portion of the training data, consisting of 67.8K sentence pairs. On the German→English task of the *9th Workshop on Statistical Machine Translation*[4], both translation model and maximum expected BLEU training is performed on all available bilingual data. Our baseline is a phrase-based translation engine with a 4-gram backoff LM trained on 2.5 billion words with `lmplz` (Heafield et al., 2013), a recurrent neural LM, a 7-gram word class LM and the HRM.

RPROP w/o leave-one-out	921K	30.7
RPROP all features	5.22M	**31.6**

Table 2: Results for the IWSLT 2013 German→English task in BLEU [%]. The comparison between update strategies is done with feature set (a) and *RPROP all features* uses feature sets (a)-(d). GT, SGD, AdaGrad and RPROP are trained with leave-one-out, unless otherwise specified.

Bilingual data statistics for all tasks are given in Table 1. We use the machine translation toolkit *Jane* (Vilar et al., 2010; Wuebker et al., 2012) and evaluate with case-insensitive BLEU [%] (Papineni et al., 2002) in all experiments.

6.2 Experimental Results

Table 2 shows the **IWSLT** results. We first compare the performance of the four update algorithms, for simplicity only on the discriminative phrase table features. Different from previous work the n-best lists of the training data were generated with leave-one-out, unless otherwise stated. In all cases we tested different values for the regularization parameter τ and in the case of SGD and AdaGrad also for the learning rate η. We selected the best configurations based on a validation set (test2011). For AdaGrad we also experimented with FOBOS regularization and feature selection (Duchi and Singer, 2009), but did not observe improved results. As

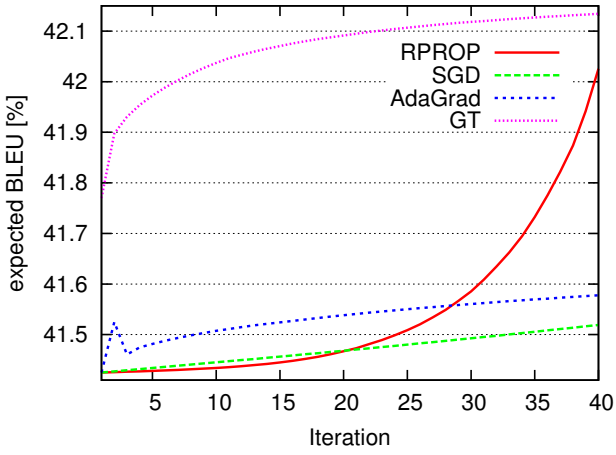

Figure 2: Expected BLEU value on IWSLT German→English for the different update strategies. Note that growth transformation (GT) applies a different regularization term and is therefore not directly comparable with the other techniques.

BOLT zh-en	# feat.	df	web	MT06

RPROP	12.4M	**18.7**	**34.8**	**40.5**
Setiawan&Zhou (GT)	150M	-	32.7	40.3

Table 3: Results for the BOLT Chinese→English task in BLEU [%] on the discussion forum test set (df), the mixed web test set and NIST MT06. The baseline is our BOLT evaluation system and contains a recurrent neural LM. We compare with (Setiawan and Zhou, 2013) who applied maximum expected BLEU training with growth transformation (GT). Note that the number of features reported by Setiawan and Zhou (2013) is artificially blown up due to renormalization.

expected, we found that in all cases regularization is not strictly necessary - results are barely affected as long as τ is sufficiently small - and that SGD is much more sensitive to η than AdaGrad. Further, SGD and RPROP need around 25 iterations to reach good results, where 5-10 iterations are sufficient for GT and AdaGrad. For a fair comparison, however, we run all algorithms for 40 iterations and select the best one on a seletion set, namely iterations 19 (AdaGrad), 23 (GT), 29 (RPROP) and 35 (SGD). Figure 2 shows how the expected BLEU function evolves in training with different update strategies. Although the value for GT is not directly comparable to the others due to a different regularization term, the respective characteristics are clearly visible. SGD exhibits a linear growth pattern, GT resembles a logarithmic and RPROP an exponential function. After initially overshooting and then retracting as the regularization kicks in, AdaGrad also displays logarithmic characteristics.

In terms of BLEU RPROP performs best, followed by AdaGrad, GT and SGD, where the RPROP-AdaGrad and AdaGrad-GT differences are small (0.2% BLEU absolute) but statistically significant on the 95% level. Altogether, RPROP improves over the baseline by 0.9 BLEU points, which is statistically significant at the 99% level. In an additional experiment we verified that leave-one-out has a clear impact on the results. The BLEU difference between RPROP with and without leave-one-out is 0.6% absolute. By adding lexical, triplet and reordering features, we get an additional gain and observe a total improvement of 1.2 BLEU points over the baseline system.

Efficiency comparison. 921K discriminative phrase table features are active in our training data. Due to the renormalization component, this results in a total of 6.08M features that are updated with GT using the same data. Consequently, it is less time and space efficient than the other algorithms. With our implementation, GT needed around 16 hours and 6.7G memory for 40 iterations, where RPROP, AdaGrad and SGD finished after less than 2.5 hours and required 2.1G memory.

For the **BOLT** task, we directly compare with the GT-trained system in (Setiawan and Zhou, 2013) using the same tune set for MERT and reporting results on the same test sets, see Table 3. With RPROP we achieve nearly twice the improvement reported by Setiawan on both *web* and *MT06* using feature sets (a)-(c)[5]. Our baseline on *web* is already much stronger and RPROP training yields +0.7 BLEU points, as opposed to +0.44 reported by Setiawan. On *MT06* our baseline system is slightly worse, but with the larger gain received by RPROP our final system outperforms the one reported by Se-

[5]Reordering features are not applicable to our hiero system.

WMT de-en	# feat.	newstest2013
baseline	19	28.3
RPROP	45.0M	**28.9**
matrix.statmt.org	14	28.1

Table 4: Results for the WMT German→English task in BLEU [%]. The baseline contains a recurrent neural LM. We compare with the best single system that is reported on `matrix.statmt.org`, which was submitted by the Unversity of Edinburgh.

tiawan by 0.2 BLEU points. We would like to stress that this is not a domain adaptation effect, as maximum expected BLEU training was performed on discussion forum (df) data. On the *df* test set, on the other hand, we probably can observe domain adaptation via RPROP training. The improvement here is 0.7% BLEU absolute with a single reference, as opposed to four references on *web* and *MT06*. We also report results training the same feature sets with SGD and AdaGrad, confirming results we observed on IWSLT. Here, SGD yields only minor improvements. AdaGrad performs better, but still 0.1 - 0.4 BLEU points worse than RPROP. Running GT is infeasible in our hierarchical phrase-based setup.

Table 4 shows the results on the **WMT** task. This is our largest setting, where max. exp. BLEU training is performed on the full training data with more than 4M sentence pairs which, to the best of our knowledge, is unsurpassed in the literature. Altogether, training took more than one month, about 3/4 of which were for generating n-best lists by decoding the training data. The triplet features did not finish in time, so we applied the feature sets (a), (b) and (d), 45M features in total. With a renormalization step as in GT, this number would grow to 309M. On *newstest2013*, our baseline already outperforms the best single system reported on matrix.statmt.org by 0.2 BLEU points. The discriminatively trained features yield an additional improvement of 0.6% BLEU absolute on this high-end system.

7 Conclusion

We have experimentally compared several update strategies for maximum expected BLEU training. The RPROP algorithm proposed in this work shows superior performance compared to AdaGrad, growth transformation (GT) and stochastic gradient descent. In terms of time and memory efficiency, GT is clearly inferior to the other algorithms due to renormalization. Applying phrasal, lexical, triplet and reordering features, the baseline is improved by 1.2% BLEU absolute on the IWSLT German→English task. On two large scale tasks we achieve clearly superior performance compared to results reported in the literature. On BOLT Chinese→English our discriminative training yields nearly twice the improvement reported by Setiawan and Zhou (2013), resulting in a superior final system. On WMT German→English, we outperform the best single system reported on matrix.statmt.org by 0.8% BLEU absolute. Here, we perform maximum expexted BLEU training on more than 4M sentence pairs, which is the largest number reported in the literature to date.

Acknowledgments

The research leading to these results has received funding from the European Union Seventh Framework Programme (FP7/2007-2013) under grant agreement n^{o} 287658. Abstract

Translation models often fail to generate good translations for infrequent words or phrases. Previous work attacked this problem by inducing new translation rules from monolingual data with a semi-supervised algorithm. However, this approach does not scale very well since it is very computationally expensive to generate new translation rules for only a few thousand sentences. We propose a much faster and simpler method that directly hallucinates translation rules for infrequent phrases based on phrases with similar continuous representations for which a translation is known. To speed up the retrieval of similar phrases, we investigate approximated nearest neighbor search with redundant bit vectors which we find to be three times faster and significantly more accurate than locality sensitive hashing. Our approach of learning new translation rules improves a phrase-based baseline by up to 1.6 BLEU on Arabic-English translation, it is three-orders of magnitudes faster than existing semi-supervised methods and 0.5 BLEU more accurate.

1 Introduction

Statistical translation models (Koehn et al. 2003, Chiang et al. 2005) are trained with bilingual data and a simple solution to improve accuracy is to train on more data. However, for many language pairs we only have a very limited amount of bilingual data and even when dealing with resource-rich languages, we still often perform poorly when dealing with rare words or phrases.

On the other hand, there is plenty of monolingual data and previous work has investigated its use in learning translation models (Rapp, 1995; Callison-Burch et al., 2006; Haghighi et al., 2008; Saluja et al., 2014). However, most methods rely on statistics that are computationally expensive. As a concrete example, the graph propagation algorithm of Saluja et al. (2014) relies on pair-wise mutual information statistics between any pair of phrases in the monolingual corpus that is very expensive to compute, even for moderately sized corpora.

In this paper, we study the use of standard continuous representations for words to generate translation rules for infrequent phrases (§2). We explore linear projections that map continuous representations of rare foreign phrases to English phrases. In particular, we propose to learn many local projections that are specific to a given foreign phrase. We find this to be much more accurate than a single globally learned mapping such as proposed by (Mikolov et al. 2013; §3).

Our method relies on the fast retrieval of similar phrases in continuous space. We explore both Locality Sensitive Hashing (LSH; Indyk and Motwani, 2008) as well as the lesser known Redundant Bit Vector method (RBV; Goldstein et al. 2005) for fast k-nearest neighbor (k-NN) search. RBV outperforms the popular LSH algorithm by a large margin, both in speed as well as accuracy (§4).

Our results show that the local linear projection method is not only three orders of magnitudes faster than the algorithm of Saluja et al. (2014) but also by 0.5 BLEU more accurate. We achieve a 1.6 BLEU improvement in Arabic-English translation compared to a standard phrase-based baseline (§5).

2 Continuous Phrase Representations

Continuous representations of words have been found to capture syntactic and semantic regularities in language (Turian et al., 2014; Collobert et al., 2011; Mikolov et al., 2013c). The induced representations often tend to cluster similar words together as illustrated in Figure 1.

Denver, Colorado, May 31 – June 5, 2015.

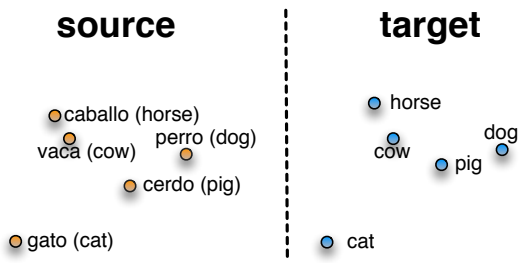

Figure 1: Illustration of word representations in Spanish and English (Figure from Mikolov et al. (2013a)). The plots are based on a two-dimensional projection of the original vectors with principal component analysis.

A logical next step is to learn representations for larger linguistic units, a topic which has received a lot of interest (Mitchell and Lapata, 2010; Socher et al., 2011; Le and Mikolov, 2014). For machine translation there have been efforts to learn representations for entire bilingual phrases (Zou et al., 2013; Zhang et al., 2014; Gao et al., 2014).

In this work, we only require representations for monolingual phrases that are relatively short.[1] We therefore decided to use off-the-shelf word representations to build phrase vectors. In particular, we chose the continuous bag-of-words model (Mikolov et al., 2013b) which is very fast to train and scales very well to large monolingual corpora.

The resulting word vectors are then used to build phrase vectors via simple element-wise addition which has been found to perform very competitively in comparison to alternative approaches (Mitchell and Lapata, 2010). Note that all the algorithms described in this paper are agnostic to the choice of phrase-representation and other schemes may perform better.

We use these monolingual phrase representations to generate translation rules for infrequent, or *unlabeled*, phrases. Unlabeled phrases do not appear in the bilingual data and thus do not have translation rules. The general idea behind the following algorithms is to identify *labeled* phrases for which we know translation rules that are similar to an unlabeled phrase, and to use them to induce translation rules for the unlabeled phrase.

[1]For simplicity, we only consider unigrams and bigrams on the source side, see §5

3 Translation Rule Generation

We first describe how we can learn a single mapping between the foreign and English continuous spaces to find translations for an infrequent foreign phrase (§3.1). Next, we make this approach more robust by learning many mappings that are specific to a given foreign phrase (§3.2). Finally, we review the semi-supervised label propagation algorithm of Saluja et al. (2014) which we make much faster using continuous word representations and k-NN algorithms (§3.3).

3.1 Global Linear Projection

Mikolov et al. (2013a) find that the relative positions between words are preserved between languages (Figure 1), and, thus, it is possible to learn a *linear* projection that maps the continuous representation of source phrases to points on the target side. The hope is to learn a mapping that captures the relationship between the source and target spaces. We call this linear transform *global linear projection*, since we use a single mapping that we apply to every source phrase.

More formally, we denote f and e as source side and target side phrases respectively, and $\mathbf{f} \in \mathbb{R}^{1\times d}$ and $\mathbf{e} \in \mathbb{R}^{1\times d}$ as the corresponding phrasal vectors with dimension d. Following Mikolov et al. (2013a), we learn a global linear projection matrix $W \in \mathbb{R}^{d\times d}$ based on the translations of the n most frequent labeled source side phrases: $(\mathbf{f}_1, \mathbf{e}_1), (\mathbf{f}_2, \mathbf{e}_2), \ldots, (\mathbf{f}_n, \mathbf{e}_n), n \geq d$.[2] Let $F = [\mathbf{f}_1^T, \mathbf{f}_2^T, \ldots, \mathbf{f}_n^T]^T$, and $E = [\mathbf{e}_1^T, \mathbf{e}_2^T, \ldots, \mathbf{e}_n^T]^T$. We calculate W by solving the following linear system:

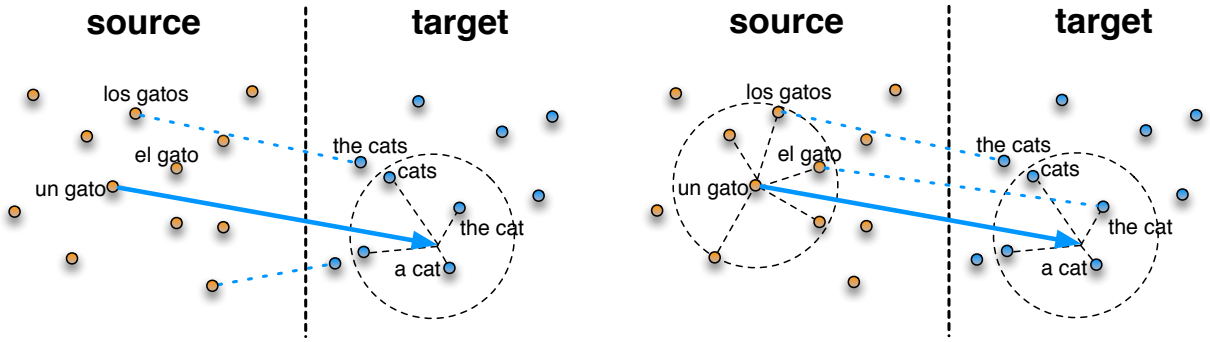
$$FW = E$$

whose solution is:

$$W \approx (F^T F)^{-1} F^T E$$

Using the linear transform W, we can compute $\bar{\mathbf{e}} = \mathbf{f}W$ for each unlabeled source phrase $\mathbf{f}$, where $\bar{\mathbf{e}}$ will be close to target phrases that are potential translation candidates for $\mathbf{f}$. We denote the set of all nearby English phrase vectors as $N(\bar{\mathbf{e}})$ and use

[2]We need more than d phrases to be fetched to make the linear system solvable. Similar is for the local linear projection in §3.2.



(a) Global Linear Projection

(b) Local Linear Projection

Figure 2: (a) Illustration of the global linear projection mapping the unlabeled Spanish phrase "un gato" to the target space. The neighbors of the projected point serve as translation candidates and are fetched via a k-NN query. (b) A local linear projection is learned individually for "un gato" based on the translations "the cats", "the cat" of the labeled neighbors "los gatos", "el gato".

fast k-NN query algorithms to retrieve this set (§4). Figure 2 (a) illustrates the method.

The translation probability for each translation candidate $\mathbf{e} \in N(\bar{\mathbf{e}})$ is based on the similarity to the projected point $\bar{\mathbf{e}}$:

$$P(e|f) = \frac{\exp\{\text{sim}(\mathbf{e}, \bar{\mathbf{e}})\}}{\sum_{\mathbf{e}' \in N(\bar{\mathbf{e}})} \exp\{\text{sim}(\mathbf{e}', \bar{\mathbf{e}})\}}. \quad (1)$$

Note that we normalize over the neighbor set $N(\bar{\mathbf{e}})$ of the projected point $\bar{\mathbf{e}}$ of foreign phrase f. This uses the similarity $\text{sim}(\bar{\mathbf{e}}, \mathbf{e})$ between $\bar{\mathbf{e}}$ and $\mathbf{e}$ which is defined symmetrically as

$$\text{sim}(\bar{\mathbf{e}}, \mathbf{e}) = \frac{1}{1 + \|\bar{\mathbf{e}} - \mathbf{e}\|}, \quad (2)$$

where $\|\bar{\mathbf{e}} - \mathbf{e}\|$ is the Euclidean distance between vectors $\bar{\mathbf{e}}$ and $\mathbf{e}$.

Before adding the generated candidate translations to the MT system, we also calculate the backward maximum likelihood translation probability using Bayes' Theorem:

$$\text{P}(f|e) = \frac{\text{P}(e|f)\text{P}(f)}{\text{P}(e)},$$

where the marginal probabilities are based on the counts of phrases seen in the monolingual corpora.

Similar to Saluja et al. (2014), we use word-based translation probabilities from the baseline system to obtain forward and backward lexicalized translation probabilities.

3.2 Local Linear Projection

The global linear projection uses a single projection matrix for all unlabeled source phrases. This is simple and fast but assumes that we can capture all relations between the source and target representation space with a single $\mathbb{R}^{d \times d}$ mapping. We show later that this is clearly not the case (§5.4) and that a single projection struggles particularly with infrequent phrases - the precise situation in which we would like our projection to be robust.

We therefore propose to learn many *local linear projections* which are individually trained for each unlabeled source phrase. Specifically, for each unlabeled source phrase $\mathbf{f}$, we learn a mapping $W_{\mathbf{f}} \in \mathbb{R}^{d \times d}$ based on the translations of m of $\mathbf{f}$'s labeled neighbors: $(\mathbf{f}_1, \mathbf{e}_1), (\mathbf{f}_2, \mathbf{e}_2), \ldots, (\mathbf{f}_m, \mathbf{e}_m)$, $\mathbf{f}_i \in N(\mathbf{f}), 1 \leq i \leq m, m \geq d$ (see Figure 2 (b)).

Compared to the global projection, we require an additional k-NN query to find the labeled neighbors for each unlabeled source phrase. However, this extra computation takes only a negligible amount of time, since the number of labeled phrases on the source side is significantly smaller than the number of phrases on the target side.

Our approach of learning many different mappings is similar to the *locality preserving projections* method of He and Niyogi (2004), which also construct a locally precise projection in order to map to another space.

3.3 Structured Label Propagation with Continuous Representation

Saluja et al. (2014) use Structured Label Propagation (SLP; Liu et al. 2012) to propagate candidate translations from frequent source phrases that are labeled to unlabeled neighbors that are infrequent.

The algorithm works as follows: for a known translation rule (f', e'), SLP propagates the target side phrases $e \in N(e')$, that are similar to e', to the unlabeled source phrases $f \in N(f')$, that are similar to f', as new translation rules. This propagation runs for several iterations. At each iteration, the translation probability between known translations is fixed. More formally, for iteration $t+1$ we have

$$\mathrm{P}^{t+1}(e|f) = \sum_{f' \in N(f)} T(f'|f) \sum_{e' \in H(f')} T(e|e') \mathrm{P}^{t}(e'|f'),$$

where $T(f'|f)$ is the probability that phrase f is propagated through phrase f', similarly for $T(e|e')$; $H(f')$ is the set of translation candidates for source phrase f', which is learned from the bilingual corpus.

In Saluja et al. (2014), both $T(f'|f)$ and $T(e|e')$ are based on the pairwise mutual information (PMI) between two phrases. Computing PMI statistics between any two phrases over a large corpus is infeasible and therefore the authors resort to a simple approximation that only considers co-occurrences with other phrases within a fixed-sized context window. Even after this simplification the running time of the SLP is vastly dominated by gathering similarity statistics and by constructing the resulting graph.

However, once the PMI statistics are collected and the graph is constructed, actual label propagation is very fast. To speed up the algorithm, we replace the costly PMI statistics by continuous phrase representations and adopt the same similarity measure that we used for the global and local projections (see Equation 1). Moreover, we replace the static graph construction with on-demand graph expansion using the fast phrase query mechanisms described in the next section. These modifications allow us to dramatically speed up the original SLP algorithm as demonstrated in our experiments (§5).

4 Fast Phrase Query with Continuous Representation

The algorithms presented in the previous section require rapid retrieval of neighboring phrases in continuous space. Linear search over all n candidate phrases is impractical, particularly for the SLP algorithm (§3.3). SLP requires the construction of a graph encoding the nearest neighbors for each target phrase, be it online or offline. To construct this graph naïvely requires $\mathcal{O}(n^2)$ comparisons which is clearly impractical for our setup where we have over one million target phrases (§5). For the linear projections, we still need to run at least one k-NN query in the target space for each infrequent foreign phrase.

Various methods, e.g., k-d trees, were proposed for fast k-NN queries but most of them are not efficient enough in high dimensional space, such as our setting. We therefore investigate *approximated* k-NN query methods which sacrifice some accuracy for a large gain in speed. Specifically, we look into locality sensitive hashing (LSH; §4.1), a popular method, as well as redundant bit vectors (RBV; §4.2), which to our knowledge has not been previously used for natural language processing tasks.

4.1 Locality Sensitive Hashing

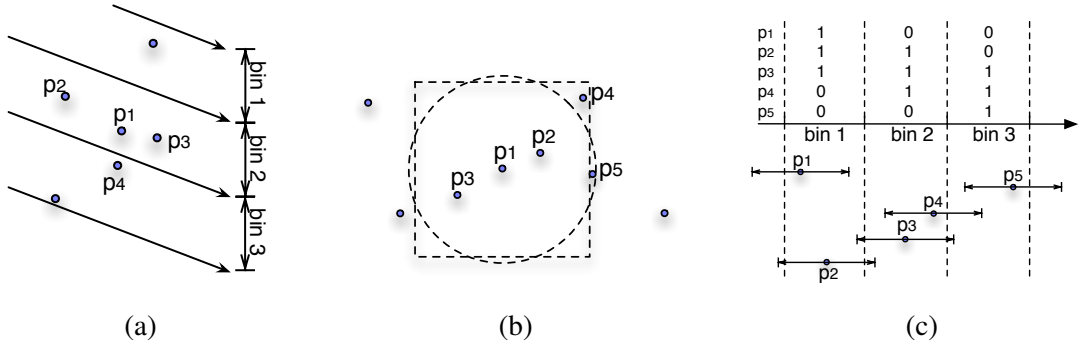
One popular approximated method is Locality Sensitive Hashing (LSH; Indyk and Motwani, 1998), which has been used in many NLP tasks such as noun clustering (Ravichandran et al., 2005), topic detection (Petrović et al., 2010), and fast k-NN query for similar words (Goyal et al., 2012).

For our particular task, assume each phrase is represented by a d-dimensional vector $\mathbf{p}$ of real values. The core of LSH is a set of hash functions. We choose p-stable distribution based functions (Datar et al., 2004) of the following form:

$$h_i(\mathbf{p}) = \lfloor \frac{\mathbf{x}_i \cdot \mathbf{p} + b_i}{w} \rfloor, 1 \leq i \leq s.$$

This function can be viewed as a quantized random projection, where each element in $\mathbf{x}_i$ is selected randomly from a Gaussian distribution $\mathcal{N}(0,1)$, w is the width of the bin, b_i is a linear bias selected from a uniform distribution $\mathcal{U}(0,w)$ (see Figure 3 (a)).

By concatenating the results from h_i, $1 \leq i \leq s$, phrase $\mathbf{p}$ is projected from d-dimensional space to



(a) (b) (c)

Figure 3: (a) A quantized random projection in LSH. The arrows show the direction of the projection. Points p_1, p_2, p_3 are correctly projected to the same bin, while p_4 falls into another bin, despite being very close to p_1. (b) A simplified example illustrating RBV in two dimensions. The circle with radius r is centered at $\mathbf{p}_1$ and contains all neighbors of $\mathbf{p}_1$. RBV approximates the circle by a square of width $d = 2 \times 0.95r$, which contains most of the neighbors of $\mathbf{p}_1$ but also $\mathbf{p}_4$, a false positive, while missing $\mathbf{p}_5$, a closer point. (c) On each dimension, RBV uses bit vectors to maintain the set of points whose hypercubes (represented as the segments on the points in 1-dimensional view) intersect with a bin.

an s-dimensional space. Phrases whose projections collide in the s-dimensional space are considered candidates to be neighbors. A fast retrieval of those colliding phrases can be done via a hash table. However, since the projection is random, it is very likely that true neighbors in the d-dimensional space fall into different bins after projection (false negatives; e.g., p_1 and p_4 in Figure 3 (a)). To ease this problem, LSH employs a set of such projections and runs a linear search over the *union* of all possible neighbor candidates resulting from these projections to find the approximated k-nearest neighbors.

4.2 Redundant Bit Vectors

The performance of LSH decreases as the number of dimensions grows. Redundant bit vectors (RBV; Goldstein et al., 2005) address this problem and can quickly search in high dimensional space, which suits our task better.

RBV is a combination of: a) an approximated neighborhood test designed for high dimensional space, and b) an efficient data structure for fast neighborhood query.

First, for a given point $\mathbf{p}$ in high dimensional space, the volume of a hypersphere of radius r centered at $\mathbf{p}$ can be approximately covered by a hypercube of width $d = 2\epsilon r$, $\epsilon \ll 1$.[3] Figure 3 (b) shows an illustration in two dimensional space where a square of width $d = 2 \times 0.95r$ covers most of a circle with radius r. In higher dimensional space, e.g., $d = 256$ as in Goldstein et al. (2005), we can cover 99% of the volume of a hypersphere of $r = 1$ with a hypercube whose width is only $\sim 2 \times 0.2r$.[4]

This surprising result allows us to use a very small hypercube to approximate the hypersphere. Furthermore, if two points $\mathbf{q}$ and $\mathbf{p}$ are within a certain radius r, i.e., $\|\mathbf{q} - \mathbf{p}\| \leq r$, then frequently $|\mathbf{q}^{(i)} - \mathbf{p}^{(i)}| \leq \epsilon r$, where $\mathbf{x}^{(i)}$ denotes the i-th element of vector $\mathbf{x}$. Thus, the neighbor query can be approximated as a check whether the distance between $\mathbf{p}$ and $\mathbf{q}$ on each dimension is less than ϵr, $\epsilon \ll 1$.

Second, each dimension is quantized into bins. Each bin *redundantly* maintains a set of points whose hypercubes intersect with the bin on that dimension. This set is an approximation of the neighbors of a query point $\mathbf{p}$ that falls into the same bin on this dimension. RBV uses *bit vectors* to store this set of points for each bin. (See Figure 3 (c).)

For a given query vector $\mathbf{p}$, we fetch the bins where $\mathbf{p}$ falls into for each dimension. We then per-

[3] Here we use $\ll$ in an imprecise way. $\epsilon \ll 1$ does not mean ϵ is smaller than 1 by orders of magnitudes; usually $\epsilon > 0.1$.

What we mean is that in high dimensional space, the volume of a hypercube of width $2\epsilon r$ is more than hundreds of magnitudes smaller than a hypercube of width $2r$.

[4] Note that this does not mean the volume of the hypercube is smaller than the hypersphere. It just means that most of the volume of the hypersphere is covered in the hypercube.

	English	Arabic	Urdu
Token count	5b	5b	75m
Word vector count	2.9m	2.7m	0.2m
Word vector train time	100hrs	100hrs	3hrs

Table 1: Monolingual corpora statistics, number of word vectors, and time to learn the word vectors (on single CPU core) for each source language.

form a bitwise *and* over the corresponding bit vectors to find the set of points that actually fall into $\mathbf{p}$'s hypercube, i.e., the approximated candidate neighbor set of $\mathbf{p}$. Finally, a linear search over this much smaller set finds the approximate k-nearest neighbors, similar to LSH.

5 Experiments

We first evaluate the speed and accuracy of the presented approximate k-NN query algorithms (§5.2). Next we experiment with the translation rule generation approaches (§5.3), and then we analyze the global and local projection methods (§5.4). Following Saluja et al. (2014), we present most results on Arabic-English translation and then validate our findings on Urdu-English (§5.5), a low-resource setting. Lastly, we discuss some qualitative results (§5.6).

5.1 Datasets & Preprocessing

We test our approach on both Arabic-English and Urdu-English translation. For Arabic-English our bilingual training data comprises of 685k sentence pairs. The NIST MT08 and MT09 data sets serve as tuning and testing sets, respectively. Both are combinations of newswire and weblog articles, and each Arabic sentence has four reference translations. For Urdu-English our bilingual training corpus contains 165k sentence pairs, and the tuning and testing sets are NIST MT08 and NIST MT09, respectively.

Table 1 shows some statistics for the monolingual data we use. The majority of the data for Arabic and English is drawn from the AFP Gigaword corpus. For Urdu most of the data is mined by a web crawler, mainly because there are not many official resources for this language.

We run standard tokenization and segmentation on the monolingual corpora. After that we use the Word2Vec tool (Mikolov et al., 2013b) to generate word embeddings for each language with the bag-of-words model, where the number of dimensions is set to $d = 300$. See Table 1 for the number of word vectors learned for each language.

	False Negative (%)	Time (s)
Linear Search	0	342
LSH	14.29	69
RBV	9.08	19

Table 2: Performance of linear search, locality sensitive hashing, and redundant bit vectors, for $k = 200$.

To obtain phrases in each language, we use a similar strategy as in Saluja et al. (2014). For Arabic and Urdu, we collect all unigrams and bigrams from the tuning and testing sets. This gives 0.66m phrases for Arabic and 0.2m phrases for Urdu. For English, we collect unigrams and bigrams from the monolingual data instead. However, the English monolingual corpus is much larger than the tuning and testing sets for Arabic and Urdu. We therefore train a language model over the monolingual data, and collect the unigrams and bigrams from the ARPA file, filtering out all candidates that have a probability smaller than 10^{-7}. Similar to Saluja et al. (2014), we use a baseline MT system to translate the Arabic or Urdu phrases and add their translations to the English phrase set. After this procedure we end up with 1.5m English phrases.

We use simple component-wise addition to generate phrase vectors from word vectors. Some rare words do not receive a vector representation after running Word2Vec, and we simply remove phrases containing those words, resulting in a total of 0.65m phrases for Arabic, 0.18m phrases for Urdu, and 1.2m phrases for English.

5.2 Evaluation of Approximated k-NN Query

We first evaluate the performances of different k-NN query approaches on English word vectors.

There are 2.9m word vectors in $d = 300$ dimensional space. We randomly select 1,000 words, and query for each word the 200 nearest neighbors, $k = 200$, with either linear search, LSH, and RBV. We measure the false negative ratio, i.e., the percentage of true neighbors missed by each query method, as well as time. For LSH and RBV, we tune the parameters for best performance (LSH: number of projected dimensions, number of layers, and width of

	Tune	Test	Time (hr)
Baseline	39.33	38.09	-
SLP w/ PMI	40.93	39.16	$\sim$10,000
SLP w/ Cont. Repr.	41.31	39.34	120+200
GLP	40.46	38.68	20+200
LLP	41.17	39.57	30+200
LLP w/ backoff	41.48	39.70	30+200

Table 3: Arabic-English translation accuracy of structured label propagation with PMI (SLP) and with continuous representations (SLP w/ PMI), the global linear projection (GLP), our local linear projection (LLP) and with an added backoff scheme (LLP w/ backoff). For applicable methods, we list the running time to compute distributional representations as a separate term in the time column. This is usually only required once per language which is why we report it separately.

the bin; RBV: hypercube width and number of bins for each dimension).

Table 2 shows that RBV gives significantly better performance than LSH, both in terms of accuracy and speed. RBV reduces the false negative ratio by $1/3$ compared to LSH and is 3.6 times faster. This is in line with Goldstein et al. (2005) who observed that the performance of LSH degrades in high dimensional space. We therefore use RBV in the following experiments.

5.3 Evaluation of Rule Generation

Next, we evaluate the quality of the generated translation rules for Arabic-English translation (Table 3) using either SLP, the global linear projection (GLP), or the local linear projection (LLP).

Our baseline system is an in-house phrase-based system similar to Moses with a 4-gram language model. The underlying log-linear model comprises of 13 features: two maximum likelihood translation probabilities, two lexicalized translation probabilities, five hierarchical reordering model features (Galley and Manning, 2008), one language model, word penalty, phrase length, and distortion penalty), and is tuned with minimum error rate training (MERT; Och 2003). Translation quality is measured with BLEU (Papineni et al., 2002).

For comparison, we reimplemented the graph-based method in Saluja et al. (2014). This method calculates the pairwise mutual information (PMI) between phrases, and employs all the techniques mentioned in Saluja et al. (2014) to speedup the computations. Our reimplementation achieves similar performance to Saluja et al. (2014) (with a negligible $\sim$ 0.06 drop in BLEU). We parallelized the algorithm on a cluster since a single core implementation would run for $\sim$10k hours.[5]

Our continuous phrase based version of SLP is orders of magnitudes faster than the SLP variant of Saluja et al. (2014) because it replaces the computationally expensive PMI calculation by an approximated k-NN query in distributional space. Moreover, our variant of SLP even improves translation quality by 0.2-0.3 BLEU. Overall, our version of SLP improves the baseline by 2.0 BLEU on the tuning set and by 1.3 BLEU on the test set.

The linear projection based methods, GLP and LLP, are in turn again several times faster than SLP with continuous representations. This is because they require significantly fewer k-NN queries. For both GLP and LLP, we retrieve the 200 nearest neighbors of the projected point. For LLP, the local projection is calculated based on the 500 nearest labeled neighbors of the infrequent source phrase. LLP achieves slightly better accuracy on the test set than PMI-based SLP but at four times the speed. GLP is the fastest method but also the least accurate, improving the baseline only by about 0.6 BLEU. We explore this result in more detail in the next section. Overall, our local projection outperforms the global projection by 0.9 BLEU on the test set.

For some infrequent source phrases, approximated k-NN query does not retrieve enough ($\geq d$) neighbors to learn a local linear projection. For these phrases, we employ a *backoff* strategy that uses the translations of their neighbors as additional translation candidates. This strategy provides helpful additional rules for LLP (Table 3).[6]

5.4 Evaluation of Global Linear Projection

To learn why GLP does not generate high quality translation rules, we run an extra experiment to measure the projection quality of GLP.

We train a global linear projection on an increas-

[5]Confirmed with the authors of Saluja et al. (2014) from personal communication.

[6]The backoff scheme in the Arabic-English setting generates around 15% of the translations rules, which adds 0.13 BLEU on the test set. This is not a big improvement and so we did not employ this scheme for our Urdu-English experiments.

Training Set	Hit Rate: Freq	Hit Rate: Infreq.
500	0.87	0
1,000	0.6	0.01
5,000	0.42	0.07
25,000	0.4	0.05

Table 4: Quality of global linear projection measured by the ratio that GLP can fetch the most possible translation in the 200-nearest neighbors.

	Tune	Test	Time (hr)
Baseline	26.32	27.41	-
SLP w/ PMI	27.26	27.89	∼7,000
SLP w/ Cont. Repr.	27.34	27.73	100+103
LLP	27.06	27.98	30+103

Table 5: Urdu-English translation accuracy (cf. Table 3).

ing amount of training data and measure its accuracy on two test sets (Table 4). The first test set contains the 100 most frequent source phrases and their translations. The second test set contains less frequent examples; we choose the 50,000 to 50,100 most frequent source phrases. The training data uses the l most frequent source phrases and their translations which are not already contained in the first test. The projection quality is measured by the ratio of how many times the correct translation is one of the 200-nearest neighbors of the projected point computed by GLP.

The results in Table 4 clearly show that GLP can find the best translation for very frequent source phrases which is in line with previous work Mikolov et al. (2013a). However, the accuracy for infrequent phrases is poor. This explains why GLP helps relatively little in our translation experiments because our setup requires a method that can find good translations for infrequent source phrases.

5.5 Evaluation on Urdu-English

Resources for Urdu are limited compared to Arabic (§5.1) which results in fewer word vectors and fewer source phrases. This will also affect the quality of the word vectors in Urdu, since more training data usually results in better representations.

Table 5 shows that the improvements of both SLP and LLP in Urdu-English are not as significant as for Arabic-English. Our reimplementation of SLP is ~ 1 BLEU better on the tuning set than the baseline, and ~ 0.5 BLEU better on the test set. As expected, the translation quality improvement on small corpora is not as significant as on large corpora like Arabic, since the monolingual data in Urdu is much smaller than for Arabic (75m tokens vs. 5b tokens) which makes it more difficult to learn good representations. In general, with continuous representations, SLP and LLP achieve similar performance to PMI-based SLP but the projection based methods are orders of magnitudes faster.

Figure 4: Examples of the generated rules from LLP.

5.6 Analysis of Output

Figure 4 shows some examples of the translation rules produced by our system. The first five examples are for the Arabic-English system, while the last five are for the Urdu-English system. All source phrases are unknown to the baseline system which usually results in sub-optimal translations. Our system on the other hand, managed to generate translation rules for them. The Arabic-English examples show mostly morphological variants of phrases which did not appear in the parallel data; this can be helpful for highly inflected languages since most of the inflectional variations are underrepresented in the parallel data. The Urdu-English examples show mostly unknown phrases since there is much less parallel data than for Arabic.

6 Conclusion and Future Work

In this work, we showed how simple continuous representations of phrases can be successfully used to induce translation rules for infrequent phrases and demonstrated substantial gains in translation accuracy. Continuous representations not only increase the speed of the semi-supervised approach of Saluja et al. (2014) by two orders of magnitude but also improve its accuracy at the same time. Simpler

linear projections are up to three orders of magnitudes faster once phrasal representations have been learned and can be as accurate. Our novel local linear projection is much more accurate than the global projection of Mikolov et al. (2013a) at only a small increase in running time. This brings us closer to generating new translation rules on-the-fly for unseen sentences. Finally, we showed that redundant bit vectors are three times faster but also significantly more accurate than locality sensitive hashing in our setting. To our knowledge this is the first application of redundant bit vectors on a natural language processing task.

In future work, we would like to investigate more elaborate projection schemes that use contextual information from the source side or non-linear projections. Furthermore, we would like to apply redundant bit vectors to other NLP tasks.

Abstract

This paper introduces a task of identifying and semantically classifying lexical expressions in running text. We investigate the online reviews genre, adding semantic supersense annotations to a 55,000 word English corpus that was previously annotated for multiword expressions. The noun and verb supersenses apply to full lexical expressions, whether single- or multiword. We then present a sequence tagging model that jointly infers lexical expressions and their supersenses. Results show that even with our relatively small training corpus in a noisy domain, the joint task can be performed to attain 70% class labeling F_1.

1 Introduction

The central challenge in computational lexical semantics for text corpora is to develop and apply abstractions that characterize word meanings beyond what can be derived superficially from the orthography. Such abstractions can be found in type-level human-curated lexical resources such as WordNet (Fellbaum, 1998), but such intricate resources are expensive to build and difficult to annotate with at the token level, hindering their applicability beyond a narrow selection of languages and domains. A more portable and scalable—yet still linguistically-grounded—way to represent lexical meanings is with coarse-grained semantic classes. Here we build on prior work with an inventory of semantic classes (for nouns and verbs) known as **supersenses**. The 41 supersenses resemble the types used for named entities (PERSON, LOCATION, etc.), but are more general, with semantic categories relevant to common nouns and verbs as well. As a result, their application to sentences is dense (describing a large proportion of tokens), in contrast to annotations that only describe named entities.

Because most supersense tagging studies have worked with data originally annotated for fine-grained WordNet senses, then automatically mapped to supersenses, the resulting systems have been tied to the lexical coverage of WordNet. Schneider et al. (2012) and Johannsen et al. (2014) overcame this limitation in part by annotating supersenses directly in text; thus, nouns and verbs not in WordNet were not neglected. However, the issue of which *units* ought to receive supersenses has not been addressed satisfactorily. We argue that the semantically holistic nature of **multiword expressions** (MWEs) including idioms, light verb constructions, verb-particle constructions, and many compounds (Baldwin and Kim, 2010) means that they should be considered as units for manual and automatic supersense tagging.

Below, we motivate the need for an integrated representation for broad-coverage lexical semantic analysis that identifies MWEs and labels single- and multiword noun and verb expressions with supersenses (§2). By annotating supersenses directly on sentences with existing comprehensive MWE annotations, we circumvent WordNet's spotty coverage of many kinds of MWEs (§3). Then we demonstrate that the two kinds of information are readily combined in a discriminative sequence tagging model (§4). Notably, our analyzer handles gappy expressions that are ignored by existing supersense taggers, and it marks miscellaneous MWEs even though they do not receive a noun or verb supersense.

Table 1: Summary of noun and verb supersense categories. Each entry shows the label along with the count and most frequent lexical item in the STREUSLE corpus.

enrich the MWE annotations of the CMWE corpus[1] (Schneider et al., 2014b), are publicly released under the name STREUSLE.[2] This includes new guidelines for verb supersense annotation. Our open-source tagger, implemented in Python, is available from that page as well.

2 Background: Supersense Tags

WordNet's **supersense** categories are the top-level hypernyms in the taxonomy (sometimes known as **semantic fields**) which are designed to be broad enough to encompass all nouns and verbs (Miller, 1990; Fellbaum, 1990).[3]

The 26 noun and 15 verb supersense categories are listed with examples in table 1. Some of the names overlap between the noun and verb inventories, but they are to be considered separate categories; hereafter, we will distinguish the noun and verb categories with prefixes, e.g. N:COGNITION vs. V:COGNITION.

Though WordNet synsets are associated with lexical entries, the supersense categories are unlexicalized. The N:PERSON category, for instance, contains synsets for both *principal* and *student*. A different sense of *principal* falls under N:POSSESSION.

As far as we are aware, the supersenses were originally intended only as a method of organizing the WordNet structure. But Ciaramita and Johnson (2003) pioneered the coarse word sense disambiguation task of **supersense tagging**, noting that the supersense categories provided a natural broadening of the traditional named entity categories to encompass all nouns. Ciaramita and Altun (2006) later expanded the task to include all verbs, and applied a supervised sequence modeling framework adapted from NER. Evaluation was against manually sense-tagged data that had been automatically converted to the coarser supersenses. Similar taggers have since been built for Italian (Picca et al., 2008) and Chinese (Qiu et al., 2011), both of which have their own WordNets mapped to English WordNet.

Although many of the annotated expressions in existing supersense datasets contain multiple words, the relationship between MWEs and supersenses has not received much attention. (Piao et al. (2003, 2005) did investigate MWEs in the context of a lexical tagger with a finer-grained taxonomy of semantic classes.) Consider these examples from online reviews:

(1) IT IS NOT A HIGH END STEAK HOUSE

(2) The white pages allowed me to get in touch with parents of my high school friends so that I could track people down one by one

HIGH END functions as a unit to mean 'sophisticated, expensive'. (It is not in WordNet, though

[1] `http://www.ark.cs.cmu.edu/LexSem/`

[2] Supersense-Tagged Repository of English with a Unified Semantics for Lexical Expressions

[3] WordNet synset entries were originally partitioned into **lexicographer files** for these coarse categories, which became known as "supersenses." The `lexname` function in WordNet/NLTK (Bird et al., 2009) returns a synset's lexicographer file.

A subtle difference is that a special file called `noun.Tops` contains each noun supersense's root synset (e.g., `group.n.01` for N:GROUP) as well as a few miscellaneous synsets, such as `living_thing.n.01`, that are too abstract to fall under any single supersense. Following Ciaramita and Altun (2006), we treat the latter cases under an N:OTHER supersense category and merge the former under their respective supersense.

it could be added in principle.) Assigning a semantic class such as N:LOCATION to *END* would, in our judgment, be overly literal. To paint a coherent picture of the meaning of this sentence, it is better to treat *HIGH END* as a single unit, and because it serves as an adjective rather than a noun or verb, leave it semantically unclassified.[4]

STEAK HOUSE is arguably an entrenched enough compound that it should receive a single supersense—in fact, WordNet spells it without a space. The phrases *white pages*, *high school*, *(get) in touch (with)*, *track... down*, and *one by one* all are listed as MWEs in WordNet. As detailed in §4.1 below, the conventional BIO scheme used in existing supersense taggers is capable of representing most of these. However, it does not allow for gappy (discontinuous) uses of an expression, such as ***track*** *people* ***down***.

The corpus and analyzer presented in this work address these shortcomings by integrating a richer, more comprehensive representation of MWEs in the supersense tagging task.

3 Supersense Annotation for English

As suggested above, supersense tags offer a practical semantic label space for an integrated analysis of lexical semantics in context. For English, we have created the STREUSLE dataset, which fully annotates the REVIEWS corpus (55k words) for noun and verb supersenses in a manner consistent with Schneider et al.'s (2014b) multiword expression annotations.

Schneider et al. (2012) offered a methodology for noun supersense annotation in Arabic Wikipedia, and predicted that it would port well to other languages and domains. Our experience with English web reviews has borne this out. We generally adhered to the same supersense annotation process (for nouns); the most important difference was that the data had already been annotated for MWEs, and supersense labels apply to any strong[5] MWEs as a whole.

The same annotators had already done the MWE annotation; whenever they encountered an apparent mistake from an earlier stage (usually an oversight), they were encouraged to correct it. Our annotation interface supports modification of MWEs as well as supersense labels in one view.

To lessen the cognitive burden when reasoning about tagsets, supersense annotation was broken into separate phases: first we annotated nearly the entire REVIEWS corpus for noun supersenses; then we made another pass to annotate for verbs. Roughly a tenth of the sentences were saved for a combined noun+verb phase at the end; annotators reported that constantly switching their attention between the two tagsets made this mode of annotation more difficult.

3.1 Nouns

Targets. Per the annotation standard, all noun singletons and noun-like MWEs should receive a noun supersense label. Annotation targets were determined heuristically from the gold (PTB-style) POS tags in the corpus: all lexical expressions containing a noun[6] were selected. This heuristic overpredicts noun-like MWEs occasionally because it does not check the syntactic status of the MWE as a whole. During this phase, the backtick symbol (`) was therefore reserved for MWEs (such as light verb constructions) that contain a noun but should not receive a noun supersense.[7] The annotation interface prevented submission of blank annotation targets to avoid oversights.

Tagset conventions. Several brief annotation rounds were devoted to practice with Schneider et al.'s (2012) noun annotation guidelines,[8] since the annotators were new to the scheme. Metonymy posed the chief difficulty in this domain: institutions with a premises (such as restaurants, hotels, and schools) are frequently ambiguous between N:GROUP (institution as a whole), N:ARTIFACT (the building), and N:LOCATION (site as a whole). Our convention was to use the reading that seemed most salient in context: for example, *restaurant* in a comment about the qual-

[4] Future supersense annotation schemes for additional parts of speech could be assimilated into our framework. Tsvetkov et al. (2014) take a step in this direction for adjectives.

[5] The CMWE corpus distinguishes **strong** and **weak** MWEs—essentially, the former are strongly entrenched and likely non-compositional, whereas weak MWEs are merely statistically collocated. See Schneider et al. (2014b) for details. Because they are deemed semantically compositional, weak MWEs do not receive a supersense as a whole.

[6] Specifically, any POS tag starting with N or ADD (web addresses); pronouns were excluded.

[7] Pronouns like *anything* also fall into this category because they are POS-tagged as nouns.

[8] http://www.ark.cs.cmu.edu/ArabicSST/corpus/guidelines.html

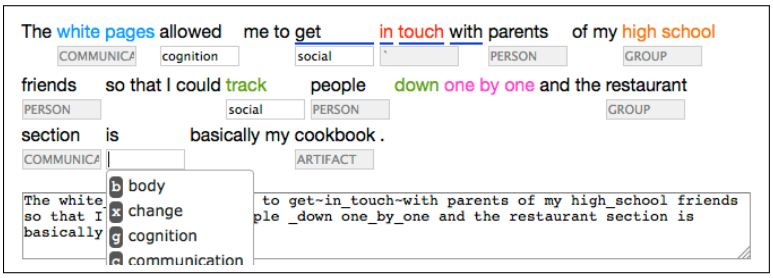

Figure 1: Annotation interface, with dropdown menu for verb supersenses. The large text box at the bottom can be used to edit the MWE annotation by typing underscores and tildes to connect tokens.

ity of the service would be labeled N:GROUP.[9] Some subjectivity is involved, suggesting that the scheme is not ideal for such multifaceted concepts.

3.2 Verbs

Targets. The set of lexical expressions that should receive a verb supersense consists of (a) all verb singletons that are not auxiliaries, and (b) all verb-like MWEs. Again, simple but overly liberal heuristics were used to detect annotation targets, so wherever the heuristics overpredicted, annotators entered:

- `a for auxiliary verbs
- `j for adjectives (some *-ing* and *-ed* adjectives are POS-tagged as VBG and VBD, respectively)
- ` for all other cases

Tagset conventions. We wrote new guidelines to characterize the verb supersenses for annotation. They briefly define and exemplify each category, and also relate them via precedence rules: e.g., the rule

$$\{\text{V:PERCEPTION}, \text{V:CONSUMPTION}\} > \text{V:BODY} > \text{V:CHANGE}$$

stipulates that verbs of perception or consumption (*hear*, *eat*, etc.) be labeled as such rather than the less specific class V:BODY. The precedence rules help to resolve many of the cases of meaning overlap between the categories. The guidelines were developed over several weeks and informed by annotation difficulties and disagreements. We release them along with the STREUSLE corpus.

3.3 Interface

We extended the online MWE annotation tool of Schneider et al. (2014b) to also support supersense labeling, as well as grouping tokens into multiword lexical expressions. This is visualized in figure 1. Specifically, singletons and strong MWEs may receive labels (subject to a POS filter). This allows the two types of annotation to be worked on in tandem, especially when a supersense annotator wishes to change a multiword grouping. The tool offers an autocomplete dropdown menu when typing a tag name, and validates that the submitted annotation is complete and internally consistent. Additionally, the tool provides a complete version history of the sentence and a "reconciliation" mode that merges two users' annotations of a sentence, flagging any differences for manual resolution; these features are extremely useful when breaking the annotation down into multiple rounds among several annotators.

3.4 Quality Control

There were 2 primary annotators and 3 others who participated in annotation to a lesser degree, including the first author of this paper, whose role was mainly supervisory. All 5 hold bachelor's degrees in linguistics. The annotators were trained in the noun supersense annotation scheme of Schneider et al. (2012) and cooperatively developed and documented interpretations for the verb supersenses. Our main quality control mechanism for the annotation process was to obtain two independent annotations for every sentence—differences between them were reconciled by negotiation (between the two annotators in most cases, and between the two primary annotators in a small number of cases).

To get a sense of the difficulty of the task, we examine the annotation history for a sample of sentences to measure inter-annotator agreement. Estimated between the 2 primary annotators on the batch of sentences annotated last during each phase (350, 302, and 379 sentences, respectively), inter-annotator F_1 scores (excluding auxiliaries and other miscellaneous categories) are: 76% for noun expression supersenses after the noun phase, 93% for verb expression supersenses after the verb phase, and 88% for all supersenses after the combined annotation phase.[10] These

[9] This rule is sometimes at odds with WordNet, which only lists N:ARTIFACT for *hotel* and *restaurant*.

[10] Cohen's κ, limited to tokens for which both annotators

are over different sentences, so they are not directly comparable, but they point to the robustness of the annotation scheme. Thanks to the double annotation plus reconciliation procedure, these numbers should underestimate the reliability of the final annotations.

3.5 Corpus Statistics

A total of 9,000 noun mentions (1,300 of them MWEs) and 7,800 verb mentions (1,200 MWEs) incorporating 20,000 word tokens are annotated.[11] Table 1 shows supersense mention counts and the most frequent example of each category in the corpus.

3.6 Copenhagen Supersense Data

An independent English noun+verb supersense annotation effort targeting the Twitter domain was undertaken by the COASTAL lab at the University of Copenhagen (Johannsen et al., 2014). The overarching goal of annotating supersenses directly in running text was the same as in the present work, but there are three important differences. First, general-purpose MWE annotations were not considered in that work; second, sentences were pre-annotated by a heuristic system and then manually corrected, whereas here the annotations are supplied from scratch; and third, Johannsen et al. (2014) provided minimal instructions and training to their annotators, whereas here we have worked hard to encourage consistent interpretations of the supersense categories. Johannsen et al. have released their annotations on two samples of tweets (over 18,000 tokens in total).

Johannsen et al.'s dataset illustrates why supersense annotation by itself is not the same as the full scheme for lexical semantic analysis proposed here. Many of the expressions that they have supersense-annotated as single-word nouns/verbs probably would have been part of larger units in MWE annotation: examining Johannsen et al.'s in-house sample, multiword chunks arguably should have been used for verb phrases like *gain entry*, *make sure*, and *make it* ('succeed'), and for verb-particle constructions like *take over*, *find out*, and *check out* ('ogle'). Moreover, in the traditional supersense annotation scheme, there are no chunks not labeled with a supersense; thus, e.g., PPs such as *on tap*, *of ALL-Time*, and *up to [value limit]* are not chunked.

Many of the nominal expressions in Johannsen et al.'s (2014) data appear to have overly liberal boundaries, grouping perfectly compositional modifiers along with their heads as a multiword chunk: e.g., *Panhandling Ban*, *Panda Cub*, *farm road crash*, and *Tomic's dad*. Presumably, some of these were boundary errors made by the heuristic pre-annotation system that human annotators failed to notice.

4 Automatic Tagging

We now turn to automating the combined multiword expression and supersense prediction task in a single statistical model.

4.1 Background: Supersense Tagging with a Discriminative Sequence Model

Ciaramita and Altun's (2006) model represents the state of the art for full[12] English supersense tagging on the standard SemCor test set, achieving an F_1 score of 77%. It is a feature-based discriminative sequence model learned in a supervised fashion with the structured perceptron (Collins, 2002).

For Ciaramita and Altun (2006) and hereafter, sequences correspond to sentences, with each sentence pre-segmented into words according to some tokenization. Figure 2 shows how token-level tags combine Ramshaw and Marcus (1995)–style BIO flags with supersense class labels to represent the segmentation and supersense labeling of a sentence. These tags are observed during training, predicted at test time, and compared against the gold standard tags.

Ciaramita and Altun's (2006) model uses a simple feature set capturing the lemmas, word shapes, and parts of speech of tokens in a small context window, as well as the supersense category of the first WordNet sense of the current word. (WordNet senses are ordered roughly by frequency.) On SemCor data, the model achieves a 10% absolute improvement in F_1 over the first sense baseline.

assigned a supersense, is very similar: .76, .93, and .90, respectively, reflecting strong agreement.

[11] This excludes 1,200 auxiliary verb mentions, 100 of which are MWEs: *have to*, *is going to*, etc.

[12] Paaß and Reichartz (2009) train a similar sequence model for classifying noun and verb supersenses, but treat multiword phrases as single words. Their model is trained as a CRF rather than a structured perceptron, and adds LDA word cluster features, but the effects of these two changes are not separated in the experiments. They also find benefit from constraining the label space according to WordNet for in-vocabulary words (with what they call "lumped labels").

Figure 3: Tagging for part of the lexical semantic analysis depicted in figure 1. Note that for nominal and verbal MWEs, the supersense label is only attached to the first tag of the expression.

Though our focus in this paper is on English, automatic supersense tagging has also been explored in Italian (Picca et al., 2008, 2009; Attardi et al., 2010, 2013; Rossi et al., 2013), Chinese (Qiu et al., 2011), and Arabic (Schneider et al., 2013).

4.2 Model

Like Ciaramita and Altun (2006) and Schneider et al. (2014a), we train a first-order structured perceptron (Collins, 2002) with averaging. This is a standard discriminative modeling setup, involving: a linear scoring function over features of input–output pairs; a Viterbi search to choose the highest-scoring valid output tag sequence given the input; and an online learning algorithm that makes M passes through the training data, searching for the best tagging given the current model and updating the parameters (linear feature weights) where the best tagging doesn't match the gold tagging. With a first-order Markov assumption and tagset $\mathcal{Y}$, the Viterbi search for a sentence $\mathbf{x}$ requires $O(|\mathcal{Y}|^2 \cdot |\mathbf{x}|)$ runtime. The dataset used to train and evaluate the model, the tagging scheme, and the features are described below.

4.3 Data

The STREUSLE dataset, as described in §3, is annotated for multiword expressions as well as noun and verb supersenses and auxiliary verbs. We use this dataset for training and testing an integrated lexical semantic analyzer. Schneider et al. (2014a) used the CMWE dataset—i.e., the same REVIEWS sentences, but annotated only for MWEs. A handful of apparent errors in the MWE analyses were fixed in the course of our supersense annotation.

4.4 Tagset

In the STREUSLE dataset, supersense labels apply to *strong* noun and verb expressions—i.e., singleton nouns/verbs as well as strong nominal/verbal MWEs. Weak MWEs are not holistically labeled with a supersense (see fn. 5).

The 8-way scheme. To encode the lexical segmentation via token-level tags, we use the 8-way scheme from Schneider et al. (2014a) for positional flags. The 8-way scheme extends Ramshaw and Marcus's (1995) BIO chunking tags to also encode (a) a strong/weak distinction for MWEs, and (b) gappy MWEs (there is no formal limit on the number of gaps per MWE or the number of other lexical expressions occurring within each gap, though there is a limit of one level of nesting). The 4 lowercase positional flags indicate that an expression is within a gap, and otherwise have the same interpretation as their uppercase counterparts, which are:

- `0` for single-word expressions
- `B` for the first word of an MWE
- `Ī` for a word continuing a *strong* MWE
- `Ĩ` for a word weakly linked to its predecessor, forming a *weak* MWE[13]

As with the original BIO scheme, a globally well-formed sequence of tags in the 8-tag scheme can be constructed by respecting bigram constraints.[14]

Adding class labels. The tagset used to annotate the data for our tagger combines 8-way positional flags with supersense class labels. We decorate class labels only on beginners of strong lexical expressions—so this includes `0` or `o` on a single-word noun or verb, but always excludes `Ī` and `ī`.[15] Figure 3

[13] Weak MWE links may join together strong MWEs.

[14] Among these constraints are: `B` must always be immediately followed by `Ī` or `Ĩ` (because `B` marks the beginning of an MWE); and within-gap (lowercase-tagged) tokens must immediately follow a tag other than `0` and precede a tag other than `0` or `B`.

[15] Unlike prior work with the plain BIO scheme, we do not include the class in tags continuing a (strong) MWE, though the

gives an example. In this formulation, bigram constraints are sufficient to ensure a globally consistent tagging of the sentence.

There are $|\mathcal{N}| = 26$ noun supersense classes and $|\mathcal{V}| = 16$ verb classes (including the auxiliary verb class, abbreviated `a). In principle, then, there are

$$\underbrace{|\{\texttt{0 o B b \tilde{I} \tilde{i}}\}|}_{6} \times \underbrace{(1 + |\mathcal{N}| + |\mathcal{V}|)}_{43} + \underbrace{|\{\bar{\texttt{I}}\ \bar{\texttt{i}}\}|}_{2} = 260$$

possible tags encoding position and class information, allowing for chunks with no class because they are neither nominal nor verbal expressions. In practice, though, many of these combinations are nonexistent in our data; for experiments we only consider tags occurring in **train**, yielding $|\mathcal{Y}| = 146$.

We also run a condition where the supersense refinements are collapsed, i.e. $\mathcal{Y}$ consists of the 8 MWE tags. This allows us to measure the impact of the supersenses on MWE identification performance.

4.5 Features

We constrast three feature sets for full supersense tagging: (a) Schneider et al.'s (2014a) basic MWE features, which include lemmas, POS tags, word shapes, and whether the token potentially matches entries in any of several multiword lexicons; (b) the basic MWE features plus the Brown clusters (Brown et al., 1992) used by Schneider et al. (2014a); and (c) the basic MWE features and Brown clusters, plus several new features shown in figure 4. Chiefly, these new features consult the supersenses of WordNet synsets associated with words in the sentence: the first WordNet supersense feature is inspired by Ciaramita and Altun (2006) and subsequent work on supersense tagging, while the has-supersense feature is novel. There is also a feature aimed at distinguishing auxiliary verbs from main verbs, and new capitalization features take into account the capitalization of the first word in the sentence and the majority of words in the sentence. To keep the system as modular as possible, we refrain from including any features that depend on a syntactic parser.

class label should be interpreted as extending across the entire expression. This is for a technical reason: as our scheme allows for gaps, the classes of the tags flanking a gap in a strong MWE would be required to match for the analysis to be consistent. To enforce this in a bigram tagger, the within-gap tags would have to encode the gappy expression's class as well as their own, leading to an undesirable blowup in the size of the state space.

New Capitalization Features

1. capitalized $\wedge$ $[\![i = 0]\!]$ $\wedge$ [majority of tokens in the sentence are capitalized]
2. capitalized $\wedge$ $i > 0$ $\wedge$ w_0 is lowercase

Auxiliary Verb vs. Main Verb Feature

3. pos_i is a verb $\wedge$ $[\![pos_{i+1}$ is a verb $\vee$ (pos_{i+1} is an adverb $\wedge$ pos_{i+2} is a verb)$]\!]$

WordNet Supersense Features (unlexicalized)

Let $cpos_i$ denote the coarse part-of-speech of token i: common noun, proper noun, pronoun, verb, adjective, adverb, etc. This feature aims primarily to inform the supersense label on the first token of nominal compounds and light verb constructions, where the "semantic head" is usually a common noun subsequent to the beginning of the expression:

4. subsequent noun's 1st supersense: where $cpos_i$ is a common noun, verb, or adjective, $cpos_i$ $\wedge$ for the smallest $k > i$ such that pos_k is a common noun, the supersense of the first WordNet synset for lemma λ_k—provided there is no intervening verb (j such that $cpos_j$ is a verb and $i < j < k$)

The following two feature templates depend on the tag y_i. Let $flag(y_i)$ denote the positional flag part of the tag (`0`, `B`, etc.) and $sst(y_i)$ denote the supersense class label:

5. 1st supersense:
   - if $flag(y_i) \in \{\texttt{0}, \texttt{o}\}$: the supersense of the first WordNet synset for lemma λ_i
   - else if $cpos_i$ is a verb and there is a subsequent verb particle at position $k > i$ with no intervening verb: the supersense of the first synset for the compound lemma $\langle \lambda_i, \lambda_k \rangle$ (provided that the particle verb is found in WordNet)
   - otherwise: the supersense of the first WordNet synset for the longest contiguous lemma starting at position i that is present in WordNet: $\langle \lambda_i, \lambda_{i+1}, \ldots, \lambda_j \rangle$ $(j \geq i)$
6. has supersense: same cases as the above, but instead of encoding the highest-ranking synset's supersense, encodes whether $sst(y_i)$ is represented in any of the matched synsets for the given lemma. Note that for a given token, this feature can take on different values for different tags.

Figure 4: New features for MWE and supersense tagging. They augment the basic MWE feature set of Schneider et al. (2014a), and are conjoined with the current tag, y_i.

The model's percepts (binary or real-valued functions of the input[16]) can be conjoined with any tag $y \in \mathcal{Y}$ to form a feature that receives its own weight

[16] We use the term **percept** rather than "feature" here to emphasize that we are talking about functions of the input only, rather than input–output combinations that each receive a parameter during learning.

(parameter). To avoid having to learn a model with tens of millions of parameters, we impose a percept cutoff during learning: only zero-order percepts that are active at least 5 times in the training data (with any tag) are retained in the model (with features for all tags). There is no minimum threshold for first-order percepts.[17] The resulting models are of a manageable size: about 4 million parameters with the full tagset.

4.6 Experimental Setup

Our setup mostly echoes that of Schneider et al. (2014a). We adopt their **train** (3312 sentences/ 48k words) vs. **test** (500 sentences/7k words) split, and tune hyperparameters by 8-fold cross-validation on **train**. By this procedure we chose a percept cutoff of 5 to use throughout, and tuned the number of training iterations for each experimental condition (early stopping within each cross-validation fold so as to greedily maximize tagging accuracy on the held-out portion, and averaging the best number of iterations across folds). For simplicity, we use oracle POS tags in our experiments and do not use Schneider et al.'s (2014a) recall-oriented cost function. Experiments were managed with Jonathan Clark's `ducttape` tool.[18]

4.7 Results

Table 2 shows full supersense tagging results, separating the MWE identification performance (measured by link-based precision, recall, and F_1; see Schneider et al., 2014a) from the precision, recall, and F_1 of class labels on the first token of each expression (segments with no class label are ignored).[19] Exact tagging accuracy (last column) is higher because it rewards true negatives, i.e. single-word segments with no nominal or verbal class label (the `0` and `o` tags).

Tag space. The sequence tagging framework makes it simple to model MWE identification jointly with supersense tagging: this is accomplished by packing information about both kinds of output into the tags. But there is always a risk that a larger tag space will impair the model's ability to generalize. By comparing the first two rows of the results, we can see that jointly modeling supersenses along with multiword expressions results in only a minor decrease (<2 F_1 points) in MWE identification performance under the most basic feature set. Further, we see that most of that decrease is recovered with richer features. Thus, we conclude that it is empirically reasonable to model these phenomena together.

Runtime. Our final system (146 tags; last row of table 2) tags ≈140 words (10 sentences) per second.

Features. Comparing the bottom three rows in the table indicates that features that generalize beyond lexical items lead to better supersense labeling. The best model has access to supersense information in the WordNet lexicon; it is 4 F_1 points better at choosing the correct class label than its nearest competitor, which relies on word clusters to abstract away from individual lexical items. Nouns, verbs, and auxiliaries all see improvements.

We also inspect the learned parameters. The highest-weighted parameters suggest that the best model relies heavily on the supersense lookup features, whereas the second-best model—lacking those—in large part relies on Brown clusters (cf. Grave et al., 2013). The auxiliary verb vs. main verb feature in the best model is highly weighted as well, helping to distinguish between `a and V:STATIVE.

Polysemy. We have motivated the task of supersense tagging in part as a coarse form of word sense disambiguation. Therefore, it is worth investigating how well the learned model manages to choose the correct supersense for nouns and verbs that are ambiguous in the data. A handful of lemmas in **test** have at least two different supersenses predicted several times; an examination of four such lemmas in table 3 shows that for three of them the tagging accuracy exceeds the majority baseline. In the case of *look*, the model is usually able to distinguish between V:COGNITION (as in *looking for a company with decent rates*) and V:PERCEPTION (as in *sometimes the broccoli looks browned around the edges*).

Out-of-domain baseline. To assess the importance of in-domain data for learning, we used a SemCor-trained supersense tagger—a reimplemen-

[17] Zero-order percepts are percepts which are to be conjoined with only the present tag to form zero-order features. First-order percepts are to be conjoined with the present and previous tags.

[18] `https://github.com/jhclark/ducttape/`

[19] We count the class label only once for MWEs—otherwise this measure would be strongly dependent on segmentation performance. However, the MWE predictions do have an effect when the prediction and gold standard disagree on which token begins a strong nominal or verbal expression.

				MWE ID			Class labeling						Tag
Feature Set	$\lvert\mathcal{Y}\rvert$	Model Size	M	P	R	F_1	P	R	F_1	NSST R	VSST R	Aux R	Acc
MWE	8	194k	4	**72.97**	**55.55**	**63.01**	—	—	—	—	—	—	—
MWE	146	3,555k	5	67.77	55.76	61.14	64.68	66.78	65.71	59.14	71.64	93.71	80.73
MWE+clusters	146	4,371k	5	68.55	**56.73**	62.04	65.69	67.76	66.71	61.49	71.34	92.45	81.20
MWE+clusters+SST	146	4,388k	4	**71.05**	56.24	**62.74**	**69.47**	**71.90**	**70.67**	**66.95**	**74.17**	**94.97**	**82.49**

Table 2: Results on **test** for lexical semantic analysis of noun and verb supersenses and MWEs with increasingly complex models. Class labeling performance is given in aggregate, and class labeling *recall* is further broken down into noun supersense tagging (NSST), verb supersense tagging (VSST), and auxiliary verb tagging. All of these results use a percept cutoff of 5. The first result row uses a collapsed tagset (just the MWE status) rather than predicting full supersense labels, as described in §4.4. The number of training iterations M was tuned by cross-validation on **train**. The best result in each column and section is bolded.

lemma	unique SSTs	majority baseline	accuracy
get	7 gold, 8 pred.	**12/28**	6/28
look	2 gold, 3 pred.	8/13	**12/13**
take	5 gold, 5 pred.	8/21	**11/21**
time(s)	3 gold, 2 pred.	8/14	**9/14**

Table 3: Four polysemous lemmas and counts of their gold vs. predicted supersenses in **test** (limited to cases where both the gold standard tag and the predicted tag included a supersense). The distribution of gold supersenses for *take*, for example, is V:SOCIAL: 8, V:MOTION: 7, V:POSSESSION: 1, V:STATIVE: 4, V:EMOTION: 1.

tation of Ciaramita and Altun (2006)[20]—to tag our test data in the reviews domain. By our class labeling evaluation, the result is 51.05% precision, 48.93% recall, and 49.97% F_1.[21] Even without word clusters or the supersense-tailored features of figure 4, our simplest in-domain model reaches 65.71% F_1. Though there are minor differences in features between the two models, both are first-order structured perceptron taggers. We believe that this wide gulf is primarily an artifact of the training data. The annotation methodology was very different (direct MWE and supersense annotation in our case, vs. relying on mappings from WordNet synsets in the case of SemCor), and the vocabulary and style are vastly different between casual online writing and edited prose. Building lexical semantic models that are robust to many domains at once will require further experimentation, and in our estimation, additional annotated resources that cover a fuller spectrum of written language.

5 Conclusion

We have integrated the multiword expression identification task formulated in Schneider et al. (2014a) with the supersense tagging task of Ciaramita and Altun (2006). Supersenses offer coarse-grained and broadly applicable semantic labels for lexical expressions and naturally complement multiword expressions in lexical semantic analysis. We have annotated English online reviews for supersenses, including developing detailed annotation criteria for verbs. Experiments with discriminative joint tagging of MWEs and supersenses establish a strong baseline for future work, which may incorporate new features, richer models, and indirect forms of supervision (cf. Grave et al., 2013; Johannsen et al., 2014) for this task. We also expect future investigations will apply our tagger to a downstream task such as semantic parsing or machine translation (for further discussion of potential applications, see Schneider, 2014, pp. 179–189). Our data and open-source software is available at `http://www.ark.cs.cmu.edu/LexSem/`.

Acknowledgments

Abstract

This paper proposes a novel approach to sentiment analysis that leverages work in sociology on symbolic interactionism. The proposed approach uses Affect Control Theory (ACT) to analyze readers' sentiment towards factual (objective) content and towards its entities (subject and object). ACT is a theory of affective reasoning that uses empirically derived equations to predict the sentiments and emotions that arise from events. This theory relies on several large lexicons of words with affective ratings in a three-dimensional space of evaluation, potency, and activity (EPA). The equations and lexicons of ACT were evaluated on a newly collected news-headlines corpus. ACT lexicon was expanded using a label propagation algorithm, resulting in 86,604 new words. The predicted emotions for each news headline was then computed using the augmented lexicon and ACT equations. The results had a precision of 82%, 79%, and 68% towards the event, the subject, and object, respectively. These results are significantly higher than those of standard sentiment analysis techniques.

1 Introduction

Natural language texts are often meant to express or impact individuals' emotions. Recognizing the underlying emotions expressed in or triggered by a text is essential to understanding the full meaning that a message conveys. Sentiment analysis (SA) researchers are increasingly interested in investigating natural language processing techniques as well as emotion theories to identify sentiment expressions in natural language texts. They typically focus on analyzing subjective documents from the writer's perspective using frequency-based word representations and mapping them to categorical labels or sentiment polarity, in which text (e.g., sentence or document) is associated, respectively, with either a descriptive label or a point in a continuum.

In this paper, we focus on analyzing objective statements. Unlike subjective statements, that contain an explicit opinion or belief about an object or aspect (e.g., *"Seventh Son is a terrible movie"*), objective statements present only factual information (e.g., *"protestors were arrested in NYC"*). Despite the limited research on fact-based sentiment analysis, many factual statements may carry or evoke sentiments (e.g., news articles, blog comments. etc.). Thus, there is a need for a new approach that attaches sentiment scores to objective (factual) statements as well as to the components that make them up. For example, a sentence like *"x kills y"* will clearly evoke a negative sentiment for the reader, and highly negative (yet different) sentiments towards each x and y (angry about x and sorry about y). Further, our affective evaluation of each entity participating in the event might affect our judgement of the situation. For example, if we know that x is a victim and y is a criminal, then the triggered sentiment will be more positive in general, positive towards x, but still negative towards y.

The proposed method in this paper builds a contextual model that maps words to a multi-dimensional emotion space by using Affect Control Theory (ACT). ACT is a social psychological

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1548–1558,
Denver, Colorado, May 31 – June 5, 2015.

theory of human social interaction (Heise, 2007). ACT proposes that peoples' social perceptions, actions, and emotional experiences are governed by a psychological need to minimize deflections between culturally shared fundamental sentiments about social situations and transient impressions resulting from the dynamic behaviours of interactants in those situations. Each event in ACT is modeled as a triplet: actor, behavior, and object. Culturally shared "fundamental" sentiments about each of these elements are measured in three-dimensions: Evaluation, Potency, and Activity (EPA). The core idea of ACT is that each of the entities (actor, behaviour and object) participating in an event has a fundamental affective sentiment (EPA value) that is shared among members of a culture, and the combination of entities in the event generates a transient impression or feeling that might be different from the fundamental sentiment. Transient impressions evolve over time according to empirically measured temporal dynamics. Emotions are functions of the difference between fundamental sentiments and transient impressions. EPA profiles of concepts can be measured with the semantic differential (Osgood, 1957), a survey technique whereby respondents rate affective meanings of concepts on numerical scales with opposing adjectives at each end (e.g., {good, nice}↔{bad, awful} for E; {weak, little}↔{strong, big} for P; {calm, passive}↔{exciting, active} for A). Affect control theorists have compiled databases of a few thousand words along with average EPA ratings obtained from survey participants who are knowledgeable about their culture (Heise, 2010). For example, the culturally shared EPA for *"mother"* in Ontario, Canada, is $[2.74, 2.04, 0.67]$, which is quite good, quite powerful, and slightly active. The *"daughter"* EPA is $[2.18, -0.01, 1.92]$, which is quite good, but less powerful and more active than *"mother"*.

ACT is advantageous for sentiment analysis applications, especially those that aim to analyze descriptive events or factual content for the following reasons: (1) EPA space is thought to provide a universal representation of individuals' sentiment; (2) the transient feeling accumulates over the course of several events and, hence, it can model larger structures in text; (3) impression formation can be computed towards different entities in the sentence, giving a more fine-grained description of the sentiments; (4) the EPA values are empirically driven, reflecting a real evaluation of human participants; and (5) the interaction between terms in ACT is compatible with the linguistic principle of a compositional semantic model, which states that the meaning of a sentence is a function of its words (Frege, 1892).

Our method uses the impression and emotion formation equations of ACT to predict human sentiments towards events. We decompose each sentence into subject-verb-object and then associate subject with actor, verb with behaviour, and object with object in ACT. We then compute the predicted emotion towards each of actor, behaviour and object using ACT equations. We use a semi-supervised method based on Wordnet-similarities to assign EPA values to words that are not in ACT lexicons. We evaluated the viability of using ACT in sentiment analysis on a news headlines dataset that we collected and annotated. This approach yielded a precision between 71% and 82% on the news headline dataset. These results are significantly higher than those results from a method that was trained using bag-of-words and Sentiwordnet lexicon.

The rest of the paper is organized as follows: the first section presents the related work in emotions elicitation and sentiment analysis fields; the following two sections describe the proposed method, providing details about affect control theory, impression formation equations, and the lexicon induction method; the last section presents the dataset used in this paper, and discusses the results obtained using our proposed methods.

2 Related Work

Emotions have been studied extensively in disciplines like anthropology, psychology, sociology, and more recently in computer science. In recent years, fields like affective computing (AC) (Picard, 2000), human-computer interaction (HCI) (Brave and Nass, 2002), and sentiment analysis (Feldman, 2013) are also contributing to this area of research, by computationally modeling and evaluating existing theories. Most of the proposed methods in SA and AC have used the appraisal theory by representing emotions with discrete labels such as happy, sad, etc. (Ekman, 1992). Only several studies have adopted di-

mensional theories by representing emotions (core affects) in three- or two-dimensional space: arousal, valence, and sometimes dominance (Russell, 2003). Although psychological evidence show that words or any other events are emotionally perceived in more than one dimension (Barrett, 2006; Russell, 2003), multi-dimensional models have rarely been used in sentiment analysis.

In sentiment analysis research, two main machine learning (ML) methods are used: supervised learning or unsupervised learning methods. Supervised learning methods generally use the occurrence frequencies of words that indicate opinion/sentiment and then classify these occurrences as either positive or negative using one of the common classification methods (e.g., Maximum Entropy, support vector machine (SVM)). Many combinations of features have been tried, such as part-of-speech tagging, n-grams, term weighting, sentiment lexicons, term presence, and syntactic dependencies (Pang et al., 2002; Lin and He, 2009). In contrast, unsupervised learning approaches often determine the semantic orientation (SO) of a sentence or document by calculating the difference between the point-wise mutual information (PMI) (Church and Hanks, 1990) for its phrases or words with sentiment seeds (Turney and Littman, 2002; Turney, 2002).

Other approaches have built more-structured models, augmenting the standard bag-of-words technique with appraisal groups, which are represented as sets of attribute values in a semantic taxonomy (Whitelaw et al., 2005) or considering the interaction between words by using a tree structured CRF based on (Nakagawa et al., 2010). Another study has taken the interaction between words into account by utilizing the compositional formal semantic models based on Frege's principle (Frege, 1892). A framework is proposed in (Coecke et al., 2010) in which a sentence vector is a function of the Kronecker product of its words. This approach was evaluated on several datasets and showed promising results and improvement over non-compositional approaches (Grefenstette et al., 2010; Grefenstette and Sadrzadeh, 2011; Mitchell and Lapata, 2008).

Much sentiment analysis work has focused on extracting emotions from the writer's perspective; only several recent studies have tackled the problem of predicting readers' sentiments. Both (Lin et al., 2008) and (Yang et al., 2009) used bag-of-words and linguistic features to classify Chinese news articles (Yahoo!-Kimo news) into one of the user emotional ratings (happy, sad, surprise, etc.). Another study presents a multi-label classification approach that uses words' polarity, and semantic frame features to classify news article into categorical emotions (Bhowmick, 2009). As a part of the SemEval-2007 task, a number of approaches have been proposed to binary-classify news headlines into positive or negative sentiment (Strapparava and Mihalcea, 2007; Katz et al., 2007; Chaumartin, 2007).

3 ACT for Sentiment Analysis

3.1 Background

Affect Control theory (ACT) is a new version of symbolic interactionism (Mead, 1938) created by David Heise (Heise, 1987). ACT proposes that individuals process gestures (including words or events) as symbols or concepts shared among groups of people or culture. These fundamental meanings or 'fundamental sentiments' are defined in a three-dimensional space of EPA profile. ACT also proposes that individuals try to maintain the transient impressions, which are generated from the interactions of the events' elements (subject-verb-object), close to the fundamental sentiments in the EPA space. ACT models emotions as arising because of the differences between fundamental sentiments and transient impressions. For example, a person who is powerful but is made to feel powerless will feel "angry". ACT equations (i.e., impression formation equations) are obtained through empirical studies, and they model the process by which the fundamental sentiments of elements in the events are combined to generate a transient impression.

The affective meanings in ACT consist of three components: Evaluation (good versus bad); Potency (powerful versus powerless); and Activity (lively versus inactive). Each affective meaning is measured on a scale from -4.3 (infinitely bad, powerless, or inactive) to +4.3 (infinitely good, powerful, or lively). These meanings are attached to concepts corresponding to identities, behaviors, settings, and modifiers. According to ACT, people from the same cultures and gender share the same fundamental sentiments (EPA) about world concepts (Berger and

Zelditch, 2002; Heise, 2007).

Lexicons of EPA values have been gathered for thousands of words from different languages and cultures including Germany, Japan, Canada and the USA. In general, within-cultural agreement about EPA meanings of social concepts is high even across subgroups of society, and cultural-average EPA ratings from as little as a few dozen survey participants have been shown to be extremely stable over extended periods of time (Heise, 2010). These findings may seem surprising in light of societal conflicts as evidenced, for instance, by competing political ideologies. Research has consistently shown that the number of contested concepts is small relative to the stable and consensual semantic structures that form the basis of our social interactions and shared cultural understanding (Heise, 2010).

3.2 Affect Control Theory

In ACT, each event has at least three elements: actor (subject, S), behavior (verb, V), and object (O). Each of these elements is represented by three values (EPA) that capture the fundamental sentiments they evoke in terms of evaluation, potency, and activity. The fundamental sentiment of an event according to ACT grammar is a nine-dimensional vector:

$$f = \{S_e\ S_p\ S_e\ V_e\ V_p\ V_a\ O_e\ O_p\ O_a\}$$

where e.g. S_e represents the fundamental sentiment about the subject (S) on the evaluation (e) dimension. The transient impression evoked by an event is another 9D vector:

$$\tau = \{S'_e\ S'_p\ S'_e\ V'_e\ V'_p\ V'_a\ O'_e\ O'_p\ O'_a\}$$

where fundamental EPA values are denoted by non-primed symbols and post-event EPA values are denoted by primed symbols. The transient impression τ is computed by multiplying t, a vector of features that are combinations of terms from the fundamental sentiment f, by a matrix M of prediction coefficients estimated by impression-formation research.

$$\begin{aligned} t = (1\ \ & S_e\ \ S_p\ \ S_a\ \ V_e\ \ V_p\ \ V_a\ \ O_e\ \ O_p\ \ O_a \\ & S_eV_e\ \ S_eV_p\ \ S_eV_a\ \ S_pV_e\ \ S_pV_p\ \ S_pO_a\ \ S_aV_a \\ & V_eO_e\ \ V_eO_p\ \ V_pO_e\ \ V_pO_p\ \ V_pO_a\ \ V_aO_e\ \ V_aO_p \\ & S_eV_eO_e\ \ S_eV_pO_p\ \ S_pV_pO_p\ \ S_pV_pO_a\ \ S_aV_aO_a) \end{aligned}$$

$$\tau = Mt \tag{1}$$

For example, the transient impression of the subject's valence, S'_e, using US male coefficients:

$$\begin{aligned} S'_e = & -.98 + .48\ S_e - .015\ S_p - .015\ S_a \\ & + .425\ V_e - .069\ V_p - .106\ V_a + .055\ O_e ... \end{aligned}$$

This part of the equation shows that our evaluation of the subject/actor is affected mainly by how the valence of this person and action are perceived by others (positive large coefficients .48 and .425 for S_e and V_e). It also shows that powerful actors (subject) or behaviours (verb) are seen a bit negatively (negative coefficients -.015, -.069 for S_p and V_p).

We also can incorporate the location (settings), which indicates where the event took place such as school, country, and etc., can be achieved by adding the EPA values for the setting and use the coefficient values of the subject-verb-object-location (SVOL) grammar instead of subject-verb-object (SVO).

Modifiers in ACT are adjectives or attributes that modify actor or object (e.g."good friend" or "abusive father"). The impression generated from combinations of identity with modifiers can be calculated as a linear combination of the EPA values of both the identity and modifiers.

$$c = B_1\, p + B_2\, i \tag{2}$$

where $p = \{P_e, P_p, P_a\}, i = \{I_e, I_p, I_a\}$, and $c = \{C_e, C_p, C_a\}$ are the EPA profiles for the modifier, identity, and the combination, respectively, and B_1 and B_2 are coefficients estimated from survey data. For example, the "father" affective rating is $[1.84, 1.78, 0.02]$, "abusive" is $[-2.23, 0.34, -0.02]$, and "abusive father" is $[-1.51, 1.37, -0.21]$.

The deflection, which is defined as the discrepancy between the fundamental sentiment and the transient impression, is calculated by the squared Euclidean distance between the sentiments and impressions given the following equation.

$$d = \sum_i (f_i - \tau_i)^2 \tag{3}$$

The deflection does not indicate positive or negative emotions, but rather indicates whether or not the event met someone's expectation.

In ACT, the emotion triggered by an event is a function of the fundamental identity for actor or object, $i \equiv \{S_e, S_p, S_a\}$ or $i \equiv \{O_e, O_p, O_a\}$, and the transient identity for actor or object, $i' \equiv \{S'_e, S'_p, S'_a\}$ or $i' \equiv \{O'_e, O'_p, O'_a\}$. ACT uses the following equation to predict emotions, with empirically measured coefficients as follows:

$$\varepsilon \propto E\,(i' - I\,i - \delta) \tag{4}$$

where E is a 3×3 matrix coefficient of the emotion profile, I is a 3×3 matrix coefficient for identity, and δ is a vector of equation constants.

3.3 Emotion Elicitation Using ACT

We implement ACT to predict the triggered sentiment of a single sentence as follows: first we extract the subject, verb, object, setting, and modifiers (adjectives of subject and object) and look them up in the augmented ACT lexicon (see section 3.4) to get EPA values (fundamental sentiments, f) for each word (MacKinnon, 2006). We next compute the transient impression τ using f and Equations 1 and 2. After that, we compute the deflection using Equation 3, and the emotion towards the subject and object using Equation 4. We then map the resulting EPA scores for emotion to the nearest emotions label in ACT. The ACT dataset (MacKinnon, 2006) has 135 emotion labels, each with an EPA score (e.g., delighted= [2.04, 0.96, 1.48]), and we find the closest label using a Euclidean distance measure. We then compare these emotions ε towards subject and object to corresponding ground truth in the news headline dataset (see Section 4) using root mean squared error (RMSE) and mean absolute error (MAE). We also discretize the predicted ε and the ground truth into negative or positive EPA values, and compare accuracy of the discretized values.

To extract the sentence's quintet (i.e., subject, verb, object, modifiers, and settings), we implement a search algorithm that takes a treebank parse tree (Socher et al., 2013) and returns a (subject, predicate , and object) triplet (Rusu et al., 2007). As Rusu *et al.*'s algorithm searches a parse tree of grammatically correct English sentences, we make some alterations to consider news headlines' grammar. News headlines are often written to be short and precise (i.e., often not grammatically correct), and usually consist of several noun phrases without articles or the verb "to be". They are written in the present tense for current or past events (e.g, *terror strikes police base*). The past tense verbs are rarely used in news headlines, whereas passive voice sentences are common. The passive voice sentences are often written without an auxiliary verb, which make it hard for standard parsers to distinguish their verbs from past tense verbs and to extract the triplet accurately (e.g, *Six killed in accident*).

Our algorithm takes a parse tree and performs a breadth-first search and identifies the last noun descendent of the first noun phrase (NP) in the sentence as the subject and the previous descendent as the attributes (in Rusu *et al.*'s algorithm the subject is the first noun in (NP)). For example, in the sentence *Super Bowl-winning quarterback Russell Wilson divorces wife*, the actor/subject *"Russell"* is the last noun in the first noun phase and the previous adjectives and nouns are attributes (modifiers) of the subject. To locate the verbs, (similar to Rusu *et al.*'s algorithm) the algorithm searches the deepest verb phrase (VP) and returns the first verb (VB) descendent. If the verb is in the past tense, we transform it to passive voice. The algorithm (similar to Rusu *et al.*'s algorithm) returns the object that is co-located with the verb in the deepest verb phrase (VP). To extract the settings, we look for a noun phrase (NP) sub-tree that has a preposition (at, in, on) and return the last noun. This algorithm yields accuracies of 43%, 53% , and 26% with the ground truth (users' annotations of the subject, verb, and object).

We also consider whether the verb type is transitive, which directly indicates positive or negative sentiment toward something (e.g., x killed y), or intransitive, which transfers sentiments into nouns (e.g., x provides help to y). For intransitive verbs, we choose the second verb as the behavior (verb) in the sentence (e.g., "x provides help to y" will be "x helps y"). We also used part-of-speech tagging to determine the elements of an event and to identify the places and names. The gender of the names is considered by training a naïve Bayes classifier on names-gender corpus of 5001 female and 2943 male names[1] which yielded an accuracy of 86% on classifying names according to their gender.

3.4 EPA lexicon Induction

The method described in the last section relies on a lexicon that maps words to EPA values. The ACT lexicon we used originally contains 2,293 words (original-EPA-lexicon) (MacKinnon, 2006). We augmented this lexicon by adding the Affective Norm for English Words (ANEW) (Bradley and Lang, 2010) data-set that contains 2,476 English words, and the Warriner *et al.* data-set (Warriner et al., 2013) that contains 13,915 words. ANEW and Warriner *et al.* data-sets were both scaled from the range of [1,9] to the range of [-4.3,4.3] using max-min scaling formula (Han, 2012). The min-max normalization preforms a linear transformation for a given value x_i of A with a minimum and maximum value of [min_A, max_A] to x'_i in range of [min_B, max_B] given this formula:

$$x'_i = \frac{x_i - min_A}{max_A - min_A}(max_B - min_B) + min_B$$

Adding ANEW and Warriner lexicons generated lexicon of 17,347 words (extended-EPA-lexicon). We then randomly divided the extended-EPA-lexicon into a training-EPA-lexicon and a testing-EPA-lexicon, with 5,782 and 11,565 words, respectively. We used the training-EPA-lexicon to add more words, using a graph-based semi-supervised learning method called label-propagation, a technique that has been commonly used for NLP (Chen et al., 2006; Niu et al., 2005; Rao and Ravichandran, 2009; Zhu and Ghahramani, 2002; Blair-Goldensohn et al., 2008), and image annotation (Cao et al., 2008; Heckemann et al., 2006). Label-propagation is a transductive algorithm that propagates information from a set of labeled nodes (seed sets) to the rest of the graph through its edges (Zhu and Ghahramani, 2002). The label-propagation algorithm starts by adding all the synonyms and lemmas in WordNet of a specific part-of-speech (verb, noun, adjective, or adverbs) to the training-EPA-lexicon. This generates a set of labeled words $L = (X_l, Y_l)$ (the 5,782 words with EPA labels), and unlabeled words $U = (X_u, Y_u)$, from which we constructed undirected weighted graph $G = \{E, V, W\}$, where V is a set of vertices (all the words in the set), E is the weighted edges, and W is an $n \times n$ weight matrix (affinity matrix) n equal to the size vocabulary $|V|$.

We initialized the labeled nodes/words with the EPA value of the words observed in the training set, and the unlabeled nodes/words with zeroes. We computed the weight matrix using the WordNet similarity (Wu and Palmer, 1994) between the two words x_i and x_j. Wu and Palmer's similarity is equal to the depth of the least common subsumer (LCS, the least common ancestor) divided by the summation of the depth of the two words in the WordNet taxonomy.

$$sim_{wup}(w_1, w_2) = \frac{2 * depth(LCS)}{depth(w_1) + depth(w_2)}$$

Each edge $E \in (v_i, v_j)$ has an associated weight T_{ij}, which is the row normalized weight w_{ij} of the edge between v_i and v_j. The labels are then propagated to adjacent nodes by computing $Y \leftarrow TY$. After each iteration the labeled nodes Y_l are reset to their initial values (see Algorithm 1).

Algorithm 1 ACT Label Propagation

procedure LABEL PROPAGATION($Synests\ C$)
  Construct a Graph $G = \{V, E, W\}$
  Initialize T^0 and Y^0 matrices, $i \leftarrow 0$
  repeat
    $Y^i \leftarrow TY^{i-1}$
    $Y_l \leftarrow L$
  until Y converges
end procedure

The label propagation algorithm generated 167 adverbs, 3,809 adjectives, 11,531 verbs, and 81,347 nouns, with their EPA ratings in which 10,249 of them are in the testing-EPA-lexicon. To evaluate the validity of this approach, we compare our generated EPA ratings for these 10,249 words with those from the testing-EPA-lexicon (from ACT/ANEW/Warriner datasets). The results are shown in Tables 1 and 2. The resulting EPA are equally distributed between -4.3 and +4.3. We used two metrics to compare the results: root mean squared error (RMSE) and mean absolute error (MAE). These metrics were both close to 1.0 for E, P, and A, suggesting that there is a reasonable degree of agreement between the induced and manually labeled EPA values. It is worth mentioning that due to the limited numbers of adverbs in the ACT

lexicon, and because the Wordnet-similarity measure that compares only words of the same part-of-speech, only several adverbs were generated using label-propagation algorithm.

POS	W	RMSE			MSA		
		E	P	A	E	P	A
Adjectives	378	1.2	1.2	0.9	0.9	1.0	0.8
Adverbs	5	1.0	1.1	1.3	0.7	0.8	0.9
Verbs	2,787	1.2	1.1	0.8	1.0	0.9	0.6
Noun	7,079	1.3	1.1	0.9	1.0	0.9	0.7
Total	10,249	1.3	1.1	0.9	1.0	0.9	0.7

4 Datasets

We evaluated the proposed method on a newly collected news-headlines dataset. We collected 2080 news-headlines from a group of news websites and archives (BBC, CNN, Reuters, The Telegraph, Times, etc). The news headlines were selected randomly from the period from 1999 to 2014. Through Mechanical Turk, we recruited participants located in North America with more than 500 approved hits and an approved rate above 90%. We asked the participants to locate the subject (actor), behavior (verb), and object of each sentence and to indicate their emotions towards them and towards the event (as a whole) in the EPA format $\in [-4.3, +4.3]$ (where -4.3 indicates strongly negative EPA value and +4.3 indicates strongly positive EPA value). The dataset was annotated by at least three judges per headline. We excluded any ratings that were filled with blanks, zeros, or similar values in all the fields. We also excluded the answers that did not have the appropriate subject, verb, or object form (e.g., behavior=Obama, subject=as). We also excluded all the answers rated by less than three participants. This screening resulted in 1658 headlines that had a mean EPA rating of 0.80, 1.04, and 1.02. Of these, 995 headlines had a positive evaluation score and 663 headlines had a negative evaluation score. Some examples from this dataset can be seen in Table 5.

Words	Testing-EPA-lexicon	LP-lexicon
Incapable (adj.)	[-1.83, -1.40, -0.54]	[-1.56, -1.18, -2.59]
Wrongly (adv.)	[-1.96, -0.22, 0.17]	[-2.02, -0.23, 0.18]
Gauge (v.)	[0.12, -0.55, 0.13]	[0.18, -1.61, 0.25]
Loser (n.)	[-1.30, -1.75, 0.30]	[-1.14, -1.52, 0.28]

Table 2: Words and their EPA ratings from Testing-EPA-lexicon and LP-lexicon=label propagation lexicon

5 Results

Our model (the augmented lexicon, and ACT equations) was evaluated in predicting the evoked sentiment towards the headlines as a whole by comparing the discretized evaluation (E) score $\in \{0, 1\}$ (where 0/1 indicates negative/positive emotions, resp.) of the generated EPA to the ground truth. This evaluation was performed using different configurations (Table 3): (1) Using users' annotated triplet (ACT-UA) (i.e., subject, verb and object), the model yielded a precision of 75% compared to the ground truth. (2) Using the parse tree triplet (ACT-PTT) (see Section 3.3 for details), the precision dropped to 71%. (3) Adding the adjectives (modifiers) and settings to the subject, verb and object, which we will called parse tree quintet (ACT-PTQ) yielded a higher precision, with 82% precision in comparison with the corresponding ground truth. These results were also compared to the results obtained from a standard sentiment classifier (STD-calssifier) that uses occurrence frequencies of positive vs. negative words using SentiWordNet (Das and Bandyopadhyay, 2010). This classifier yielded a precision of 57% in comparison to the ground truth (Table 3).

The parse tree quintet (ACT-PTQ) were also used to evaluate the ACT predicted emotions towards the actor (subject) and the object in the headline (Table 4). Three metrics were used in this evaluation: precision, MAS, and RMSE. We used precision to compare the disctized EPA scores $\in \{0, 1\}$ and MAS and RMSE to compare the real EPA scores $\in [-4.3, +4.3]$. As shown in Table 4, the RMSE and MAS are almost all less than 1.5, and the precision varies from 67% to 79% across discretized E,P,A for subject and object. To put these results in context, a difference of 1.4 in the EPA space would equate to the difference between "accusing" someone ($\{-1.03, 0.26, 0.29\}$) and "pun-

Classifier	Precision	Recall	F1-score
ACT-PTQ	**82**	**67**	**73**
ACT-UA	75	62	67
ACT-PTT	71	63	66
STD-classifier	57	51	53

ishing" someone ($\{0.19, 0.79, 0.76\}$), or between the identity of "mother" ($\{2.48, 1.96, 1.15\}$) and "girl"($\{1.96, 0.67, 0.99\}$), or between the emotion of "joyful" ($\{2.43, 1.97, 1.33\}$) and "euphoric" ($\{1.42, 1.09, 0.99\}$). These words seem quite close in an affective sense, which indicates that our sentiment analysis method is able to uncover sentiments at a level that is reasonable on an intuitive level, and shows the method's power in uncovering sentiments about specific elements of sentences.

6 Discussion and Future Work

Human emotions are more complicated than several labels or binary scores. ACT models emotions in a three-dimensional space which is found to be a comprehensive and universal representation of human emotions, and models emotions towards event- or fact-based sentences as a combination of several emotions towards their entities (subject and object). To evaluate the effectiveness of using ACT in sentiment analysis, we chose to analyze news headlines as they represent real-world statements that describe single or multiple events/facts.

Analysing sentiment in news headlines is a challenging task for several reasons: (1) news headlines are ungrammatically structured, which makes it hard for standard parsers to extract their words' part-of-speech and dependency correctly; (2) they are written to be short and precise, providing little information for typical bag-of-word classifiers to work properly; (3) they are objective, containing words that might not exist in the commonly used sentiment lexicon. To overcome the limitation of news headline sentiment analysis, three main contributions that we present in this paper: (1) we extracted the sentences' triplets by considering the headline grammar and structure; (2) we augmented ACT lexicon using label-propagation and word similarity; (3) we model the interaction between the words in the sentence by modelling the transient and fundamental sentiments.

The label propagation algorithm generated 96,853 words in which 10,249 of them are in the testing data set. The EPA values of these words were found to be quite close in the affective space to their corresponding ground truth, Table 1. Table 2 also shows several good examples of the generated EPA and their corresponding ground truth. The label-propagation results could be further improved by adding words antonyms and by employing another similarity measure. The results of predicting the sentiment towards the event and their entities as shown in Tables 4, 3, and 5 are computed using *only* the ACT lexicons and the ACT impression formation equations. With such a simple, parsimonious and theoretically well-grounded approach, we are able to compute fine-grained sentiment analysis in a dimensional space that is known to be a universal representation of human affect. Mapping these three-dimensional EPA scores to a specific emotion provides a detailed label for objects and subjects within a sentence, as shown in Table 5. For example, in a sentence like*" Russia says 4 militants killed in Dagestan siege"*, the reader will be feeling negative, yet different emotions towards the subject *"furious"* and the object *"sorry"*.

Table 5 (obtained with ACT-PTQ) shows the deflection (d), emotions towards the events (ε), and towards the subject and object (e_a) and (e_o) of some of the examples in the data set. As shown in Table 5, we can see that the deflection (d) is very high when we do not expect an event to occur (e.g.,*"Baby dies after being left in car for over 8 hours"*). The deflection in this sentence is high (17.42) because the EPA value of the object *"Baby"* is equal to

Table 5: ACT model's results on news headlines, d=deflection, ETS, ETO= emotion towards subject and object, T_e = emotions towards the event (ground truth), ε=emotions towards the event (ACT), and e_s, e_o = the evaluation value of the emotion towards subject and object. Parse elements are coded as: *subject*, verb, object, and setting.

$[2.40, -2.28, 2.58]$, which is considered to be quite good, quite weak, and quite active identity and a car is considered to be a quite positive place, with EPA value equal to $[1.62, 1.65, 2.01]$. While if an event took place in a war zone or if the subject has negative evaluation, the deflection will not be very high (e.g., *"Bomb kills 18 on military bus in Iran"*) the deflection is equal to 3.40 because *"Bomb"* has a negative evaluation. In Table 5, we can see the emotions (ε) and the ground truth evaluation toward the events (T_e) are often quite close.

The aforementioned results are obtained by extracting single subject, verb, object, modifier, and setting. These results could further improved by taking adverbs (e.g, *"lived happily"*), phrasal verbs (e.g,*"get along" and "get back"*), numbers (e.g,*"45 killed"*), and negations (e.g.,*"no more funding"*) into consideration. Finally, accumulating the emotions of multiple consequent behaviors could also be very useful. For example, in the sentence *"Man arrested after beating cops in a restaurant"* the behavior will be *"arrested"*, and *"beating"* is not taken into account. We could address this using more complex parse trees and accumulating the emotions of multiple behaviors by considering the previously generated sentiment as the fundamental sentiment. Finally, using ACT predictions to bootstrap supervised learning could also yield improvements.

7 Conclusions

We have proposed a new direction for sentiment analysis, employing Affect Control Theory (ACT) to assign different emotions towards events-based/objective statements and their entities (subject, object). Unlike the majority of sentiment analysis models that are trained on highly subjective words to obtain descriptive labels, our model incorporates ACT, that models emotions as points in three-dimensional space, and analyzes how objective texts trigger different emotions. We use a semi-supervised method based on Wordnet similarities to compute emotional ratings for words not in the ACT lexicons. Evaluated on a news headline dataset, our model yielded higher accuracy than a widely used classifier, with a highest precision of 82%. We also analyzed the sentiment evaluation of ACT on (actor/subject and the object) in the news headlines, yielding a precision of 79% and 68% when analyzing the emotions towards the subject and the object, respectively. These results have been obtained without performing any supervised learning and without taking consequent behaviors, phrasal verbs, or sentence negations into account. Thus, they demonstrate the potential of ACT for sentiment analysis. Affect control theory can also handle consequent behaviors and modifiers. In future, we plan to augment our method with more complex levels of detail, gather more extensive datasets, and evaluate ACT for more precise and detailed sentiments.

Abstract

Most of the current approaches to sentiment analysis of product reviews are dependent on lexical sentiment information and proceed in a bottom-up way, adding new layers of features to lexical data. In this paper, we maintain that a typical product review is not a bag of sentiments, but a narrative with an underlying structure and reoccurring patterns, which allows us to predict its sentiments knowing only its general polarity and discourse cues that occur in it. We hypothesize that knowing only the review's score and its discourse patterns would allow us to accurately predict the sentiments of its individual sentences. The experiments we conducted prove this hypothesis and show a substantial improvement over the lexical baseline.

1 Introduction

For years, sentiment analysis has heavily relied on lexical resources, whether compiled by hand (Wilson et al., 2005) or automatically extracted from a large corpus (Hu and Lui, 2004). In addition to an overwhelming task of trying to capture *all* words and expressions that can convey a sentiment there are many other problems to solve: resolving the scope of negation to determine the shift of polarity (Lapponi et al., 2012), determining if an opinion is present in interrogative or conditional sentences (Narayanan et al., 2009), dealing with irony (Tsur, 2010), etc. But even if we manage to solve all aforementioned problems and create an efficient classifier, there will always be cases where reliance on lexical cues for subjectivity will betray us. Consider, for instance, the following examples from reviews of online universities[1]:

(1) The lectures are interactive and recorded. So, if you can't attend you can listen in later.
(2) I assure you, online learning at Capella was the most difficult form of education I have undergone!
(3) UMUC provided really good quality education until about 5 years ago.

In the first example, the author expresses a positive opinion of the university, but it will fail to be detected because it does not include any explicit sentiment cues (such opinions are referred to as "implicit" by Liu (2012) or as "polar facts" by Toprak et al. (2010)). Because the sentiment (and its presence) of such sentences is highly domain-dependent, they cannot be covered by any lexicons or learned in a supervised or a non-supervised way.

The second example does have a sentiment cue *difficult*, and judging by it the sentiment should be

[1] The examples in this section are taken from Darmstadt Service Review Corpus, available from https://www.ukp.tu-darmstadt.de/data/sentiment-analysis/darmstadt-service-review-corpus (Toprak et al., 2010). The corpus was also used as a development set for extracting features for this study.

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1559–1568,
Denver, Colorado, May 31 – June 5, 2015.

negative. However, in this case the author actually expresses a positive view of an online university, defending it from people who claim that online education is "too easy". In the third example, the correct sentiment (negative) would again be impossible to determine because of a complicated structure.

These are just a few examples of what is currently impossible to classify correctly relying on lexical resources. To improve the classification results, there have been attempts to use local discourse information, such as discourse cues and polarity of adjacent sentences, in order to correct some of the misclassified sentences (Somasundaran, 2010). However, though such attempts resulted in some improvements, they also required quite complicated frameworks.

While such bottom-up approach (starting from lexical polarity and adding supplementary information to improve classification on a phrase and text level) is commonly used in sentiment analysis, we are wondering if it is the only valid one. Provided that we have a reliable external measure of a text's general polarity (such as a product rating for a product review) and the narrative has a predictable discourse structure, would not it be possible to classify its sentences in a top-down manner, without using any sentiment lexicons? In this paper, we experiment with this approach and compare its results with those of the traditional bottom-up method.

This paper is organized as follows. Section 2 presents a brief overview of previous studies related to sentiment analysis of product reviews, while section 3 explains the motivation behind taking an alternative approach. In section 4 we give the details of the experiments, and then in section 5 present their results. Lastly, section 6 summarizes our findings.

2 Previous Studies

Sentiment analysis so far has largely relied on explicit lexical information, either in the form of sentiment dictionaries and lexicons, such as SentiWordNet[2] or Subjectivity lexicon[3], opinion phrases extracted from a manually-annotated corpus or a dataset compiled in real time using machine learning with such lexical features as bag-of-words features, n-grams, collocations, or more sophisticated lexical patterns (Tang, 2009). As researchers realized the limitations of a purely lexical approach, they tried to augment it by using negation resolution, word meaning disambiguation or hand-crafted rules (Ding, 2008). However, though such efforts improved classification on the sentence level, they were not able to deal with the sentences where an opinion was implicit (i.e. there were no appraisal words or other lexical cues, see example 1 above) or the polarity of the sentiment word was different from the usual one (see example 2 above). To correct such misclassified instances, another level of complexity was added by using discourse features. Somasundaran (2010) defines opinion frames to enforce discourse constraints on the polarity of segments with the same or alternative target relations. Using a similar approach, Zhou et al. (2011) employ simplified Rhetorical Structure Theory (RST) relation cues (contrast, condition, continuation, cause and purpose) to eliminate polarity ambiguities. Yang (2014) concentrates on discovering opinionated sentences which do not have strong sentiment signals (implicit opinions), using discourse knowledge to improve the results of a Conditional Random Fields classifier. While such approaches are a definite improvement over the lexical baseline, they are computationally complex and still overly dependent on the lexical cues.

While machine learning algorithms such as Naïve Bayes or SVM are still the primary tools used for sentiment analysis, lately such texts as product reviews have been recognized as having an internal structure and inter-sentential relations, and thus structural conditional frameworks have been used for their classification. One popular tool is Conditional Random Fields (CRF), which was used, among others, by Zhao (2008) to classify sentiments on a sentence level, by Breck (2007) to identify subjective expressions, and by Li (2010) to summarize product reviews taking their structure into account.

3 Motivation behind Top-down Approach

Though most of the previous studies treat product reviews as a bag of sentences or even words, in fact they are narratives that have a specific structure. While their structure is less rigid and

[2] http://sentiwordnet.isti.cnr.it/ (Baccianella et al., 2010)

[3] http://mpqa.cs.pitt.edu/lexicons/subj_lexicon/ (Wilson et al., 2005)

predicable than, say, that of research papers, it nevertheless has some recurring patterns which lend themselves to generalization.

The same principle applies to sentiments appearing in product reviews. The authors of reviews do not simply pile up some random facts about the product or their evaluations of it. To the best of their abilities, they try to convince the reader to buy or not to buy a particular product, and, according to Grice's Maxims (Grice, 1975), they do it in the clearest and most effective way possible. Thus, if an author has in general a positive opinion of a product, the probability of a negative sentence appearing in a review is lower than that of a positive sentence, and even if a negative sentence is introduced, it is likely to appear together with a concession or a contrast marker, such as *although* or *but*, or be modified by a hedging expression, such as *might, only, could* be, which mitigate the negative effect on the reader. Thus the author makes us understand that his primary opinion of the product is still positive, and uses the discourse relation of *contrast* to present an opposite opinion.

Likewise, if an objective sentence appears in a review, it is not a random event, but a tool serving some purpose, such as interacting with a reader by asking questions which do not require an answer (*Where do I start?*) or supporting one's view by showing that you have some expertise necessary to provide a valid opinion. While in this paper we cover only objective sentences that are used to provide background information (the discourse relation of *background*), it is clear that other reasons for usage of objective sentences are present and capable of being formalized.

The facts mentioned above make us consider a product review as a text which has a primary polarity and optionally includes some segments which have an opposite polarity or no polarity at all (objective sentences). Instead of relying on lexical sentiment information, which makes it difficult to distinguish between objective and subjective sentences on one hand (implicit opinions) and between positive and negative opinions on the other (sarcasm, context-dependent polarity), we suggest using a top-down approach: determining the primary polarity of a review based on an external source of information, such as product rating, and then locating segments which do not conform with this polarity (have no polarity or an opposite polarity) by finding cues that mark a change in a discourse flow.

In the next section we describe an experiment which we conducted to confirm that this approach is viable.

4 Experiment

4.1 Data and Task

For the experiments in this study we use Filatova's Amazon product reviews corpus (so called Sarcasm Corpus[4]), consisting of 817 ironic and regular reviews. We chose to use this corpus because we believed that segments in ironic reviews would be difficult to classify by purely lexical means. Out of these 817 reviews we randomly selected 100 reviews for training and 20 reviews for test data. We did not use the whole dataset because the number of reviews with a particular review score differs greatly (60% of reviews are 5-star, while only 5% are 2-star). To prevent a skew towards positive labels we used equal-size random samples of reviews with all possible scores. Reviews were annotated by one of the authors and an external annotator on a clause level if a sentence contained opinions with opposite polarities, and on a sentence level otherwise. The inter-annotator agreement was measured by using Fleiss' kappa and Krippendorff's alpha, and the results showed that the annotation was highly reliable ($\kappa = 0.912$, $\alpha = 0.913$). Overall the training corpus consisted of 843 segments (438 negative, 268 positive and 137 objective), while the test set contained 145 segments (78 negative, 41 positive and 26 objective).

While the studies in sentiment analysis usually make distinction between subjective and objective sentences on one hand and between negative, positive and neutral sentences on the other, in this paper we make a twofold distinction, first classifying a segment as objective or subjective, and then, in case of subjective (polar) sentences, further subdividing them into positive and negative. To our mind the classification into positive, negative and neutral sentences, commonly adopted for product reviews, is incorrect, as neutral sentiments rarely, if ever, appear in reviews. What is com-

[4] http://storm.cis.fordham.edu/~filatova/SarcasmCorpus.html (Filatova, 2012).

monly referred to as neutral sentences should be classified as objective segments, as they do not carry any sentiment related to the subject matter.

When annotating the corpus we considered the intended semantic orientation of a segment, not its literal meaning and the presence and polarity of lexical cues. Thus, segments without any lexical cues could be annotated both as subjective and objective:

(4) I bought this mobo from Amazon, after buying the same month the DG31PR Classic for my wife. (*objective*)

(5) After I install my new PC, the 2do. day of use, the LAN failed. (*subjective, negative*)

Segments with a lexical cue of a certain polarity could be annotated both as positive and negative:

(6) The ring is **nice** and heavy. (*positive*)

(7) It's going to be a **nice** paperweight. (*negative*, from a review of a camera)

Finally, segments where an alternative product was praised or preferred were understood to be a criticism towards the reviewed product:

(8) I will never buy another Panasonic product. There are plenty of other brands that are loyal to their customers. (both segments are *negative)*

We view each of the reviews as a separate discourse with its own sentiment flow, and thus treat the sentiment analysis problem as a sequence classification task. We employ the CRF method, which outperforms other methods of sequence labeling (Lafferty, 2001). In CRFs the probability of a sequence is defined as

$$p_\lambda(Y \mid X) = \frac{\exp \lambda \cdot F(Y, X)}{Z_\lambda(X)}$$

where

$$Z_\lambda(x) = \sum_y \exp \lambda \cdot F(y, x)$$

where X is a set of input random variables, Y is a set of labels, and λ is a weight for the feature function $F(Y,X)$. (Sha, 2003).

All experiments in this paper were conducted using a C++ implementation of a linear Conditional Random Fields classifier (CRF++)[5]. Though more complex or constrained types of CRF classifiers and models based on them proved to be more suitable for sentiment analysis (Mao, 2006; Yang, 2014), we use the simplest model as a proof of concept in this study.

Each review in the training and test data is converted into a sequence of polarity segments assigned to it. For example, the following short review:

(9) The ring is nice and heavy. Have been wearing if for almost a month and still not a scratch!

is presented as a sequence of tokens POSITIVE POSITIVE, based on the sentiment labels from the annotation. The tokens are assigned features, as defined in the following sections, which are then fed into the classifier.

4.2 Features for Experiments

4.2.1 Lexical Features

To set a baseline, we use a state-of-art lexical classifier – Stanford Sentiment Analysis Classifier from Stanford CoreNLP toolkit[6] – to determine the lexical polarity of each individual sentence. Thus the *lexical* classifier considers only lexical features available in a particular sentence without looking at neighboring sentences or discourse cues. For the *local context classifier* we also determine the lexical polarity of the previous and next sentences and use the sequence of {prev_polarity, current_polarity, next_polarity} as a feature (a similar approach is taken by Somasundaran (2010)). This is done to disambiguate and, if necessary, to correct the polarity of misclassified instances that are sandwiched between the correctly classified ones. For example, if the lexical classifier fails to detect an implicit opinion

[5] Available from http://taku910.github.io/crfpp/
[6] Available from http://nlp.stanford.edu/sentiment/code.html

in a sentence that appears between two explicit opinions, it might correct it as follows:

POSITIVE OBJECTIVE POSITIVE ->
POSITIVE POSITIVE POSITIVE

4.2.2 Contrast Features

The main drawback of the *local context* classifier is that it can misclassify sentences with the opposite polarity, lumping them together with sentences of the primary polarity. To prevent this, for the *contrast* classifier we add another set of features – discourse cues with a Rhetoric Structure Theory (RST) (Mann and Thompson, 1988) relation of *contrast*. We consider both explicit and implicit discourse markers of contrast for this set of features:

4.2.2.1 Explicit Contrast Markers

Contrast relations are primarily realized by using explicit *discourse markers*, which, depending on their type, mark the sentence they appear in (in case of *although* type) or the previous sentence (in case of *but* type) as contrasting:

(10) The Phillips screwdriver on the end of one of the tines is helpful for things like tightening eyeglasses, POSITIVE CONTR
but it is slightly offset from the opposing blade and I've nicked or jabbed myself with it more than once while it's in my pocket. NEGATIVE NCONTR

(11) **Although** it has 10 workable buttons which come in handy for some games, POSITIVE CONTR
it has some major flaws. NEGATIVE NCONTR

The segment with the NCONTR marker usually has the primary polarity of the review, while the segment with a CONTR marker presents a contrasting opinion.

4.2.2.2 Implicit Contrast Relations

Contrast relations can also be manifested implicitly through the use of *hedges*. Hedging is often used when the review's author wants to mention some negative side of a product they like (or a positive aspect of a product they hate), but does not want to put an unnecessary emphasis on it. Such hedging expressions as *the only good/bad point, the only drawback, I would only recommend it*… etc are used for this purpose:

(12) With all the upgrades that Apple has done with their macbooks, I think I finally feel that it's worth the spending to buy my first mac. NHEDGE
My *only complain* is that it's still a lot more expensive than PC laptops with similar specs. HEDGE

4.2.3 Background Classifier

The *background* classifier allows us to capture some of the objective sentences that are related to the polar ones using a *background* RST relation. We identify three types of patterns where background relations are used:

1. *Acquirement patterns*: people often start reviews with an explanation of how they got the product.
2. *Personal background patterns*: people often support their evaluation of a product by stating who there are, what they do for a living, what kind of lifestyle they lead etc.
3. *Personal experience patterns*: again, to support their views the writers prime their readers by describing their experiences or achievements.

Unfortunately, background relations, unlike contrast relations, are almost never explicit. They are paratactic and lack discourse cues, so we need to rely on lexical and grammatical features for classification. However, we believe that because background information is usually presented in easy-to-predict patterns, it is more feasible and computationally inexpensive to use lexical cues to single out objective sentences than to try to capture infinitely large number of ways sentiments can be expressed. In the following subsections, we describe these patterns in more detail and explain which lexical and grammatical cues can be used to detect them.

4.2.3.1 Acquirement Patterns

At the beginning of a review people often explain how they acquired the product:

(13) I bought this camera for my deployment to Iraq. (*objective*)
It was in my cargo pants pocket one day I took it out and the lens was cracked and the silver trim ring had fallen off. (*negative*)

We formalize this feature as follows:

[I | we] [verb synonymous to "acquire"|verb of decision + verb synonymous to "acquire"],

or, more specifically:

[I | we] [ordered | bought | got .* as a gift | purchased | decided to buy…]

All verbs are in past simple tense, as only in this tense they are unlikely to bear any sentiment (compare, for example, sentences with the same verbs in present perfect tense:

(14) However, I am glad that I **have bought** a mac.(*positive*)

(15) This is probably the worst book **I've bought.** (*negative*)

Moreover, this pattern is likely to be used at the beginning of the review, so we add ACQUIRE feature only to those segments which appear in the first 25% of a review.

4.2.3.2 Personal Background Patterns

In these patterns, the authors offer their personal information that is relevant to the subject matter of the review and can support their opinion. For instance, in the following review the author refers to his pets as the major reason for buying a particular vacuum cleaner:

(16) I **have a cat and a dog**, and there is lots of shedding hair, all the time. (*objective, personal background*)
When I saw the DC25 Animal, I **decided to spend the money** hoping that this vacuum would do the job. (*objective, acquirement*)
It has lived up to my wildest dreams, it is wonderfully easy to handle, so easy to maneuver, the 16 lbs make such a difference compared to those very heavy machines I had before, I had no problem carrying it upstairs. (*positive*)

We formalize this feature as follows:

[I|we] [am (a|an)|have (a|an)|'m (a|an)|am not (a|an)]

The indefinite article is used to prevent matching such polar expressions, as *I'm very pleased with the quality of this product.* Again, such patterns are searched for only at the beginning of a review.

4.2.3.3 Personal Experience Patterns

These patterns also serve to provide some background information about user's experiences to back up his opinion on a product:

(17) Usually **I am a huge fan** of hats that look like food. (*objective, personal background*).
My meatloaf hat **has been** a hit for years. (*objective, personal experience*)
When I received my turkey hat I carefully unwrapped the bubble wrap and gazed upon its tan beauty. (*positive*).

To capture this pattern we search for verbs in perfect forms (except for the verbs of possession). We exclude verbs in perfect continuous forms, as they are more often used to describe positive or negative results of using a product. Compare, for example:

(18) I **have been using** it for almost a month and my lashes are so long, they touch my eyebrows... (*positive*)

We also exclude phrases that have "should/could" before "have", as they often express negative sentiments (Liu, 2014):

(19) Would have been nice if the stilts could accommodate multiple/varying heights. (*negative*)

4.2.4 Primary Polarity Features

Lastly, we use reviews' scores to predict their global semantic orientation (primary polarity). The intuition behind this is that the reviews with a higher score will contain more positive sentences than reviews with a lower score, and thus global polarity information might help us to amend incorrect predictions of a lexical classifier (a similar approach was taken, among others, by (Yang, 2014)). This is supported by the statistics of our corpus: the polarity of sentences in a review in general correlates with its score. Highly positive (5-star) and highly negative (1-star) reviews contain few segments of the opposite polarity, and even reviews with a less extreme score demonstrate a clear preference of one of the polarities (see Table 1). Thus it can be predicted that the classifier using this feature will tend to assign the primary polarity (positive for 4- and 5-star reviews, negative for 1-, 2-, and 3-star reviews) unless there is some strong evidence preventing it.

Review score	Positive	Negative	Objective
1	0.01	0.85	0.13
2	0.10	0.77	0.12
3	0.22	0.65	0.13
4	0.62	0.23	0.15
5	0.68	0.04	0.27

Table 1. Percentage of positive, negative and objective sentences in reviews with different product ratings

4.3 Bottom-up vs Top-down Approach: Experiment Design

4.3.1 Bottom-up Approach

This is a widely-used approach which relies on a lexical polarity classifier to determine the semantic orientation of each segment and then corrects the misclassified segments by employing more general features: discourse features (in our study – *contrast* and *background*) and global semantic orientation features (called *primary polarity* features in this paper).

The bottom-up approach has become a standard in sentiment analysis, so we believe there is no need to explain it in detail. The main focus of this study is on the top-down approach, which we describe below.

4.3.2. Top-down Approach

In this set of experiments, we do not use any lexical information about the presence of sentiments in segments and their types. Instead, we rely on rating scores assigned to the reviews to determine their primary polarity, and then correct the misclassified instances using discourse features. In general, the feature set used for this classifier is the same as for the bottom-up approach. The only important exception is that lexical features are completely omitted.

We adopt the following process for sentiment classification:

1. All sentences in a review are assigned a polarity label determined by the corresponding review rating.
2. We look for discourse patterns that are associated with a change of the primary polarity (POSITIVE -> NEGATIVE, NEGATIVE -> POSITIVE). These are usually manifested through **contrast** relation and enable us to correct some of misclassified polarity labels.
3. We look for discourse patterns where a polar statement is accompanied by an objective statement. A common example of such discourse relations in product reviews is **background**. At this stage, unnecessary POSITIVE and NEGATIVE labels are changed into OBJECTIVE.

Schematically this can be shown as follows using an arbitrary example of a 4-star review, where light-gray blocks stand for positive segments, dark-gray for negative segments and white for objective ones (here we assume that all segments will be initialized as positive, as it is the primary class for 4-star reviews):

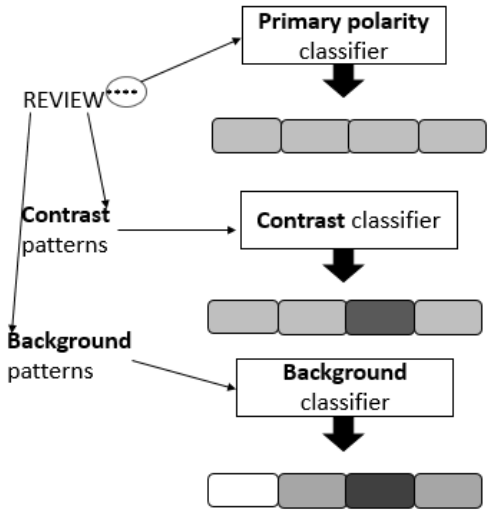

Figure 1. Top-down approach classification flow

In the next section, we discuss the results of experiments conducted to show that such features can improve sentiment classification.

5 Experiment Results

In this section, we compare the results achieved by using the top-down approach with those of the traditional bottom-up method.

5.1 Bottom-up Approach

The *lexical* classifier results, used as a baseline in this study, are listed in Table 2 below. As can be seen from the results, the recall and precision of positive and especially objective segments is low, which shows that purely lexical classifier cannot reliably distinguish between objective and subjective sentences and between positive and negative ones. The accuracy of the classifier is also low (0.6138).

When we add local discourse context, the recall of positive and negative segments improves, as does the overall accuracy (to 0.6758). However, the *local discourse* classifier completely ignores the objective sentences, assigning polarity to them. The precision of the negative class and overall precision also gets lower, as some positive segments sandwiched between negative ones are assigned a negative label.

Adding *contrast* discourse cues does not help to improve this situation, because it leads to overestimation of positive segments and lower accuracy (0.6620). In fact, the *contrast* classifier performs even worse than the local discourse one. It seems that lexical information introduces too much noise, and building up on such an unreliable basis does not produce expected results.

The *background* classifier improves the performance, especially for objective sentences, classifying them with a high precision and at least some recall. It also improves the overall accuracy (to 0.6896).

However, the most significant improvement is seen after adding the review scores (*primary polarity*) as features. It helps improve almost all scores, including accuracy, which reaches 0.7241.

5.2 Top-down Approach

The *primary polarity* classifier, which uses the review's rating to predict its overall polarity, has a high recall and an accuracy of 0.7379 (see Table 3). However, it again ignores the objective class, because it is distributed more or less evenly between reviews with different ratings and thus cannot be correlated with a particular review score.

	Subjective				**Objective**		**Total**			
	Negative		**Positive**							
	Prec	**Rec**	**Prec**	**Rec**	**Prec**	**Rec**	**Prec**	**Rec**	**F1**	**Acc**
Lexical	0.71	0.77	0.61	0.54	0.29	**0.27**	0.60	0.61	0.61	0.6138
Local discourse	0.69	**0.87**	**0.64**	0.73	0.00	0.00	0.55	0.68	0.61	0.6758
+ Contrast	0.69	**0.87**	0.62	0.68	0.00	0.00	0.55	0.66	0.60	0.6620
+ Background	0.73	0.85	0.60	0.75	**1.00**	0.12	0.74	0.69	0.65	0.6896
+ Primary pol.	**0.78**	**0.87**	0.62	**0.82**	**1.00**	0.12	**0.77**	**0.72**	**0.68**	**0.7241**

Table 2. Precision, recall, F1 and accuracy scores for the bottom-up approach

	Subjective				Objective		Total			
	Negative		Positive							
	Prec	**Rec**	**Prec**	**Rec**	**Prec**	**Rec**	**Prec**	**Rec**	**F1**	**Acc**
Primary polarity	0.75	0.94	0.71	0.83	0.00	0.00	0.61	0.74	0.66	0.7379
+ Contrast	0.81	0.90	0.68	**0.95**	0.00	0.00	0.63	0.75	0.68	0.7517
+ Background	**0.82**	**0.91**	**0.73**	**0.95**	**1.00**	**0.19**	**0.83**	**0.79**	**0.76**	**0.7931**

Table 3. Precision, recall, F1 and accuracy scores for the top-down approach

Also, because 3-star reviews contain more negative sentences than positive ones, all of them are lumped into the negative class. Thus the recall for the positive class is substantially low than for the negative class.

To single out the segments whose polarity is different from the primary one, we add explicit and implicit *contrast* features and train the contrast classifier. *Contrast* features help to raise recall for positive and precision for negative sentences, though, as might be expected, they do not affect the classification of objective segments. However, the overall precision and recall are improved, as well as the overall accuracy (to 0.7517)

The *background* classifier allows us to find some of objective sentences. *Acquirement, personal background* and *personal experience* patterns turn out to be precise features that also guarantee us at least some recall for objective sentences. Overall precision, recall and F1 scores are improved accordingly, as well as accuracy (to 0.7931).

As can be seen from comparing these results, even the most primitive rating-based classifier (*primary polarity*) achieves better recall and accuracy than any of lexical classifiers (even the one with primary polarity features). Moreover, adding discourse features to it consistently improves the results, allowing us to build a high-precision, high-recall sentiment classifier. On the other hand, building up on the lexical classifier does not show such consistent improvements.

6 Conclusion

Until now the sentiment analysis has been primarily done in a bottom-up way, starting with the classification of lexical items, then resolving the polarity of the sentence, then using discourse information to improve the lexical classification. However, lexical classifiers so far produce results that are too unreliable to become a basis of a discourse-level classification. We assert that starting from the top by roughly defining a text's polarity and assigning it to all its segments, and then fine-tuning the classification by "chiseling out" incorrect bits based on reliable discourse relations can be a more productive and effective approach. Our experiments show that such approach can lead to a substantial improvement over lexical baseline at least in texts with a predictable structure and recurring patterns, such as product reviews. Because each of the discourse features we tested led to improvement, we believe that the top-down classifier can be made even more accurate by employing other discourse relations in the form of carefully selected linguistic features.

How to Memorize a Random 60-Bit String

Abstract

User-generated passwords tend to be memorable, but not secure. A random, computer-generated 60-bit string is much more secure. However, users cannot memorize random 60-bit strings. In this paper, we investigate methods for converting arbitrary bit strings into English word sequences (both prose and poetry), and we study their memorability and other properties.

1 Introduction

Passwords chosen by users (e.g., "Scarlet%2") are easy to remember, but not secure (Florencio and Herley, 2007). A more secure method is to use a system-assigned 60-bit random password, such as 0010100010100...00101001. However, this string is hard to memorize. In this paper, we convert such strings into English phrases, in order to improve their memorability, using natural language processing to select fluent passphrases.

Our methods are inspired by an XKCD cartoon[1] that proposes to convert a randomly-chosen 44-bit password into a short, nonsensical sequence of English words. The proposed system divides the 44-bit password into four 11-bit chunks, and each chunk provides an index into a 2048-word English dictionary. XKCD's example passphrase is *correct horse battery staple*:

```
44-bit password   English phrase
---------------   --------------
10101101010    -> correct
10010110101    -> horse
01010101010    -> battery
10110101101    -> staple
```

The four-word sequence is nonsense, but it is easier to memorize than the 44-bit string, and XKCD hypothesizes that users can improve memorability by building an image or story around the four words.

In this paper, we investigate other methods for converting a system-generated bit string into a memorable sequence of English words. Our methods produce whole sentences, e.g.

```
Fox news networks are seeking
views from downtown streets.
```

as well as short poems, e.g.

```
Diversity inside replied,
Soprano finally reside.
```

We also move to 60-bit passwords, for better security. One source claims:

> As of 2011, available commercial products claim the ability to test up to 2,800,000,000 passwords a second on a standard desktop computer using a high-end graphics processor.[2]

If this is correct, a 44-bit password would take one hour to crack, while a 60-bit password would take 11.3 years.

Our concrete task is as follows:

[1] http://xkcd.com/936

					Diversity inside replied retreats or colors justified
					Surprise celebrity without the dragging allison throughout

Table 1: Comparison of methods that convert system-assigned 60-bit strings into English word sequences. Average word lengths range from 4 (XKCD) to 15 (First Letter Mnemonic). Average character lengths include spaces. LM score refers to the log probability assigned by a 5-gram English language model trained on the Gigaword corpus. Capacity tells how many English word sequences are available for an individual 60-bit input string.

- **Input:** A random, system-generated 60-bit password.
- **Output:** An English word sequence with two properties:
  - It is memorable.
  - We can deterministically recover the original input 60-bit string from it.

This implies that we map 2^{60} distinct bit strings into 2^{60} distinct English sequences. If a user memorizes the English word sequence supplied to them, then they have effectively memorized the 60-bit string.

2 Password Generation Methods

We now describe our baseline password generation method, followed by four novel methods. In Section 3 we experimentally test their memorability.

2.1 XKCD Baseline

Our baseline is a version of XKCD. Instead of a 2048-word dictionary, we use a 32,7868-word dictionary. We assign each word a distinct 15-bit code.

At runtime, we take a system-assigned 60-bit code and split it into four 15-bit sequences. We then substitute each 15-bit segment with its corresponding word. By doing this, we convert a random 60-bit code into a 4-word password.

The first row of Table 1 shows three sample XKCD passwords, along with other information, such as the average number of characters (including spaces).

2.2 First Letter Mnemonic

XKCD passwords are short but nonsensical, so we now look into methods that instead create longer but fluent English sentences. We might think to guarantee fluency by selecting sentences from an already-existing text corpus, but no corpus is large enough to contain 2^{60} ($\sim 10^{18}$) distinct sentences. Therefore, we must be able to synthesize new English strings.

In our first sentence generation method (*First Letter Mnemonic*), we store our input 60-bit code in the first letters of each word. We divide the 60-bit code into 4-bit sections, e.g., '0100-1101-1101-...'. Every 4-bit sequence type corresponds to an English letter or two, per Table 2. We build a word-confusion network (or "sausage lattice") by replacing each 4-bit code with all English words that start with a corresponding letter, e.g.:

Bit Sequence	Mapped Character	Bit Sequence	Mapped Character
0000	e	1000	r,x
0001	t	1001	d,j
0010	a	1010	l,k
0011	o	1011	c,v
0100	i	1100	u,b
0101	n	1101	m,p
0110	s,z	1110	w,y
0111	h,q	1111	f,g

Table 2: Mapping function between 4-bit sequences and English letters in the First Letter Mnemonic method.

```
0100     1101     1111         ... 0011
----     ----     ----             ----
income   my       frog         ... octopus
is       miner    feast        ... of
inner    priest   gratuitous   ... oregon
 ...      ...      ...              ...
```

This yields about 10^{74} paths, some good (*is my frog...*) and some bad (*income miner feast...*). To select the most fluent path, we train a 5-gram language model with the SRILM toolkit (Stolcke, 2002) on the English Gigaword corpus.[3] SRILM also includes functionality for extracting the best path from a confusion network.

Table 1 shows sample sentences generated by the method. Perhaps surprisingly, even though the sentences are much longer than XKCD (15 words versus 4 words), the n-gram language model (LM) score is a bit better. The sentences are locally fluent, but not perfectly grammatical.

We can easily reconstruct the original 60-bit code by extracting the first letter of each word and applying the Table 2 mapping in reverse.

2.3 All Letter Method

Most of the characters in the previous methods seem "wasted", as only the word-initial letters bear information relevant to reconstructing the original 60-

[3] https://catalog.ldc.upenn.edu/LDC2011T07

Bit Sequence	Mapped Characters
0	e, o, i, h, r, c, u, f, g, b, v, x ,q
1	t, a, n, s, d, l, m, w, y, p, k, j, z

Table 3: Mapping function between bits and English characters in the All Letter Method.

bit string. Our next technique (*All Letter Method*) non-deterministically translates *every* bit into an English letter, per Table 3. Additionally, we non-deterministically introduce a space (or not) between each pair of letters.

This yields $4 \cdot 10^{84}$ possible output strings per input, $3 \cdot 10^{56}$ of which consist of legal English words. From those $3 \cdot 10^{56}$ strings, we choose the one that yields the best word 5-gram score.

It is not immediately clear how to process a letter-based lattice with a word-based language model. We solve this search problem by casting it as one of machine translation from bit-strings to English. We create a phrase translation table by pairing each English word with a corresponding "bit phrase", using Table 3 in reverse. Sample entries include:

```
din ||| 1 0 1
through ||| 1 0 0 0 0 0 0
yields ||| 1 0 0 1 1 1
```

We then use the Moses machine translation toolkit (Koehn et al., 2007) to search for the 1-best translation of our input 60-bit string, using the phrase table and a 5-gram English LM, disallowing re-ordering.

Table 1 shows that these sentences are shorter than the mnemonic method (11.8 words versus 15 words), without losing fluency.

Given a generated English sequence, we can deterministically reconstruct the original 60-bit input string, using the above phrase table in reverse.

2.4 Frequency Method

Sentence passwords from the previous method contain 70.8 characters on average (including spaces). Classic studies by Shannon (1951) and others estimate that printed English may ultimately be compressible to about one bit per character. This implies we might be able to produce shorter output (60 characters, including space) while maintaining normal English fluency.

Our next technique (*Frequency Method*) modifies the phrase table by assigning short bit codes to frequent words, and long bit codes to infrequent words. For example:

```
din ||| 0 1 1 0 1 0 1 0 0
through ||| 1 1 1 1
yields ||| 0 1 0 1 1 1 0 1
```

Note that the word *din* is now mapped to a 9-bit sequence rather than a 3-bit sequence. More precisely, we map each word to a random bit sequence of length $\lfloor \max(1, -\alpha \times log\ \mathrm{P}(word) + \beta) \rfloor$. By changing variables α and β we can vary between smooth but long sentences ($\alpha = 1$ and $\beta = 0$) to XKCD-style phrases ($\alpha = 0$ and $\beta = 15$).

Table 1 shows example sentences we obtain with $\alpha = 2.5$ and $\beta = -2.5$, yielding sentences of 9.7 words on average.

2.5 Poetry

In ancient times, people recorded long, historical epics using poetry, to enhance memorability. We follow this idea by turning each system-assigned 60-bit string into a short, distinct English poem. Our format is the *rhyming iambic tetrameter couplet*:

- The poem contains two lines of eight syllables each.
- Lines are in iambic meter, i.e., their syllables have the stress pattern 01010101, where 0 represents an unstressed syllable, and 1 represents a stressed syllable. We also allow 01010100, to allow a line to end in a word like *Angela*.
- The two lines end in a pair of rhyming words. Words rhyme if their phoneme sequences match from the final stressed vowel onwards. We obtain stress patterns and phoneme sequences from the CMU pronunciation dictionary.[4]

Monosyllabic words cause trouble, because their stress often depends on context (Greene et al., 2010). For example, *eighth* is stressed in *eighth street*, but not in *eighth avenue*. This makes it hard to guarantee that automatically-generated lines will scan as intended. We therefore eject all monosyllabic words

[4] http://www.speech.cs.cmu.edu/cgi-bin/cmudict

from the vocabulary, except for six unstressed ones (*a*, *an*, *and*, *the*, *of*, *or*).

Here is a sample poem password:

```
The le-gen-da-ry Ja-pan-ese
 ↓   ↑   ↓  ↑  ↓  ↑   ↓   ↑
Sub-si-di-ar-ies ov-er-seas
 ↓   ↑  ↓  ↑   ↓   ↑  ↓  ↑
```

Meter and rhyme constraints make it difficult to use the Moses machine translation toolkit to search for fluent output, as we did above; the decoder state must be augmented with additional short- and long-distance information (Genzel et al., 2010).

Instead, we build a large finite-state acceptor (FSA) with a path for each legal poem. In each path, the second line of the poem is reversed, so that we can enforce rhyming locally.

The details of our FSA construction are as follows. First, we create a finite-state transducer (FST) that maps each input English word onto four sequences that capture its essential properties, e.g.:

```
create -> 0 1
create -> 0 1 EY-T
create -> 1r 0r
create -> EY-T 1r 0r
```

Here, `EY-T` represents the rhyme-class of words like *create* and *debate*. The *r* indicates a stress pattern in the right-to-left direction.

We then compose this FST with an FSA that only accepts sequences of the form:

`0 1 0 1 0 1 0 1 X X 1r 0r 1r 0r 1r 0r 1r 0r`

where X and X are identical rhyme classes (e.g., EY-T and EY-T).

It remains to map an arbitrary 60-bit string onto a path in the FSA. Let k be the integer representation of the 60-bit string. If the FSA contains exactly 2^{60} paths, we can easily select the kth path using the following method. At each node N of the FSA, we store the total number of paths from N to the final state—this takes linear time if we visit states in reverse topological order. We then traverse the FSA deterministically from the start state, using k to guide the path selection.

Our FSA actually contains 2^{79} paths, far more than the required 2^{60}. We can say that the information capacity of the English rhyming iambic tetrameter couplet is 79 bits! Some are very good:

```
Sophisticated potentates
misrepresenting Emirates.

The supervisor notified
the transportation nationwide.

Afghanistan, Afghanistan,
Afghanistan, and Pakistan.
```

while others are very bad:

```
The shirley emmy plebiscite
complete suppressed unlike invite

The shirley emmy plebiscite
complaints suppressed unlike invite

The shirley emmy plebiscite
complaint suppressed unlike invite
```

Fortunately, because our FSA contains over a million times the required 2^{60} paths, we can avoid these bad outputs. For any particular 60-bit string, we have a million poems to choose from, and we output only the best one.

More precisely, given a 60-bit input string k, we extract not only the kth FSA path, but also the $k + i \cdot 2^{60}$ paths, with i ranging from 1 to 999,999. We explicitly list out these paths, reversing the second half of each, and score them with our 5-gram LM. We output the poem with the 1-best LM score. Table 1 shows sample outputs.

To reconstruct the original 60-bit string k, we first find the FSA path corresponding to the user-recalled English string (with second half reversed). We use depth-first search to find this path. Once we have the path, it is easy to determine which numbered path it is, lexicographically speaking, using the node-labeling scheme above to recover k.

3 Experiments

We designed two experiments to compare our methods.

The first experiment tests the memorability of passwords. We asked participants to memorize a password from a randomly selected method[5] and recall it two days later. To give more options to users,

[5] In all experiments, we omit the First Letter Mnemonic, due to its low performance in early tests.

Method	Participants	Recalls	Correct Recalls
XKCD	16	12	58.3%
All Letter Method	15	9	33.3%
Frequency Method	15	10	40.0%
Poetry	16	13	61.5%

Table 4: Memorability of passwords generated by our methods. "Recalls" indicates how many participants returned to type their memorized English sequences, and "Correct Recalls" tells how many sequences were accurately remembered.

Method Name	User preference
XKCD	5%
All Letter Method	39%
Frequency Method	37%
Poetry	19%

Table 5: User preferences among passwords generated by our methods.

we let them select from the 10-best passwords according to the LM score for a given 60-bit code. Note that this flexibility is not available for XKCD, which produces only one password per code.

62 users participated in this experiment, 44 returned to recall the password, and 22 successfully recalled the complete password. Table 4 shows that the Poetry and XKCD methods yield passwords that are easiest to remember.

In the second experiment, we present a separate set of users with passwords from each of the four methods. We ask which they would prefer to use, without requiring any memorization. Table 5 shows that users prefer sentences over poetry, and poetry over XKCD.

4 Analysis

Table 4 shows that the Poetry and XKCD methods yield passwords that are easiest to memorize. Complete sentences generated by the All Letter and Frequency Methods are harder to memorize. At the same time Table 5 shows that people like the sentences better than XKCD, so it seems that they overestimate their ability to memorize a sentence of 10-12 words. Here are typical mistakes (S = system-generated, R = as recalled by user):

```
(S) Still looking for ruben sierra could
    be in central michigan
(R) I am still looking for ruben sierra
    in central michigan

(S) That we were required to go to
    college more than action movies
(R) We are required to go to
    college more than action movies

(S) No dressing allowed under canon law
    in the youth group
(R) No dresses allowed under canon law
    for youth groups
```

Users remember the gist of a sentence very well, but have trouble reproducing the exact wording. Post-experiment interview reveal this to be partly an effect of overconfidence. Users put little mental work into memorizing sentences, beyond choosing among the 10-best alternatives presented to them. By contrast, they put much more work into memorizing an XKCD phrase, actively building a mental image or story to connect the four otherwise unrelated words.

5 Future Directions

Actually, we can often *automatically* determine that a user-recalled sequence is wrong. For example, when we go to reconstruct the 60-bit input string from a user-recalled sequence, we may find that we get a 62-bit string instead. We can then automatically prod the user into trying again, but we find that this is not effective in practice. An intriguing direction is to do automatic error-correction, i.e., take the user-recalled sequence and find the closest match among the 2^{60} English sequences producible by the method. Of course, it is a challenge to do this with 1-best outputs of an MT system that uses heuristic beam search, and we must also ensure that security is maintained.

We may also investigate new ways to re-rank n-best lists. Language model scoring is a good start, but we may prefer vivid, concrete, or other types of words, or we may use text data associated with the user (papers, emails) for secure yet personalized password generation.

6 Related Work

Gasser (1975), Crawford and Aycock (2008), and Shay et al. (2012) describe systems that produce meaningless but pronounceable passwords, such as "tufritvi" . However, their systems can only assign $\sim 2^{30}$ distinct passwords.

Jeyaraman and Topkara (2005) suggest generating a random sequence of characters, and finding a mnemonic for it in a text corpus. A limited corpus means they again have a small space of system-assigned passwords. We propose a similar method in Section 2.2, but we automatically synthesize a new mnemonic word sequence.

Kurzban (1985) and Shay et al. (2012) use a method similar to XKCD with small dictionaries. This leads to longer nonsense sequences that can be difficult to remember.

7 Conclusion

We introduced several methods for generating secure passwords in the form of English word sequences. We learned that long sentences are seemingly easy to remember, but actually hard to reproduce, and we also learned that our poetry method produced relatively short, memorable passwords that are liked by users.

Acknowledgments

A Bayesian Model for Joint Learning of Categories and their Features

Lea Frermann and **Mirella Lapata**

Abstract

Categories such as ANIMAL or FURNITURE are acquired at an early age and play an important role in processing, organizing, and conveying world knowledge. Theories of categorization largely agree that categories are characterized by features such as `function` or `appearance` and that feature and category acquisition go hand-in-hand, however previous work has considered these problems in isolation. We present the first model that jointly learns categories and their features. The set of features is shared across categories, and strength of association is inferred in a Bayesian framework. We approximate the learning environment with natural language text which allows us to evaluate performance on a large scale. Compared to highly engineered pattern-based approaches, our model is cognitively motivated, knowledge-lean, and learns categories and features which are perceived by humans as more meaningful.

1 Introduction

Categorization is one of the most basic cognitive functions. It allows individuals to organize their subjective experience of their environment by structuring its contents. This ability to group different objects into the same category based on their common characteristics underlies major cognitive activities such as perception, learning, and the use of language. Global categories (such as FURNITURE or ANIMAL) are shared among members of societies, and influence how we perceive, interact with, and argue about the world.

Given its fundamental importance, categorization is one of the most studied problems in cognitive science. The literature is rife with theoretical and experimental accounts, as well as modeling simulations focusing on the emergence, representation, and learning of categories. Most theories assume that basic level concepts such as *dog* or *chair* are characterized by features such as `barks` or `used-for-sitting`, and are grouped into categories based on those features. Although the precise grouping mechanism has been subject to considerable debate (including arguments in favor of *exemplars* (Nosofsky, 1988), *prototypes* (Reed, 1972), and category *utility* (Corter and Gluck, 1992)), it is fairly uncontroversial that categories are associated with featural representations.

Experimental studies show that the development of categories and feature learning mutually influence each other (Goldstone et al., 2001; Schyns and Rodet, 1997): concepts are categorized based on their features, but the perception of features is influenced by already established categories, and, like categories, features evolve over time. There is also evidence that features such as `barks` or `runs` are grouped into types like `behavior` (Ahn, 1998; McRae et al., 2005; Spalding and Ross, 2000), and the distribution of feature types varies across categories. For instance, living-things such as ANIMALS have characteristic `behavior`, whereas artifacts such as TOOLS have characteristic `functions`, and both categories have characteristic `appearance`.

In this paper, we investigate the problem of *jointly* learning categories and their feature types. Previous modeling work has largely considered these problems in isolation, focusing either on category learning with a fixed set of simplistic features (Anderson, 1991; Sanborn et al., 2006) or feature learning (Austerweil and Griffiths, 2013; Baroni et al., 2010;

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1576–1586,
Denver, Colorado, May 31 – June 5, 2015.

Kelly et al., 2014), but not both.

We present a Bayesian model which induces (semantic) categories and feature types from natural language text. Although language is one of many factors influencing category formation (others include the physical world, how we perceive it, and interact with it), large text corpora encode a surprising amount of extralinguistic information (Riordan and Jones, 2011), and can thus be viewed as an approximation of the learning environment. Moreover, focusing on textual data, allows us to build categorization models with theoretically unlimited scope, and evaluate categories and their features on a much larger scale than previous work in the cognitive science literature.

Our model induces categories (e.g., ANIMALS) and their feature types (e.g., `behavior`) from observations of target concepts (e.g., *lion*, *cow*) and their co-occurring contexts (e.g., *eats*, *sleeps*, *large*). While we can directly evaluate learnt categories through comparison against behavioral data, evaluating feature types is less straightforward. Previous work has shown that the kinds of features learnable from text are qualitatively different from those produced by humans, which makes direct comparison difficult (Baroni et al., 2010; Kelly et al., 2014). We circumvent this problem by assessing in a crowd-sourcing experiment whether the induced feature types are *relevant* for a given category and whether they form a *coherent* class. Evaluation results show that our joint model learns accurate categories and feature types achieving results competitive with highly engineered approaches focusing exclusively on feature learning.

2 Related Work

The problems of category formation and feature learning have been considered largely independently in the literature. Bayesian categorization models were pioneered by Anderson (1991) and recently reformalized by Sanborn et al. (2006). These models are aimed at replicating human behavior in small scale category acquisition studies, where a fixed set of simple (e.g., binary) features is assumed. Frermann and Lapata (2014) propose a model similar in spirit, which they apply to large scale corpora, while investigating incremental learning in the context of child category acquisition (see also Fountain and Lapata (2011) for a non-Bayesian approach). Their model associates sets of features with categories as a by-product of the learning process, however these feature sets are independent across categories and are not optimized during learning.

Previous approaches on feature learning have primarily focused on emulating or complementing norming studies by automatically extracting norm-like properties from textual corpora (e.g., *elephant* `has-trunk`, *scissors* `used-for-cutting`). A common theme in this line of research is the use of pre-defined syntactic patterns (Baroni et al., 2010), or manually created rules specifying possible connection paths of concepts to features in dependency trees (Devereux et al., 2009; Kelly et al., 2014). Once extracted, the features are typically weighted in order to filter out noisy instances. Features are learnt for individual concepts rather than categories. Austerweil and Griffiths (2013) also focus exclusively on feature learning, however from sensory data. They develop a nonparametric Bayesian model which is able to infer unlimited features, based on distributional patterns as well as category information.

To our knowledge, we propose the first Bayesian model that jointly learns categories and their features, arguing that the two tasks are mutually dependent. Our model is knowledge-lean, it learns from raw text in a single process, without relying on parsing resources, manually crafted rule patterns, or post-processing steps. Our work also differs from approaches which combine topic models with human-produced feature norms (Steyvers, 2010). Our aim is not to boost the generalization performance of a topic model, rather we investigate how both categories and features can be jointly learnt from data.

3 The BCF Model

In this section we present our Bayesian model of category and feature induction (henceforth, BCF). BCF jointly learns categories, feature types, and their associations. Specifically, it infers one global set of feature types which is shared across categories (e.g., ANIMALS and VEHICLES can be described in terms of `colors`). However, categories

Generate category distribution, $\theta \sim Dir(\alpha)$

  Generate category, $k^{\ell} \sim Mult(\theta)$
for category k **do**
  Generate feature type distribution, $\mu_k \sim Dir(\beta)$
for feature type g **do**
  Generate feature distribution, $\phi_g \sim Dir(\gamma)$
for stimulus d **do**
  Observe concept c^d and retrieve category k^{c^d}
  Generate a feature type, $g^d \sim Mult(\mu_{k^{c^d}})$
  for feature position i **do**
    Generate a feature $f_{d,i} \sim Mult(\phi_{g^d})$

Figure 1: The generative story of the BCF model. Observations f and latent labels k and g are drawn from Multinomial distributions (*Mult*). Parameters for the multinomial distributions are drawn from Dirichlet distributions (*Dir*).

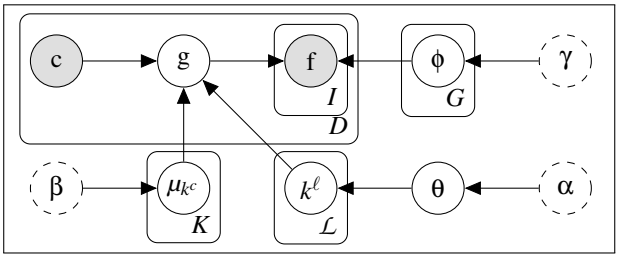

Figure 2: The plate diagram of the BCF model. Shaded nodes indicate observed variables, and dotted nodes indicate hyperparameters.

differ in their strength of association with feature types (e.g., the feature type `function` will be highly associated with TOOLS but less so with ANIMALS). BCF jointly optimizes categories and their featural representation: the learning objective is to obtain a set of meaningful categories, each characterized by relevant and coherent feature types.

The generative story and plate diagram for the BCF model are shown in Figures 1 and 2, respectively. The input to the model is a collection of *stimuli* $d \in \{1..D\}$ extracted from a large text corpus. Each stimulus consists of a target concept $c \in \{1..\mathcal{L}\}$ and its context $\mathbf{f} \in \{1..F\}$. We adopt a simple representation of context as the set of words making up the sentence c occurs in (except c). The model assigns concepts to categories $k \in \{1..K\}$ and features to feature types $g \in \{1..G\}$. It learns a set of concept clusters (i.e., categories), as well as a clustering over features (i.e., feature types), and a distribution over those feature clusters for each category (i.e., category-feature type associations). Specifically, the occurrences of a concept will be assigned a category, based on how similar the concept's feature types are compared to the feature types of all other potential categories. Simultaneously, upon observing a stimulus (i.e., a concept in context), the model assigns the context to a particular feature type based on its probability under all potential feature types, and the prior probability of observing that feature type with the concept's assigned category.

More formally, we can describe the model through the generative story given in Figure 1. We assume a global multinomial distribution over categories $Mult(\theta)$, drawn from a symmetric Dirichlet distribution with hyperparameter α. For each category k, we assume an independent set of multinomial parameters over feature types μ_k, drawn from a symmetric Dirichlet distribution with hyperparameter β. For each concept type ℓ, we draw a category k^{ℓ} from $Mult(\theta)$. Finally, for each feature type g, we draw a multinomial distribution over features $Mult(\phi_g)$ from a symmetric Dirichlet distribution with hyperparameter γ. With these global assignments in place, we can generate stimuli d as follows: we first retrieve the category k^{c^d} of the observed concept c^d; we then generate a feature type g^d from the category's feature type distribution $Mult(\mu_{k^{c^d}})$; and finally, for each feature position i we generate feature $f_{d,i}$ from the feature type's distribution $Mult(\phi_{g^d})$. The joint probability of the model over latent categories, latent feature types, model parameters, and data can be factorized as:

$$P(g,f,\mu,\phi,\theta,k|c,\alpha,\beta,\gamma) = \quad (1)$$
$$P(\theta|\alpha)\prod_{\ell}P(k^{\ell}|\theta)\prod_{k}P(\mu_k|\beta)\prod_{g}P(\phi_g|\gamma)$$
$$\prod_{d}P(g^d|\mu_{k^{c^d}})\prod_{i}P(f^{d,i}|\phi_{g^d}).$$

Since we use conjugate priors throughout, we can integrate out the model parameters analytically, and perform inference only over the latent variables, namely the category and feature type labels associ-

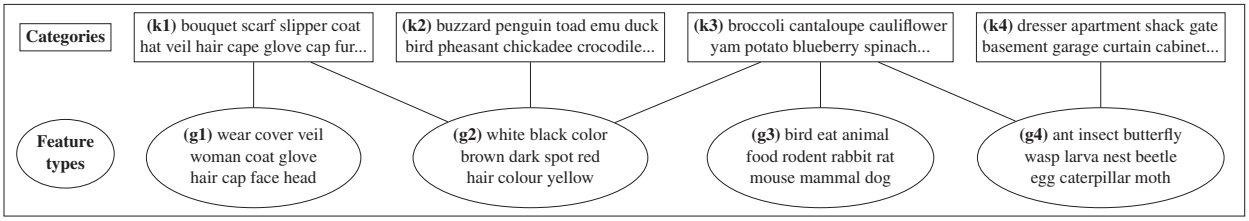

Figure 3: Example of categories (top) and feature types (bottom) inferred by the BCF model. Connecting lines indicate a strong association between the category and the respective feature type.

ated with the stimuli.

Exact inference in the BCF model is intractable, so we turn to approximate posterior inference to discover the assignments of latent variables that best explain our data. We construct a Gibbs sampler (Geman and Geman, 1984) which iteratively re-assigns single variables based on the current assignments of all other variables. One Gibbs iteration for our model consists of one sweep through the input stimuli, resampling feature type assignments from:

$$P(g^d_{k^{c^d}} = i | \mathbf{g}^{-d}_{k^{c^d}}, \mathbf{f}^{-}, k^{c^d}, \beta, \gamma) \quad (2)$$
$$\propto P(g^d_{k^{c^d}} = i | \mathbf{g}^{-d}_{k^{c^d}}, k^{c^d}, \beta) \times P(f^d | \mathbf{f}^{-}, g^d_{k^{c^d}} = i, \gamma),$$

followed by one sweep through the concept types, resampling category assignments from:

$$P(k^\ell = j | \mathbf{g}_{k^\ell}, \mathbf{k}^{-}, \alpha, \beta) \quad (3)$$
$$\propto P(k^\ell = j | \mathbf{k}^{-}, \alpha) \times P(\mathbf{g}_{k^\ell} | \mathbf{g}^{-}_{k^\ell}, k^\ell = j, \beta),$$

where $g^d_{k^{c^d}}$ denotes the feature type assignment to stimulus d given the category k^{c^d} of d's observed target concept c^d. k^ℓ refers to the category assignment of concept type ℓ, $\mathbf{g}_{k^\ell}$ refers to the feature type associations of category k^ℓ, and f^d refers to the observed features in stimulus d. The superscript $^-$ indicates the absence of the variable assignment(s) which are currently resampled from the current representation of the model state.

Figure 3 illustrates example output produced by our model, in terms of learnt categories, learnt feature types and their associations. Connecting lines indicate category-feature type associations. Feature types are shared across categories, e.g., categories CLOTHING (k1), BIRDS (k2), and FOOD (k3) are all associated with feature type `color` (g2).

4 Experimental Design

In this section we outline our experimental set-up for assessing the performance of the BCF model described above. We present our data set, briefly introduce the models used for comparison with our approach, and explain how system output was evaluated. We then report results on a series of experiments which evaluate the quality of the categories and feature types learnt by BCF.

Data Our experiments used basic-level target concepts (e.g., *cat* or *chair*) from two norming studies (McRae et al., 2005; Vinson and Vigliocco, 2008). In these studies, humans were presented with concepts and asked for each concept to produce a set of characteristic features. In a subsequent study (Fountain and Lapata, 2010), the concepts were classified into 41 categories (with possible multi-category membership), 34 of which we use as a goldstandard in our categorization experiments (comprising 492 concepts in total). We excluded very general categories such as THING or STRUCTURE, based on the intuition that it is difficult to identify characteristic features for them. As a heuristic concepts were excluded if they were close to the root of WordNet (e.g., with depth 2 or 4).

To obtain the input stimuli for the BCF model, we used a subset of the Wackypedia corpus (Baroni et al., 2009), an automatically extracted and POS tagged dump of the English Wikipedia. For each target concept, we identified one corresponding article in Wackypedia. Next, we extracted a set of stimuli which consists of (a) every sentence from the concept's corresponding article, and (b) any sentence in a different article which mentions the concept. This resulted in a data set of 63,076 stimuli which we split into 60% training, 20% development and 20% test.

We removed stopwords as well as words with a part of speech other than noun, verb, and adjective. Furthermore, we discarded words with an age of acquisition above 10 years (Kuperman et al., 2012) to restrict the vocabulary to frequent and generally familiar words.

Models and Parameters We compared the performance of BCF against BayesCat, a Bayesian model of category acquisition (Frermann and Lapata, 2014) and Strudel, a pattern-based model which extracts concept features from text (Baroni et al., 2010).

BayesCat induces categories, which are represented through a distribution over target concepts, and a distribution over features (i.e., individual context words). In contrast to BCF, it does not learn types of features. In addition, while BCF induces a hard assignment of concepts to categories, BayesCat learns soft distributions over target concepts for each category. Soft assignments can be converted into hard assignments by assigning each concept to its most probable category. We ran BayesCat on the same input stimuli as BCF, with the following parameters: the number of categories was set to $K = 40$, and the hyperparameters to $\alpha = 0.7, \beta = 0.1, \gamma = 0.1$. For the BCF model, we used the same number of categories, namely $K = 40$. The number of feature types was set to $G = 75$, and the hyperparameters to $\alpha = 0.5, \beta = 0.5$, and $\gamma = 0.1$. Parameters were tuned on the development set. For both models, we report results averaged over 10 Gibbs runs, each time we ran the sampler for 1,000 iterations. We used annealing during learning which proved effective for avoiding local optima.

Strudel automatically extracts features for concepts from text collections following a pattern-based approach. It takes as input a set of target concepts and a set of patterns, and extracts a list of features for each concept, where each concept-feature pair is weighted with a log-likelihood ratio expressing the pair's strength of association. Baroni et al. (2010) show that the learnt representations can be used as a basis for various tasks such as typicality rating, categorization, or clustering of features into types. In our experiments we obtained Strudel representations from the same Wackypedia corpus used for extracting the input stimuli for BCF (and BayesCat). Note that Strudel, unlike the two Bayesian models, is not a cognitively motivated *acquisition* model, but an optimized system developed with the aim of obtaining the best possible features from data.

4.1 Experiment 1: Evaluation of Categories

In our first experiment we evaluate the quality of the categories induced by the three models presented above. The models produce hard categorizations, however, the cognitive gold standard we use for evaluation (Fountain and Lapata, 2010) represents soft categories. We obtained a hard categorization by assigning members of multiple categories to their most typical category (typicality scores are provided with the data).[1]

Method BCF and BayesCat learn a set of categories which we can directly compare to the gold standard. For Strudel, we produce a categorization as follows: we represent each concept as a vector over features (obtained from Wackypedia), where each component corresponds to the concept-feature log-likelihood ratios provided by Strudel; following Baroni et al. (2010), we then cluster the vectors using K-means and the Cluto toolkit.[2] As for the other models, we set the number of categories to $K = 40$.

Metrics To assess the quality of the clusters produced by the models, we measure purity (*pur*; the extent to which each learnt cluster corresponds to a single gold class) as well as its inverse, collocation (*col*; the extent to which all items of a particular gold class are represented in a single learnt cluster). Both measures are based on set-overlap, and we also report their harmonic mean ($f1$; Lang and Lapata 2011). In addition, we report the V-measure ($v1$; Rosenberg and Hirschberg 2007) and its factors measuring the homogeneity of clusters (*hom*) and their completeness (*com*). The two factors intuitively correspond to purity and collocation, but are based on information-theoretic measures.

Results Our results are summarized in Table 1. They show that BCF and Strudel perform almost identically, and both outperform BayesCat. BCF *learns* the categories from data, whereas for Strudel

[1] http://homepages.inf.ed.ac.uk/s0897549/data/.

[2] http://glaros.dtc.umn.edu/gkhome/cluto/cluto/overview

	hom	*com*	*v*1	*pur*	*col*	*f*1
BCF	0.68	0.64	**0.66**	0.59	0.52	**0.55**
BayesCat	0.65	0.59	0.62	0.57	0.45	0.50
Strudel	0.70	0.62	**0.66**	0.61	0.48	0.54

Table 1: Model performance on the category induction task.

we construct the categories post-hoc after a highly informed feature extraction process (relying on grammatical patterns). It is therefore not surprising that Strudel performs well, and it is encouraging to see that BCF does too. Also, note that Strudel tends to learn very clean clusters at the cost of recall, whereas the tradeoff is less extreme for BCF. Again, this is expected given Strudel's pattern-based approach. While BCF and Strudel are constrained to assign each concept to only one category, BayesCat induces a soft categorization which is turned into a hard categorization in a post-learning step. While this setting allows for more flexibility, it also induces more uncertainty and results in categorizations which resemble the gold standard less closely compared to the two other models.

4.2 Experiment 2: Evaluation of Features

We next investigate the quality of the features our model learns. We do this by letting the model predict the right concept solely from a set of features. If the model has acquired informative features, they will be predictive of the unknown concept. Specifically, the model is presented with a set of previously unseen test stimuli with the target concept removed. For each stimulus, the model ranks all possible target concepts based on the features **f** (i.e., context words).

Method In our experiments we compared the ranking performance of BCF, BayesCat, and Strudel. For the Bayesian models, we directly exploit the learnt distributions. For BCF, we compute the score of a target concept c given a set of features as:

$$Score(c|\mathbf{f}) = \sum_{g} P(g|c)P(\mathbf{f}|g). \quad (4)$$

		pr@1	*pr*@10	*pr*@20	*avg*
BCF	full	**0.12**	**0.50**	0.63	56.1
	−tgt	0.09	0.40	0.53	78.5
BayesCat	full	0.11	0.49	**0.64**	**37.7**
	−tgt	0.09	0.39	0.53	52.4
Strudel	full	0.07	0.33	0.47	64.4
	−tgt	0.07	0.35	0.49	62.2

Table 2: Model performance on the concept prediction task. Precision at rank 1, 10, 20, and average rank assigned (*avg*). −tgt refers to the condition where we remove context words which are identical to the target concept as opposed to using the full context.

Similarly, for BayesCat we compute the score of a concept c given a set of features as follows:

$$Score(c|\mathbf{f}) = \sum_{k} P(c|k)P(\mathbf{f}|k). \quad (5)$$

For Strudel, we rank concepts according to the cumulative log-likelihood ratio-based association score over all observed features for a particular concept c:

$$Score(c|\mathbf{f}) = \sum_{f \in \mathbf{f}} association(c, f). \quad (6)$$

Metrics Since we can directly compare model predictions against the actual target concept of the stimulus, we report precision at rank 1, 10, and 20. We also report the average rank assigned to the correct concept. All results are based on a random test set of 2,000 previously unseen stimuli. To control for the possibility that the models are learning a strong (yet trivial) correlation between target concepts and identical words occurring as features, we also report results on a modification of our test set where we remove any mention of the target concept from the context, if present (the −tgt condition).

Results Our results on the concept prediction task are shown in Table 2. The Bayesian models outperform Strudel across all metrics and conditions. Strudel's extraction algorithm, which relies on predefined patterns, might be too restrictive with respect to the set of features it extracts and as a result they are not discriminative. BayesCat and BCF

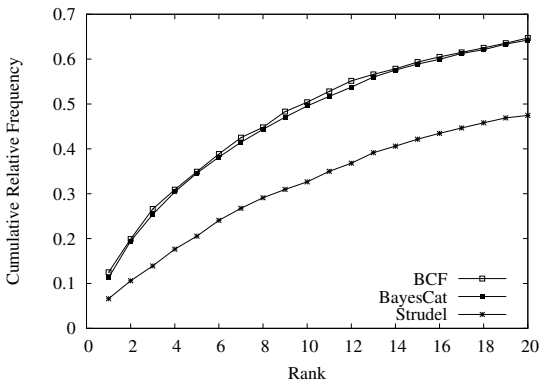

Figure 4: Number of times the correct target concept was placed within the top 20 ranks by BCF, BayesCat, and Strudel.

salmon	`journey move hundred mile strong current reproduce`				
BCF	**salmon**	tuna	goldfish	lobster	fish
BayesCat	fish	radio	goldfish	**salmon**	clock
Strudel	train	house	apartment	ship	car

finger	`avoid cut quick claw tip painful`				
BCF	tent	ski	peg	curtain	hut
BayesCat	eye	ear	spider	leg	hair
Strudel	**finger**	toe	hair	tail	hand

Table 3: Model output on the concept prediction task for *salmon* (top) and *finger* (bottom): the top part of each table shows the true concept (left) and the context provided to the model as input (right). The bottom part of the table shows the five most highly ranked concepts (left to right) for each model.

perform comparably given that they learn from exactly the same data and exploit local co-occurrence relations in similar ways. BayesCat produces better average rank scores than BCF, while achieving lower precision scores. This can be explained by the fact that BCF assigns low ranks to correct concepts more reliably than BayesCat. Figure 4 shows the relative cumulative frequencies of the ranks assigned by the three models. We display the top ranks 1 through 20 (out of 492). As can be seen, BCF performs slightly better than BayesCat. Pairwise differences between the systems are all statistically significant ($p \ll 0.01$); using a one-way ANOVA with post-hoc Tukey HSD test).

Note that performance decreases for the Bayesian models in the $-$tgt condition, i.e., when occurrences of the target concept are removed from the context. Strudel is less affected by this given its pattern-based learning mechanism which is not prone to associating target word types with themselves. However, repetitions are a natural phenomenon from a cognitive standpoint and it seems reasonable to consider multiple occurrences of a concept as a canonical feature of the learning environment.

Overall, the precision scores may seem low. However, the models rank a set of 492 target concepts; a random baseline would achieve a $pr@1$ of only 0.002%. In addition, the target concepts we are considering are by design highly confusable: they were selected so that they form categories and are thus bound to share some features which makes the prediction task harder. Example output for all three models is shown in Table 3. The models take context features "*journey move hundred mile strong*" and "*avoid cut quick claw tip*" as input and are expected to predict *salmon* and *finger*, respectively. Unlike Strudel, BCF and BayesCat rank *salmon* almost correctly and the other high ranked concepts are reasonable in the given context as well. For the second example, only Strudel predicts the correct concept correctly, but again the top-ranked concepts of the other two models are reasonable in the given context.

4.3 Experiment 3: Evaluation of Feature Types

In this suite of experiments we evaluate two aspects of the feature types induced by our model: (1) Are they *relevant* to their associated category? and (2) Do they form a *coherent* class? Our evaluation followed the intrusion paradigm originally introduced to assess the output of topic models (Chang et al., 2009). We performed two intrusion studies using Amazon's Mechanical Turk crowd-sourcing platform.

In the feature intrusion study, participants were shown examples of categories and their feature types both of which were represented as word clusters (see Figure 6 top). They were asked to detect the feature type which did not belong to the category. If a model creates *relevant* feature types, we would expect participants to be able to identify the intruder relatively easily. We also conducted a word intrusion

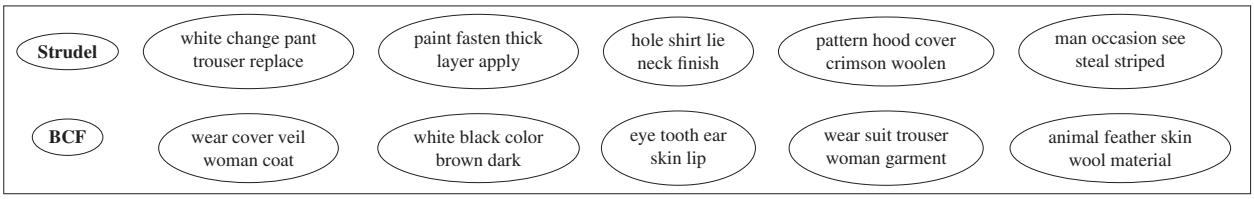

Figure 5: Example feature types learnt for the category CLOTHING by Strudel (top) and BCF (bottom).

'Select intruder feature type (right) wrt category (left).'

Figure 6: Illustration of the feature type intrusion task (top); and the word intrusion task (bottom).

study, where participants were shown a single feature type (again represented as a word cluster) and asked to detect the intruder feature/word (see Figure 6 bottom). If the features are overall *coherent* and meaningful, it should be relatively straightforward to identify the intruder.

Method We compared the feature types learnt by BCF and Strudel. We omitted BayesCat from this evaluation as it does not naturally produce feature types, rather it associates unstructured lists of features with categories. As mentioned earlier, Strudel does not induce feature types either, however, it associates concepts with features which can be post-processed to obtain feature types as follows. Given a category induced by Strudel (as explained in Experiment 1), we collected the features associated with at least half of the concepts in the category with a log likelihood score no less than 19.51.[3] We then clustered these features with K-means (using the Cluto toolkit) into $K = 5$ feature types.

For BCF, for each category k, we select the five feature types g with highest association $P(g|k)$, together with one intruder feature type g' which is highly associated with some other category k' but not with k. For Strudel we took the five feature types elicited through the procedure described above, and one random feature type from the global set of feature types. Each feature type was represented by a cluster of five words.

With respect to the word intrusion task, participants were only shown feature types (i.e., word clusters) irrespectively of the associated category. BCF feature types g were represented as the set of the five words w with highest probability $P(f|g)$. In addition, we added one intruder word which had low probability under g but high probability under some other feature type. For Strudel, we represented feature types as a random subset of five words, and added an additional intruder word from the global set of features.

For the feature type intrusion task, We evaluated a total of 40 categories for each model. Each participant assessed 10 categories per session (5 per model). Categories and feature types were presented in random order. For the word intrusion task, we evaluated a total of 66 feature types for each model. Participants saw 11 feature types per session, in randomized order. In both cases, we collected 10 responses per item.

Metrics We evaluated feature type relevance and coherence by measuring precision (the proportion of intruders identified correctly). We also use the Kappa coefficient to measure inter-subject agreement (Fleiss, 1981) on our two tasks.

Results Our results are presented in Table 4. Participants identify the intruder feature type correctly more than 50% of the time. The performance of Strudel is slightly better compared to BCF, both in terms of accuracy and Kappa (however the dif-

[3]Following Baroni et al. (2010), this number corresponds to a probability of co-occurrence below 0.00001, assuming independence.

	Feat Type Intrusion		Word Intrusion	
	Prec	Kappa	Prec	Kappa
BCF	0.52	0.23	**0.78**	**0.60**
Strudel	**0.56**	**0.26**	0.36	0.21

Table 4: Performance of Strudel and BCF on the feature type and word intrusion tasks. We report precision (Prec) and inter-subject agreement (Fleiss' Kappa; all Kappa values are statistically significant at $p \ll 0.05$).

ferences are not statistically significant, using a *t*-test). Again this is not surprising considering that Strudel's feature types were elicited through a highly informed, pipelined process. The results show that the simpler and cognitively plausible BCF model learns feature types of a quality comparable to a highly engineered, competitive system. Examples of feature types discovered by BCF and Strudel are shown in Figure 5, for the category CLOTHING. As can be seen, Strudel obtains a large number of action-related features (e.g., *replace, change, steal*). BCF creates more varied feature types. For example, the second cluster refers to external properties (e.g., color), and the last cluster contains CLOTHING materials.

Concerning the word intrusion task, we observe that participants are able to detect the intruder more accurately when presented with BCF feature types as compared to Strudel feature types (differences between Strudel and BCF are statistically significant at $p \ll 0.05$, again using a *t*-test). The results suggest that the feature types learnt by BCF are more coherent, and indeed express meaningful properties shared by concepts belonging to the same category. While being relevant to the category, Strudel's feature types do not seem to exhibit internal coherence to a similar extent. The mutual dependence of category formation and feature learning allows BCF to learn feature types which are both relevant and individually interpretable.

5 Discussion

In this paper we presented a cognitively motivated Bayesian model which jointly learns categories and their features, arguing that the two tasks are co-dependent. Our model learns from raw text without relying on elaborate post-processing and high-precision patterns. Evaluation of the inferred categories and their features shows that BCF performs competitively compared to a system specifically engineered to extract high quality features, despite the more complex learning objective, and the knowledge-lean approach. We approximate the cognitive learning environment with large text corpora. However, we do not claim to learn features qualitatively similar to features produced in human elicitation studies. Instead, we show, through a crowdsourcing-based human evaluation, that the learnt features are meaningful in that they are relevant to their associated category and form a coherent class.

An interesting direction for future work would be to learn feature types from multiple modalities (not only text) and to investigate how different information sources (e.g., visual or pragmatic input) influence feature learning. The BCF model learns descriptive feature types represented as a collection of feature values. In addition to such descriptive features (e.g., `behavior`) categories also possess *defining* features (e.g., `animate`) which are bound to one particular value. Extending the model in a way that allows to learn qualitatively different types of features is desirable from a cognitive perspective. We will also develop an incremental learning algorithm for joint category and feature learning (e.g., using sequential Monte Carlo methods such as Particle Filtering). In addition, it would be interesting to investigate the emergence of feature types with nonparametric Bayesian methods.

Finally, the BCF model can be applied to tasks beyond those discussed here. For example, one could learn definitions (aka features) of terms (aka concepts) in specialist fields (e.g., finance, law, medicine) or monitor how the meaning of words or concepts as represented by their features changes over time.

Acknowledgments We thank Micha Elsner and Charles Sutton for helpful discussions, William Schuler for his comments, and Carina Silberer for providing the Strudel features. We acknowledge the support of EPSRC through project grant EP/I037415/1.

Shared common ground influences information density in microblog texts

Abstract

If speakers use language rationally, they should structure their messages to achieve approximately uniform information density (UID), in order to optimize transmission via a noisy channel. Previous work identified a consistent increase in linguistic information across sentences in text as a signature of the UID hypothesis. This increase was derived from a predicted increase in context, but the context itself was not quantified. We use microblog texts from Twitter, tied to a single shared event (the baseball World Series), to quantify both linguistic and non-linguistic context. By tracking changes in contextual information, we predict and identify gradual and rapid changes in information content in response to in-game events. These findings lend further support to the UID hypothesis and highlights the importance of non-linguistic common ground for language production and processing.

1 Introduction

There are many ways express a given message in natural language, so how do speakers decide between potential structures? One prominent hypothesis is that they aim for structures that best convey the intendeed message in the context of the communication. On this view, the use of natural languages is assumed to follow optimal information transmission results from information theory (Shannon, 1948). In particular, speakers should structure their messages to approximate *uniform information density* across symbols (words and phonemes), which is optimal for transmission of information through a noisy channel.

At least three lines of evidence suggest that speakers do make choices to increase the uniformity of information density across their utterances. First, speakers phonologically reduce more predictable material (Aylett and Turk, 2004; Aylett and Turk, 2006; Bell et al., 2003). Second, they omit or reduce optional lexical material in cases where the subsequent syntactic information is relatively more predictable (Levy and Jaeger, 2007; Frank and Jaeger, 2008; Jaeger, 2010). Third, and most relevant to our current hypothesis, speakers appear to increase the complexity of their utterances as a discourse develops (Genzel and Charniak, 2002; Genzel and Charniak, 2003; Qian and Jaeger, 2012). We expand on this finding below.

Following the UID hypothesis, Genzel and Charniak 2002 proposed that $H(Y_i)$, the total entropy of part i of a message (e.g., a word) is constant. They compute this expression by considering X_i, the random variable representing the precise word that will appear at position i, conditioned on all the previously observed words. They then further factor this expression into two terms:

$$\begin{aligned} H(Y_i) &= H(X_i|C_i, L_i) \\ &= H(X_i|L_i) - I(X_i; C_i|L_i) \end{aligned} \quad (1)$$

where the first term $H(X_i|L_i)$ is the dependence of the current word on only the local linguistic context (e.g. within the rest of the sentence L_i) and the second is the mutual information between the current word and the broader linguistic context C_i, given the rest of the current sentence. On their logic, with

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1587–1596,
Denver, Colorado, May 31 – June 5, 2015.

greater amounts of contextual information, the predictability of linguistic material based on context, $I(X_i|C_i, L_i)$, must go up. Therefore, they predicted that $H(X_i|L_i)$ should also increase, so as to maintain a constant total amount of information.

Genzel and Charniak then approximated $H(X_i|L_i)$ using a number of methods and showed that it did increase systematically in documents. Later work showed that this increase was strongest within paragraphs and was general across document types (Genzel and Charniak, 2003) and languages (Qian and Jaeger, 2012). This work, however, did not attempt to measure shared context (and its influence on message expectations) directly. This challenge is the focus of our current work.

1.1 Contextual effects on complexity

In psycholinguistics, the notion of shared *common ground* is a more precise replacement for the general notion of "context" (Clark, 1996). Common ground is defined as the knowledge that participants in a discourse have and that participants know other participants have, including the current conversational context. A large literature supports the idea that speakers consider referential context and other linguistic common ground in selecting the appropriate expression to refer to a particular physical object (Brennan and Clark, 1996; Metzing and Brennan, 2003; Dale and Reiter, 1995; Sedivy et al., 1999). In principle, Genzel and Charniak's formulation can be considered as capturing the relationship between all of the shared common ground—both linguistic and non-linguistic—and the predictability of language, even though in the previous work only linguistic information was considered.

When there is both linguistic and non-linguistic information passing through the noisy channel, the relevant quantity is not the marginal entropy of only the linguistic stream but the joint entropy of both streams. Let T_j be the linguistic information in part j of the discourse, and E_j be the non-linguistic information in part j. If C_j is the built-up context from the preceding parts $\{1, \cdots, j-1\}$ of the discourse, then we can break down the joint entropy as:

$$\begin{aligned} & H(T_j, E_j|C_j) \\ &= H(T_j|E_j, C_j) + H(E_j|C_j) \\ &= H(T_j|C_j) - I(T_j; E_j|C_j) + H(E_j|C_j) \\ &= H(T_j) - I(T_j; C_j) \\ &\quad - I(T_j; E_j|C_j) + H(E_j|C_j) \\ &= H(T_j) - I(T_j; E_j, C_j) + H(E_j|C_j) \quad (2) \end{aligned}$$

By the UID hypothesis, we expect the left-hand side of this equation, the information content of each part of the discourse, to be constant. The first term of the right-hand side is the out-of-context entropy of the linguistic information. The second term is the mutual information of the linguistic information and the union of the preceding context plus the current non-linguistic information (the events occurring at the time). The third term is the entropy of the non-linguistic information, given the preceding context.

This breakdown suggests that rational participants in a discourse will exhibit both slow and fast adaptation to context in order to maintain overall constant entropy. As context slowly builds, the mutual information term grows (and the non-linguistic entropy likely shrinks), resulting in the time-based increase in $H(T_j)$ that previous work has found. In addition, an individual event can have high or low information content given the context, without having a large effect on the mutual information term. To maintain constant entropy, high-information events should be accompanied by low-information linguistic responses, and vice versa. With an operationalization of shared context, we should be able to observe these two types of adaptation directly, not just via the increasing trend shown in previous work (Genzel and Charniak, 2002; Qian and Jaeger, 2012).

To test this prediction, we leverage Twitter, a popular microblogging service, to operationalize common ground. Because of its structure, Twitter is an ideal platform for this investigation. One common method of using Twitter is to mark messages with hashtags, which serve as ad-hoc categories, allowing anyone interested in a topic to find the messages relevant to that topic. This strategy is especially used when users are commenting on an external event (e.g. a sporting, media, or political event). We focus here on the World Series of baseball, an annual sporting event with large viewership and a single broadcast stream; in this case, the hashtag is `#worldseries`. Hashtagged messages are part of a discourse with extremely limited prior linguistic context, as no two tweeters will have seen the same set of tweets. The total shared context with the au-

dience that can be assumed by the writer of a tweet is the non-linguistic content of the event being hashtagged.

We begin by describing our corpus and our method of calculating linguistic content (by computing entropy within a simple n-gram model). We then investigate gradual changes in word-by-word information content as the event goes on (testing adaptation driven by contextual mutual information in Equation 2, replicating Genzel and Charniak 2002) and rapid changes in the total information content of tweets in response to important in-game events (testing adaptation driven by non-linguistic information in Equation 2). We end by considering control analyses that provide evidence against alternative accounts of our results.

2 Corpus and Methods

2.1 #Worldseries Corpus

Our current analysis looked at tweets during the 2014 World Series, a series of seven baseball games in late October 2014. We obtained these tweets by searching publicly-available tweets through the Twitter API, using an adaptation of SeeTweet (Doyle, 2014) to compile tweets containing the hashtag `#WorldSeries`. To synchronize tweets with game events, we used the Major League Baseball Advance Media XML repository,[1] which contains pitch-by-pitch data including the ongoing state of the game and timestamps at the start of each at-bat. Using this timestamp information, we binned tweets by at-bats so that they could be co-registered with other in-game statistics. These bins extend from the time of the first pitch in an at-bat to the beginning of the next at-bat, and thus provide time for reactions to the events of the at-bat.[2] The mean at-bat length was 2.76 minutes, and there were 512 total at-bats. We limited our analysis to tweets timestamped during one of these at-bats, resulting in a total corpus of 109,207 tweets. Each game had its first pitch at approximately 0008 UTC, and lasted between three and four hours.

Our tweet corpus was compiled from the "gardenhose" Twitter search API, which returns a subset of all relevant tweets. Our searches captured approximately 4% of all relevant tweets; Twitter reported 420,329 relevant tweets during Game 1 of the World Series[3], and our dataset contained 17,538 tweets during the same time period. We address potential confounds from this sampling process in Section 5.2.

2.2 Entropy Computation

Estimating the linguistic information content of each tweet is a key task in this work. Social media text has been described as "bad language" (Eisenstein, 2013): It can be difficult to model due to its idiosyncratic abbreviations, typographic errors, and other non-standard forms. Relevant to our goal of assessing information content, it can also be difficult to create an appropriate training corpus for language models, since the vocabulary and composition of tweets of change rapidly (Eisenstein, 2013).

We attempted to minimize these difficulties in two ways. First, we estimated language models with domain-specific corpora. In particular, for tweets from each game we used a training corpus consisting of the tweets from all the other games. This training set provided a vocabulary and structure that was similar in topic and style to the test set. We removed all punctuation and emoji except word-initial @ and #, which refer to users and hashtags, respectively. Usernames were replaced with *[MENTION]* to reduce sparsity; hashtags were not altered, as these often function as words or phrases within the tweet's syntax. Words with fewer than 5 occurrences in the training corpus were marked as out-of-vocabulary items. We estimated trigram models using a modification of NLTK (Bird, 2006)[4] with Witten-Bell smoothing, and estimated per-word and total entropy for each tweet from these models.

Second, we included tweet length (in characters) as an alternative metric of information content (see Section 5.2). Unless information rate varies sys-

[1] `http://gd2.mlb.com/components/game/mlb/`

[2] We tested a series of potential offset times in case Twitter and MLB used different clocks or at-bats were not long enough to capture reactions. We did not adjust the times as there was no significant increase in the correlation between Leverage Index (Sect. 5.1) and tweet rate for these offsets.

[3] `http://Twitter.com/TwitterData/status/524972545930301440`

[4] Smoothing on n-gram models in NLTK can be inaccurate (see `http://github.com/nltk/nltk/issues/367`), so we used a modified version courtesy of B. C. Roy (personal communication).

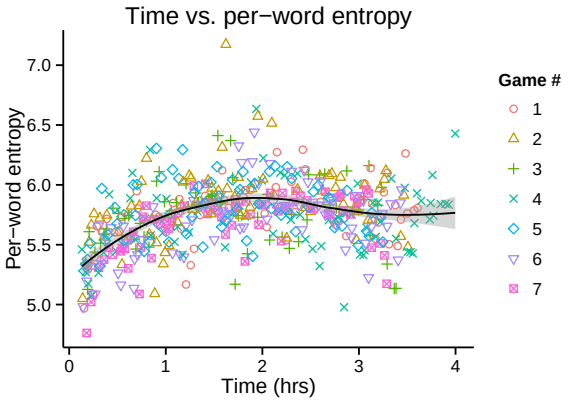

Figure 1: Per-word entropy increases with time for the first two hours of the games, then levels off and slightly declines. Color reflects in-game time; line shows loess fit with 95% confidence intervals.

tematically and substantially across tweets of different lengths—counter to existing results suggesting uniform information density operates at multiple structural levels (e.g., Qian and Jaeger 2009)—longer tweets will generally carry more information.

3 Gradual Changes in Information Rate

Our first analytic goal was to examine changes in the information content of tweets due to the long-term build-up of context in a shared event. We predicted that we would see similar developments in information structure as in more traditional conversational settings, even though there was no formal conversation or explicit linguistic history to develop common ground. Specifically, we predicted that the build-up of contextual information would cause the context-independent per-word entropy to rise over time, replicating the effect that has been observed across languages and genres (Genzel and Charniak, 2003; Qian and Jaeger, 2012).

Figure 1 shows evidence for changes in per-word entropy over the course of games. Per-word entropy rises throughout in the first two hours of each game, slowly levels off and finally declines slightly over time. This pattern is consistent with the constant entropy rate proposal of Genzel and Charniak 2002, and more specifically with the context decay model of Qian and Jaeger 2012.[5]

[5]A late decline in per-word entropy also appeared in Qian and Jaeger 2012's analysis of Swedish.

We used mixed-effects linear regression to quantify this relationship, using the time of an at-bat to predict both per-word and per-tweet entropy during the at-bat. Specifically, we used the logarithm of time as our fixed-effect predictor, per the context-decay models of Qian and Jaeger 2012. We added game-specific random intercepts and slopes of log-time to capture cross-game variation. This model showed significant positive effects of time on entropy, using likelihood-ratio tests for both models (per-word entropy: $.348 \pm .045; p < .001, \chi^2(3) = 104.6$, per-tweet entropy: $10.31 \pm 2.08; p = .001, \chi^2(3) = 74.65$).

We hypothesize that this finding—greater linguistic entropy for later tweets—is due to the accrual of common ground across users from shared non-linguistic information. As they watch more of the game, they share more referents and have stronger expectations about what aspects of the game will be discussed. This shared common ground licenses more complex language and more sophisticated linguistic references. Table 1 gives example tweets at different time points; as a game progresses, references can expand from generic references to the teams or series, to specific individuals and events, and eventually to sequences of events.

While this finding is consistent with previous work on the effect of context, it expands the definition of context. In previous work, the context came from explicit linguistic information built up through paragraphs in a formally-structured, written document. In the Twitter dataset, the context comes from real-world events during the games, as there is no canonical shared sequence of tweets that the tweeters can refer back to (indeed, two random users of the #Worldseries hashtag probably have relatively little Twitter context in common). In sum, contextual influences on entropy need not be explicitly linguistic, so long as discourse participants have reason to believe that the other participants share their knowledge.

4 Fast Changes In Information Content

Intuitively, after an exciting, game-changing event, tweets will be shorter and make more reference to the shared knowledge that this event has just happened. Such events should also generate more re-

sponses, suggesting that the number of tweets per unit time can serve as a proxy for the information content of an event. This relationship is captured by Equation 2, in which unexpected events have large information content, so linguistic information content should be reduced correspondingly to maintain constant entropy. Our next set of analyses test this relationship.

The examples shown in Table 2 provide anecdotal evidence for the hypothesized relationship between in-game events and linguistic complexity, with examples of consecutive tweets from high-rate and low-rate at-bats, along with their information content. The top triplet comes from one of the highest-rate at-bats, in which Gregor Blanco committed a crucial error in the last inning of the last game. The bottom triplet comes from a low-rate at-bat, mid-game, with one team well ahead of the other; in this case, tweets all refer to different events as there is no single salient shared event.

We quantified the predicted relationship by again fitting a mixed-effect linear regression model, in this case using the logarithm of per-minute tweet rate as a predictor of tweet entropy. Given its significance in the previous model, we included log(time) as a control factor in this analysis, and added by-game random intercepts and slopes for log(rate) and log(time). The log of the tweet rate had a significant negative effect on per-word and per-tweet entropy by likelihood-ratio tests (per-word-entropy: $-.333 \pm .073; p < .001, \chi^2(4) = 59.37$, per-tweet-entropy: $-21.82 \pm 2.43; p < .001, \chi^2(4) = 194.6$).

Log(time) retained significance ($p < .001$) as a predictor for both entropy measures even when rate was accounted for, showing evidence for both

slow and fast adaptation occurring in the discourse. The effects are both in the predicted directions: Entropy increases with time as more informative context builds up, but decreases with tweet rate as more exciting events encourage less information-laden tweets.

5 Control Analyses

5.1 Non-Rate Metrics of Context

Since tweet rate is an organic reflection of the interest accrued by in-game events, it is an important metric for examining fast adaptation. Nevertheless, it could be confounded with other factors influencing tweet production. For instance, there is evidence that online interactions exhibit rational responses to information overload, the state where the amount of incoming information exceeds a user's ability to process it (Miller, 1956; Schoberth et al., 2003). Previous investigations into forum posting behavior have shown that users adapt to overload by posting shorter messages (Jones et al., 2001b; Jones et al., 2001a; Whittaker et al., 2003; Schoberth et al., 2003), and a similar result was found for the more explicitly conversational setting of IRC chat channels (Jones et al., 2008).

To show that the changes in information content are not merely reactions to increased tweet competition—that they have independent informational motivations—we need metrics of event importance and predictability that are not dependent on social media behavior. Luckily, baseball has a long history of statistical analysis, and as a result, there

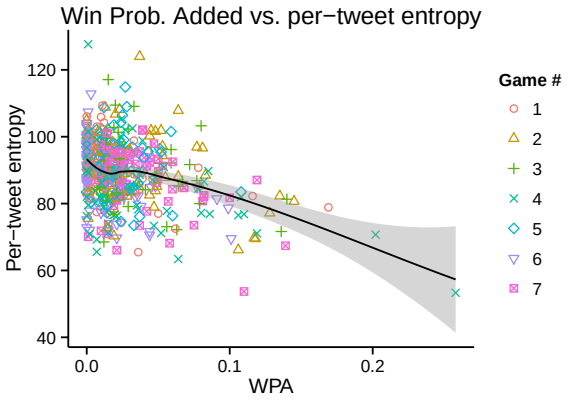

Figure 3: Total entropy decreases for at-bats with greater win probability changes. Loess curve fitting with 95% confidence intervals.

are independently-derived metrics that fit this bill. Two that are appropriate for this purpose are *Leverage Index* (LI)[6] and *Win Probability Added* (WPA) (Tango et al., 2007).

LI is an estimate of how critical an at-bat is to the outcome of the game. It is based on the difference in resultant win probability if the current batter gets a hit or an out, normalized by the mean change in win probability over all at-bats. 1 is the average LI, and greater LI indicates greater importance. LI, as a measure of the expected change in win probability, is similar to non-linguistic entropy term in Equation 2.

WPA depends on the result of an at-bat, and es-

[6] http://www.hardballtimes.com/crucial-situations/

timates how much the win probability changed as a result of what happened during the at-bat. WPA thus provides an estimate of how much information about the game outcome this at-bat has provided, conditioned on the current game context. These measures are well-correlated (Kendall's $\tau = .77$), since a high-LI at-bat's value comes from its ability to affect win probability.

As high LI or WPA values indicate an at-bat whose result has a large effect on the game, these metrics provide an estimate for non-linguistic informativity that is independent of medium-specific influences on tweet production. To assess their effects, we constructed four mixed-effects linear regression models, using LI and WPA to predict per-word and per-tweet entropy in all pairwise combinations (we built separate models for LI and WPA due to their high collinearity). Fixed- and by-game random-effects of log(time) and log(rate) were included as controls in all models; if there is an effect of LI or WPA beyond the effect of rate, this effect can be interpreted as evidence of speaker adaptation to non-linguistic information content.

Both LI and WPA had significant negative effects on per-tweet entropy (LI: $-1.52 \pm .43; p = .001, \chi^2(5) = 20.1$, WPA: $-2.27 \pm .40; p < .001, \chi^2(5) = 44.18$), over and above the effect of tweet rate. Per-word entropy did not show a significant effect of LI or WPA when rate was included as a control factor. Each was a significant factor on per-word entropy ($p = .008, p = .005$) when rate was not included as a control, though, suggesting that the explanatory power of these independent metrics may be subsumed in the more complex factor of tweet rate.

5.2 Speaker Normalization

A second alternative hypothesis for the observed behavioral changes with tweet rate is that they arise not from changes in the behavior of individuals but rather from a change in demographics. It is plausible that rising tweet rates come from an influx of new tweeters using the hashtag, and that these new tweeters simply produce shorter, less informative tweets in general. For instance, spambots often include trending hashtags in their spam tweets (Martinez-Romo and Araujo, 2013). To account for this, we treated the users whose tweets are in our corpus as

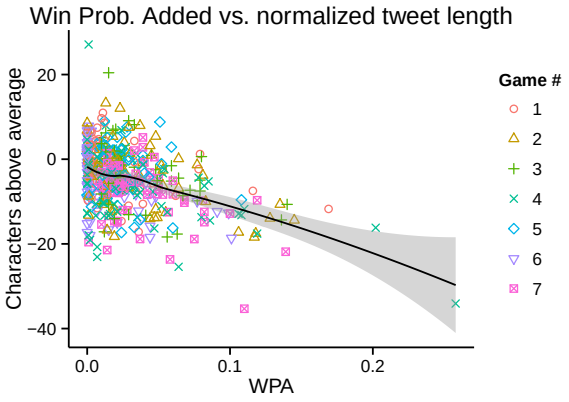

Figure 4: Speaker-normalized tweet length also decreases for at-bats with greater win probability changes. Loess curve fitting with 95% confidence intervals.

a "computational focus group" (Lin et al., 2013; Lin et al., 2014), and used the Twitter API to collected a further 100 tweets from each user outside the timeframe of the games. We used these tweets to estimate an average tweet length for each user, and subtracted this value from the length of their #worldseries tweets during the games.[7] If this baselined metric displays the same effects as shown above, we have reason to believe that users are in fact changing their individual behaviors in response to information factors, rather than that a demographic shift is mimicking a behavioral shift.

For this analysis, we created a mixed-effects model with WPA, log(rate) and log(time) as predictors of tweet length. All three factors were significant (WPA: $-1.64 \pm .36; p < .001, \chi^2(5) = 72.3$; log(rate): $-6.15 \pm .47; p < .001, \chi^2(5) = 303.6$; log(time): $.82 \pm .40; p = .001, \chi^2(5) = 20.6$). We then created a second model using the same factors to predict the mean change in tweet length from the baseline length. Again, all three factors were significant (WPA: $-2.01 \pm .29; p < .001, \chi^2(5) = 70.2$; log(rate): $-5.10 \pm .49; p < .001, \chi^2(5) = 252.6$; log(time): $.61 \pm .35; p = .016, \chi^2(5) = 14.0$). By ruling out demographic shifts (e.g., an influx of terser tweeters), this analysis provides additional support for the idea that tweeters indeed shift their behavior in response to in-game information.

[7] Note that these analyses are conducted over tweet length, rather than total entropy, as there was no obvious way of normalizing entropy by speaker.

6 Discussion

We investigated the hypothesis that speakers optimize their language production so as to approximate *uniform information density*, a signature of efficient communication through a noisy channel (Shannon, 1948; Levy and Jaeger, 2007). Previous work had observed indirect evidence for UID via increases in linguistic complexity (which were hypothesized to reflect increasing discourse/contextual knowledge), but this work neither measured contextual information directly nor included non-linguistic measures of context (Genzel and Charniak, 2002; Genzel and Charniak, 2003; Qian and Jaeger, 2012). Our current work takes a first step towards addressing these issues by using microblog texts around shared events (baseball games) as a case study in which a known context can be characterized more precisely. With this approach, we find systematic differences in information rate and total information content as a function of nonlinguistic factors.

We successfully replicated the effect found in previous work: a gradual increase in entropy rate over the course of individual baseball games. But in addition to this effect, we found a striking pattern of short-timescale changes in total message entropy (reflected in the changing lengths of messages). When in-game events were exciting, unpredictable, and outcome-relevant (hence, highly informative), message length and total entropy went down. This regularity suggests that Twitter users were regulating the information content of their messages relative to the total communicative content of the context more broadly, a prediction that can be derived directly from the UID model.

Our work highlights the importance of non-linguistic context for the informational content of language. This relationship is widely acknowledged in theories of pragmatic communication (Grice, 1975; Sperber and Wilson, 1986; Clark, 1996; Frank and Goodman, 2012), but has been largely absent in information-theoretic treatments of linguistic complexity. The omission of this information has largely been for pragmatic, rather than theoretical, reasons: As Genzel and Charniak 2002 note, it is typically very difficult to compute semantic—let alone non-linguistic—information content. Our work suggests that internet communications surrounding shared media events may be a promising source of grounded language use where context can be quantified more effectively due to the existence of substantial metadata.

A growing literature suggests that the information content of language is the critical variable for understanding processing difficulty in language comprehension (Levy, 2008; Demberg and Keller, 2008; Boston et al., 2008; Smith and Levy, 2013). Under surprisal theory (Hale, 2001; Levy, 2008), the overall predictability of individual elements of language is assumed to be due to a predictive model of its likelihood in the current context. Given this model of processing difficulty, our work here makes a strong prediction: that the information processing difficulty of a word or sentence should track with its total information content (including its relationship to the non-linguistic context), rather than its linguistic information content alone. Some preliminary evidence supports this idea. In a study of the processing complexity of negative utterances, Nordmeyer and Frank 2014 found that the processing cost of negation was predicted by the surprisal of encountering the negation in a particular pragmatic context. But future work should test this hypothesis across a wider variety of structures and contexts.

In sum, our work contributes to the growing body of evidence in favor of the UID hypothesis. The mechanisms underlying the tendency to regulate information content are still unknown, however. While UID would follow from a strong form of *audience design*, in which speakers explicitly consider the processing difficulty of different content (Clark, 1996), the UID hypothesis could also emerge from simpler production processes. Untangling these possibilities will not be trivial. Regardless of the resolution of this issue, however, UID appears to be an important descriptive tool in capturing how speakers make production choices.

Hierarchic syntax improves reading time prediction

Marten van Schijndel **William Schuler**
Department of Linguistics
The Ohio State University
{vanschm,schuler}@ling.osu.edu

Abstract

Previous work has debated whether humans make use of hierarchic syntax when processing language (Frank and Bod, 2011; Fossum and Levy, 2012). This paper uses an eye-tracking corpus to demonstrate that hierarchic syntax significantly improves reading time prediction over a strong *n*-gram baseline. This study shows that an interpolated 5-gram baseline can be made stronger by combining *n*-gram statistics over entire eye-tracking regions rather than simply using the last *n*-gram in each region, but basic hierarchic syntactic measures are still able to achieve significant improvements over this improved baseline.

1 Introduction

In NLP, a concern exists that models of hierarchic syntax may be increasingly used exclusively to compensate for *n*-gram sparsity (Lease et al., 2006). In the context of psycholinguistic modeling, Frank and Bod (2011) find that hierarchic measures of syntactic processing are not as good at predicting reading times as sequential part-of-speech-based models of processing.[1] Fossum and Levy (2012) follow up on this finding and show that, when better *n*-gram information is present in the models, measures of hierarchic syntactic processing cost (PCFG surprisal; Hale, 2001; Levy, 2008) are as good at predicting reading times as the sequential models presented by Frank and Bod.

[1] Frank and Bod (2011) find that hierarchic measures significantly improve the descriptive linguistic accuracy of models but that such measures are unable to improve upon a strong linear baseline when predicting reading times.

The present study builds on this finding by showing that cumulative *n*-gram probabilities significantly improve an *n*-gram baseline to better capture sequential frequency statistics. Further, this study shows that measures of hierarchic structural frequencies (as captured by PCFG surprisal) significantly improve reading time predictions over that improved sequential baseline.

First, this work defines a stronger *n*-gram baseline than that used in previous studies by replacing a bigram baseline computed from 101 million words with an interpolated 5-gram baseline computed over 2.96 billion words. Second, while previous work has used *n*-grams from the end of each eye-movement region to model reading times in that region, this paper finds that such models can be significantly improved by combining *n*-gram statistics over the entire region (Section 3). Even when this improved baseline is combined with a standard *n*-gram baseline, this paper demonstrates that PCFG surprisal is a significant predictor of reading times (Section 4). This paper also applies region accumulation to total surprisal and finds that it is not significantly better than non-accumulated total surprisal. In fact, cumulative surprisal is shown not to be a significant predictor of reading times at all when a cumulative *n*-gram factor is included in the baseline. Finally, this paper compares two different models of hierarchic syntax: the Penn Treebank (PTB) representation (Marcus et al., 1993) and the psycholinguistically-motivated Nguyen et al. (2012) Generalized Categorial Grammar (GCG). Each model of syntax is shown to provide orthogonal improvements to reading time predictions (Section 5).

2 Modeling

This study fits models to reading times from the Dundee corpus (Kennedy et al., 2003), which consists of eye-tracking data from 10 subjects who read 2388 sentences of news text from the newspaper, *The Independent*. Prior to using this corpus for evaluations, the first and last fixation of each sentence and of each line are filtered out to avoid potentially confounding wrap-up effects. Additionally, all fixations after saccades (eye movements) over more than 4 words are removed to avoid confounds with eye-tracker track-loss.

All evaluations are done with linear mixed effects models using lme4 (version 1.1-7; Bates et al., 2014).[2] There are two dependent reading time variables of interest in this study: first pass durations and go-past durations. During reading, a person's eye can jump over multiple words each time it moves, this study refers to that span of words as a *region*. First pass durations measure elapsed time until a person's eye leaves a given region. Go-past durations measure elapsed time until a person's eye moves further in the text. For example, in the fixation sequence: word 4, word 6, word 3, word 7, the first region would be from word 4 to word 6 and the second region would be from word 6 to word 7. The first pass duration for the first region would consist of the time fixated on word 6 before leaving the region for word 3, while the go-past duration would consist of the duration from the fixation of word 6 until the fixation of word 7. Separate models are fit to each centered dependent variable.

There are a number of independent variables in all evaluations in this study: sentence position (sentpos), word length (wlen), region length in words (rlen), whether the previous word was fixated (prevfix), and basic 5-gram log probability of the current word given the preceding context (5-gram). All independent predictors are centered and scaled before being added to each model. The 5-gram probabilities are interpolated 5-grams computed over the Gigaword 4.0 corpus (Graff and Cieri, 2003) using KenLM (Heafield et al., 2013). Gigaword 4.0 consists of around 2.96 billion words from around 4 million English newswire documents, which provides appropriate *n*-gram statistics since the Dundee corpus is also English news text.

Each mixed effects model contains random intercepts for subject and word, and random by-subject slopes for all fixed effects. Since the following evaluations use ablative testing to determine whether a fixed effect significantly improves the fit of a model compared to a model without that fixed effect, all models in a given evaluation include random slopes for all fixed effects used in that evaluation, even if the fixed effect is absent from that particular model.

3 A Cumulative *N*-gram Predictor

Since *n*-gram frequencies can have such a dramatic impact on the contribution of hierarchic syntax, this study tests whether *n*-gram factors can be improved. Models include a measure of *n*-gram frequencies to capture the rarity of observed sequences. Readers fixate longer on less predictable lexemes than on more predictable lexemes, but the predictability of a lexeme depends on the preceding context. Therefore, it is common for psycholinguistic models to include a measure of *n*-gram predictability for each fixated word conditioned on its context, but unless probabilities for words between fixations are also included, the probabilities used in this calculation are

[2]The models are fit using both the default *bobyqa* and the gradient *nlminb* algorithms to work around convergence issues.

Table 3: Goodness of fit of *N*-gram models to reading times.[3] Significance testing was done between each model and the models in the section above it. Significance for Base+Both applies to improvement over each of the *n*-gram models. † $p < .05$ * $p < .01$

not probabilities of complete word sequences and may miss words that are parafovially previewed or simply inferred.

For example, in Table 1, the standard bigram factor (top line) predicts that the reading time of the region that ends with word 6 depends on word 5, but the probability of word 5 given its context is never included in the model, so an improbable transition between words 4 and 5 would not be caught. This might allow another factor to inappropriately receive credit for an extra long fixation on word 6. Instead, a better model would include the probabilities of every word in the sequence since that is the information that will need to be processed by the reader. Using log-probabilities, a *cumulative n*-gram factor can be created simply by summing the log probabilities over each region (comparable to the last line of Table 1). The cumulative *n*-gram predictor is able to account for the frequency of the entire lexical sequence and so should provide a better reading time predictor than the standard fixation-only *n*-gram predictor (see Table 2 for an example).

For this initial evaluation (Table 3), the baseline omits the fixed *n*-gram factor. Instead, a model is constructed without any fixed effects for *n*-gram. Then, the same model is fit to reading times after adding just a fixed effect for *n*-gram and after adding just a fixed effect for cumulative *n*-gram. Finally, a model is fit with both the cumulative and non-cumulative *n*-gram factors as fixed effects.[4] Significance between the models is determined using likelihood ratio testing.[5]

Table 3 shows that both *n*-gram factors significantly improve the fit of the model and the final line shows that each factor provides a significant orthogonal improvement. Both *n*-gram factors will therefore be included as fixed effects and as by-subject random slopes in the baselines of the remaining evaluations in this study.

4 Hierarchic Syntax Predictors

This section tests the main hypothesis of this study: that hierarchic syntactic processing is a significant contributor to reading times. For the purposes of this evaluation, total PCFG surprisal (Hale, 2001; Levy, 2008; Roark et al., 2009) will be used as a measure of hierarchic syntactic processing. Specifically, PCFG surprisal will be calculated using the van Schijndel et al. (2013a) incremental parser trained on sections 02-21 of the Wall Street Journal section of the Penn Treebank (Marcus et al., 1993) using 5 iterations of split-merge (Petrov et al., 2006) and a beam width of 5000.

[3] Log-likelihood values are rounded to the nearest whole number, which is why the difference between Base and Base+Both can be larger than the cumulative difference between Base and the other two models.

[4] To ensure effects are not driven by individual subject differences, by-subject random slopes for both predictors of interest are included in the baseline. This practice is repeated throughout this study.

[5] Twice the log-likelihood difference of two nested models can be approximated by a χ^2 distribution with degrees of freedom equal to the difference in degrees of freedom of the models in question. The probability of obtaining a given log-likelihood difference D between the two models is therefore analogous to $P(2 \cdot D)$ under the corresponding χ^2 distribution.

Factors	Durations	
	R_{w4}^{w4}	R_{w5}^{w6}
surp	$-\log \mathrm{P}(w_4 \mid T_3)$	$-\log \mathrm{P}(w_6 \mid T_5)$
cumusurp	$-\log \mathrm{P}(w_4 \mid T_3)$	$\sum_{i=5}^{6} -\log \mathrm{P}(w_i \mid T_{i-1})$

Table 4: PCFG surprisal factors and their predictions of reading times in example eye-tracking regions. w_i represents word i. T_i represents the set of trees that can span from w_1 to w_i. R_{wi}^{wj} represents the region from w_i to w_j (inclusive).

4.1 Surprisal

PCFG surprisal (Hale, 2001; Levy, 2008) is a measure of incremental hierarchic syntactic processing. It reflects the information gained by observing a given word in a given context. In PCFG surprisal calculations, *context* is usually taken to refer to the preceding words in the sentence and their underlying syntactic structure. The PCFG surprisal $S(w_i)$ of a word at position i may be calculated as:

$$S(w_i) = \sum_{t \in T_{i-1}} -\log \mathrm{P}(w_i \mid t) \qquad (1)$$

where T_i represents the set of syntactic structures that can span from w_1 to w_i. PCFG surprisal in psycholinguistic models captures the influence of incremental hierarchic context when processing a given word.

For space considerations, in Table 4, the summation over T_{i-1} is notationally implicit:

$$S(w_i) = -\log \mathrm{P}(w_i \mid T_{i-1}) \qquad (2)$$

4.2 Evaluation

As in the previous section, a baseline model is fit to reading times without a fixed effect for surprisal, then surprisal is added as a fixed effect and significance of the fixed effect is determined using a likelihood ratio test with the baseline. The results (Table 5) show that PCFG surprisal is a significant predictor of both first pass and go-past durations even over a strong baseline including both types of *n*-gram factors.

The preceding section showed that applying region accumulation to an *n*-gram factor improves a model's fit to reading times. Previous work suggests region accumulation might improve the fit of syntactic factors to reading times (van Schijndel and Schuler, 2013; van Schijndel et al., 2013b), but the baselines in those studies only included unigram and bigram statistics and did not apply region accumulation to the *n*-gram models. It does make intuitive sense that region accumulation would help improve the fit of total PCFG surprisal for the same reason accumulating *n*-grams helps. For an example, see Table 4. A non-cumulative total PCFG surprisal factor (top line) would predict that duration of region R_{w5}^{w6} depends on T_5 (the set of trees that can span from w_1 to w_5), but the probability of generating the prefix of T_5 is never fully calculated by this factor. As with cumulative *n*-grams, cumulative PCFG surprisal of a region can be calculated by simply summing the PCFG surprisal of each word in the region.

When tested, however, the present work does not find any improvement from region accumulation of PCFG surprisal when stronger *n*-gram factors are also included (Table 5, Row 2), suggesting that the improvement in previous studies may have been due to latent *n*-gram information captured by cumulative PCFG surprisal. This finding is interesting because it suggests non-local hierarchic structure does not significantly influence reading times. The next section explores this hypothesis further by testing the fit of a hierarchic syntactic formalism whose strength lies in modeling long-distance dependencies.

5 Grammar Formalism Comparison

So far, this study has tried to allay previous concerns that models of hierarchic syntax may just be accounting for the sparsity of *n*-gram statistics (Charniak et al., 2006; Frank and Bod, 2011). This section investigates whether a representation of hierarchic syntax that preserves long-distance dependencies can improve reading time predictions over a hierarchic representation based on the Penn Treebank which discards long-distance dependencies. This evaluation compares total PCFG surprisal as calculated by the original Penn Treebank grammar to total PCFG surprisal calculated by the Nguyen et al. (2012) Generalized Categorial Grammar (GCG).

5.1 GCG

A GCG has a category set C, which consists of a set of primitive category types U, typically labeled

Model	First Pass		Go-Past	
	Log-Likelihood	AIC	Log-Likelihood	AIC
Baseline	-1212260	2424627	-1261488	2523084
Base+Surp	-1212253^{*}	2424617	-1261481^{*}	2523072
Base+CumuSurp	-1212259	2424627	-1261487	2523085
Base+Both	-1212253^{*}	2424619	-1261481^{*}	2523073

Baseline random slopes: sentpos, wlen, rlen, prevfix, 5-gram, cumu-5-gram, surp, cumusurp
Baseline fixed effects: sentpos, wlen, rlen, prevfix, 5-gram, cumu-5-gram

Table 5: Goodness of fit of hierarchic syntax models to reading times. Significance testing was done between each model and the models in the section above it. Significance for Base+Both applies only to improvement over the CumuSurp model. * $p < .01$

with the part of speech of the head of a category (e.g. **V**, **N**, **A**, etc., for phrases or clauses headed by verbs, nouns, adjectives, etc.), followed by one or more unsatisfied dependencies, each consisting of an operator (**-a** and **-b** for adjacent argument dependencies preceding and following a head, **-c** and **-d** for adjacent conjunct dependencies preceding and following a head, **-g** for filler-gap dependencies, **-r** for relative pronoun dependencies, and some others), followed by a dependent category type. For example, the category for a transitive verb would be **V-aN-bN**, since it is headed by a verb and has unsatisfied dependencies to satisfied noun-headed categories preceding and following it (for the subject and direct object noun phrase, respectively).

As in other categorial grammars, inference rules for local argument attachment apply functors of category c-**a**d or c-**b**d to initial or final arguments of category d:

$$d \;\; c\text{-}\mathbf{a}d \Rightarrow \; c \qquad \text{(Aa)}$$

$$c\text{-}\mathbf{b}d \;\; d \Rightarrow \; c \qquad \text{(Ab)}$$

However, the Nguyen et al. (2012) GCG uses distinguished inference rules for modifier attachment, which allows modifier categories to be consolidated with categories for modifiers in other contexts (preverbal, post-verbal, etc.), and with certain predicative categories. This allows derivations in the training corpus involving different modifier types to also be consolidated, which increases the power of the extracted statistics. Inference rules for modifier attachment apply initial or final modifiers of category u-**a**d to modificands of category c, for $u \in U$ and $c, d \in C$:

$$u\text{-}\mathbf{a}d \;\; c \Rightarrow c \qquad \text{(Ma)}$$

$$c \;\; u\text{-}\mathbf{a}d \Rightarrow c \qquad \text{(Mb)}$$

The Nguyen et al. (2012) GCG also uses distinguished inference rules to introduce, propagate, and bind missing non-local arguments, similar to the gap or slash rules of Generalized Phrase Structure Grammar (Gazdar et al., 1985) and Head-driven Phrase Structure Grammar (Pollard and Sag, 1994). Inference rules for gap attachment hypothesize gaps as initial arguments, final arguments, or modifiers, for $c, d \in C$:

$$c\text{-}\mathbf{a}d \Rightarrow c\text{-}\mathbf{g}d \qquad \text{(Ga)}$$

$$c\text{-}\mathbf{b}d \Rightarrow c\text{-}\mathbf{g}d \qquad \text{(Gb)}$$

$$c \Rightarrow c\text{-}\mathbf{g}d \qquad \text{(Gc)}$$

Non-local arguments, using non-local operator and argument category $\psi \in \{\text{-}\mathbf{g}, \text{-}\mathbf{h}, \text{-}\mathbf{i}, \text{-}\mathbf{r}\} \times C$, are then propagated to the consequent from all possible combinations of antecedents. For each rule $d \;\; e \Rightarrow c \in \{\text{Aa–b,Ma–b}\}$:

$$d \;\; e\psi \Rightarrow c\psi \qquad \text{(Ac–d,Mc–d)}$$

$$d\psi \;\; e \Rightarrow c\psi \qquad \text{(Ae–f,Me–f)}$$

$$d\psi \;\; e\psi \Rightarrow c\psi \qquad \text{(Ag–h,Mg–h)}$$

In order to consolidate relative and interrogative pronouns in different pied-piping contexts into just two reusable categories, this grammar uses distinguished inference rules for relative and interrogative pronouns as well as tough constructions (e.g. *this*

Model	First Pass		Go-Past	
	Log-Likelihood	AIC	Log-Likelihood	AIC
Baseline	-1212242	2424592	-1261474	2523055
Base+PTB	-1212239^{*}	2424587	-1261468^{*}	2523047
Base+GCG	$-1212239^{\dagger}$	2424589	-1261470^{*}	2523050
Base+Both	$-1212235^{\dagger}$	2424583	-1261465^{*}	2523043

Baseline random slopes: sentpos, wlen, rlen, prevfix, 5-gram, cumu-5-gram, surp-GCG, surp-PTB
Baseline fixed effects: sentpos, wlen, rlen, prevfix, 5-gram, cumu-5-gram

Table 6: Goodness of fit of models with differing syntactic calculations to reading times. Significance testing was done between each model and the models in the section above it. Base+Both first pass significance applies to improvement over PTB ($p < .05$) and to improvement over GCG ($p < .01$), Base+Both go-past significance applies to improvement over each independent model. † $p < .05$ * $p < .01$

bread is easy to cut), which introduce clauses with gap dependencies, for $c, d, e \in C$, $\psi \in \{\textbf{-g}\} \times C$:

$$d\textbf{-i}e\ c\textbf{-g}d \Rightarrow c\textbf{-i}e \quad \text{(Fa)}$$

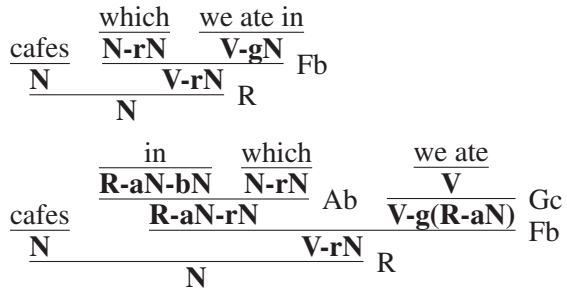
$$d\textbf{-r}e\ c\textbf{-g}d \Rightarrow c\textbf{-r}e \quad \text{(Fb)}$$

$$c\textbf{-b}(d\psi)\ d\psi \Rightarrow c \quad \text{(Fc)}$$

Also, inference rules for relative pronoun attachment apply pronominal relative clauses of category $c\textbf{-r}d$ to modificands of category e:

$$e\ \ c\textbf{-r}d \Rightarrow e \quad \text{(R)}$$

Because of its richer set of language-specific inference rules, the GCG grammar annotated by Nguyen et al. (2012) does not require different categories for words like *which* in different pied-piping contexts:



5.2 Evaluation

Following van Schijndel et al. (2013b), the GCG calculation of PCFG surprisal comes from a GCG-reannotated version of the Penn Treebank whose grammar rules have undergone 3 iterations of the split-merge algorithm (Petrov et al., 2006). A k-best beam with a width of 5000 is used in order to be comparable to the PTB calculation.

Significance testing is done as in the preceding evaluations: a baseline model is fit to reading times, each PCFG surprisal factor is added independently to the baseline, and both PCFG surprisal factors are added concurrently to the baseline. Each model is compared to the next simpler models using likelihood ratio tests.

The results (Table 6) show that GCG PCFG surprisal is a significant predictor of reading times even in the presence of the stronger n-gram baseline. Moreover, both PTB and GCG PCFG surprisal significantly improve reading time predictions even when the other PCFG surprisal measure is also included. This suggests that each is contributing something the other is not. Since the GCG grammar is derived from an automatically reannotated version of the Penn Treebank, there may be errors in the GCG annotation which cause errors in the estimates of underlying GCG structure. Since the PTB grammar is manually annotated by experts, the PTB grammar may be receiving credit for correct structural prediction in cases where GCG's estimates are incorrect. However, it seems likely that GCG may be providing a better fit in cases of long-distance dependencies because such relations are omitted from the PTB grammar.

A follow-up evaluation (not shown here) using the experimental design from Section 4 but using GCG PCFG surprisal rather than PTB PCFG surprisal revealed that cumulative PCFG surprisal is still not a significant predictor when calculated using GCG. The failure of cumulative PCFG surprisal to improve over basic GCG PCFG surprisal could be expected

Predictor	First Pass		Go-Past	
	coef	t value	coef	t value
sentpos	−2.47	−3.59	−2.82	−3.38
wlen	25.90	8.67	28.98	9.97
prevfix	−30.16	−7.81	−37.42	−11.49
n-gram	−2.39	−1.81	−6.70	−3.36
cumu-*n*-gram	−14.69	−7.36	−11.68	−5.01
rlen	−5.67	−1.31	−12.51	−2.59
surp-GCG	4.97	2.87	5.74	2.73
surp-PTB	4.20	3.23	4.85	3.29

Table 7: Fixed effect predictor coefficients for Base+PTB+GCG model.

since a strength of GCG is in enabling non-local decisions on a local basis (by propagating non-local decisions into the category labels), so any non-local advantage cumulative PCFG surprisal might confer is already compressed into the GCG categories.

The results of this evaluation suggest that reading times are mostly affected by local hierarchic structure, but the fact that GCG PCFG surprisal is able to provide a significant fit even in the presence of the PTB PCFG surprisal predictor suggests that some non-local information affects reading times. In particular, while this evaluation showed that accumulated syntactic context is not generally a good predictor of reading times, some or all of the non-local information contained in the GCG categories is used by readers and so influences reading time durations over the local structural information reflected in the PTB PCFG surprisal measure.

6 Discussion

The finding that the hierarchic grammars orthogonally improve reading time predictions suggests that hierarchic structural information has a significant influence on reading times. Since both the PTB and GCG calculations of surprisal contain sequential information (e.g., of part-of-speech tags), if the effect in this study was driven by purely sequential information as suggested by Frank and Bod (2011), one might expect either the PTB or the GCG calculations of surprisal (but not both) to be a significant predictor of reading times.

Instead, the present set of results support recent claims made by van Schijndel et al. (2014) that non-local subcategorization decisions are made early during processing and so would have a strong influence on the reading time measures used in the present study. Such decisions would have to be conditioned on hierarchic structural information not present in either PTB PCFG surprisal or the sequential structure models of Frank and Bod (2011).

Further, predictability has been shown to affect word duration during speech production (Jurafsky et al., 2001; Aylett and Turk, 2006), and Demberg et al. (2012) found that hierarchic structure significantly improves over *n*-gram computations of predictability in that domain as well. Together, these findings suggest that hierarchic structure is not only a convenient descriptive tool for linguists, but that such structure is deeply rooted in the human language processor and is used during online language processing.

Previous work has made a distinction between lexical surprisal, syntactic surprisal, and total surprisal (Demberg and Keller, 2008; Roark et al., 2009). Given a prefix derivation of the structure of the context, syntactic surprisal measures the information obtained by generating the structure that will enable the attachment of a newly observed lexical item. Lexical surprisal conveys the amount of information obtained by attaching the particular lexical observation to the new syntactic structure. Total surprisal is the original formulation of surprisal and is the composition of the other two types of surprisal (the information gained by generating a structure for the current lexical observation and attaching the observation to that structure). Fossum and Levy (2012) show that, with a non-cumulative bigram baseline, this distinction is not significant when predicting

reading times, so the present study simply uses total surprisal. It may be interesting in future work to see if the distinction between surprisal types becomes more or less useful as the sequential baseline improves.

The finding that cumulative *n*-gram information is useful in predicting reading times bears some resemblance to the finding that the spillover effect of a word is proportional to its logarithmic probability given the context (Smith and Levy, 2013). However, the spillover effect studied by Smith and Levy (2013) is one of a given fixation on the following fixation. The cumulative *n*-grams, in contrast, permit finer predictability of a word given the unfixated intervening context. The two measures are similar in that they both permit better modeling of the predictability of a word given its context, but the spillover measure could also be easily conceived as continued spillover processing from the preceding fixation, while cumulative *n*-grams reflect the predictability of the entire region between one fixation and the next. Further, cumulative *n*-grams could conceivably also capture processing of parafovial preview obtained during the previous fixation. Since the cumulative *n*-gram measure improves the computation of predictability of a word, it could also provide a better measure of the spillover effect a given word will have. Future work could investigate this by using cumulative *n*-grams both to compute the predictability of the current word and to predict the spillover effect from the preceding fixation. The present work suggests that doing so would provide even better reading time predictors.

7 Conclusion

First, this work suggests that the standard accounting for *n*-gram frequencies needs to change in psycholinguistic studies. Currently, the standard procedure is to use *n*-gram statistics only from the end of an eye-tracking region. This standard calculates the influence of the final word in each region given the lexical context, but that context is never accounted for in regions greater than one word in length. Instead, psycholinguistic models need to additionally account for the probability of the *context* given its own preceding context to provide a coherent model of the probability of the observed lexical sequence.

This work also shows that, even with good cumulative and non-cumulative estimates of the frequency effects generated by a given lexical sequence, measures of hierarchic structure provide a significant improvement to reading time predictions. Further, even in the presence of both a strong *n*-gram baseline and a linguistically accurate measure of hierarchic structure (PTB with 5 iterations of split-merge), a linguistically-motivated model of hierarchic structure is a significant predictor of reading times. As data coverage grows, some may worry that models of syntax will be superseded by better *n*-gram models. This study suggests that hierarchic syntax retains its value even in a world of big data.

Abstract

Vector space word representations are learned from distributional information of words in large corpora. Although such statistics are semantically informative, they disregard the valuable information that is contained in semantic lexicons such as WordNet, FrameNet, and the Paraphrase Database. This paper proposes a method for refining vector space representations using relational information from semantic lexicons by encouraging linked words to have similar vector representations, and it makes no assumptions about how the input vectors were constructed. Evaluated on a battery of standard lexical semantic evaluation tasks in several languages, we obtain substantial improvements starting with a variety of word vector models. Our refinement method outperforms prior techniques for incorporating semantic lexicons into word vector training algorithms.

1 Introduction

Data-driven learning of word vectors that capture lexico-semantic information is a technique of central importance in NLP. These word vectors can in turn be used for identifying semantically related word pairs (Turney, 2006; Agirre et al., 2009) or as features in downstream text processing applications (Turian et al., 2010; Guo et al., 2014). A variety of approaches for constructing vector space embeddings of vocabularies are in use, notably including taking low rank approximations of cooccurrence statistics (Deerwester et al., 1990) and using internal representations from neural network models of word sequences (Collobert and Weston, 2008).

Because of their value as lexical semantic representations, there has been much research on improving the quality of vectors. *Semantic lexicons*, which provide type-level information about the semantics of words, typically by identifying *synonymy*, *hypernymy*, *hyponymy*, and *paraphrase* relations should be a valuable resource for improving the quality of word vectors that are trained solely on unlabeled corpora. Examples of such resources include WordNet (Miller, 1995), FrameNet (Baker et al., 1998) and the Paraphrase Database (Ganitkevitch et al., 2013).

Recent work has shown that by either changing the objective of the word vector training algorithm in neural language models (Yu and Dredze, 2014; Xu et al., 2014; Bian et al., 2014; Fried and Duh, 2014) or by relation-specific augmentation of the cooccurence matrix in spectral word vector models to incorporate semantic knowledge (Yih et al., 2012; Chang et al., 2013), the quality of word vectors can be improved. However, these methods are limited to particular methods for constructing vectors.

The contribution of this paper is a graph-based learning technique for using lexical relational resources to obtain higher quality semantic vectors, which we call "retrofitting." In contrast to previous work, retrofitting is applied as a *post-processing step* by running belief propagation on a graph constructed from lexicon-derived relational information to update word vectors (§2). This allows retrofitting to be used on pre-trained word vectors obtained using *any* vector training model. Intuitively, our method encourages the new vectors to be (i) similar to the vectors of related word types and (ii) similar to their purely distributional representations. The retrofitting process is fast, taking about 5 seconds for a graph of 100,000 words and vector length 300, and its runtime is independent of the original word vector training model.

Denver, Colorado, May 31 – June 5, 2015.

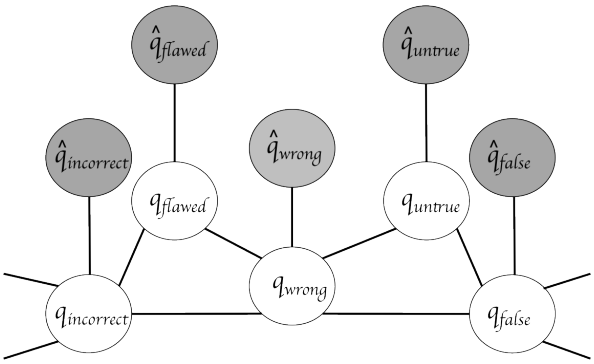

Figure 1: Word graph with edges between related words showing the observed (grey) and the inferred (white) word vector representations.

Experimentally, we show that our method works well with different state-of-the-art word vector models, using different kinds of semantic lexicons and gives substantial improvements on a variety of benchmarks, while beating the current state-of-the-art approaches for incorporating semantic information in vector training and trivially extends to multiple languages. We show that retrofitting gives consistent improvement in performance on evaluation benchmarks with different word vector lengths and show a qualitative visualization of the effect of retrofitting on word vector quality. The retrofitting tool is available at: `https://github.com/mfaruqui/retrofitting`.

2 Retrofitting with Semantic Lexicons

Let $V = \{w_1, \ldots, w_n\}$ be a **vocabulary**, i.e, the set of word types, and Ω be an **ontology** that encodes semantic relations between words in V. We represent Ω as an undirected graph (V, E) with one vertex for each word type and edges $(w_i, w_j) \in E \subseteq V \times V$ indicating a semantic relationship of interest. These relations differ for different semantic lexicons and are described later (§4).

The matrix $\hat{Q}$ will be the collection of vector representations $\hat{q}_i \in \mathbb{R}^d$, for each $w_i \in V$, learned using a standard data-driven technique, where d is the length of the word vectors. Our objective is to learn the matrix $Q = (q_1, \ldots, q_n)$ such that the columns are both close (under a distance metric) to their counterparts in $\hat{Q}$ *and* to adjacent vertices in Ω. Figure 1 shows a small word graph with such edge connections; white nodes are labeled with the Q vectors to be retrofitted (and correspond to V_Ω); shaded nodes are labeled with the corresponding vectors in $\hat{Q}$, which are observed. The graph can be interpreted as a Markov random field (Kindermann and Snell, 1980).

The distance between a pair of vectors is defined to be the Euclidean distance. Since we want the inferred word vector to be close to the observed value $\hat{q}_i$ and close to its neighbors $q_j, \forall j$ such that $(i, j) \in E$, the objective to be minimized becomes:

$$\Psi(Q) = \sum_{i=1}^{n} \left[\alpha_i \|q_i - \hat{q}_i\|^2 + \sum_{(i,j)\in E} \beta_{ij} \|q_i - q_j\|^2 \right]$$

where α and β values control the relative strengths of associations (more details in §6.1).

In this case, we first train the word vectors independent of the information in the semantic lexicons and then retrofit them. Ψ is convex in Q and its solution can be found by solving a system of linear equations. To do so, we use an efficient iterative updating method (Bengio et al., 2006; Subramanya et al., 2010; Das and Petrov, 2011; Das and Smith, 2011). The vectors in Q are initialized to be equal to the vectors in $\hat{Q}$. We take the first derivative of Ψ with respect to one q_i vector, and by equating it to zero arrive at the following online update:

$$q_i = \frac{\sum_{j:(i,j)\in E} \beta_{ij} q_j + \alpha_i \hat{q}_i}{\sum_{j:(i,j)\in E} \beta_{ij} + \alpha_i} \quad (1)$$

In practice, running this procedure for 10 iterations converges to changes in Euclidean distance of adjacent vertices of less than 10^{-2}. The retrofitting approach described above is modular; it can be applied to word vector representations obtained from any model as the updates in Eq. 1 are agnostic to the original vector training model objective.

Semantic Lexicons during Learning. Our proposed approach is reminiscent of recent work on improving word vectors using lexical resources (Yu and Dredze, 2014; Bian et al., 2014; Xu et al., 2014) which alters the learning objective of the original vector training model with a prior (or a regularizer) that encourages semantically related vectors (in Ω) to be close together, except that our technique is applied as a second stage of learning. We describe the

prior approach here since it will serve as a baseline. Here semantic lexicons play the role of a prior on Q which we define as follows:

$$p(Q) \propto \exp\left(-\gamma \sum_{i=1}^{n} \sum_{j:(i,j)\in E} \beta_{ij} \|q_i - q_j\|^2\right) \quad (2)$$

Here, γ is a hyperparameter that controls the strength of the prior. As in the retrofitting objective, this prior on the word vector parameters forces words connected in the lexicon to have close vector representations as did $\Psi(Q)$ (with the role of $\hat{Q}$ being played by cross entropy of the empirical distribution).

This prior can be incorporated during learning through maximum a posteriori (MAP) estimation. Since there is no closed form solution of the estimate, we consider two iterative procedures. In the first, we use the sum of gradients of the log-likelihood (given by the extant vector learning model) and the log-prior (from Eq. 2), with respect to Q for learning. Since computing the gradient of Eq. 2 has linear runtime in the vocabulary size n, we use lazy updates (Carpenter, 2008) for every k words during training. We call this the **lazy** method of MAP. The second technique applies stochastic gradient ascent to the log-likelihood, and after every k words applies the update in Eq. 1. We call this the **periodic** method. We later experimentally compare these methods against retrofitting (§6.2).

3 Word Vector Representations

We now describe the various publicly available pretrained English word vectors on which we will test the applicability of the retrofitting model. These vectors have been chosen to have a balanced mix between large and small amounts of unlabeled text as well as between neural and spectral methods of training word vectors.

Glove Vectors. Global vectors for word representations (Pennington et al., 2014) are trained on aggregated global word-word co-occurrence statistics from a corpus, and the resulting representations show interesting linear substructures of the word vector space. These vectors were trained on 6 billion words from Wikipedia and English Gigaword and are of length 300.[1]

Lexicon	Words	Edges
PPDB	102,902	374,555
WordNet$_{syn}$	148,730	304,856
WordNet$_{all}$	148,730	934,705
FrameNet	10,822	417,456

Table 1: Approximate size of the graphs obtained from different lexicons.

Skip-Gram Vectors (SG). The `word2vec` tool (Mikolov et al., 2013a) is fast and currently in wide use. In this model, each word's Huffman code is used as an input to a log-linear classifier with a continuous projection layer and words within a given context window are predicted. The available vectors are trained on 100 billion words of Google news dataset and are of length 300.[2]

Global Context Vectors (GC). These vectors are learned using a recursive neural network that incorporates both local and global (document-level) context features (Huang et al., 2012). These vectors were trained on the first 1 billion words of English Wikipedia and are of length 50.[3]

Multilingual Vectors (Multi). Faruqui and Dyer (2014) learned vectors by first performing SVD on text in different languages, then applying canonical correlation analysis (CCA) on pairs of vectors for words that align in parallel corpora. The monolingual vectors were trained on WMT-2011 news corpus for English, French, German and Spanish. We use the Enligsh word vectors projected in the common English–German space. The monolingual English WMT corpus had 360 million words and the trained vectors are of length 512.[4]

4 Semantic Lexicons

We use three different semantic lexicons to evaluate their utility in improving the word vectors. We include both manually and automatically created lexicons. Table 1 shows the size of the graphs obtained

[1] `http://www-nlp.stanford.edu/projects/glove/`

[2] `https://code.google.com/p/word2vec`

[3] `http://nlp.stanford.edu/~socherr/ACL2012_wordVectorsTextFile.zip`

[4] `http://cs.cmu.edu/~mfaruqui/soft.html`

from these lexicons.

PPDB. The paraphrase database (Ganitkevitch et al., 2013) is a semantic lexicon containing more than 220 million paraphrase pairs of English.[5] Of these, 8 million are lexical (single word to single word) paraphrases. The key intuition behind the acquisition of its lexical paraphrases is that two words in one language that align, in parallel text, to the same word in a different language, should be synonymous. For example, if the words *jailed* and *imprisoned* are translated as the same word in another language, it may be reasonable to assume they have the same meaning. In our experiments, we instantiate an edge in E for each lexical paraphrase in PPDB. The lexical paraphrase dataset comes in different sizes ranging from S to XXXL, in decreasing order of paraphrasing confidence and increasing order of size. We chose XL for our experiments. We want to give higher edge weights (α_i) connecting the retrofitted word vectors (q) to the purely distributional word vectors ($\hat{q}$) than to edges connecting the retrofitted vectors to each other (β_{ij}), so all α_i are set to 1 and β_{ij} to be $\text{degree}(i)^{-1}$ (with i being the node the update is being applied to).[6]

WordNet. WordNet (Miller, 1995) is a large human-constructed semantic lexicon of English words. It groups English words into sets of synonyms called synsets, provides short, general definitions, and records the various semantic relations between synsets. This database is structured in a graph particularly suitable for our task because it explicitly relates concepts with semantically aligned relations such as hypernyms and hyponyms. For example, the word *dog* is a synonym of *canine*, a hypernym of *puppy* and a hyponym of *animal*. We perform two different experiments with WordNet: (1) connecting a word only to synonyms, and (2) connecting a word to synonyms, hypernyms and hyponyms. We refer to these two graphs as WN_{syn} and WN_{all}, respectively. In both settings, all α_i are set to 1 and β_{ij} to be $\text{degree}(i)^{-1}$.

[5] http://www.cis.upenn.edu/~ccb/ppdb

[6] In principle, these hyperparameters can be tuned to optimize performance on a particular task, which we leave for future work.

FrameNet. FrameNet (Baker et al., 1998; Fillmore et al., 2003) is a rich linguistic resource containing information about lexical and predicate-argument semantics in English. Frames can be realized on the surface by many different word types, which suggests that the word types evoking the same frame should be semantically related. For example, the frame Cause_change_of_position_on_a_scale is associated with *push*, *raise*, and *growth* (among many others). In our use of FrameNet, two words that group together with any frame are given an edge in E. We refer to this graph as FN. All α_i are set to 1 and β_{ij} to be $\text{degree}(i)^{-1}$.

5 Evaluation Benchmarks

We evaluate the quality of our word vector representations on tasks that test how well they capture both semantic and syntactic aspects of the representations along with an extrinsic sentiment analysis task.

Word Similarity. We evaluate our word representations on a variety of different benchmarks that have been widely used to measure word similarity. The first one is the **WS-353** dataset (Finkelstein et al., 2001) containing 353 pairs of English words that have been assigned similarity ratings by humans. The second benchmark is the **RG-65** (Rubenstein and Goodenough, 1965) dataset that contain 65 pairs of nouns. Since the commonly used word similarity datasets contain a small number of word pairs we also use the **MEN** dataset (Bruni et al., 2012) of 3,000 word pairs sampled from words that occur at least 700 times in a large web corpus. We calculate cosine similarity between the vectors of two words forming a test item, and report Spearman's rank correlation coefficient (Myers and Well, 1995) between the rankings produced by our model against the human rankings.

Syntactic Relations (SYN-REL). Mikolov et al. (2013b) present a syntactic relation dataset composed of analogous word pairs. It contains pairs of tuples of word relations that follow a common syntactic relation. For example, given *walking* and *walked*, the words are differently inflected forms of the same verb. There are nine different kinds of relations and overall there are 10,675 syntactic pairs of word tuples. The task is to find a word *d* that best

fits the following relationship: "*a* is to *b* as *c* is to *d*," given a, b, and c. We use the vector offset method (Mikolov et al., 2013a; Levy and Goldberg, 2014), computing $q = q_a - q_b + q_c$ and returning the vector from Q which has the highest cosine similarity to q.

Synonym Selection (TOEFL). The TOEFL synonym selection task is to select the semantically closest word to a target from a list of four candidates (Landauer and Dumais, 1997). The dataset contains 80 such questions. An example is "*rug* $\rightarrow$ {*sofa*, *ottoman*, *carpet*, *hallway*}", with *carpet* being the most synonym-like candidate to the target.

Sentiment Analysis (SA). Socher et al. (2013) created a treebank containing sentences annotated with fine-grained sentiment labels on phrases and sentences from movie review excerpts. The coarse-grained treebank of positive and negative classes has been split into training, development, and test datasets containing 6,920, 872, and 1,821 sentences, respectively. We train an ℓ_2-regularized logistic regression classifier on the average of the word vectors of a given sentence to predict the coarse-grained sentiment tag at the sentence level, and report the test-set accuracy of the classifier.

6 Experiments

We first show experiments measuring improvements from the retrofitting method (§6.1), followed by comparisons to using lexicons during MAP learning (§6.2) and other published methods (§6.3). We then test how well retrofitting generalizes to other languages (§6.4).

6.1 Retrofitting

We use Eq. 1 to retrofit word vectors (§3) using graphs derived from semantic lexicons (§4).

Results. Table 2 shows the absolute changes in performance on different tasks (as columns) with different semantic lexicons (as rows). All of the lexicons offer high improvements on the word similarity tasks (the first three columns). On the TOEFL task, we observe large improvements of the order of 10 absolute points in accuracy for all lexicons except for FrameNet. FrameNet's performance is weaker, in some cases leading to worse performance (e.g., with Glove and SG vectors). For the extrinsic sentiment analysis task, we observe improvements using all the lexicons and gain 1.4% (absolute) in accuracy for the Multi vectors over the baseline. This increase is statistically significant ($p < 0.01$, McNemar).

We observe improvements over Glove and SG vectors, which were trained on billions of tokens on all tasks except for SYN-REL. For stronger baselines (Glove and Multi) we observe smaller improvements as compared to lower baseline scores (SG and GC). We believe that FrameNet does not perform as well as the other lexicons because its frames group words based on very abstract concepts; often words with seemingly distantly related meanings (e.g., *push* and *growth*) can evoke the same frame. Interestingly, we almost never improve on the SYN-REL task, especially with higher baselines, this can be attributed to the fact that SYN-REL is inherently a syntactic task and during retrofitting we are incorporating additional semantic information in the vectors. In summary, we find that PPDB gives the best improvement maximum number of times aggreagted over different vetor types, closely followed by WN_{all}, and retrofitting gives gains across tasks and vectors. An ensemble lexicon, in which the graph is the union of the WN_{all} and PPDB lexicons, on average performed slightly worse than PPDB; we omit those results here for brevity.

6.2 Semantic Lexicons during Learning

To incorporate lexicon information during training, and compare its performance against retrofitting, we train log-bilinear (LBL) vectors (Mnih and Teh, 2012). These vectors are trained to optimize the log-likelihood of a language model which predicts a word token w's vector given the set of words in its context (h), also represented as vectors:

$$p(w \mid h; Q) \propto \exp\left(\sum_{i \in h} q_i^\top q_j + b_j\right) \qquad (3)$$

We optimize the above likelihood combined with the prior defined in Eq. 2 using the lazy and periodic techniques described in §2. Since it is costly to compute the partition function over the whole vocabulary, we use *noise constrastive estimation* (NCE) to estimate the parameters of the model (Mnih and Teh, 2012) using AdaGrad (Duchi et al., 2010) with a learning rate of 0.05.

Lexicon	MEN-3k	RG-65	WS-353	TOEFL	SYN-REL	SA

Table 3: Absolute performance changes for including PPDB information while training LBL vectors. Spearman's correlation (3 left columns) and accuracy (3 right columns) on different tasks. Bold indicates greatest improvement.

We train vectors of length 100 on the WMT-2011 news corpus, which contains 360 million words, and use PPDB as the semantic lexicon as it performed reasonably well in the retrofitting experiments (§6.1). For the lazy method we update with respect to the prior every k = 100,000 words[7] and test for different values of prior strength $\gamma \in \{1, 0.1, 0.01\}$. For the periodic method, we update the word vectors using Eq. 1 every $k \in \{25, 50, 100\}$ million words.

Results. See Table 3. For lazy, $\gamma = 0.01$ performs best, but the method is in most cases not highly sensitive to γ's value. For **periodic**, which overall leads to greater improvements over the baseline than **lazy**, $k = 50$M performs best, although all other values of k also outperform the the baseline. Retrofitting, which can be applied to any word vectors, regardless of how they are trained, is competitive and sometimes better.

[7] k = 10,000 or 50,000 yielded similar results.

Corpus	Vector Training	MEN-3k	RG-65	WS-353	TOEFL	SYN-REL	SA

6.3 Comparisons to Prior Work

Two previous models (Yu and Dredze, 2014; Xu et al., 2014) have shown that the quality of word vectors obtained using `word2vec` tool can be improved by using semantic knowledge from lexicons. Both these models use constraints among words as a regularization term on the training objective during training, and their methods can only be applied for improving the quality of SG and CBOW vectors produced by the `word2vec` tool. We compared the quality of our vectors against each of these.

Yu and Dredze (2014). We train word vectors using their joint model training code[8] while using exactly the same training settings as specified in their best model: CBOW, vector length 100 and PPDB for enrichment. The results are shown in the top half of Table 4 where our model consistently outperforms the baseline and their model.

Xu et al. (2014). This model extracts categorical and relational knowledge among words from Freebase[9] and uses it as a constraint while training. Unfortunately, neither their word embeddings nor model training code is publicly available, so we train the SG model by using exactly the same settings as described in their system (vector length 300) and on the same corpus: monolingual English Wikipedia text.[10] We compare the performance of our retrofitting vectors on the SYN-REL and WS-353 task against the best model[11] reported in their paper. As shown in the lower half of Table 4, our model outperforms their model by an absolute 5.5 points absolute on the SYN-REL task, but a slightly inferior score on the WS-353 task.

6.4 Multilingual Evaluation

We tested our method on three additional languages: German, French, and Spanish. We used the Universal WordNet (de Melo and Weikum, 2009), an automatically constructed multilingual lexical knowledge base based on WordNet.[12] It contains words connected via different lexical relations to other words both within and across languages. We construct separate graphs for different languages (i.e., only linking words to other words in the same language) and apply retrofitting to each. Since not many word similarity evaluation benchmarks are available for languages other than English, we tested our baseline and improved vectors on one benchmark per language.

We used RG-65 (Gurevych, 2005), RG-65 (Joubarne and Inkpen, 2011) and MC-30 (Hassan and Mihalcea, 2009) for German, French and Spanish, respectively.[13] We trained SG vectors for each language of length 300 on a corpus of 1 billion tokens, each extracted from Wikipedia, and evaluate them on word similarity on the benchmarks before and after retrofitting. Table 5 shows that we obtain high improvements which strongly indicates that our method generalizes across these languages.

7 Further Analysis

Retrofitting vs. vector length. With more dimensions, word vectors might be able to capture higher orders of semantic information and retrofitting might be less helpful. We train SG vec-

[8] `https://github.com/Gorov/JointRCM`

[9] `https://www.freebase.com`

[10] `http://mattmahoney.net/dc/enwik9.zip`

[11] Their best model is named "RC-NET" in their paper.

[12] `http://www.mpi-inf.mpg.de/yago-naga/uwn`

[13] These benchmarks were created by translating the corresponding English benchmarks word by word manually.

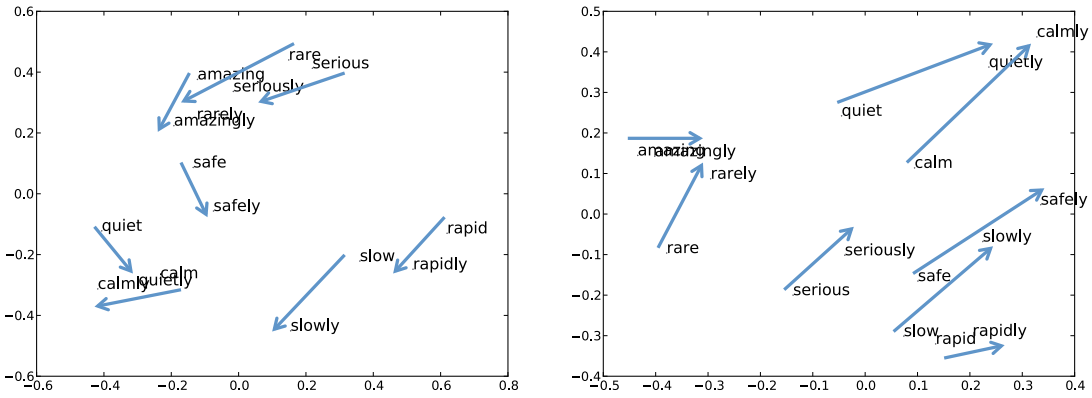

Figure 3: Two-dimensional PCA projections of 100-dimensional SG vector pairs holding the "adjective to adverb" relation, before (left) and after (right) retrofitting.

Language	Task	SG	Retrofitted SG
German	RG-65	53.4	**60.3**
French	RG-65	46.7	**60.6**
Spanish	MC-30	54.0	**59.1**

Table 5: Spearman's correlation for word similarity evaluation using the using original and retrofitted SG vectors.

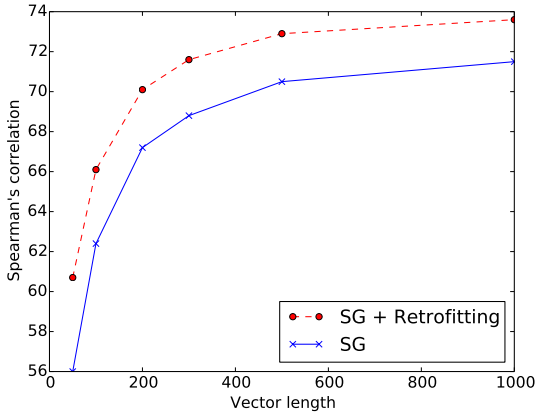

Figure 2: Spearman's correlation on the MEN word similarity task, before and after retrofitting.

tors on 1 billion English tokens for vector lengths ranging from 50 to 1,000 and evaluate on the MEN word similarity task. We retrofit these vectors to PPDB (§4) and evaluate those on the same task. Figure 2 shows consistent improvement in vector quality across different vector lengths.

Visualization. We randomly select eight word pairs that have the "adjective to adverb" relation from the SYN-REL task (§5). We then take a two-dimensional PCA projection of the 100-dimensional SG word vectors and plot them in $\mathbb{R}^2$. In Figure 3 we plot these projections before (left) and after (right) retrofitting. It can be seen that in the first case the direction of the analogy vectors is not consistent, but after retrofitting all the analogy vectors are aligned in the same direction.

8 Related Work

The use of lexical semantic information in training word vectors has been limited. Recently, word similarity knowledge (Yu and Dredze, 2014; Fried and Duh, 2014) and word relational knowledge (Xu et al., 2014; Bian et al., 2014) have been used to improve the `word2vec` embeddings in a joint training model similar to our regularization approach. In latent semantic analysis, the word cooccurrence matrix can be constructed to incorporate relational information like antonym specific polarity induction (Yih et al., 2012) and multi-relational latent semantic analysis (Chang et al., 2013).

The approach we propose is conceptually similar to previous work that uses graph structures to propagate information among semantic concepts (Zhu, 2005; Culp and Michailidis, 2008). Graph-based belief propagation has also been used to induce POS tags (Subramanya et al., 2010; Das and Petrov, 2011) and semantic frame associations (Das and Smith, 2011). In those efforts, labels for unknown words were inferred using a method similar to ours. Broadly, graph-based semi-supervised learning (Zhu, 2005; Talukdar and Pereira, 2010) has been applied to machine translation (Alexandrescu

and Kirchhoff, 2009), unsupervised semantic role induction (Lang and Lapata, 2011), semantic document modeling (Schuhmacher and Ponzetto, 2014), language generation (Krahmer et al., 2003) and sentiment analysis (Goldberg and Zhu, 2006).

9 Conclusion

We have proposed a simple and effective method named **retrofitting** to improve word vectors using word relation knowledge found in semantic lexicons. Retrofitting is used as a post-processing step to improve vector quality and is more modular than other approaches that use semantic information while training. It can be applied to vectors obtained from any word vector training method. Our experiments explored the method's performance across tasks, semantic lexicons, and languages and showed that it outperforms existing alternatives. The retrofitting tool is available at: `https://github.com/mfaruqui/retrofitting`.

Abstract

We present an unsupervised model for inducing signed social networks from the content exchanged across network edges. Inference in this model solves three problems simultaneously: (1) identifying the sign of each edge; (2) characterizing the distribution over content for each edge type; (3) estimating weights for triadic features that map to theoretical models such as structural balance. We apply this model to the problem of inducing the social function of **address terms**, such as *Madame*, *comrade*, and *dude*. On a dataset of movie scripts, our system obtains a coherent clustering of address terms, while at the same time making intuitively plausible judgments of the formality of social relations in each film. As an additional contribution, we provide a bootstrapping technique for identifying and tagging address terms in dialogue.[1]

1 Introduction

One of the core communicative functions of language is to modulate and reproduce **social dynamics**, such as friendship, familiarity, formality, and power (Hymes, 1972). However, large-scale empirical work on understanding this communicative function has been stymied by a lack of labeled data: it is not clear what to annotate, let alone whether and how such annotations can be produced reliably. Computational linguistics has made great progress in modeling language's informational dimension, but — with a few notable exceptions — computation has had little to contribute to our understanding of language's social dimension.

Yet there is a rich theoretical literature on social structures and dynamics. In this paper, we focus on one such structure: signed social networks, in which edges between individuals are annotated with information about the nature of the relationship. For example, the individuals in a dyad may be friends or foes; they may be on formal or informal terms; or they may be in an asymmetric power relationship. Several theories characterize signed social networks: in structural balance theory, edge signs indicate friendship and enmity, with some triads of signed edges being stable, and others being unstable (Cartwright and Harary, 1956); conversely, in status theory (Leskovec et al., 2010b), edges indicate status differentials, and triads should obey transitivity. But these theoretical models can only be applied when the sign of each social network connection is known, and they do not answer the sociolinguistic question of how the sign of a social tie relates to the language that is exchanged across it.

We present a unified statistical model that incorporates both network structure and linguistic content. The model connects signed social networks with **address terms** (Brown and Ford, 1961), which include names, titles, and "placeholder names," such as *dude*. The choice of address terms is an indicator of the level of formality between the two parties: for example, in contemporary North American English, a formal relationship is signaled by the use of titles such as *Ms* and *Mr*, while an informal relationship is signaled by the use of first names and

[1] Code and data for this paper is available at https://github.com/vinodhkris/signed-social.

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1616–1626,
Denver, Colorado, May 31 – June 5, 2015.

placeholder names. These tendencies can be captured with a multinomial distribution over address terms, conditioned on the nature of the relationship. However, the linguistic signal is not the only indicator of formality: network structural properties can also come into play. For example, if two individuals share a mutual friend, with which both are on informal terms, then they too are more likely to have an informal relationship. With a log-linear prior distribution over network structures, it is possible to incorporate such triadic features, which relate to structural balance and status theory.

Given a dataset of unlabeled network structures and linguistic content, inference in this model simultaneously induces three quantities of interest:

- a clustering of network edges into types;
- a probabilistic model of the address terms that are used across each edge type, thus revealing the social meaning of these address terms;
- weights for triadic features of signed networks, which can then be compared with the predictions of existing social theories.

Such inferences can be viewed as a form of **sociolinguistic structure induction**, permitting social meanings to be drawn from linguistic data. In addition to the model and the associated inference procedure, we also present an approach for inducing a lexicon of address terms, and for tagging them in dialogues. We apply this procedure to a dataset of movie scripts (Danescu-Niculescu-Mizil and Lee, 2011). Quantitative evaluation against human ratings shows that the induced clusters of address terms correspond to intuitive perceptions of formality, and that the network structural features improve predictive likelihood over a purely text-based model. Qualitative evaluation shows that the model makes reasonable predictions of the level of formality of social network ties in well-known movies.

We first describe our model for linking network structure and linguistic content in general terms, as it can be used for many types of linguistic content and edge labels. Next we describe a procedure which semi-automatically induces a lexicon of address terms, and then automatically labels them in text. We then describe the application of this procedure to a dataset of movie dialogues, including quantitative and qualitative evaluations.

2 Joint model of signed social networks and textual content

We now present a probabilistic model for linking network structure with content exchanged over the network. In this section, the model is presented in general terms, so that it can be applied to any type of event counts, with any form of discrete edge labels. The application of the model to forms of address is described in Sections 4 and 5.

We observe a dataset of undirected graphs $G^{(t)} = \{i, j\}$, with a total ordering on nodes such that $i < j$ in all edges. For each edge $\langle i, j \rangle$, we observe directed content vectors $\boldsymbol{x}_{i \rightarrow j}$ and $\boldsymbol{x}_{i \leftarrow j}$, which may represent counts of words or other discrete events, such as up-votes and down-votes for comments in a forum thread. We hypothesize a latent edge label $y_{ij} \in \mathcal{Y}$, so that $\boldsymbol{x}_{i \rightarrow j}$ and $\boldsymbol{x}_{i \leftarrow j}$ are conditioned on y_{ij}. In this paper we focus on binary labels (e.g., $\mathcal{Y} = \{+, -\}$), but the approach generalizes to larger finite discrete sets, such as directed binary labels (e.g., $\mathcal{Y} = \{++, +-, -+, --\}$) and comparative status labels (e.g., $\mathcal{Y} = \{<, >, \approx\}$).

We model the likelihood of the observations conditioned on the edge labels as multinomial,

$$\boldsymbol{x}_{i \rightarrow j} \mid y_{ij} \sim \text{Multinomial}(\boldsymbol{\theta}^{\rightarrow}_{y_{ij}}) \quad (1)$$

$$\boldsymbol{x}_{i \leftarrow j} \mid y_{ij} \sim \text{Multinomial}(\boldsymbol{\theta}^{\leftarrow}_{y_{ij}}). \quad (2)$$

Parameter tying can be employed to handle special cases. For example, if the edge labels are undirected, then we add the constraint $\boldsymbol{\theta}^{\rightarrow}_{y} = \boldsymbol{\theta}^{\leftarrow}_{y}, \forall y$. If the edge labels reflect relative status, then we would instead add the constraints $(\boldsymbol{\theta}^{\rightarrow}_{<} = \boldsymbol{\theta}^{\leftarrow}_{>})$, $(\boldsymbol{\theta}^{\rightarrow}_{>} = \boldsymbol{\theta}^{\leftarrow}_{<})$, and $(\boldsymbol{\theta}^{\rightarrow}_{\approx} = \boldsymbol{\theta}^{\leftarrow}_{\approx})$.

The distribution over edge labelings $P(\boldsymbol{y})$ is modeled in a log-linear framework, with features that can consider network structure and signed triads:

$$P(\boldsymbol{y}; G, \boldsymbol{\eta}, \boldsymbol{\beta}) = \frac{1}{Z(\boldsymbol{\eta}, \boldsymbol{\beta}; G)} \times \exp \sum_{\langle i,j \rangle \in G} \boldsymbol{\eta}^{\top} \boldsymbol{f}(y_{ij}, i, j, G) \times \exp \sum_{\langle i,j,k \rangle \in \mathcal{T}(G)} \beta_{y_{ij}, y_{jk}, y_{ik}}, \quad (3)$$

where $\mathcal{T}(G)$ is the set of triads in the graph G. The first term of Equation 3 represents a normalizing constant. The second term includes weights $\boldsymbol{\eta}$, which apply to network features $\boldsymbol{f}(y_{ij}, i, j, G)$. This can include features like the number of mutual friends between nodes i and j, or any number of more elaborate structural features (Liben-Nowell and Kleinberg, 2007). For example, the feature weights $\boldsymbol{\eta}$ could ensure that the edge label $Y_{ij} = +$ is especially likely when nodes i and j have many mutual friends in G. However, these features cannot consider any edge labels besides y_{ij}.

In the third line of Equation 3, each weight $\beta_{y_{ij},y_{jk},y_{ik}}$ corresponds to a signed triad type, invariant to rotation. In a binary signed network, structural balance theory would suggest positive weights for β_{+++} (all friends) and β_{+--} (two friends and a mutual enemy), and negative weights for β_{++-} (two enemies and a mutual friend) and β_{---} (all enemies). In contrast, a status-based network theory would penalize non-transitive triads such as $\beta_{>><}$. Thus, in an unsupervised model, we can examine the weights to learn about the semantics of the induced edge types, and to see which theory best describes the signed network configurations that follow from the linguistic signal. This is a natural next step from prior work that computes the frequency of triads in explicitly-labeled signed social networks (Leskovec et al., 2010b).

3 Inference and estimation

Our goal is to estimate the parameters θ, β, and $\boldsymbol{\eta}$, given observations of network structures $G^{(t)}$ and linguistic content $\boldsymbol{x}^{(t)}$, for $t \in \{1, \ldots, T\}$. Eliding the sum over instances t, we seek to maximize the variational lower bound on the expected likelihood,

$$\begin{aligned}\mathcal{L}_Q =& E_Q[\log P(\boldsymbol{y}, \boldsymbol{x}; \boldsymbol{\beta}, \boldsymbol{\theta}, G)] - E_Q[\log Q(\boldsymbol{y})] \\ =& E_Q[\log P(\boldsymbol{x} \mid \boldsymbol{y}; \boldsymbol{\theta})] + E_Q[\log P(\boldsymbol{y}; G, \boldsymbol{\beta}, \boldsymbol{\eta})] \\ & - E_Q[\log Q(\boldsymbol{y})]. \end{aligned} \tag{4}$$

The first and third terms factor across edges,

$$\begin{aligned}E_Q[\log P(\boldsymbol{x} \mid \boldsymbol{y}; \boldsymbol{\theta})] =& \sum_{\langle i,j\rangle \in G} \sum_{y' \in \mathcal{Y}} q_{ij}(y') \boldsymbol{x}_{i \rightarrow j}^\top \log \boldsymbol{\theta}_{y'}^{\rightarrow} \\ & + q_{ij}(y') \boldsymbol{x}_{i \leftarrow j}^\top \log \boldsymbol{\theta}_{y'}^{\leftarrow} \\ E_Q[\log Q(\boldsymbol{y})] =& \sum_{\langle i,j\rangle \in G} \sum_{y' \in \mathcal{Y}} q_{ij}(y') \log q(y').\end{aligned}$$

The expected log-prior $E_Q[\log P(\boldsymbol{y})]$ is computed from the prior distribution defined in Equation 3, and therefore involves triads of edge labels,

$$\begin{aligned}E_Q[\log P(\boldsymbol{y}; \boldsymbol{\eta}, \boldsymbol{\beta})] =& -\log Z(\boldsymbol{\eta}, \boldsymbol{\beta}; G) \\ & + \sum_{\langle i,j\rangle \in G} \sum_{y'} q_{ij}(y') \boldsymbol{\eta}^\top \boldsymbol{f}(y', i, j, G) \\ & + \sum_{\langle i,j,k\rangle \in \mathcal{T}(G)} \sum_{y,y',y''} q_{ij}(y) q_{jk}(y') q_{ik}(y'') \beta_{y,y',y''}.\end{aligned}$$

We can reach a local maximum of the variational bound by applying expectation-maximization (Dempster et al., 1977), iterating between updates to $Q(\boldsymbol{y})$, and updates to the parameters $\boldsymbol{\theta}, \boldsymbol{\beta}, \boldsymbol{\eta}$. This procedure is summarized in Table 1, and described in more detail below.

3.1 E-step

In the E-step, we sequentially update each q_{ij}, taking the derivative of Equation 4:

$$\begin{aligned}\frac{\partial \mathcal{L}_Q}{\partial q_{ij}(y)} =& \log P(\boldsymbol{x}_{i \rightarrow j} \mid Y_{ij} = y; \boldsymbol{\theta}^{\rightarrow}) \\ & + \log P(\boldsymbol{x}_{i \leftarrow j} \mid Y_{ij} = y; \boldsymbol{\theta}^{\leftarrow}) \\ & + E_{Q(\boldsymbol{y}_{-(ij)})}[\log P(\boldsymbol{y} \mid Y_{ij} = y; \boldsymbol{\beta}, \boldsymbol{\eta})] \\ & - \log q_{ij}(y) - 1. \end{aligned} \tag{5}$$

After adding a Lagrange multiplier to ensure that $\sum_y q_{ij}(y) = 1$, we obtain a closed-form solution for each $q_{ij}(y)$. These iterative updates to q_{ij} can be viewed as a form of mean field inference (Wainwright and Jordan, 2008).

3.2 M-step

In the general case, the maximum expected likelihood solution for the content parameter $\boldsymbol{\theta}$ is given by the expected counts,

$$\boldsymbol{\theta}_y^{\rightarrow} \propto \sum_{\langle i,j\rangle \in G} q_{ij}(y) \boldsymbol{x}_{i \rightarrow j} \tag{6}$$

$$\boldsymbol{\theta}_y^{\leftarrow} \propto \sum_{\langle i,j\rangle \in G} q_{ij}(y) \boldsymbol{x}_{i \leftarrow j}. \tag{7}$$

As noted above, we are often interested in special cases that require parameter tying, such as $\boldsymbol{\theta}_y^{\rightarrow} = \boldsymbol{\theta}_y^{\leftarrow}, \forall y$. This can be handled by simply computing expected counts across the tied parameters.

1. Initialize $Q(Y^{(t)})$ for each $t \in \{1 \dots T\}$
2. Iterate until convergence:

   E-step update each q_{ij} in closed form, based on Equation 5.

   M-step: content Update $\boldsymbol{\theta}$ in closed form from Equations 6 and 7.

   M-step: structure Update $\boldsymbol{\beta}, \boldsymbol{\eta}$, and c by applying L-BFGS to the noise-contrastive estimation objective in Equation 8.

Table 1: Expectation-maximization estimation procedure

Obtaining estimates for $\boldsymbol{\beta}$ and $\boldsymbol{\eta}$ is more challenging, as it would seem to involve computing the partition function $Z(\boldsymbol{\eta}, \boldsymbol{\beta}; G)$, which sums over all possible labeling of each network $G^{(t)}$. The number of such labelings is exponential in the number of edges in the network. West et al. (2014) show that for an objective function involving features on triads and dyads, it is NP-hard to find even the single optimal labeling.

We therefore apply noise-contrastive estimation (NCE; Gutmann and Hyvärinen, 2012), which transforms the problem of estimating the density $P(\boldsymbol{y})$ into a classification problem: distinguishing the observed graph labelings $\boldsymbol{y}^{(t)}$ from randomly-generated "noise" labelings $\tilde{\boldsymbol{y}}^{(t)} \sim P_n$, where P_n is a noise distribution. NCE introduces an additional parameter c for the partition function, so that $\log P(\boldsymbol{y}; \boldsymbol{\beta}, \boldsymbol{\eta}, c) = \log P^0(\boldsymbol{y}; \boldsymbol{\beta}, \boldsymbol{\eta}) + c$, with $P^0(\boldsymbol{y})$ representing the unnormalized probability of $\boldsymbol{y}$. We can then obtain the NCE objective by writing $D = 1$ for the case that $\boldsymbol{y}$ is drawn from the data distribution and $D = 0$ for the case that $\boldsymbol{y}$ is drawn from the noise distribution,

$$\begin{aligned} J_{NCE}(\boldsymbol{\eta}, \boldsymbol{\beta}, c) \\ = \sum_t \log P(D = 1 \mid \boldsymbol{y}^{(t)}; \boldsymbol{\eta}, \boldsymbol{\beta}, c) \\ - \log P(D = 0 \mid \tilde{\boldsymbol{y}}^{(t)}; \boldsymbol{\eta}, \boldsymbol{\beta}, c), \end{aligned} \quad (8)$$

where we draw exactly one noise instance $\tilde{\boldsymbol{y}}$ for each true labeling $\boldsymbol{y}^{(t)}$.

Because we are working in an unsupervised setting, we do not observe $\boldsymbol{y}^{(t)}$, so we cannot directly compute the log probability in Equation 8. Instead, we compute the expectations of the relevant log probabilities, under the distribution $Q(\boldsymbol{y})$,

$$\begin{aligned} E_Q[\log P^0(\boldsymbol{y}; \boldsymbol{\beta}, \boldsymbol{\eta})] = \\ \sum_{\langle i,j \rangle \in G} \sum_y q_{ij}(y) \boldsymbol{\eta}^\top \boldsymbol{f}(y, i, j, G) \\ + \sum_{k: \langle i,j,k \rangle \in \mathcal{T}(G)} \sum_{y,y',y''} q_{ij}(y) q_{jk}(y') q_{ik}(y'') \beta_{y,y',y''}. \end{aligned} \quad (9)$$

We define the noise distribution P_n by sampling edge labels y_{ij} from their empirical distribution under $Q(\boldsymbol{y})$. The expectation $E_q[\log P_n(\boldsymbol{y})]$ is therefore simply the negative entropy of this empirical distribution, multiplied by the number of edges in G. We then plug in these expected log-probabilities to the noise-contrastive estimation objective function, and take derivatives with respect to the parameters $\boldsymbol{\beta}$, $\boldsymbol{\eta}$, and c. In each iteration of the M-step, we optimize these parameters using L-BFGS (Liu and Nocedal, 1989).

4 Identifying address terms in dialogue

The model described in the previous sections is applied in a study of the social meaning of **address terms** — terms for addressing individual people — which include:

Names such as *Barack*, *Barack Hussein Obama*.

Titles such as *Ms., Dr., Private, Reverend*. Titles can be used for address either by preceding a name (e.g., *Colonel Kurtz*), or in isolation (e.g., *Yes, Colonel.*).

Placeholder names such as *dude* (Kiesling, 2004), *bro*, *brother*, *sweetie*, *cousin*, and *asshole*. These terms can be used for address only in isolation (for example, in the address *cousin Sue*, the term *cousin* would be considered a title).

Because address terms connote varying levels of formality and familiarity, they play a critical role in establishing and maintaining social relationships. However, we find no prior work on automatically identifying address terms in dialogue transcripts. There are several subtasks: (1) distinguishing addresses from mentions of other individuals, (2) identifying a lexicon of titles, which either precede name addresses or can be used in isolation, (3) identifying

Text:	I	'm	not	Mr.	Lebowski	;	you	're	Mr.	Lebowski	.
POS:	PRP	VBP	RB	NNP	NNP	:	PRP	VBP	NNP	NNP	.
Address:	O	O	O	B-ADDR	L-ADDR	O	O	O	B-ADDR	L-ADDR	O

Figure 1: Automatic re-annotation of dialogue data for address term sequences

Feature	Description
Lexical	The word to be tagged, and its two predecessors and successors, $w_{i-2:i+2}$.
POS	The part-of-speech of the token to be tagged, and the POS tags of its two predecessors and successors.
Case	The case (lower, upper, or title) of the word to be tagged, and its two predessors and successors.
Constituency parse	First non-NNP ancestor node of the word w_i in the constituent parse tree, and all leaf node siblings in the tree.
Dependency parse	All dependency relations involving w_i.
Location	Distance of w_i from the start and the end of the sentence or turn.
Punctuation	All punctuation symbols occurring before and after w_i.
Second person pronoun	All forms of the second person pronoun within the sentence.

Table 2: Features used to identify address spans

a lexicon of placeholder names, which can only be used in isolation. We now present a tagging-based approach for performing each of these subtasks.

We build an automatically-labeled dataset from the corpus of movie dialogues provided by Danescu-Niculescu-Mizil and Lee (2011); see Section 6 for more details. This dataset gives the identity of the speaker and addressee of each line of dialogue. These identities constitute a minimal form of manual annotation, but in many settings, such as social media dialogues, they could be obtained automatically. We augment this data by obtaining the first (given) and last (family) names of each character, which we mine from the website `rottentomatoes.com`. Next, we apply the CoreNLP part-of-speech tagger (Manning et al., 2014) to identify sequences of the NNP tag, which indicates a proper noun in the Penn Treebank Tagset (Marcus et al., 1993). For each NNP tag sequence that contains the name of the addressee, we label it as an address, using BILOU notation (Ratinov and Roth, 2009): **B**eginning, **I**nside, and **L**ast term of address segments; **O**utside and **U**nit-length sequences. An example of this tagging scheme is shown in Figure 1.

Next, we train a classifier (Support Vector Machine with a linear kernel) on this automatically labeled data, using the features shown in Table 2. For simplicity, we do not perform structured prediction, which might offer further improvements in accuracy. This classifier provides an initial, partial solution to the first problem, distinguishing second-person addresses from references to other individuals (for name references only). On heldout data, the classifier's macro-averaged F-measure is 83%, and its micro-averaged F-measure is 98.7%. Class-by-class breakdowns are shown in Table 3.

4.1 Address term lexicons

To our surprise, we were unable to find manually-labeled lexicons for either titles or placeholder names. We therefore employ a semi-automated approach to construct address term lexicons, bootstrapping from the address term tagger to build candidate lists, which we then manually filter.

Titles To induce a lexicon of titles, we consider terms that are frequently labeled with the tag B-ADDR across a variety of dialogues, performing a binomial test to obtain a list of terms whose frequency of being labeled as B-ADDR is significantly higher than chance. Of these 34 candidate terms, we manually filter out 17, which are mainly common first names, such as *John*; such names are frequently labeled as B-ADDR across movies. After this manual filtering, we obtain the following titles: *agent, aunt, captain, colonel, commander, cousin, deputy, detective, dr, herr, inspector, judge, lord, master, mayor, miss, mister, miz, monsieur, mr, mrs, ms, professor, queen, reverend, sergeant, uncle.*

Placeholder names To induce a lexicon of placeholder names, we remove the CURRENT-WORD feature from the model, and re-run the tagger on all dialogue data. We then focus on terms which are frequently labeled U-ADDR, indicating that they are the sole token in the address (e.g., *I'm*/O *perfectly*/O *calm*/O, *dude*/U-ADDR.) We again perform a binomial test to obtain a list of terms whose frequency of being labeled U-ADDR is significantly higher than chance. We manually filter out 41 terms from a list of 96 possible placeholder terms obtained in the previous step. Most terms eliminated were plural forms of placeholder names, such as *fellas* and *dudes*; these are indeed address terms, but because they are plural, they cannot refer to a single individual, as required by our model. Other false positives were fillers, such as *uh* and *um*, which were ocassionally labeled as I-ADDR by our tagger. After manual filtering, we obtain the following placeholder names: *asshole, babe, baby, boss, boy, bro, bud, buddy, cocksucker, convict, cousin, cowboy, cunt, dad, darling, dear, detective, doll, dude, dummy, father, fella, gal, ho, hon, honey, kid, lad, lady, lover, ma, madam, madame, man, mate, mister, mon, moron, motherfucker, pal, papa, partner, peanut, pet, pilgrim, pop, president, punk, shithead, sir, sire, son, sonny, sport, sucker, sugar, sweetheart, sweetie, tiger.*

4.2 Address term tokens

When constructing the content vectors $\boldsymbol{x}_{i \rightarrow j}$ and $\boldsymbol{x}_{i \leftarrow j}$, we run the address span tagger described above, and include counts for the following types of address spans:

- the bare first name, last name, and complete name of individual j;
- any element in the title lexicon if labeled as B-ADDR by the tagger;
- any element in the title or placeholder lexicon, if labeled as U-ADDR by the tagger.

5 Address terms in a model of formality

Address terms play a key role in setting the formality of a social interaction. However, understanding this role is challenging. While some address terms, like *Ms* and *Sir*, are frequent, there is a long tail of rare terms whose meaning is more difficult to ascertain from data, such as *admiral*, *dude*, and *player*. Moreover, the precise social meaning of address terms can be context-dependent: for example, the term *comrade* may be formal in some contexts, but jokingly informal in others.

Class	F-measure	Total Instances
I-ADDR	0.58	53
B-ADDR	0.800	483
U-ADDR	0.987	1864
L-ADDR	0.813	535
O-ADDR	0.993	35975

Table 3: Breakdown of f-measure and number of instances by class in the test set.

Both problems can be ameliorated by adding social network structure. We treat $Y = \text{V}$ as indicating formality and $Y = \text{T}$ as indicating informality. (The notation invokes the concept of T/V systems from politeness theory (Brown, 1987), where T refers to the informal Latin second-person pronoun *tu*, and V refers to the formal second-person pronoun *vos*.)

While formality relations are clearly asymmetric in many settings, for simplicity we assume symmetric relations: each pair of individuals is either on formal or informal terms with each other. We therefore add the constraints that $\boldsymbol{\theta}^{\leftarrow}_{\text{V}} = \boldsymbol{\theta}^{\rightarrow}_{\text{V}}$ and $\boldsymbol{\theta}^{\leftarrow}_{\text{T}} = \boldsymbol{\theta}^{\rightarrow}_{\text{T}}$. In this model, we have a soft expectation that triads will obey transitivity: for example, if i and j have an informal relationship, and j and k have an informal relationship, then i and k are more likely to have an informal relationship. After rotation, there are four possible triads, TTT, TTV, TVV, and VVV. The weights estimated for these triads will indicate whether our prior expectations are validated. We also consider a single pairwise feature template, a metric from Adamic and Adar (2003) that sums over the mutual friends of i and j, assigning more weight to mutual friends who themselves have a small number of friends:

$$AA(i,j) = \sum_{k \in \Gamma(i) \cap k \in \Gamma(j)} \frac{1}{\log \#|\Gamma(k)|}, \qquad (10)$$

where $\Gamma(i)$ is the set of friends of node i. (We also tried simply counting the number of mutual friends, but the Adamic-Adar metric performs

slightly better.) This feature appears in the vector $\boldsymbol{f}(y_{ij}, i, j, G)$, as defined in Equation 3.

6 Application to movie dialogues

We apply the ideas in this paper to a dataset of movie dialogues (Danescu-Niculescu-Mizil and Lee, 2011), including roughly 300,000 conversational turns between 10,000 pairs of characters in 617 movies. This dataset is chosen because it not only provides the script of each movie, but also indicates which characters are in dialogue in each line. We evaluate on quantitative measures of predictive likelihood (a token-level evaluation) and coherence of the induced address term clusters (a type-level evaluation). In addition, we describe in detail the inferred signed social networks on two films.

We evaluate the effects of three groups of features: address terms, mutual friends (using the Adamic-Adar metric), and triads. We include address terms in all evaluations, and test whether the network features improve performance. Ablating both network features is equivalent to clustering dyads by the counts of address terms, but all evaluations were performed by ablating components of the full model. We also tried ablating the text features, clustering edges using only the mutual friends and triad features, but we found that the resulting clusters were incoherent, with no discernible relationship to the address terms.

6.1 Predictive log-likelihood

To compute the predictive log-likelihood of the address terms, we hold out a randomly-selected 10% of films. On these films, we use the first 50% of address terms to estimate the dyad-label beliefs $q_{ij}(y)$. We then evaluate the expected log-likelihood of the second 50% of address terms, computed as $\sum_y q_{ij}(y) \sum_n \log P(x_n \mid \theta_y)$ for each dyad. This is comparable to standard techniques for computing the held-out log-likelihood of topic models (Wallach et al., 2009).

As shown in Table 4, the full model substantially outperforms the ablated alternatives. This indicates that the signed triad features contribute meaningful information towards the understanding of address terms in dialogue.

Address terms	Mutual friends	Signed triads	Log-likelihood
✓			-2133.28
✓		✓	-2018.21
✓	✓		-1884.02
✓	✓	✓	-1582.43

son	*sweetheart*
mister+FIRSTNAME	*buddy*
mrs	*sweetie*
mrs+LASTNAME	*hon*
FIRSTNAME+LASTNAME	*dude*

Table 5: The ten strongest address terms for each cluster, sorted by likelihood ratio.

6.2 Cluster coherence

Next, we consider the model inferences that result when applying the EM procedure to the entire dataset. Table 5 presents the top address terms for each cluster, according to likelihood ratio. The cluster shown on the left emphasizes full names, titles, and formal address, while the cluster on the right includes the given name and informal address terms such as *man*, *baby*, and *dude*. We therefore use the labels "V-cluster" and "T-cluster", referring to the formal and informal clusters, respectively.

We perform a quantitative evaluation of this clustering through an intrusion task (Chang et al., 2009). Specifically, we show individual raters three terms, selected so that two terms are from the same cluster, and the third term is from the other cluster; we then ask them to identify which term is least like the other two. Five raters were each given a list of forty triples, with the order randomized. Of the forty triples, twenty were from our full model, and twenty were from a text-only clustering model. The raters agreed with our full model in 73% percent of cases, and agreed with the text-only model in 52% percent

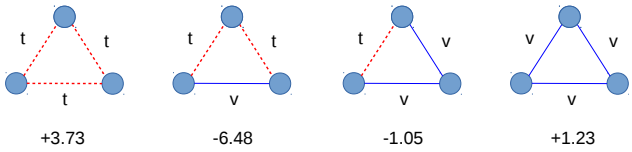

Figure 2: Estimated triad feature weights

of cases. By Fisher's exact test, this difference is statistically significant at $p < 0.01$. Both results are significantly greater than chance agreement (33%) by a binomial test, $p < 0.001$.

6.3 Network feature weights

Figure 2 shows the feature weights for each of the four possible triads. Triads with homogeneous signs are preferred, particularly TTT (all informal); heterogeneous triads are dispreferred, particularly TTV, which is when two individuals have a formal relationship despite having a mutual informal tie. Less dispreferred is TVV, when a pair of friends have an informal relationship despite both having a formal relationship with a third person; consider, for example, the situation of two students and their professor. In addition, the informal sign is preferred when the dyad has a high score on the Adamic-Adar metric, and dispreferred otherwise. This coheres with the intuition that highly-embedded edges are likely to be informal, with many shared friends.

6.4 Qualitative results

Analysis of individual movies suggests that the induced tie signs are meaningful and coherent. For example, the film "Star Wars" is a space opera, in which the protagonists Luke, Han, and Leia attempt to defeat an evil empire led by Darth Vader. The induced signed social network is shown in Figure 3. The V-edges seem reasonable: C-3PO is a robotic servant, and Blue Leader is Luke's military commander (BLUE LEADER: *Forget it, son.* LUKE: *Yes, sir, but I can get him...*). In contrast, the character pairs with T-edges all have informal relationships: the lesser-known character Biggs is Luke's more experienced friend (BIGGS: *That's no battle, kid*).

The animated film "South Park: Bigger, Longer & Uncut" centers on three children: Stan, Cartman, and Kyle; it also involves their parents, teachers, and friends, as well as a number of political and religious figures. The induced social network is shown in Figure 4. The children and their associates mostly have T-edges, except for the edge to Gregory, a British character with few speaking turns. This part of the network also has a higher clustering coefficient, as the main characters share friends such as Chef and The Mole. The left side of the diagram centers on Kyle's mother, who has more formal relationships with a variety of authority figures.

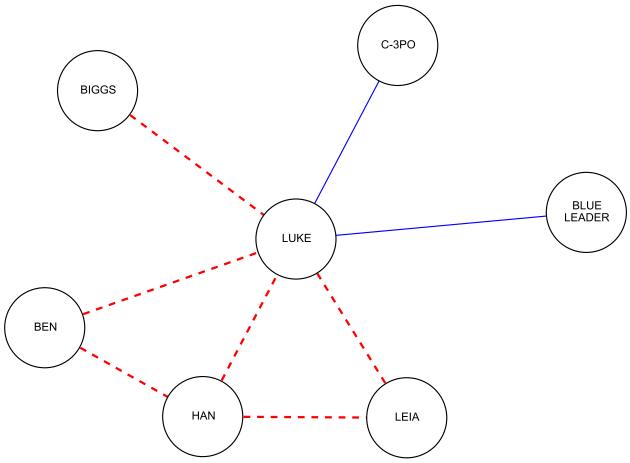

Figure 3: Induced signed social network from the film *Star Wars*. Blue solid edges are in the V-cluster, red dashed edges are in the T-cluster.

7 Related work

Recent work has explored the application of signed social network models to social media. Leskovec et al. (2010b) find three social media datasets from which they are able to identify edge polarity; this enables them to compare the frequency of signed triads against baseline expectations, and to build a classifier to predict edge labels (Leskovec et al., 2010a). However, in many of the most popular social media platforms, such as Twitter and Facebook, there is no metadata describing edge labels. We are also interested in new applications of signed social network analysis to datasets outside the realm of social media, such as literary texts (Moretti, 2005; Elson et al., 2010; Agarwal et al., 2013) and movie scripts, but in such corpora, edge labels are not easily available.

In many datasets, it is possible to obtain the textual content exchanged between members of the network, and this content can provide a signal for network structure. For example, Hassan et al. (2012) characterize the sign of each network edge in terms

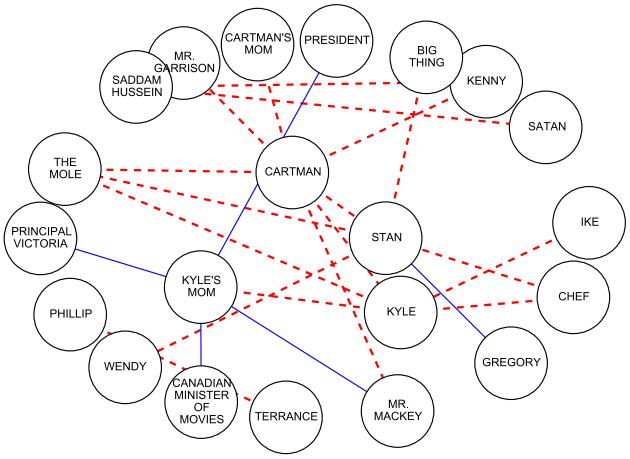

Figure 4: Induced signed social network from the film *South Park: Bigger, Longer & Uncut*. Blue solid edges are in the V-cluster, red dashed edges are in the T-cluster.

of the **sentiment** expressed across it, finding that the resulting networks cohere with the predictions of structural balance theory; similar results are obtained by West et al. (2014), who are thereby able to predict the signs of unlabeled ties. Both papers leverage the relatively mature technology of sentiment analysis, and are restricted to edge labels that reflect sentiment. The unsupervised approach presented here could in principle be applied to lexicons of sentiment terms, rather than address terms, but we leave this for future work.

The issue of address formality in English was considered by Faruqui and Padó (2011), who show that annotators can label the formality of the second person pronoun with agreement of 70%. They use these annotations to train a supervised classifier, obtaining comparable accuracy. If no labeled data is available, annotations can be projected from languages where the T/V distinction is marked in the morphology of the second person pronoun, such as German (Faruqui and Padó, 2012). Our work shows that it is possible to detect formality without labeled data or parallel text, by leveraging regularities across network structures; however, this requires the assumption that the level of formality for a pair of individuals is constant over time. The combination of our unsupervised approach with annotation projection might yield models that attain higher performance while capturing change in formality over time.

More broadly, a number of recent papers have proposed to detect various types of social relationships from linguistic content. Of particular interest are power relationships, which can be induced from n-gram features (Bramsen et al., 2011; Prabhakaran et al., 2012) and from **coordination**, where one participant's linguistic style is asymmetrically affected by the other (Danescu-Niculescu-Mizil et al., 2012). Danescu-Niculescu-Mizil et al. (2013) describe an approach to recognizing politeness in text, lexical and syntactic features motivated by politeness theory. Anand et al. (2011) detect "rebuttals" in argumentative dialogues, and Hasan and Ng (2013) employ extra-linguistic structural features to improve the detection of stances in such debates. In all of these cases, labeled data is used to train supervised model; our work shows that social structural regularities are powerful enough to support accurate induction of social relationships (and their linguistic correlates) without labeled data.

8 Conclusion

This paper represents a step towards unifying theoretical models of signed social network structures with linguistic accounts of the expression of social relationships in dialogue. By fusing these two phenomena into a joint probabilistic model, we can induce edge types with robust linguistic signatures and coherent structural properties. We demonstrate the effectiveness of this approach on movie dialogues, where it induces symmetric T/V networks and their linguistic signatures without supervision. Future work should evaluate the capability of this approach to induce asymmetric signed networks, the utility of partial or distant supervision, and applications to non-fictional dialogues.

Unsupervised Morphology Induction Using Word Embeddings

Abstract

We present a language agnostic, unsupervised method for inducing morphological transformations between words. The method relies on certain regularities manifest in high-dimensional vector spaces. We show that this method is capable of discovering a wide range of morphological rules, which in turn are used to build morphological analyzers. We evaluate this method across six different languages and nine datasets, and show significant improvements across all languages.

1 Introduction

Word representations obtained via neural networks (Bengio et al., 2003; Socher et al., 2011a) or specialized models (Mikolov et al., 2013a) have been used to address various natural language processing tasks (Mnih et al., 2009; Huang et al., 2014; Bansal et al., 2014). These vector representations capture various syntactic and semantic properties of natural language (Mikolov et al., 2013b). In many instances, natural language uses a small set of concepts to render a much larger set of meaning variations via morphology. We show in this paper that morphological transformations can be captured by exploiting regularities present in word-representations as the ones trained using the SkipGram model (Mikolov et al., 2013a).

In contrast to previous approaches that combine morphology with vector-based word representations (Luong et al., 2013; Botha and Blunsom, 2014), we do not rely on an external morphological analyzer, such as Morfessor (Creutz and Lagus, 2007). Instead, our method automatically induces morphological rules and transformations, represented as vectors in the same embedding space.

At the heart of our method is the SkipGram model described in (Mikolov et al., 2013a). We further exploit the observations made by Mikolov et al (2013b), and further studied by (Levy and Goldberg, 2014; Pennington et al., 2014), regarding the regularities exhibited by such embedding spaces. These regularities have been shown to allow inferences of certain types (e.g., *king* is to *man* what *queen* is to *woman*). Such regularities also hold for certain morphological relations (e.g., *car* is to *cars* what *dog* is to *dogs*). In this paper, we show that one can exploit these regularities to model, in a principled way, prefix- and suffix-based morphology. The main contributions of this paper are as follows:

1. provides a method by which morphological rules are learned in an unsupervised, language-agnostic fashion;

2. provides a mechanism for applying these rules to known words (e.g., *boldly* is analyzed as *bold+ly*, while *only* is not);

3. provides a mechanism for applying these rules to rare and unseen words;

We show that this method improves state-of-the-art performance on a word-similarity rating task using standard datasets. We also quantify the impact of our morphology treatment when using large amounts of training data (tens/hundreds of billions of words).

The technique we describe is capable of inducing transformations that cover both typical, regular morphological rules, such as adding suffix *ed*

Denver, Colorado, May 31 – June 5, 2015.

to verbs in English, as well as exceptions to such rules, such as the fact that pluralization of words that end in *y* require substituting it with *ies*. Because each such transformation is represented in the high-dimensional embedding space, it therefore captures the semantics of the change. Consequently, it allows us to build vector representations for any unseen word for which a morphological analysis is found, therefore covering an unbounded (albeit incomplete) vocabulary.

Our empirical evaluations show that this language-agnostic technique is capable of learning morphological transformations across various language families. We present results for English, German, French, Spanish, Romanian, Arabic, and Uzbek. The results indicate that the induced morphological analysis deals successfully with sophisticated morphological variations.

2 Previous Work

Many recent proposals in the literature use word-representations as the basic units for tackling sentence-level tasks such as language modeling (Mnih and Hinton, 2007; Mikolov and Zweig, 2012), paraphrase detection (Socher et al., 2011a), sentiment analysis (Socher et al., 2011b), discriminative parsing (Collobert, 2011), as well as similar tasks involving larger units such as documents (Glorot et al., 2011; Huang et al., 2012; Le and Mikolov, 2014). The main advantage offered by these techniques is that they can be both trained in an unsupervised manner, and also tuned using supervised labels. However, most of these approaches treat words as units, and fail to account for phenomena involving the relationship between various morphological forms that affect word semantics, especially for rare or unseen words.

Previous attempts at dealing with sub-word units and their compositionality have looked at explicitly-engineered features such as stems, cases, POS, etc., and used models such as factored NLMs (Alexandrescu and Kirchhoff, 2006) to obtain representations for unseen words, or compositional distributional semantic models (Lazaridou et al., 2013) to derive representations for morphologically-inflected words, based on the composing morphemes. A more recent trend has seen proposals that deal with morphology using vector-space representations (Luong et al., 2013; Botha and Blunsom, 2014). Given word morphemes (affixes, roots), a neural-network architecture (recursive neural networks in the work of Luong et al (2013), log-bilinear models in the case of Botha and Blunsom (2014)), is used to obtain embedding representations for existing morphemes, and also to combine them into (possibly novel) embedding representations for words that may not have been seen at training time.

Common to these proposals is the fact that the morphological analysis of words is treated as an external, preprocessing-style step. This step is done using off-the-shelf analyzers such as Morfessor (Creutz and Lagus, 2007). As a result, the morphological analysis happens within a different model compared to the model in which the resulting morphemes are consequently used. In contrast, the work presented here uses the same vector-space embedding to achieve both the morphological analysis of words and to compute their representation. As a consequence, the morphological analysis can be justified in terms of the relationship between the resulting representation and other words that exhibit similar morphological properties.

3 Morphology Induction using Embedding Spaces

The method we present induces *morphological transformations* supported by evidence in terms of regularities within a word-embedding space. We describe in this section the algorithm used to induce such transformations.

3.1 Morphological Transformations

We consider two main transformation types, namely prefix and suffix substitutions. Other transformation types can also be considered, but we restrict the focus of this work to morphological phenomena that can be modeled via prefixes and suffixes.

We provide first a high-level description of our algorithm, followed by details regarding the individual steps. The following steps are applied to monolingual training data over a finite vocabulary V:

1. Extract candidate prefix/suffix rules from V
2. Train embedding space $E^n \subset \mathbb{R}^n$ for all words in V

3. Evaluate quality of candidate rules in E^n

4. Generate lexicalized morphological transformations

We provide more detailed descriptions next.

Extract candidate rules from V

Starting from $(w_1, w_2) \in V^2$, the algorithm extracts all possible prefix and suffix substitutions from w_1 to w_2, up to a specified size[1]. We denote such substitutions using triplets of the form `type:from:to`. For instance, triplet `suffix:ed:ing` denotes the substitution of suffix *ed* with suffix *ing*; this substitution is supported by many word pairs in an English vocabulary, e.g. (*bored, boring*), (*stopped, stopping*), etc. We call these triplets candidate rules, because they form the basis of an extended set from which the algorithm extracts morphological rules.

At this stage, the candidate rules set contains both rules that reflect true morphology phenomena, e.g. `suffix:s:`ϵ (replace suffix *s* with the null suffix, extracted from (*stops, stop*), (*weds, wed*), etc.), or `prefix:un:`ϵ (replace prefix *un* with the null prefix, from (*undone, done*), etc.), but also rules that simply reflect surface-level coincidences, e.g. `prefix:S:`ϵ (delete *S* at the beginning of a word, from (*Scream, cream*), (*Scope, cope*), etc.).

Train embedding space

Using a large monolingual corpus, we train a word-embedding space E^n of dimensionality n for all words in V using the SkipGram model (Mikolov et al., 2013a). For the experiments reported in this paper, we used our own implementation of this model (which varies only slightly from the publicly-available `word2vec` implementation[2]).

Evaluate quality of candidate rules

The extracted candidate rules set is evaluated by using, for each proposed rule r, its support set:

$$S_r = \{(w_1, w_2) \in V^2 | w_1 \xrightarrow{r} w_2\}$$

The notation $w_1 \xrightarrow{r} w_2$ means that rule r applies to word w_1 (e.g., for rule `suffix:ed:ing`, word w_1 ends with suffix *ed*), and the result of applying the rule to word w_1 is word w_2. To speed up computation, we downsample the sets S_r to a large-enough number of word pairs (1000 has been used in the experiments in this paper).

[1] A maximum size of 6 is used in our experiments.

[2] At `code.google.com/p/word2vec`.

rule	hit rate	Example $\uparrow d_w$
`suffix:er:o`	0.8	$\uparrow d_{\text{Voter}}$
`suffix:ton:`ϵ	1.1	$\uparrow d_{\text{Galeton}}$
`prefix:S:`ϵ	1.6	$\uparrow d_{\text{SDK}}$
`prefix:`ϵ`:in`	28.8	$\uparrow d_{\text{competent}}$
`suffix:ly:`ϵ	32.1	$\uparrow d_{\text{officially}}$
`prefix:`ϵ`:re`	37.0	$\uparrow d_{\text{sited}}$
`prefix:un:re`	39.0	$\uparrow d_{\text{unmade}}$
`suffix:st:sm`	52.5	$\uparrow d_{\text{egoist}}$
`suffix:ted:te`	54.9	$\uparrow d_{\text{imitated}}$
`suffix:ed:ing`	68.1	$\uparrow d_{\text{procured}}$
`suffix:y:ies`	69.6	$\uparrow d_{\text{foundry}}$
`suffix:t:ts`	73.0	$\uparrow d_{\text{pugilist}}$
`suffix:sed:zed`	80.1	$\uparrow d_{\text{serialised}}$

Table 1: Candidate rules evaluated in E^n.

We define a generic evaluation function Ev^F over paired couples in $S_r \times S_r$, using a function $F : \mathbb{R}^n \times \mathbb{R}^n \rightarrow \mathbb{R}$, as follows:

$$Ev^F((w_1, w_2), (w, w')) = F_E(w_2, w_1 + \uparrow d_w) \quad (1)$$
$$(w_1, w_2), (w, w') \in S_r, \ \uparrow d_w = w' - w$$

Word-pair combinations in $S_r \times S_r$ are evaluated using Eq. 1 to assess the meaning-preservation property of rule r. We use as F_E function rank_E, the cosine-similarity rank function in E^n. We can quantitatively measure the assertion "*car* is to *cars* what *dog* is to *dogs*", as $\text{rank}_E(cars, car + \uparrow d_{dog\_})$. We use a single threshold t^0_{rank} to capture meaning preservation (all the experiments in this paper use $t^0_{\text{rank}} = 100$): for each proposed rule r, we compute a hit rate based on the number of times Eq. 1 scores above t^0_{rank}, over the number of times it has been evaluated. In Table 1 we present some of these candidate rules and their hit rate.

We note that rules that are non-meaning–preserving receive low hit rates, while rules that are morphological in nature, such as `suffix:ed:ing` (verb change from past/participle to present-continuous) and `suffix:y:ies` (pluralization of *y*–ending nouns), receive high hit rates.

Table 2: Examples of lexicalized morphological transformations evaluated in E^n using rank and cosine.

Generate lexicalized morphological transformations

The results in Table 1 indicate the need for creating *lexicalized* transformations. For instance, rule `suffix:ly:ϵ` (drop suffix *ly*, a perfectly reasonable morphological transformation in English) is evaluated to have a hit rate of 32.1%. While such transformations are desirable, we want to avoid applying them when firing without yielding meaning-preserving results (the rest of 67.9%), e.g., for word-pair (*only, on*). We therefore create lexicalized transformations by restricting the rule application to the vocabulary subset of V which passes the meaning-preservation criterion.

The algorithm also computes best direction vectors $\uparrow d_w$ for each rule support set S_r. It greedily selects a direction vector $\uparrow d_{w_0}$ that explains (based on Equation 1) the most pairs in S_r. After subset $S_r^{w_0}$ is computed for direction vector $\uparrow d_{w_0}$, it applies recursively on set $S_r - S_r^{w_0}$. This yields a new best direction vector $\uparrow d_{w_1}$, and so on. The recursion stops when it finds a direction vector $\uparrow d_{w_k}$ that explains less than a predefined number of words (we used 10 in all the experiments from this paper).

We consider multiple direction vectors $\uparrow d_{w_i}$ because of the possibly-ambiguous nature of a morphological transformation. Consider rule `suffix:ϵ:s`, which can be applied to the noun *walk* to yield plural-noun *walks*; this case is modeled with a transformation like *walk* + $\uparrow d_{invention\_}$, since $\uparrow d_{invention\_}$=*inventions*−*invention* is a direction that our procedure deems to explain well noun pluralization; it can also be applied to the verb *walk* to yield the 3rd-person singular form of the verb, in which case it is modeled as *walk* + $\uparrow d_{enlist\_}$, since $\uparrow d_{enlist\_}$=*enlists*−*enlist* is a direction that our procedure deems to explain well 3rd-person singular verb forms. In that sense, our algorithm goes beyond proposing simple surface-level morphemes, with direction vectors encoding well-defined semantics for our morphological analysis.

Lexicalized rules enhanced with direction vectors are called *morphological transformations*. For each morphological transformation, we evaluate again how well it passes a proximity test in E^n for the words it applies to. As evaluation criteria, we use two instances of Eq 1, with F_E instantiated to rank_E and cosine_E, respectively. We apply more stringent criteria in this second pass, using thresholds on the resulting rank (t_{rank}) and cosine (t_{cosine}) values to indicate meaning preservation (we used $t_{\text{rank}} = 30$ and $t_{\text{cosine}} = 0.5$ in all the experiments in this paper). We present in Table 2 a sample of the results of this procedure. For instance, word *create* can be transformed to *creates* using two different transformations: `suffix:te:tes:↑evaluate` and `suffix:ϵ:s:↑contradict`, passing the meaning-preservation criteria with rank=0, cosine=0.65, and rank=1, cosine=0.62, respectively.

Lexicalized morphological transformations over a vocabulary V have a graph-based interpretation: words represent nodes, transformations represent edges in a labeled, weighted, cyclic, directed multigraph (weights are (r, c) pairs, rank and cosine values; multiple direction vectors create multiple edges between two nodes; cycles may exist, see

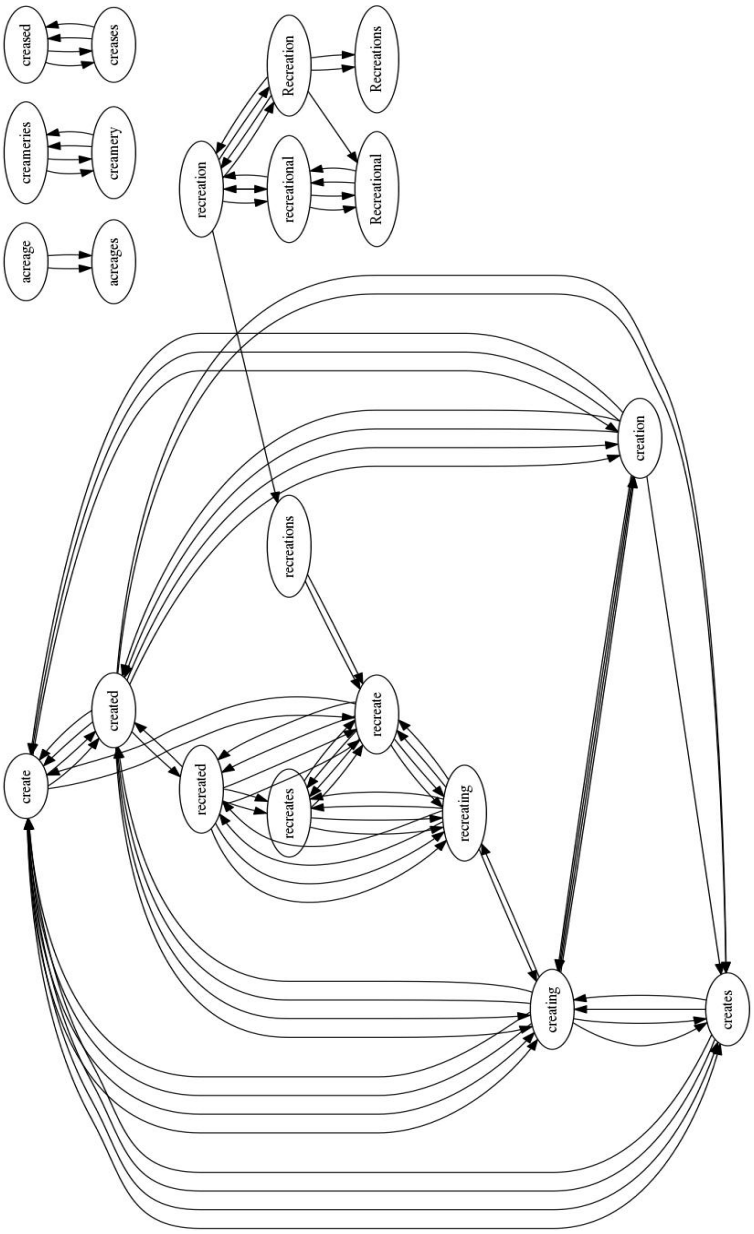

Figure 1: A few strongly connected components of a G^V_{Morph} graph for English.

e.g. *created→create→created* in Table 2). We use the notation G^V_{Morph} to denote such a graph. G^V_{Morph} usually contains many strongly connected components, with components representing families of morphological variations. As an illustration, we present in Figure 1 a few strongly connected components obtained for an English embedding space (for illustration purposes, we show only a maximum of 2 directed edges between any two nodes in this multigraph, even though more may exist).

3.2 Inducing 1-to-1 Morphological Mappings

The induced graph G^V_{Morph} encodes a lot of information about words and how they relate to each other. For some applications, however, we want to normalize away morphological diversity by mapping to a canonical surface form. This amounts to selecting, from among all the candidate morphological transformations generated, specific 1-to-1 mappings. In graph terms, this means building a labeled, weighted, acyclic, directed graph D^V_{Morph} starting

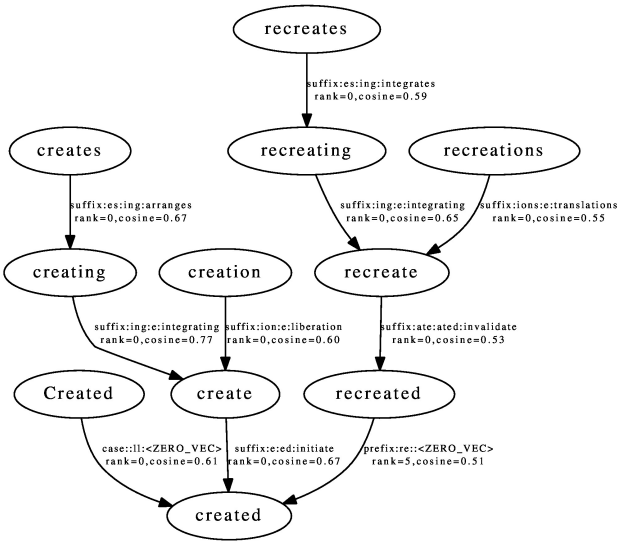

Figure 2: A part of a D^V_{Morph} graph, with the morphological family for the normal-form *created*.

from G^V_{Morph}, using the nodes from G^V_{Morph} and retaining only edges that meet certain criteria.

For the experiments presented in Section 4, we build a directed graph D^V_{Morph} as follows:

1. edge $w_1 \overset{(r,c)}{\rightarrow} w_2$ in G^V_{Morph} is considered only if count$(w_1) \leq$ count(w_2) in V;
2. if multiple such edges exist, chose the one with minimal rank r;
3. if multiple such edges still exist, chose the one with the maximal cosine c.

The interpretation we give is word-normalization: a normalization of w to w' is guaranteed to be meaning preserving (using the direction-vector semantics), and to a more frequent form. A snippet of the resulting graph D^V_{Morph} is presented in Figure 2.

One notable aspect of this normalization procedure is that these are not "traditional" morphological mappings, with morphology-inflected words mapped to their linguistic roots. Rather, our method produces morphological mappings that favor frequency over linguistic normalization. An example of this can be seen in Figure 2, where the root form *create* is morphologically-explained by mapping it to the form *created*. This choice is purely based on our desire to favor the accuracy of the word-representations for the normal forms; different choices regarding how this pruning procedure is performed lead to different normalization procedures, including some that are more linguistically-motivated (e.g., length-based).

3.3 Morphological Transformations for Rare and Unknown Words

For some count threshold C, we define $V_C = \{w \in V | C \leq \text{count}(w)\}$. The method we presented up to this point induces a morphology graph $D^{V_C}_{Morph}$ that can be used to perform morphological analysis for any words in V_C. We analyze the rest of the words we may encounter (i.e., rare words and OOVs) by mapping them directly to nodes in $D^{V_C}_{Morph}$.

We extract such mappings from $D^{V_C}_{Morph}$ using all the sequences of edges that start at nodes in the graph and end in a normal-form (i.e., nodes that have out-degree 0). The result is a set of rule sequences denoted *RS*. A count cutoff on the rule sequence counts is used, since low-count sequences tend to be less reliable (in the experiments reported in this paper we use a cutoff of 50). We also denote with *R* the set of all edges in D_{Morph}. Using sets *RS* and *R*, we map $w \notin V_C$ to a node $w' \in D^{V_C}_{Morph}$, as follows:

1. for rule-sequences $s \in RS$ from highest-to-lowest count, if $w \overset{s}{\rightarrow} w'$ and $w' \in D^{V_C}_{Morph}$, then s is the morphological analysis for w;
2. if no s is found, do breadth-first search in $D^{V_C}_{Morph}$ using $r \in R$, up to a predefined[3] depth d; for $k \leq d$, word w' with $w \overset{r_1 \ldots r_k}{\longrightarrow} w' \in D^{V_C}_{Morph}$ and the highest count in V_C is the morphological analysis for w.

For example, this procedure uses the RS sequence s=`prefix:un:`ϵ, `suffix:ness:`ϵ to perform the OOV morphological analysis *unassertiveness* $\overset{s}{\longrightarrow}$*assertive*. We perform an in-depth analysis of the performance of this procedure in Section 4.2.

4 Empirical Results

In this section, we evaluate the performance of the procedure described in Section 3. Our evaluations aim at answering several empirical questions: how

[3]We use d=1 in the experiments reported in Section 4.2.

Table 3: Statistics regarding the size of the training data and the induced morphology graphs.

well does our method capture morphology, and how does it compare with previous approaches that use word-representations for morphology? How well does this method handle OOVs? How does the impact of morphology analysis change with training data size? We provide both qualitative and quantitative answers for each of these questions next.

4.1 Quality of Morphological Analysis

We first evaluate the impact of our morphological analysis on a standard word-similarity rating task. The task measures word-level understanding by comparing the correlation between human-produced similarity ratings for word pairs, e.g. (*intraspecific, interspecies*), with those produced by an algorithm. For the experiments reported here, we train SkipGram models[4] using a dimensionality of $n = 500$. We denote a system using only SkipGram model embeddings as SG. To evaluate the impact of our method, we perform morphological analysis for words below a count threshold C. For a word $w \in D^{V_C}_{Morph}$, we simply use the SkipGram vector-representation; for a word $w \notin D^{V_C}_{Morph}$, we use as word-representation its mapping in $D^{V_C}_{Morph}$; we denote such a system SG+Morph. For both SG and SG+Morph systems, we compute the similarity of word-pairs using the cosine distance between the vector-representations.

Data

We train both the SG and SG+Morph models from scratch, for all languages considered. For English, we use the Wikipedia data (Shaoul and Westbury, 2010). For German, French, and Spanish, we use the monolingual data released as part of the WMT-2013 shared task (Bojar et al., 2013). For Arabic we use the Arabic GigaWord corpus (Parker et al., 2011). For Romanian and Uzbek, we use collections of News harvested from the web and cleaned (boilerplate removed, formatting removed, encoding made consistent, etc.). All SkipGram models are trained using a count cutoff of 5 (all words with count less than the cutoff are ignored). Table 3 presents statistics on the data and vocabulary size, as well as the size of the induced morphology graphs. These numbers illustrate the richness of the morphological phenomena present in languages such as German, Romanian, Arabic, and Uzbek, compared to English.

As test sets, we use standard, publicly-available word-similarity datasets. Most relevant for our approach is the Stanford English Rare-Word (RW) dataset (Luong et al., 2013), consisting of 2034 word pairs with a higher degree of English morphology compared to other word-similarity datasets. We also use for English the WS353 (Finkelstein et al., 2002) and RG65 datasets (Rubenstein and Goodenough, 1965). For German, we use the Gur350 and ZG222 datasets (Zesch and Gurevych, 2006). For French we use the RG65 French version (Joubarne and Inkpen, 2011); for Spanish, Romanian, and Arabic we use their respective versions of WS353 (Hassan and Mihalcea, 2009).

Results

We present in Table 4 the results obtained across 6 language pairs and 9 datasets, using a count threshold for SG+Morph of $C = 100$. We also include the results obtained by two previously-proposed methods, LSM2013 (Luong et al., 2013) and BB2014 (Botha and Blunsom, 2014), which share some of the characteristics of our method.

Even in the absence of any morphological treatment, our word representations are better than previously used ones. For instance, LSM2013 uses exactly the same EN Wikipedia (Shaoul and Westbury, 2010) training data, and achieves 26.8 and 34.4 Spearman ρ correlation on RW, with and without morphological treatment, respectively. The word representations we train yield a ρ of 35.8 for SG, and a ρ of 41.8 for SG+Morph (+7.4 improve-

[4] Additional settings include a window-size of 5 and negative sampling set to 5. Unseen words receive a zero-vector embedding and a cosine score of 0.

	Spearman ρ

System									
LSM2013 w/o morph	26.8	62.6	62.8	-	-	-	-	-	-
LSM2013 w/ morph	34.4	64.6	65.5	-	-	-	-	-	-
BB2014 w/o morph	18.0	32.0	47.0	36.0	6.0	33.0	26.0	-	-
BB2014 w/ morph	30.0	40.0	41.0	56.0	**25.0**	45.0	28.0	-	-
SG	35.8	71.2	75.1	62.4	16.6	63.6	36.5	51.7	37.1
SG+Morph	**41.8**	**71.2**	**75.1**	**64.1**	21.5	**67.3**	**47.3**	**53.1**	**43.1**
# pairs	2034	353	65	350	222	65	353	353	353

Table 4: Performance of previously proposed methods, compared to SG and SG+Morph trained on Wiki1b. LSM2013 uses exactly the same training data for EN, whereas BB2014 uses the same training data for DE, FR, ES.

ment under the morphology condition). The morphological treatment used by LSM2013 also has a small effect on the words present in the English WS and RG sets; our method does not propose any separate morphological treatment for the words in these datasets, since all of them have been observed more than our $C = 100$ threshold in the training data (therefore have reliable representations). The SG word-representations for all the other languages (German, French, Spanish, Romanian, and Arabic) also perform well on this task, with much higher Spearman scores obtained by SG compared with the previously-reported scores.

The results in Table 4 also show that our morphology treatment provides consistent gains across all languages considered. For morphologically-rich languages, all datasets reflect the impact of morphology treatment. We observe significant gains between the performance of the SG and SG+Morph systems, on top of the high correlation numbers of the SG system. For German, the relatively small increase we observe is due to the fact the German noun-compounds are not covered by our morphological treatment. For French, Spanish, Romanian, and Arabic, the gains by the SG+Morph support the conclusion that our method, while completely language-agnostic, handles well the variety of morphological phenomena present in these languages.

4.2 Quality of Morphological Analysis for Unknown/Rare Words

In this section, we quantify the accuracy of the morphological treatment for OOVs presented in Section 3.3. We assume that the statistics for unseen words (with respect to their morphological make-up) are similar with the statistics for low-frequency words. Therefore, for some relatively-low counts L and H, the set $V_{[L,H)} = V_L - V_H$ is a good proxy for the population of OOV words that we see at runtime. We evaluate OOV morphology as follows:

1. Run the procedure for morphology induction on V_L, resulting in $D^{V_L}_{Morph}$;
2. Run the procedure for morphology induction on V_H, resulting in $D^{V_H}_{Morph}$;
3. Apply OOV morphology using $D^{V_H}_{Morph}$ for each $w \in V_{[L,H]}$; evaluate resulting $w \rightarrow w'$ against reference $w \rightarrow w'_{ref}$ from $D^{V_L}_{Morph}$, as normal-form$(w') \equiv$ normal-form(w'_{ref}).

To make the analysis more revealing, we split the entries in $V_{[L,H)}$ in two: type T1 entries are those that have in-degree > 0 in $D^{V_L}_{Morph}$ (i.e., words that have a morphological mapping in the reference graph); type T2 entries are those that have 0 in-degree in $D^{V_L}_{Morph}$ (i.e., words with no morphological mapping in the reference, e.g., proper-nouns in English). Note that the T1/T2 distinction reflects a recall/precision trade-off: T1-words should be morphologically analyzed, while T2-words should not; a method that over-analyses has poor performance on T2, while one that under-analyses performs poorly on T1.

We use the same datasets as the ones presented in Section 4.1, see Table 3. The results for all the languages are shown in Table 6, with all rows using

	EN (RW testset)				DE (RG testset)

SG	80	177	35.8	44.7	0	20	62.4	62.1
SG+Morph	1	0	41.8	52.0	0	0	64.1	69.1

Table 5: Comparison between models SG and SG+Morph at different training-data sizes.

	$\|V_{[1000,2000)}\|$		Accuracy	
Lang	T1	T2	T1	T2
EN	3421	10617	89.7%	89.6%
DE	10778	21234	90.8%	93.1%
FR	6435	9807	90.3%	90.4%
ES	5724	7412	91.1%	90.3%
RO	11905	9254	86.5%	85.3%
AR	7913	5202	92.4%	69.0%
UZ	11772	9027	81.3%	84.1%

Table 6: Accuracy of Rare&OOV analysis.

the same setup. Count $L = 1000$ was chosen such that $D^{V_L}_{Morph}$ is reliable enough to be used as reference. The accuracy results are consistently high (in the 80-90% range) for both T1- and T2-words, even for morphologically-rich languages such as Uzbek. These results indicate that our method does well at both identifying a morphological analysis when appropriate, as well as not proposing one when not justified, and therefore provides accurate morphology analysis for rare and OOV words.

4.3 Morphology and Training Data Size

We also evaluate the impact of our morphology analysis under a regime with substantially more training data. To this end, we use large collections of English and German News, harvested from the web and cleaned (boiler-plate removed, formatting removed, encoding made consistent). Statistics regarding the resulting vocabularies and the induced morphology are presented in Table 7 (vocabulary cutoffs of 400 for EN and 50 for DE). We present results using the word-similarity task using the same Stanford Rare-Word (RW) dataset for EN and RG dataset for DE, compared against the setup using only 1-2 billion training tokens. For SG+Morph, we use count thresholds of 3000 for EN and 100 for DE. The results are given in Table 5. For English, a 100x increase in the training data for EN brings a 10-point increase in Spearman ρ (from 35.8 to 44.7, and from 41.8 to 52.0). The morphological analysis provides substantial gains at either level of training-data size: 6 points in ρ for Wiki1b (from 35.8 to 41.8), and 7.3 points for News120b EN (from 44.7 to 52.0). For German, the increase in training-data size does not bring visible improvements (perhaps due the high vocabulary cutoff), but the morphological treatment has a large impact under the large training-data condition (7 points for News20b DE, from 62.1 to 69.1).

Lang	|Tokens|	$\|V\|$	$\|G^V_{Morph}\|$	$\|D^V_{Morph}\|$
EN	120b	1.0m	2.9m	98,268
DE	20b	1.8m	6.7m	351,980

Table 7: Statistics for large training-data sizes.

5 Conclusions and Future Work

We have presented an unsupervised method for morphology induction. The method derives a morphological analyzer from scratch, and only requires a monolingual corpus for training, with no additional knowledge of the language. Our evaluation shows that this method performs well across a large variety of language families, and we present here results that improve on current state-of-the-art for the morphologically-rich Stanford Rare-word dataset.

We acknowledge that certain languages exhibit phenomena (such as word-compounds in German) that require a more focused approach for solving them. But techniques like the ones presented here have the potential to exploit vector-based word representations successfully to address such phenomena as well.
