Modern NLP systems face the challenge of interpreting language as close to human perception as possible. Modeling gradable terms as well as their associated meaning and ordering is an important aspect of this challenge. Such information can be very useful for a variety of inference tasks, such as sentiment analysis (Pang and Lee, 2008) and textual inference (Dagan et al., 2006). However, current lexical resources, like WordNet (Fellbaum, 1998), lack annotations capturing the gradability of words. This weakens the notion of similarity: although words such as *small* and *minuscule* illustrate varying degrees of size, they are listed as synonyms in WordNet.

Recently, there has been a lot of interest in exploring different approaches to derive an ordering among gradable adjectives based on their semantics (Ruppenhofer et al., 2014; Sheinman et al., 2013; Schulam and Fellbaum, 2010). de Melo and Bansal (2013) propose a novel Mixed Integer Linear Programming (MILP) based approach, publish a gold standard dataset and report the best performance on ordering scalar adjectives on this dataset. However, these approaches are limited in two ways. First, they depend on a manually created resource, such

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 483–493,
Denver, Colorado, May 31 – June 5, 2015.

as WordNet or FrameNet (Baker et al., 1998). Lexical patterns (e.g., 'not just x but y') are used both to extract words that belong to the same scale and to determine the direction of the ordering (e.g., in the above pattern, x is weaker than y). However, this extraction process gives noisy results that require filtering using an electronic thesaurus. The domain of application is thus restricted to words that exist in an electronic thesaurus. Second, previous work is limited to the study of adjectives.

In this paper, we propose a fully automated pipeline that uses structural patterns to extract gradable terms from a corpus, cluster them into groups that reflect the same semantic scale of comparison, and finally rank them using de Melo and Bansal's MILP technique to establish an ordering among them. We also explore how the technique fares on domain-specific (biomedical) text, deriving scales for domain-specific terms that might not exist in thesauri. Our approach achieves a comparable performance to previous studies on scalar adjectives, and can be reliably extended to adverbs.

2 Related work

Hatzivassiloglou and McKeown (1993) present the first work on automatically clustering adjectives that belong to the same scale, identifying scalar adjectives based on the intuition that similar nouns are modified by similar adjectives. They use a hierarchical clustering algorithm on a newswire corpus for grouping similar adjectives, but do not provide ranking among a given cluster of related adjectives.

Assuming a pair of related adjectives, de Marneffe et al. (2010) use reviews from the Internet Movie Database and their associated ratings to infer an ordering in the adjective pair. Kim and de Marneffe (2013) also obtain an ordering given a pair of adjectives, using distributional word vectors derived from a recursive neural network.

Sheinman et al. (2013) and de Melo and Bansal (2013) present similar approaches, which make use of WordNet *dumbbells* to determine words that belong to the same scale as proposed in Sheinman et al. (2012). A WordNet *dumbbell* is a representation involving an antonym pair (e.g., *small* and *large*) as two ends of a semantic scale with semantically similar adjectives arranged in a radial fashion around each adjective. The antonym acting as a centroid and its synonyms as members of a cluster represent words that most likely participate in the same scale. For example, the antonym pair (*small, large*) results in the dumbbell with clusters (*small, tiny, pocket-size, smallish*) and (*large, gigantic, monstrous, huge*) at the two ends. It should be noted that even with such a representation, there can be words that fall into the same WordNet synset but do not participate in the scalar relationship (e.g., *violent* with respect to *supernatural* and *affected*). This is primarily because of polysemy and semantic drift (de Melo and Bansal, 2013).

Sheinman et al. (2013) present a two-step approach for establishing an ordering among scalar adjectives. They extract adjectives from the Web using lexical patterns indicative of the direction of the scalar relationship between a pair of adjectives. Two sets of patterns are defined: *mild* patterns in which participating words are such that the first word has a weaker semantic intensity than the second word (e.g., '$*$ but not $*$' – *good but not great*); and *intense* patterns, in which the first word has a stronger semantic intensity than the second word (e.g., 'not $*$ but still $*$' – *not freezing but still cold*). In the first step, they assign a positive score to an adjective if it is seen as a part of the intense pattern and a negative score if seen as part of the mild pattern. In the second step, they use these scores to partition the adjectives into two subsets one representing *mild* and the other representing *intense* adjectives. They perform this partitioning recursively to obtain a complete ordering for a given cluster of adjectives from a WordNet dumbbell.

de Melo and Bansal (2013) improve upon Sheinman et al. (2013) by refining their lexical patterns, and refer to them as "strong-weak" and "weak-strong" patterns. Using frequencies of occurrence for a pair of adjectives across the strong-weak and weak-strong patterns in a corpus, they define an overall weak-strong score. They optimize for this score using MILP. The constraints of the MILP model two types of strength relationships: the strength relationships between two adjectives in a pair with a possible third adjective, and synonymy relationship between two adjectives based on information from an external resource. Given a cluster of terms, the MILP produces an ordering of the

cluster members using frequency counts of instances where these members are found in strong-weak and weak-strong patterns. To evaluate their approach, de Melo and Bansal construct a manually curated gold standard of 88 clusters, each with a cardinality of three or more adjectives. These 88 clusters are randomly drawn from all possible clusters that are either half of a WordNet dumbbell. Two annotators manually examined these clusters to remove words that did not belong to the same scale. Further, all pairs within these clusters were annotated for scalar relationship: is the adjective in a pair weaker than the other, stronger than the other, or of equivalent intensity. The output of the MILP was tested on these 88 clusters (569 word pairs). They achieve a pairwise accuracy of 78.2%.

3 Our approach

3.1 Extraction using structural patterns

As observed by Ruppenhofer et al. (2014), lexical pattern-based approaches suffer from a coverage issue. This is because these patterns consist of longer n-grams, which are sparsely found in a small dataset. Therefore, Sheinman et al. (2013) use the Web as their corpus, and de Melo & Bansal use Google N-grams (Brants and Franz, 2006). However, this results in a large number of instances where satisfied lexical patterns do not correspond to adjectives (e.g., *sometimes but not always*). Moreover, since the Google N-grams corpus is limited to 5-grams, adjective pairs of interest beyond a five-word window are lost.

To deal with these shortcomings, we use *Tregex* (Levy and Andrew, 2006), which enables pattern matching on parse trees based on syntactic relationships and regular expression matches on nodes. Using Tregex, we transform de Melo and Bansal's weak-strong and strong-weak lexical patterns into structural patterns. For example, one way of expanding the lexical pattern '$*$ but not $*$' into a structural Tregex pattern for adjectives is 'ADJP< ((ADJP<JJ) $ (CC<but)$(RB<not)$ (ADJP<JJ)).' Similarly, a structural pattern for adverbs can be written as 'ADVP< ((ADVP<RB) $ (CC<but)$(RB<not)$ (ADVP<RB)).' These patterns are available for download[1].

[1]http://web.cse.ohio-state.edu/~shivade/naacl2015

Introducing tree patterns requires parsing a corpus: while this additional step in the pipeline might lead to error propagation, the advantages of the structural patterns are that (i) they are more robust than the lexical ones and (ii) restricting results to a desired part-of-speech comes for free. In the experiments reported here, we use the Stanford parser v3.3.1 (Klein and Manning, 2003).

3.2 Automatic clustering

In order to determine a ranking of words based on their semantic intensity, the first step is to determine words that belong to the same scale of meaning. As pointed out earlier, previous work (de Melo and Bansal, 2013; Sheinman et al., 2013) use WordNet *dumbbells*, and this restricts the utility of these approaches to the scope of a manually created lexical resource. We overcome this limitation by automatically clustering words that belong to the same scale. As the clustering algorithm, we use the Matlab (2014) implementation of K-means++ (Arthur and Vassilvitskii, 2007), a hard clustering algorithm[2] with cosine similarity as a distance metric. Following Hatzivassiloglou and McKeown (1993), we use context vectors to represent the words to cluster. They make use of standard context vectors for clustering adjectives, where context for every adjective comprises of nouns it modifies across all sentences in a corpus.

However, recent work shows promise for context vectors embedded in a compressed semantic space that are derived using neural networks: Baroni et al. (2014) compare standard context vectors with embedded vectors for a wide range of lexical semantic tasks and found embedded vectors to yield better results. We therefore generate context vectors and compare the utility of both skip-gram and continuous bag of words (CBOW) representations using the `word2vec` tool (Mikolov et al., 2013) for our task. These two representations have demonstrated varying degrees of success in different NLP tasks (Baroni et al., 2014; Bansal et al., 2014). Given a

[2]The choice of a hard-clustering algorithm was mostly for implementational convenience, but carries with it the issue that polysemous words can only appear in one semantic cluster. We leave the issue of deriving a soft clustering approach that works with context vectors, a separate research problem in its own right, to future work.

window size w, the CBOW model predicts the current word given the neighboring words as context. In contrast, the skip-gram model predicts the neighboring words given the current word. We used $w = 5$ and found CBOW to yield better results for our task. Thus the terms extracted from a corpus by the structural patterns are automatically clustered, and these clusters are used as an input to the ranking algorithm.

3.3 Ranking based on semantic intensity

Once the terms have been clustered, the second step is to provide a ranking between the cluster members. To do so, we use the MILP implementation provided by de Melo and Bansal (2013). This method computes an overall weak-strong score for a pair of adjectives based on the frequency of that pair in the matches for weak-strong and strong-weak patterns. The MILP then uses these scores among all relevant pairs of adjectives belonging to the same scale, capturing complex interactions to infer an ordering among them.

3.4 Data: PubMed corpus

In this work, we want to provide an approach that can infer scalar orderings for any domain-specific terms. Such terms might be absent from existing thesauri. Our approach is thus corpus-based as outlined above. We chose to test the robustness of our technique on PubMed, a large domain-specific corpus of biomedical texts. It is a free resource developed and maintained by the National Center for Biotechnology Information at the National Library of Medicine. It provides access to scientific abstracts, full text articles and associated resources. We used $10,875,982$ freely available abstracts (not full text articles) from PubMed as our corpus. This corresponds to $88,303,272$ sentences in total, where the average length of a sentence is 28 words (including punctuations). We used this corpus to find instances of the structural strong-weak and weak-strong patterns, both for adjectives and adverbs.

4 Comparison with the gold standard of de Melo & Bansal

To evaluate our approach, we need to establish how good the clustering step is, as well as how good the ranking step is. Each step is evaluated separately using annotations obtained from Amazon Mechanical Turk.

4.1 Clustering

In order to evaluate the automatic clustering procedure that uses K-means++ and word vectors, we start with the gold standard provided by de Melo and Bansal (2013): as mentioned above, their data set has 88 gold standard clusters, corresponding to 346 adjectives, annotated by humans for scale ordering. One problem with evaluating a hard clustering algorithm is that the same word may appear in multiple WordNet synsets, corresponding to multiple clusters (soft clustering). We therefore made a "hard cluster version" of the de Melo & Bansal dataset by removing any adjectives that occur in multiple clusters, and then eliminating any singleton clusters. This resulted in a gold standard set of 256 adjectives belonging to 84 clusters.

We clustered the 256 adjectives from the gold standard data subset into 84 clusters: the representation for each adjective was a neural embedding derived using the `word2vec` tool trained on our PubMed data. We experimented with both the skip-gram and continuous bag of words (CBOW) models to derive vectors of dimension sizes varying from 200 to 800 in increments of 100. To choose the right dimensionality and the best model, we evaluated the quality of the automatically derived 84 clusters against the gold standard. As a metric of evaluation for cluster quality, we follow Hatzivassiloglou and McKeown (1993) and use F1 calculated by comparing equivalence relations generated by the clusters (as implemented in LingPipe (2008)). We found that the CBOW model gave clusters closer to the gold standard than the skip-gram model. We found that a dimension size of 600 for the vectors yielded clusters with a maximum F1 score of 57%. Thus, we were able to fix the parameters for our clustering task. Figure 1 summarizes the results of this experiment.

In their study, Hatzivassiloglou and McKeown (1993) evaluate the results of their clustering on a small set of 21 adjectives. They presented the 21 adjectives to 9 annotators and asked them to partition these adjectives such that each partition contain adjectives that belong to the same scale. They re-

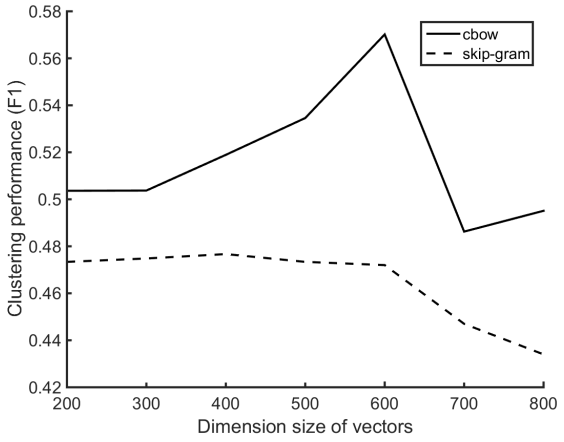

Figure 1: Comparison of CBOW and skip-gram for clustering of adjectives.

port a best F1 score of 48% but note that such score does not seem to reflect the quality of the clustering. We observe the same problem: our automatically derived clusters have a different organization for words that belong to the same cluster than the gold standard clusters, but in a way that seems intuitive. Some differences between our automatically derived clusters and the gold standard clusters are illustrated in Table 1. For example, the adjectives *false* and *misleading* belong to the same cluster in both the gold standard as well as the automatic clustering output. However, the automatic clustering groups the adjectives *false* and *misleading* together with *unreliable* and *wrong*, whereas the gold standard groups *false* and *misleading* with *deceptive* and *fraudulent*. Both clusterings are plausible, though. The adjectives *fraudulent* and *deceptive* become part of new clusters in our automatic clustering. It could be argued that the gold standard cluster "deceptive, false, fraudulent, misleading" represents different degrees of "trickery," whereas the automatic cluster "false, misleading, unreliable, wrong" represent different degrees of "wrongness." Thus, although both clusters contain different adjectives, they group adjectives that are on the same scale of a different meaning.

Therefore, to evaluate the quality of the automatic clustering, we sampled 50 clusters containing three or more adjectives (corresponding to a total of 190 adjectives) from all the generated clusters and obtained annotations using Amazon Mechanical Turk (AMT), a crowdsourcing platform that has been shown useful for a number of NLP tasks (Snow et al., 2008). Annotators (workers, in AMT parlance) were presented with 15 clusters in each worker session, whose members were each associated with a checkbox. For each cluster, workers had to uncheck the adjectives that did not belong to the same scale. The nature of the annotation task does involve inherent subjectivity which cannot be avoided. We tried to minimize this by giving detailed instructions with accompanying examples to achieve coherent annotations. To make sure workers were paying attention to the task, 2 clusters among the 15 clusters they saw were clusters for which we a priori knew which adjectives should be removed (e.g., *beautiful, pretty,* and *rainy* where *rainy* had to be unchecked). Most workers did the task well: we only had to discard annotations from 4 worker sessions (out of 140). We ended up with annotations from 8 to 10 workers per cluster. To create a gold standard, we retained in each cluster only those words that were ascertained to be in the same cluster by 6 or more annotators.

For each cluster, we calculated an accuracy score equivalent to the number of correct adjectives (determined to be on the same scale by the annotators) divided by the total number of adjectives in the generated cluster. This accuracy was averaged across all 50 clusters, and yielded a final micro-averaged accuracy of 74.36% as seen in Table 2.

4.2 Ranking

Since our end goal is to establish an ordering among scalar adjectives, we use the automatically derived clusters (rather than the WordNet dumbbells) as input to the MILP algorithm. To determine the performance of the ranking produced by the MILP algorithm, we use AMT to obtain pairwise ranking annotations for all unique adjective pairs within a cluster. Workers were presented with 15 word pairs in each worker session. For each pair $(a1, a2)$, the worker had to pick one of four options: (1) $a1$ is stronger than $a2$, (2) $a2$ is stronger than $a1$, (3) both are equally strong, and (4) $a1$ and $a2$ are not comparable. Option (4) was present because our clusters possibly contained adjectives that are not on the same scale. As in the previous task for getting annotations for clusters, we inserted two items with a clear ranking (e.g., *hot, hotter*) for every set of 15

Gold standard clusters	Automatic clusters
deceptive, false, fraudulent, misleading	false, misleading, unreliable, wrong
evil, immoral, sinful, wrong	desperate, humiliated, immoral, insane, sinful
dangerous, risky, suicidal, unreliable	dangerous, harmful, toxic

Table 1: Example comparison of automatically derived clusters against gold standard clusters from WordNet.

Data	Corpus for strength counts in MILP ranking	Clustering Accuracy	Ranking Pairwise Accuracy
Clusters automatically derived from	Google N-grams	74.36	84.74
non-polysemous WordNet adjectives	PubMed	74.36	69.23
PubMed-derived clustering:			
Regular adjectives	PubMed	86.26	70.37
Domain-specific adjectives	PubMed	64.30	–
PubMed-derived clustering:			
Regular adverbs	PubMed	89.36	71.00
Domain-specific adverbs	PubMed	53.80	–

Table 2: AMT-based evaluations of cluster accuracy and pairwise ranking accuracy of systems that vary in the source of clustering data, source of strength counts, and part of speech. For comparison, the approach used by de Melo and Bansal (2013) achieves a pairwise ranking accuracy of 76.1% on the non-polysemous WordNet clusters.

pairs to avoid random annotations. Each set was annotated by 10 workers. All workers passed all the checks and we did not discard any annotations for this task. To create a gold standard we assigned each pair one of four labels, *weaker, stronger, equal,* or *not comparable*. A value was assigned based on a majority vote. In case of a tie, the pair was assigned a label of being *equal*.

In order to compute a ranking, the MILP needs two inputs: 1) the cluster of terms that are on the same scale, and 2) the counts for how many times all pairs of adjectives in that cluster satisfied the weak-strong and strong-weak patterns (henceforth referred to as "strength counts"). In the first experiment of ranking adjectives, we ran the full pipeline used by (de Melo and Bansal, 2013) on the 256 adjective (84 hard cluster) subset of their gold standard (see Section 4.1). Thus, this experiment uses hand-corrected WordNet dumbbells to determine adjectives on the same scale of semantic intensity, followed by the MILP using strength counts from the Google N-gram corpus, to determine the ranking. Their pipeline resulted in a pairwise accuracy of 76.1% which serves as a baseline for comparison. In the second experiment of ranking adjectives, we used the 50 automatically derived adjective clusters described in Section 4.1 as an input for the MILP. Since these adjectives originate from WordNet dumbbells, we refer to them as "WordNet adjective clusters." We determined the ranking for adjectives within these clusters using strength counts obtained from our PubMed corpus. We obtained an accuracy of 69.23% across 105 pairs. The strength counts for all adjectives in these clusters, from Google N-grams corpus, used in the experiments of (de Melo and Bansal, 2013) were also available to us by the authors. We repeated the previous experiment by substituting strength counts from PubMed corpus with these strength counts from the Google N-grams corpus and obtained an accuracy of 84.74% across 119 pairs.[3] It appears from our experiment that pattern counts from a general corpus

[3]The MILP does not produce a strength relationship between a pair of adjectives if there are no strength counts for this pair. Hence, we observe a difference in the number of pairs for which accuracy is determined in the two ranking experiments.

is a better match for determining the adjective ordering than a more-limited domain corpus, despite the limitation of Google N-grams being restricted to 5-word sequences. We think this is because of two reasons: First, Google N-grams is a very large corpus compared to the one we use. Second, our corpus consists of abstracts and not full text of scientific articles from PubMed. Hence there is less variety in the language used; capturing fewer comparative constructs than Google N-grams. However, it is interesting that we can still extract patterns from domain-specific corpora to act as constraints for the MILP process.

5 Rankings for adjectives extracted from PubMed

We also desired to see how well our approach does on terms that are not specifically in WordNet, but present in a domain-specific corpus such as PubMed. We therefore also evaluate the clustering and ranking steps on a set of adjectives extracted from the PubMed data using structural patterns.

5.1 Clustering

Since there was no gold standard reflecting ideal clustering of data, we explored heuristic measures to choose parameters for our clustering step. We used CBOW vectors over skip-gram vectors since these were more effective in the previous experiment. Since the true value for number of clusters k was unknown, we chose k such that the average cardinality of a cluster was three. The value of k was found to be the same ($k = 375$) for all clustering experiments conducted using vector dimension sizes varying from 200 to 800 in increments of 100. To choose the right dimension size d of the CBOW vectors for this fixed value of k, we obtained clusters for incremental values of d from 200 to 800 in increments of 100. We determined the number of identical clusters obtained using a particular value of d with its next increment. The lowest value of d which resulted in a maximum number of identical clusters with its next increment was chosen: $d = 400$.

Using vectors of 400 dimensions, we obtained 375 adjective clusters with cardinality varying from 1 to 9. Since these clusters were derived from our biomedical dataset, they comprised of domain-specific adjectives, which are quite unfamiliar even to native English speakers. We manually partitioned the clusters into two sets: (i) containing domain-specific words, and (ii) containing words used in day-to-day English (henceforth referred to as "regular" terms). Examples of clusters from both sets are summarized in Table 3. The clusters we obtain look reasonable, grouping together adjectives that pertain to the same scale. The first cluster of domain-specific adjectives qualifies the nouns corresponding to different types of protein with varying degree of specificity, the second cluster contains different qualifications of a tumor, and adjectives in the third cluster qualify different parts of a living cell. For the regular adjective clusters, the clusters look intuitive too, except for the first cluster. The adjectives *male* and *female* are not scalar, but match the structural patterns, and are grouped together with adjectives describing age qualifications, due to a strong context overlap in which these words are used.

Clusters of domain-specific adjectives
cytokine, gm-csf, ifn-gamma, il-10, il-12, il-2
benign, malignant, metastatic, neoplastic, squamous
mitochondrial, nuclear, ribosomal
Clusters of regular adjectives
female, male, middle-aged, older, young, younger
accurate, precise, reliable, reproducible, robust
additive, insignificant, negligible

Table 3: Examples of automatically derived adjective clusters from PubMed abstracts.

We randomly sampled 25 clusters from each set, "regular adjectives" and "domain-specific adjectives", for our evaluation. We evaluated the clustering quality of the regular adjectives using the exact same approach as described in Section 4.1. We obtained a clustering accuracy of 86.26% for 25 clusters across 101 regular adjectives. This is substantially better than the performance of clustering in the previous experiment. We believe that this is due to the fact that the adjectives in the dataset used in the previous experiment originate from WordNet and contain many words (e.g., *handsome*, *crazy*, *spicy*),

which are less likely to be found in scientific abstracts. Therefore, the context vectors learnt for these words are possibly less accurate compromising the clustering quality.

For the domain-specific adjectives, the annotations require specialized skills. PubMed hosts scientific articles from different disciplines of biological sciences. We obtained annotations from three annotators specializing in disciplines of Biomedical Informatics, Biochemistry, and Nursing. To create the gold standard, a word was retained or discarded from a cluster if two or more annotators agreed on it. We obtained a clustering accuracy of 64.3% for 25 clusters across 101 domain-specific adjectives.

5.2 Ranking

We obtained gold standard annotations for ranking using AMT for these 25 "regular adjective" clusters derived from the PubMed corpus using the exact same methodology as described in Section 4.2. The strength counts for these adjectives were also derived from the PubMed corpus. We obtained an accuracy of 70.37% across 109 pairs, indicating a similar level of performance to WordNet-based clusters.

Our expert annotators for the domain-specific adjectives faced problems in assessing an ordering between adjectives in a cluster. They report that for majority of the clusters, the ordering of the words would vary given the context. For example, consider the following modifications of the domain specific adjectives of the third cluster in Table 3: ribosomal particles, mitochondiral compartments and nuclear compartments, representing different parts of a living cell. If we consider "number of" as the relation in context, we get (*ribosomal* $>$ *mitochondrial* $>$ *nuclear*) as an ordering since number of ribosomal particles is greater than number of mitochondrial compartments, and number of mitochondrial compartments is greater than number of nuclear compartments. However, if we consider "size of" as the context, the ordering is reversed.

6 Extension to adverbs

A novelty of our approach is that we can also apply the technique to other parts of speech (e.g., adverbs). The structural patterns we describe in Section 3.1 also enable us to extract candidate scalar adverbs. We follow a similar approach to adjectives: extract adverbs, derive strength counts and rank them using the MILP.

Clusters of domain-specific adverbs
anteriorly, caudally, distally, proximally
chromosomally, clonally, genetically, phenotypically
neonatally, prenatally, postnatally
Clusters of regular adverbs
always, certainly, inevitably, invariably, universally
marginally, modestly, slightly, somewhat
excessively, inappropriately, overly

Table 4: Examples of automatically derived adverb clusters from PubMed abstracts.

6.1 Clustering

We used CBOW vectors to perform clustering and derived $k = 300$ and $d = 250$ using the approach described in Section 5. As with the adjective clusters, we found that there were also domain-specific adverbs, illustrated in Table 4. Again, the clusters obtained look reasonable. The first cluster of domain-specific adverbs describes relative position of a body part, the second cluster corresponds to adverbs describing identity of a gene that may have an observable effect, the third cluster represents temporal descriptions that relate an event to child birth. The clustering of regular adverbs is accurate, except for the third cluster where *inappropriately* was found to be an outlier based on our annotations. We followed a similar approach to the adjective experiment, creating two partitions for domain-specific and regular adverbs and sampling 25 clusters from each. Annotations for regular adverbs were obtained from AMT while annotations for domain-specific adverbs were obtained from 3 domain experts. The annotation process for both clusters of adverbs was identical to that of adjectives. We obtained a micro-averaged accuracy of 89.36% for 25 clusters across 104 regular adverbs and a 53.8% for 25 clusters across 89 domain-specific adverbs.

Accuracy	POS	Examples
Good	Adj	serious < life-threatening < fatal
Good	Adv	considerably < significantly < dramatically
Average	Adj	common < frequent = prevalent
Average	Adv	slightly < modestly < marginally
Bad	Adj	useful < helpful
Bad	Adv	continuously = regularly

Table 5: Example rankings for adjectives and adverbs from PubMed data.

6.2 Ranking

As in the case of adjectives, our annotators for domain-specific adverbs faced a challenge in ranking adverbs due to lack of context. Therefor we do not report results on ranking of adverbs. We obtained gold standard annotations for ranking using AMT for 25 clusters of regular adverbs derived from the PubMed corpus, using the exact same methodology as described in Section 4.2. The strength counts for these adverbs were also derived from the PubMed corpus. We obtained an accuracy of 71.00% across 38 pairs – a performance similar to the adjectives. However, we observe that there are a large number of pairs for which there are no strength counts, and the MILP does not generate a ranking. Table 5 shows sample results for ranking adjectives and adverbs from the PubMed data.

7 Limitations and future work

We present an approach to gradable modifier ordering that replaces WordNet-based clusters with automatically derived word clusters, replaces lexical patterns with structural patterns, and show that the approach has utility for not only discovering adjective patterns but also adverb patterns in biomedical text. We observe that while automatic ranking based on semantic intensity can be successful established between regular terms, doing so for domain-specific terms requires knowledge of context.

We plan to expand the structure patterns derived from the lexical patterns of de Melo and Bansal (2013), looking for new patterns that could be more suited for adverbs. We also plan to investigate soft clustering algorithms such as (Pereira et al., 1993) that may allow us to model polysemous words better. Furthermore, recent studies have compared traditional vectors against embedded vectors (such as the CBOW vectors used in this study) for different lexical semantic tasks (Levy and Goldberg, 2014; Baroni et al., 2014), which suggests that such a comparison for our clustering task could be insightful.

Our experimental results show that automatic clustering of gradable words produces promising results. However, we also observe that with domain-specific words, context is important for establishing a ranking between words that is based on semantic intensity. Thus, rather than clustering adjectives or adverbs in isolation, a joint with the clustering of nouns or verbs with which they occur is a possible direction of research. Finally, studies deriving a ranking based on semantic intensities are limited to unigrams belonging to different parts of speech. Our future work would focus on performing a similar task on bigrams consisting of adverb-adjective pairs (e.g., *somewhat unclear* < *quite hard* < *very difficult*) that exhibit properties of gradability.

Acknowledgements

We would like to thank Mohit Bansal and Gerard de Melo for providing the implementation and results of the experiments from their previous work. Dialogue focus tracking for zero pronoun resolution

Abstract

We take a novel approach to zero pronoun resolution in Chinese: our model explicitly tracks the flow of focus in a discourse. Our approach, which generalizes to *deictic* references, is not reliant on the presence of overt noun phrase antecedents to resolve to, and allows us to address the large percentage of "non-anaphoric" pronouns filtered out in other approaches. We furthermore train our model using readily available parallel Chinese/English corpora, allowing for training without hand-annotated data. Our results demonstrate improvements on two test sets, as well as the usefulness of linguistically motivated features.

1 Introduction

"Pro-drop" languages like Chinese, Japanese and Turkish allow for dropping of pronouns when the referents of those pronouns can be inferred. English is typically *not* pro-drop, but is unusual in that regard: two thirds of languages documented in WALS (Haspelmath et al., 2005) can be categorized as pro-drop. In such languages, sentences are frequently characterized by "zero pronouns": gaps in the sentence which in English would hold an overt pronoun. In some languages, verbal morphology or clitics elsewhere in the sentence are sufficient to resolve the ambiguity of dropped pronouns; in other languages, there is *no* overt marking at all in the sentence and the referent of the dropped pronoun must be resolved using pragmatic information.

Our work departs from mainstream work on zero pronoun resolution in that we focus primarily on the resolution of *deictic* zero pronouns. Unlike an

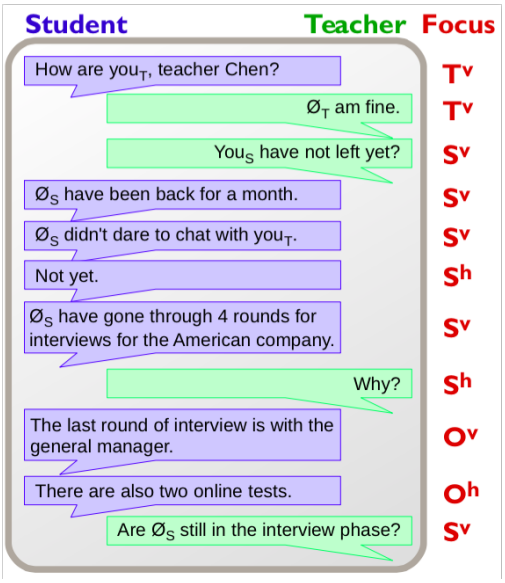

Figure 1: A conversation between a student and a teacher. The text has been translated from Mandarin, but zero pronouns are retained and indexed with their referent: (T)eacher or (S)tudent.

anaphoric zero pronoun (Section 2), whose reference must be specified by a noun phrase occurring previously in the text, a *non-anaphoric* zero pronoun refers to an entity that is salient from larger units of discourse (such as full sentences or passages) or from the extralinguistic environment (outside of the text altogether). Although anaphoric zero pronoun resolution has been the focus of most past work (Yeh and Chen, 2007; Chen and Ng, 2014), 50% or fewer of zero pronouns in natural Chinese text are anaphoric (Zhao and Ng, 2007; Kong and Zhou, 2010). Our approach allows for generalization to non-anaphoric pronouns, focusing in particular on *deictic* non-anaphoric zero pronouns, which

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 494–503,
Denver, Colorado, May 31 – June 5, 2015.

refer to salient entities in the environment (such as the speaker, hearer or pragmatically accessible referent) without requiring any introduction in the preceding text. Figure 1 shows an example conversation in which zero pronouns are frequently used to refer to speaker or listener, and would be translated to English as "I" or "you."

We propose a model for resolving deictic zero pronouns that draws inspiration from ideas in Centering Theory (Grosz et al., 1995): discourses tend to settle on a particular *focus* for a time, before switching. Furthermore, we presume that *when* a switch happens, there is likely to be an overt cue of this. For example, in Figure 1, the initial focus on **T** is signaled with the overt second person pronoun in the first utterance; the switch of focus to **S** in the third utterance is also signaled by an overt "you." However, at that point, the focus remains on **S** for several utterances until "The last round…" at which point it switches away from the speakers. It is brought back to **S** in the last utterance, which can be inferred from the fact that **S** is the most recent focus that fits the required semantic constraints.

To account for these phenomena, **we develop a novel sequential model for zero pronoun resolution that explicitly tracks the conversation focus in a dialogue** (Section 3). We test, using data from Chinese SMS ("texting") dialogues, the hypothesis that our model can predict the identity of pronouns (at a granularity of the person attribute: first, second, or third person—with particular focus on first and second person) based on a variety of features of the utterance context, without reference to a particular antecedent (Section 4.3). In this way, we address a much higher percentage of the zero pronouns found in Chinese texts, and particularly in dialogue.

Our second contribution is to show that **one can train a zero pronoun resolution system using supervision coming from English translations of the Chinese text** (Section 2.2). This obviates the need for expensive linguistic annotation of Chinese and allows us to use plentiful parallel data to train our model. Our results confirm that even though this "translation as annotation" process is noisy, it is still possible to learn on large amounts of "bronze standard" data.

2 Linguistic motivation

Handling zero pronouns in Chinese (or other pro-drop language) involves two separate tasks: (1) Zero pronoun identification: locating and marking the gaps corresponding to zero pronouns; and (2) Zero pronoun resolution: determining the entity referred to by the zero pronoun. Our focus is the latter task.

Zero pronoun resolution, like general pronoun resolution, is almost universally approached as a problem of linking a pronoun to an overt noun phrase antecedent in the text. However, while some zero pronouns do have overt noun phrase antecedents, many other zero pronouns do not. In fact, (Zhao and Ng, 2007) report that just 52% of zero pronouns in their training set (and 46% of zero pronouns in their test set) are "anaphoric." Kong and Zhou (Kong and Zhou, 2010) report just 41%. Some zero pronouns fail to link to an antecedent because they refer to facts or events described by larger phrases or full sentences earlier in the text, preventing coreference with a single noun phrase. Other zero pronouns, particularly in dialogue settings, are *deictic*, pointing to salient entities in the environment without requiring introduction by an overt mention in the text.

2.1 Dialogue focus

A central principle of document cohesion that underlies frameworks such as Centering Theory (Grosz et al., 1995) states that discourses tend to settle on a particular focus for a time, before eventually switching to a new one. The status of a particular focus within this flow of discourse is typically signaled by the form of the expression chosen to point to it. When a focus is introduced (or returned to), a full (overt) noun phrase is generally used to indicate it. While that entity remains in focus, subsequent mentions can be realized with less explicit forms. In English, these less explicit forms are overt pronouns. In Chinese (and pro-drop languages more generally), these focus continuations are generally realized as zero pronouns.

We see in this example an illustration of these discourse principles:

1. In pro-drop languages (Chinese), overt pronouns introduce switches in focus, while zero

pronouns are used while an established focus continues.

2. In non-pro-drop languages (English), overt pronouns serve the focus-continuation function.
3. There are "deictic" exceptions to these rules, licensed by environmental salience of the referent and inferable from the meaning of the utterance (final question of the example).

Importantly, these continuations and switches of foci occur for the most part at the level of the syntactic clause. This is thus the level at which we model, assigning labels to individual clauses, which will in turn indicate the identity of any dropped subject pronoun in that clause.[1] In identifying focus, we remain at the granularity of the "person" attribute (first, second, or third person). This is the most relevant granularity for deictic pronoun resolution, as the intent is to capture the alternation between speakers within that dialogue (first and second person), along with switches of focus to any referents external to the dialogue (third person).

2.2 Translation as annotation

Currently, most state-of-the-art machine learning systems for Chinese zero pronoun resolution are supervised, requiring manually resolved pronouns for training. We hypothesize comparable distribution between zero pronouns in a pro-drop language, and overt pronouns in a *non*-pro-drop language. More specifically, because non-pro-drop languages lack zero pronouns, the discourse functions that are served by zero pronouns in pro-drop languages *must* in non-pro-drop languages be served by overt pronouns.

To be more concrete, the original Mandarin SMS conversation from Figure 1 is reproduced in Table 1, together with a human translation into English. Indeed, we see in the example in Figure 1 that the zero pronouns on the Chinese side correspond to overt pronouns on the English side. For this reason we make use of a parallel (Chinese/English) corpus for training of our sequence labeling model, deriving the identities of missing pronouns from the English translation of the Chinese text rather than from coreference relations with antecedents in the Chinese text. Our model thus does not rely on the availability of hand-annotated data for training.

[1] Although Mandarin does license dropped object pronouns, we focus in this paper only on subject pronouns, as the syntactic subject is (a) more consistently dropped in Mandarin, and (b) more tightly tied to the notion of focus of conversation that motivates our model; see also a discussion of the centering hierarchy in Chinese (Wang, 2011). Relatedly, we filter out possessive pronouns in subject position, as they do not point to the topical entity represented by the full noun phrase.

3 Our focus tracking model

Given a Chinese dialogue, our goal is to identify zero pronouns and resolve them either as deictic (first or second person) or non-deictic (third person). We use off-the-shelf tools for the identification of the zero pronouns (described in Section 4.1) and focus on the *resolution* task.

In our implementation, we *jointly* predict the *focus* and identify the number of the pronoun that would be used. For instance, when **S** is speaking about herself, we consider this a "**1**" label; when **S** is speaking about her conversation partner, we consider this a "**2**" label. This numbering corresponds to which pronominal form would be required in English.[2]

3.1 Supervision via bronze standard data

We obtain "bronze" standard (as opposed to "gold" standard) data by looking at human-produced English translations of Chinese utterances, such as those seen in Table 1. Our label set consists of two properties: the *person* being referred to (first person, second person or third person), and whether the reference is overt or not (visible or hidden). The "visible" three labels correspond to clauses in which an overt subject pronoun appears *on the English side.* Chinese clauses bearing this label may have an overt or a zero pronoun subject—if the Chinese side contains a zero pronoun subject, then this label will be used to determine the correct person attribute (first, second, or third) of the unseen pronoun.

1v: Overt English first person pronoun: "I" or "we"
2v: Overt English second person pronoun: "you"
3v: Overt English third person pronoun: "he", "she", "it", "they"

[2] We ignore morphological issues in English dealing with possession and grammatical role, since these are exogenous to the resolution task.

	Original Mandarin	English Translation	Label
1) **Student**	陈老师你还好吗	How are you, Teacher Chen?	2v
2) **Teacher**	∅ 好啊，你还没走？	I am fine. You have not left yet?	1v, 2v
3) **Student**	∅ 回来有一个月 ∅ 不敢给你说话	I have been back for a month. I didn't dare to chat with you.	1v, 1v
4) **Student**	没呢	Not yet.	1h
5) **Student**	美国的面试 ∅ 进行了 4 轮了	I have gone through 4 rounds of interviews for the American (company).	1v
6) **Teacher**	为什么	Why?	2h
7) **Student**	最后一轮是跟总经理	The last round of interview is with the general manager.	3v
8) **Student**	还有两次网上测验	There are also two online tests.	3h
9) **Teacher**	∅ 还在面试阶段吗	Are you still in the interview phase?	2v

Table 1: Sample Chinese SMS conversation with English translation and derived labels.

However, there are plenty of utterances (e.g., Table 1 lines 4 and 6) in which the English translation does not contain an overt subject. This can happen in English in imperative constructions, (some) questions, and general informal communication.[3] In these cases, we introduce "hidden" person labels whose role is to carry forward the focus from the previous utterance. For instance, in utterance 4, even though there is no subject on the English side, we carry forward the fact that the most-recent referent was "first person" and denote this with "1h."

Because we are jointly modeling the focus shift and the pronoun realization aspects, when the speaker shifts, the "hidden" person must flip. For example, in utterance (5) the **Student** overtly refers to herself, yielding a label of "1v." The next utterance is by the **Teacher** but lacks an English subject. The focus remains on the **Student** and therefore this utterance is labeled "2h" meaning that the focus is on the *other* speaker, and it is non-overt in English.

1h: subject being continued is first person
2h: subject being continued is second person
3h: subject being continued is anything else

Finally, we introduced a seventh label for instances in which no overt subject pronoun appears on the English side, and no focus has yet been established from prior clauses (this applies only at the beginning of a discourse).

None: no subject and no focus yet established

[3]This can also happen due to imperfect zero pronoun identification (Section 4.1).

In Table 1, the rightmost column shows the label assignment for the sample SMS exchange. (The utterances on lines 2 and 3 contain two clauses each, and thus two labels each.)

3.2 Features

We included in our model the following features. Note that these features are based solely on the *Chinese side*. Linguistic motivations for each feature category are described.

Subject continuation: a value indicating the *person* (1, 2, 3) of the most recent overt NP that was a direct descendent of an IP node (the most recent overt NP in structural subject position—including, if overt, the subject of the current clause). *The most recent overt NP subject is a strong candidate for coreference with a zero pronoun. This feature comes closest to attempting antecedent selection.*

Verb: the first verb in the VP that is sister to the subject NP (the VP of which that NP is the subject). *The nature of the verb can provide information relevant to inferring the identity of deictic forms.* For example: the Chinese verb *guji* ("reckon") is intuitively biased toward first-person subject; our training data accordingly show 68% of clauses with *guji* as verb feature were assigned first-person subject labels.

Participant index: a value indicating the index of the conversational participant. *To capture regularities, if any exist, in the pronoun use of a speaker.*

Participant switch: a binary value indicating whether the current utterance represents a change of speaker relative to the previous clause. *Switches in*

speaker may, particularly in tandem with other features, be informative about topic.

Object (downstream): the direct object of the VP sister to the subject (if any). *This feature exploits the fact that pronouns occurring as direct objects within a clause cannot be the same as the (zero) pronoun in subject position of that clause.*

Has question particle: a binary value indicating whether the clause contains a) a question particle or *wh*-word, or b) a question mark. *This feature is likely to be a strong indicator of that the subject pronoun is* not *first person (also used by (Chen and Ng, 2013)).* For example, in our training data we found that only 16% of the clauses with question particle were marked with first person label i.e. 1v or 1h.

Bag of words: all words occurring in the clause. *Apart from the verb, other words can also be highly informative about the nature of the subject.*

Bag of parts of speech: all parts of speech occurring in the clause. *The structural make-up of clause may be informative about focus, for instance in the case of passive or possessive constructions.*

Hidden subject particles: a feature indicating whether the clause consists of a list of phrases consistently tagged with empty categories on the Chinese side, but consistently translated without subject pronouns on the English side (thus likely to correspond to labels 1h-3h). *This feature is intended to help the model in recognizing clauses consistently corresponding to "hidden" labels.*

In addition, for the features that consist of sequence (bag of words, bag of part of speech, object, etc.) we additionally compute bigrams and trigrams.

3.3 Structured prediction

We cast the above model as a sequence labeling problem over visible and hidden labels. We consider each conversation segment in the SMS as an input data sequence $\boldsymbol{x} = \langle x_1, x_2, \ldots, x_n \rangle$ where each x_i corresponds to a clause in Chinese. Each clause in Chinese is assigned a label from the label space Y = {1v, 2v, 3v, 1h, 2h, 3h, none}. The task then is to assign labels $\boldsymbol{y} = \langle y_1, y_2, \ldots, y_n \rangle$ to the input data sequence from the label space Y based on the features described in Section 3.2. At training time we assign labels to the input sequence using the "bronze standard" method described in Section 3.1.

To train the sequence labeling model, we use an online variant of the DAgger imitation learning algorithm (Ross et al., 2011) as implemented in the Vowpal Wabbit machine learning library (Langford et al., 2007; Daumé III et al., 2014). DAgger, like its predecessor SEARN (Daumé III et al., 2009), solves structured prediction problems by transforming them into sequential decision making problems. In the case of sequence labeling, the natural order for sequence decision making is left-to-right. At test time, inference is performed greedily. At training time, the learning algorithm attempts to balance between training on "oracle" states (prefixes of decisions made optimally according to the true labels) and training on "system" states (prefixes of decisions made sub-optimally according to the learned model). The online variant of DAgger balances this trade-off by slowly transitioning from making past decisions optimally to making them using the currently learned predictor.

4 Experiments

Our goal in our experiments is to answer the following questions:

1. How well does the bronze-standard annotation capture the underlying truth? (Section 4.2).
2. Is our model able to leverage both dialogue structure and semantic content to accurately resolve pronouns? (Section 4.3)
3. How important are the different components in our model in making effective predictions? (Section 4.4)

In the following sections, we describe the experiments we perform aimed at answering these questions. First, we describe the data we use for experimentation.

4.1 Experimental setup

For training our focus-tracking model, we use Chinese-English parallel data from the SMS/chat domain available as part of training data used in the Machine Translation task under the DARPA BOLT project. The training data consisted of $117k$ sentences. We test our model on heldout SMS/Chat data consisting of 1152 sentences (hand-annotated,

	Bronze Training	SMS Test	OntoNotes Test
# tokens	1,007,722	8104	108,531
# sents	129,190	1152	9607
# dialog	3309	34	257
# types	26,519	1747	4753

Table 2: Dataset statistics; numbers are for the Chinese side of the data. English has 25% more tokens and roughly as many types.

as described in Section 4.2), and on telephone conversation data from the OntoNotes corpus (Hovy et al., 2006), consisting of 5000 sentences. Full data statistics are provided in Table 2.

We perform zero pronoun identification using the method of (Cai et al., 2011), which automatically recovers empty categories corresponding to dropped pronouns, integrating these empty categories into syntactic parses. Syntactic parses were obtained with the Berkeley parser (Petrov and Klein, 2007). These parses were then used to split the Chinese utterances into single-clause units, based on IP and CP clausal nodes. These clauses were aligned with clauses in the English translation, which were used to determine the identity of the clausal subject, for extracting the 1v, 2v, ... label for each utterance.[4]

For our machine learning systems, we use Vowpal Wabbit (Langford et al., 2007) with default hyperparameter settings. We train on 75% of the training data and retain 25% as development data on which to perform early stopping. We run 20 iterations by default and take the parameters with best development performance based on sequence labeling accuracy.

4.2 Gold standard test set

Although we can use "bronze standard" annotations for learning, evaluating against a bronze standard is not directly useful. Therefore, we annotated our test set (1152 utterances) by hand. In particular, for the SMS/chat test set, we recruited three linguistically-informed native Mandarin speakers to annotate Chinese clauses containing empty categories. The clauses were labeled with a person number (1,2,3) when the empty category corresponded to such a pronoun; or "none" in spurious cases.[5]

[4]Sometimes English syntactic parses were not well-aligned with the Chinese IP/CP nodes; in practice, we split the English utterances based on end-of-clause punctuation and aligned Chinese and English clauses based on a simple order heuristic.

Pronoun	Precision	Recall	F-measure
1p	0.75	0.43	0.55
2p	0.61	0.32	0.42
3p	0.52	0.45	0.49
Micro-avg	0.62	0.41	0.50

Table 3: Bronze vs Gold labels

In our annotated data,[6] 32% of identified zero pronouns were first person, 17% were second person, 25% were third person and 26% do not have a referent (were spurious). Of the correctly identified zero pronouns, a majority of pronouns (about 2/3) are deictic: referring either to the speaker or listener. The remainder are third person and mostly anaphoric.[7] Since the annotators labeled the empty categories obtained from an automatic zero pronoun identification method (Cai et al., 2011), 26% spurious cases suggest that the accuracy of this method is only 74% on the SMS test data set.

We then used these annotations to evaluate our bronze standard label assignment method against the gold standard judgments. Table 3 shows the precision, recall and F-measure of the bronze annotations when evaluated against the gold annotations. We use micro-averaging to average the precision, recall and F-measure values against different sets. In this method we sum up the individual true positives (TP), false positives (FP), and false negatives (FN) of the system for different sets and then apply them to get the statistics. For example, precision across two sets 1 and 2 is given by (TP1 + TP2)/(TP1 + TP2 + FP1 + FP2). We can see a fairly significant discrepancy between our bronze labels and the gold labels. One major—and unfortunately inevitable—reason for this discrepancy is a high proportion of utterances in the English translation data which have

[5]Note that under this annotation scheme, our evaluations will be partially constrained by (Cai et al., 2011) performance, in including no zero pronouns that were missed by that method—however, use of the "none" label allows filtering out of any spuriously-identified zero pronouns.

[6]Annotations are available at www.umiacs.umd.edu/∼raosudha/LDC2013E83-BOLT-P2R2-cmn-SMS-CHT-dev.annotated.

[7]In an in-person dialogue, a third person pronoun might be used in a deictic manner, as in "*She* is really smart" while pointing at someone. This rarely occurs in SMS/chat because there is no shared environment beyond the two dialogue participants.

been translated with the subject pronouns still absent. This is partially due to the casual nature of the text, and partially because the quality (fluency) of English translations in this data is at times dubious.

While there may be a systematicity to this kind of subject omission on the English side, this was not a factor taken into account by our human annotators. So while our own model may stand a chance at predicting "hidden" labels (no overt pronoun on English side) in such instances, the annotators will never assign a label of "none" to a location at which a pronoun could reasonably have been inserted.

4.3 Overall system efficacy

In this section we discuss the overall efficacy of our proposed method in comparison to a few alternatives. These alternatives are:

Random guessing baseline. A naïve system that makes predictions uniformly at random.

Subject continuation baseline. This is a rule-based approach that mimics the intuitions described in Section 2. In particular, for a Chinese utterance, we check whether the current utterance has an overt pronominal subject. If so, we assign a label of 1v, 2v or 3v depending on the person of this subject. If the current utterance has a non-pronominal subject, we assign 3h. Otherwise we "carry forward" the subject from the previous utterance, flipping the 1p/2p as necessary when the speaker changes; these are labeled as 1h, 2h or 3h.

Minimal model baseline. In the minimal model, we restrict our model to use just three features: participant index, participant switch and subject continuation feature. This is a machine learning variant of the rule-based subject continuation baseline.

Oracle upper bound. None of the proposed models can hope to achieve 100% accuracy on this task because the gold annotation data consists of 26% "no pronoun" cases. Since all of our approaches *must* predict a pronoun when a zero pronoun has been identified, their performance (namely, their precision) is upper-bounded away from 100%.

The summary of results (micro-averaged across 1p, 2p and 3p) are shown in Table 5. These results show that on both the SMS data (on which the model was developed) and the OntoNotes data (on which the model was applied blindly), our full model is able to substantially outperform the baselines. In fact, on OntoNotes, despite a potential domain mismatch (from SMS/chat to telephone conversations), our full model was the only baseline to beat random guessing! Across both data sets, the minimal model tends to have high precision and low recall; the behavior of the other approaches varies across the tasks. On the SMS/chat data, our model achieves a 14% relative improvement over the best baseline; on an OntoNotes data, a 50% relative improvement.

	SMS/chat Micro-average			OntoNotes Micro-average		
System	**Pre**	**Rec**	**F**	**Pre**	**Rec**	**F**
Random	0.24	0.25	0.24	0.18	0.26	0.22
Minimal	0.42	0.23	0.30	0.30	0.07	0.11
SubjCont	0.32	**0.42**	0.36	**0.31**	0.15	0.20
Full Model	**0.59**	0.31	**0.41**	0.30	**0.36**	**0.33**
Upper Bound	0.74	1.00	0.85	0.55	1.00	0.71

Table 5: Summary of results for different comparator models against the gold standard labels from SMS data (left) and OntoNotes (right).

More specific breakdowns of performance by different pronouns (1p, 2p and 3p) are shown for the subject continuation baseline and the full model in Table 4. In these tables, we also report results when evaluated on the OntoNotes test set in these Tables. As we can see, the subject continuation baseline massively overpredicts third person pronouns in the SMS data, leading to an overall low score. In comparison, our model tends to have much higher precision (at the expense of recall) across the board on the SMS data, leading to a 14% relative improvement over the subject continuation baseline.

Since, to our knowledge, no prior work (see Section 5) has focused on deictic pronoun restoration, it is not possible to directly compare our results to previously published results. Although it is an apples-to-oranges comparison, a state-of-the-art *anaphoric* zero pronoun resolution system (Chen and Ng, 2014) achieves a precision of 13.3, a recall of 32.2 and an F-measure of 18.8 on the *telephone conversation* part of the OntoNotes data, but does so addressing the complementary problem of correctly choosing antecedents from previous overt noun phrases.

Another reasonable comparison would be with a

Subject Continuation Baseline

Table 6: Summary of results for feature ablation against the gold standard labels from SMS data (left) and OntoNotes (right).

model trained on gold annotated data (instead of bronze data). Owing to cost, we could not obtain gold annotations for the full training set; however, a leave-one-out cross validation on the gold annotated test set (of SMS data) gave an F-measure of 0.47, versus 0.41 for our model trained on bronze labels. This suggests the noisy bronze labels are indeed useful for this task.

4.4 Feature ablations

In order to investigate the individual contributions of each of our features, we performed feature ablation experiments, pairing our Minimal Model with a single feature at a time and retraining the model with this pairing. The results of these experiments can be seen in Table 6. We see in this table that for the SMS data, the Verb feature creates the greatest improvement over the Minimal Model, followed by Bag of Words and Bag of POS. This supports the hypothesis that the verb is informative with respect to the nature of its subject, as are the other words of the clause, and their parts of speech. For the OntoNotes corpus, however, the Bag of Words feature performs best by a large margin. Interesting, although the Bag of Words features are clearly the most useful, the linguistically motivated features (verb/question) performing well supports our linguistic intuitions.

5 Discussion and related work

Past approaches to zero pronoun resolution focus exclusively on anaphoric zero pronouns approached as a task of antecedent identification. Almost all work makes use of syntactic structure, with differences primarily in how that structure is used. (Yeh and Chen, 2007) take a rule-based, Centering Theory-inspired approach based on a system of constraints to guide selection of zero pronoun antecedents. In the same year, (Zhao and Ng, 2007) introduced a supervised learning approach for both zero pronoun identification and antecedent selection based on engineered features; these engineered features were replaced with a tree-kernel by (Kong and Zhou, 2010), who jointly perform zero pronoun identification, anaphoricity determination, and antecedent selection. Recently, (Chen and Ng, 2013) built upon the model introduced by Zhao and Ng, introducing additional features and allowing coreference links between multiple zero pronouns. Chen and Ng (2013) also test their model on automatically identified zero pronouns and automatically gener-

ated parse trees, thus presenting the first end-to-end Chinese zero pronoun resolver.

These approaches are mostly complementary to our task, since they focus on resolving anaphoric zero pronouns (the minority!) while we focus on resolving deictic non-anaphoric zero pronouns. In particular, for an end-to-end system that resolves both deictic and anaphoric zero pronouns, one could first take our approach and whenever our model predicts "third person," which is often an anaphoric reference, one could apply one of these prior approaches for further reference resolution.

The only work we are aware of that does not require linguistically annotated data for zero pronoun resolution is that of (Chen and Ng, 2014). They hypothesize that zero pronouns and overt pronouns have *similar* distributions, and train an unsupervised model on *overt* pronouns and then apply this model to *zero* pronouns. This model performs on par with their previous (2013) supervised model. Despite this, their unsupervised model only agrees with their supervised model on 55% of zero pronoun antecedents, suggesting that this hypothesis is weak.

In particular, the complementarity of zero versus overt pronoun usage has been studied within various domains of linguistics. The Position of Antecedent Hypothesis (Carminati, 2002) states that null and overt pronouns have different antecedent selection preferences: null pronouns prefer antecedents in subject positions, while overt pronouns prefer antecedents in non-subject positions. This hypothesis has been supported by studies in a variety of pro-drop languages (e.g., (Alonso-Ovalle et al., 2002) (Kweon, 2011)). Switching of reference has been identified as one of the main constraints regulating use of zero versus overt pronouns in the variationist literature (see (Cameron, 1992) for sociolinguistic studies of the phenomenon in Spanish). The importance of topically-coherent discourse sequences—and the role of linguistic and extralinguistic indicators of such sequences—has also been examined in child language acquisition, e.g., (Rohde and Frank, 2014).

Our main result shows that although our bronze standard labels are noisy (Section 4.3), they are nonetheless useful for learning to resolve deictic pronouns. Moreover, one oft-heralded advantage of the translation-as-annotation scheme (Carpuat and Wu, 2007) is that it naturally integrates into a machine translation framework, since one is learning to predict precisely what is necessary for successful translation; evaluating whether this hypothesis is true is currently an open question. One limitation of our approach is the coarseness of the labeling granularity (1p, 2p, 3p). Our ultimate plan is to provide all possibilities (e.g., both singular and plural for 1p, weighted) to a machine translation system, and let other components (e.g., language model) determine selection. For now, we believe that there is significant value in intrinsic evaluation of our approach for a problem that has not previously received significant attention.

Abstract

We present a new approach to harvesting a large-scale, high quality image-caption corpus that makes a better use of already existing web data with no additional human efforts. The key idea is to focus on *Déjà Image-Captions*: *naturally* existing image descriptions that are *repeated almost verbatim* – by more than one individual for different images. The resulting corpus provides association structure between 4 million images with 180K unique captions, capturing a rich spectrum of everyday narratives including figurative and pragmatic language. Exploring the use of the new corpus, we also present new conceptual tasks of visually situated paraphrasing, creative image captioning, and creative visual paraphrasing.

1 Introduction

The use of multimodal web data has been a recurring theme in many recent studies integrating language and vision, e.g., image captioning (Ordonez et al., 2011; Hodosh et al., 2013; Mason and Charniak, 2014; Kuznetsova et al., 2014), text-based image retrieval (Rasiwasia et al., 2010; Rasiwasia et al., 2007), and entry-level categorization (Ordonez et al., 2013; Feng et al., 2015).

However, much research integrating complex textual descriptions to date has been based on datasets that rely on substantial human curation or annotation (Hodosh et al., 2013; Rashtchian et al., 2010; Lin et al., 2014), rather than using the web data in the wild as is (Ordonez et al., 2011; Kuznetsova et al., 2014). The need for human curation limits the potential scale of the multimodal dataset. Without human curation, however, the web data introduces significant noise. In particular, everyday captions often contain extraneous information that is not directly relevant to what the image shows (Kuznetsova et al., 2013b; Hodosh et al., 2013).

In this paper, we present a new approach to harvesting a large-scale, high quality image-caption corpus that makes a better use of already existing web data with no additional human efforts. Figure 1 shows sample captions in the resulting corpus, e.g., *"butterfly resting on a flower"* and *"evening walk along the beach"*. Notably, some of these are figurative, e.g., *"rippled sky"* and *"sun is going to bed."*

The key idea is to focus on *Déjà Image-Captions*, i.e., naturally existing image captions that are *repeated almost verbatim* by more than one individual for different images. The hypothesis is that such captions represent common visual content across multiple images, hence are more likely to be free of unwanted extraneous information (e.g., specific names, time, or any other personal information) and better represent visual concepts. A surprising aspect of our study is that such a strict data filtration scheme can still result in a large-scale corpus; sifting through 760 million image-caption pairs, we harvest as many as 4 million image-caption pairs with 180K unique captions.

The resulting corpus, *Déjà Image Captions*, provides several unique properties that complement human-curated or crowd-sourced datasets. First, as our approach is fully automated, it can be readily applied to harvesting a new dataset from the ever changing multimodal web data. Indeed, a recent internet report estimates that billions of new photographs are being uploaded daily (Meeker, 2014). In contrast, human-annotated datasets are costly to scale to different domains.

Second, datasets that are harvested from the web

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 504–514,
Denver, Colorado, May 31 – June 5, 2015.

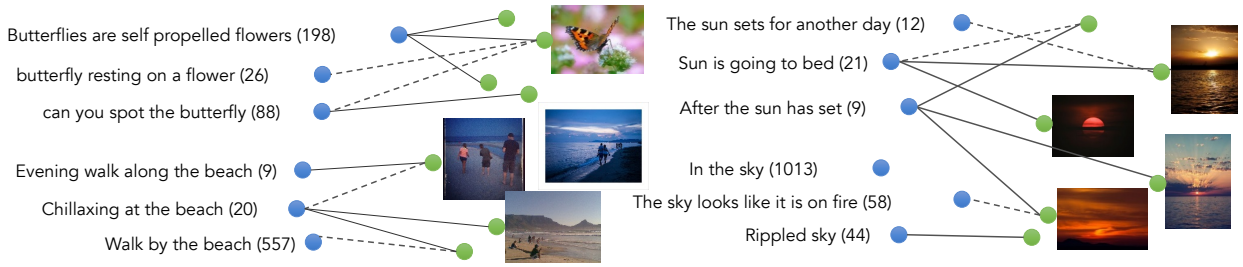

Figure 1: The image-caption association graph of *Déjà Image-Captions*. Solid lines represent original captions and dotted lines represent paraphrase captions. This corpus reflects a rich spectrum of everyday narratives people use in online activities including figurative language (e.g., *"Sun is going to bed"*), casual language (e.g., *Chillaxing at the beach"*), and conversational language (e.g., *"Can you spot the butterfly"*). The numbers in the parenthesis show the cardinality of images associated with each caption. Surprisingly, some of these descriptions are highly expressive, almost *creative*, and yet not unique — as all these captions are repeated almost verbatim by different individuals describing different images.

can complement those based on prompted human annotations. The latter in general are literal and mechanical readings of the visual scenes, while the former reflect a rich spectrum of natural language utterances in everyday narratives, including figurative, pragmatic, and conversational language, e.g., *"can you spot the butterfly"* (Figure 1). Therefore, this dataset offers unique opportunities for grounding figurative and metaphoric expressions using visual context.

In conjunction with the new corpus, publicly shared at `http://www.cs.stonybrook.edu/~jianchen/deja.html`, we also present three new tasks: *visually situated paraphrases* (§5); *creative image captioning* (§7), and *creative visual paraphrasing* (§7). The central algorithm component in addressing all these tasks is a simple and yet effective approach to image caption transfer that exploits the unique association structure of the resulting corpus (§3).

Our empirical results collectively demonstrate that when the web data is available at such scale, it is possible to obtain a large-scale, high-quality dataset with significantly less noise. We hope that our approach would be only one of the first attempts, and inspire future research to develop better ways of making use of ever-growing multimodal web data. Although it is unlikely that the automatically gathered datasets can completely replace the curated descriptions written in a controlled setting, our hope is to find ways to complement human annotated datasets in terms of both the scale and also the diversity of the domain and language.

The remainder of this paper is organized as follows. First we describe the dataset collection procedure and insights (§2). We then present a new approach to image caption transfer based on the association structure of the corpus (§3) followed by experimental results (§4). After then we present new conceptual tasks: *visual paraphrasing* (§5), *creative image captioning*, and *creative visual paraphrasing* (§7), interleaved with corresponding experimental results (§6, §8).

2 Dataset - Captions in Repetition

Our corpus consists of three components (Table 1):

MAIN SET The first step is to crawl as many image-caption pairs as possible. We use flickr.com search API to crawl 760 million pairs in total. The API allows searching images within a given time window, which enables exhaustive search over any time span. To ensure visual correspondence between images and captions, we set query terms using 693 most frequent nouns from the dataset of Ordonez et al. (2011), and systematically slide time windows over the year 2013.[1] For each image, we segment its title and the first line of its description into sentences.

The crawled dataset at this point includes a lot of noise in the captions. Hence we apply initial filtering rules to reduce the noise. We retain only those image-sentence pairs in which the sentence contains the query noun, and does not contain personal information indicators such as first-person pronouns. We

[1]To ensure enough number of images are associated with each caption, we further search captions with no more than 10 associated images across *all* years.

set	# captions	# images
MAIN	176,780	3,967,524
PARAPHRASE	7,570 human-annotated triples 353,560 auto-generated triples	
FIGURATIVE	6,088 quotations	180,185
	18,179 quotations + predicted figurative captions	413,698

Table 1: Corpus Statistics

	mean	std	25%	50%	75%	max
#imgs.	22.4	47.6	4	10	25	4617
#tokens	4.9	3.3	3	4	5	178

Table 2: Percentiles of the image count associated with each caption and the number of tokens in each caption.

want captions that are more than simple keywords, thus we discard trivial captions that do not include at least one verb, preposition, or adjective.

The next step is to find captions in repetition. For this purpose, we transform captions into *canonical forms*. We lemmatize all words, convert prepositions to a special token "IN"[2], and discard function words, numbers, and punctuations. For instance, "*The bird flies in blue sky*" and "*A bird flying into the blue sky*" have the same canonical form, "*bird fly IN blue sky*". We then retain only those captions that are repeated with respect to their canonical forms by more than one user, and for distinctly different images to ensure the generality of the captions.

Retaining only captions that are repeated verbatim may seem overly restrictive. Nonetheless, because we start with as many as 760 million pairs, this procedure yields nearly 180K unique captions associated with nearly 4M images.[3] What is more surprising, as will be shown later, is that many of these captions are highly expressive. Table 2 shows the distribution of the number of images associated with each caption.[4] The median and mean are 10 and 22.4 respectively, showing a high degree of connectivities between captions and images.

PARAPHRASE SET Our dataset collection procedure finds *one-to-many* relations between captions and images. To extend these relations to *many-to-many*, we introduce *visually-situated paraphrases* (or *visual paraphrases* for shorthand) (§5). A visual paraphrase relation is a triple (i, c, p), where image i has an original caption c, caption p is the visual paraphrase for c situated in image i. We collect visual paraphrases for sample images in our dataset, using both crowd sourcing (7,570 triples) and an automatic algorithm (353,560 triples) (see §5 for details). Figure 2 shows example visual paraphrases.

Formally, our corpus represents a bipartite graph $G = (T, V, E)$, in which the set of captions T and the set of images V are connected by typed edges $e(c, i, t)$, where caption $c \in T$, image $i \in V$, and edge type $t \in \{original, paraphrase\}$, which denotes whether the image-caption association is given by the original caption or by a visual paraphrase.

FIGURATIVE SET We find that many repeating captions are surprisingly lengthy and expressive, most of which turn out to be idiomatic expressions and quotations, e.g., *"faith is the bird that feels the light when the dawn is still dark"* from Tagore's poem. We look up `goodreads.com`

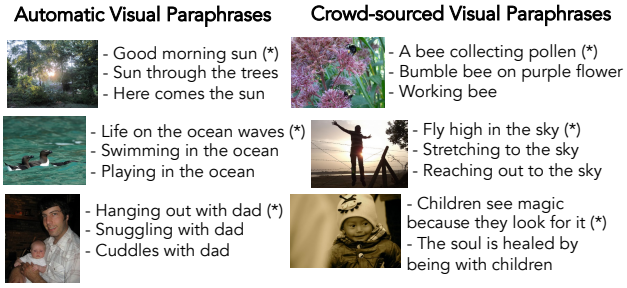

Figure 2: Example visual paraphrases: automatic (left) and crowd-sourced (right). The first caption marked with * indicates the original caption of the corresponding image. Some paraphrases are not strictly equivalent to the original caption if considered out of context, while they are pragmatically adequate paraphrases given the image.

figure of speech	#caps.	example (#imgs.)
quotation&idiom	70	The early bird gets the worm (77)
personification	43	Meditating cat (38)
metaphor	24	Wine is the answer (7)
question	18	Do you see the moon (82)
dialog	11	Hello little flower (37)
anaphora	6	Beads, beads and more beads (62)
simile	5	The lake is like glass (23)
hyperbole	1	In the land of a billion lights (3)

Table 3: Distribution of figurative language out of 1000 random captions (171 figurative captions in total)

[2]We do this transformation so as not to over-count unique captions with trivial variations, but merging prepositions can sometimes combine prepositions that are not semantically compatible. We therefore also keep original captions with original prepositions.

[3]We also keep user annotated image tags if available.

[4]Without counting additional edges created by visual paraphrasing (§5).

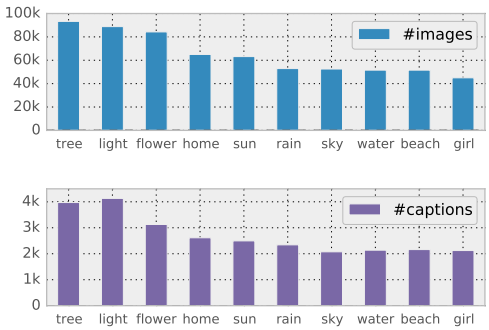

Figure 3: Top 10 queries with the largest number of images and unique captions

polarity	% in all caps.	mean/median #imgs. per cap.	example (#imgs)
pos.	8%	20 / 8	Happy bride and groom (282) The rock and pool, is nice and cool (4)
neg.	2%	19.5 / 7	Bad day at the office (269) Crying lightning (147)

Table 4: Distribution of caption sentiment. The polarity is determined by comparing number of positive words and negative words (>: positive; <: negative) according to a sentiment lexicon (Wilson et al., 2005) (counting only words of *strong* polarity).

and `brainyquotes.com` to identify 6K quotation captions illustrated by 180K images. We also present a manual labeling on a small subset of the data (Table 3) to provide better insights into the degree and types of figurative speech used in natural captions. Using these labels we build a classifier (§7) to further detect 18K figurative captions associated with 410K images.

INSIGHTS As additional insights into the dataset, Figure 3 shows statistics of the visual content, Table 5 shows syntactic types of the captions, and Table 4 shows positive and negative sentiment in captions.

3 Image Captioning using Association Structure

We demonstrate the usefulness of the association between images and captions via retrieval-based image captioning. Given a query image q and the corpus $G = (T, V, E)$, the task is to find a caption $c \in T$ that maximizes an affinity function $\mathcal{A}(q, c)$, which measures how well the caption c fits the query image q,

$$c^* = \arg\max_{c \in T} \{\mathcal{A}(q, c)\} \quad (1)$$

Visual Neighborhood: Each textual description, e.g., *"reading a book"*, can associate with many different visual instantiations (Figure 4a). Our dataset $G = (T, V, E)$ serves as a database to navigate the possible visual instantiations of descriptive captions as observed in online photo sharing communities. Let $\mathcal{N}_c = \{i | e(c, i, original) \in E\}$ denote the set of adjacent nodes (i.e., visual instantiations) of a caption c. To quantify how well a caption c describe a query image q, we propose to examine caption c's visual neighborhood $\mathcal{N}_c$ as provided in our dataset. Concretely, the affinity $\mathcal{A}(q, c)$ of a query image q to a caption c is a function $\phi(q, \mathcal{N}_c)$ of q and the visual neighborhood $\mathcal{N}_c$ defined as:

$$\mathcal{A}(q, c) = \phi(q, \mathcal{N}_c) = \frac{1}{\sigma} \sum_{i=1}^{\sigma} sim(q, \mathcal{N}_c^i) \quad (2)$$

where σ is a parameter; $sim(\cdot, \cdot)$ is a similarity function of two images; and $\mathcal{N}_c = [\mathcal{N}_c^1, \mathcal{N}_c^2, ..., \mathcal{N}_c^{|\mathcal{N}_c|}]$ is sorted by $sim(q, \mathcal{N}_c^i)$ in *descending* order.

Figure 4a illustrates the key insight: instead of directly transferring the caption of the single image with the closest visual similarity to the query image (Ordonez et al., 2011), we propose to retrieve a caption based on the aggregated visual similarity between its visual neighborhood and the query image. The idea is to prefer a caption for which the query image is likely to be a *prototypical* visual rendering (Ordonez et al., 2013; Deselaers and Ferrari, 2011), hence avoid an unusual association between the text

type	%caps.	%imgs.	mean #imgs.	std #imgs.
verb	45%	44%	22	9
	be, have, do, look,		Sky is the limit (3057)	
	go, make, come, get,		Home is where the heart is (2480)	
	wait, take, love, play,		Lunch is served (2443)	
	walk, fly, see, watch,		Let them eat cake (2193)	
	find, live, sleep, fall		Follow the yellow brick road (2077)	
prep	44%	41%	21	9
	in, of, on,		On the road (4617)	
	at, with, for,		After the rains (4450)	
	from, by,		Under the bridge (3443)	
	over, through		At the beach (3203)	
adj	11%	15%	30	15
	old, little, new,		Home sweet home (2398)	
	red, blue, more,		Good morning sun (1122)	
	white, big, beautiful,		Cabbage white butterfly (976)	
	black		Next door neighbors (838)	

Table 5: Statistics on the syntactic composition of captions. *verb*: captions with at least one verb. *prep*: prepositional phrases (without any verbs). *adj*: adjective phrases (without any verbs and prepositions). For each caption type, we also show the *top words* that appear in the most number of captions (left), and the *top captions* that are associated with largest number of images (right).

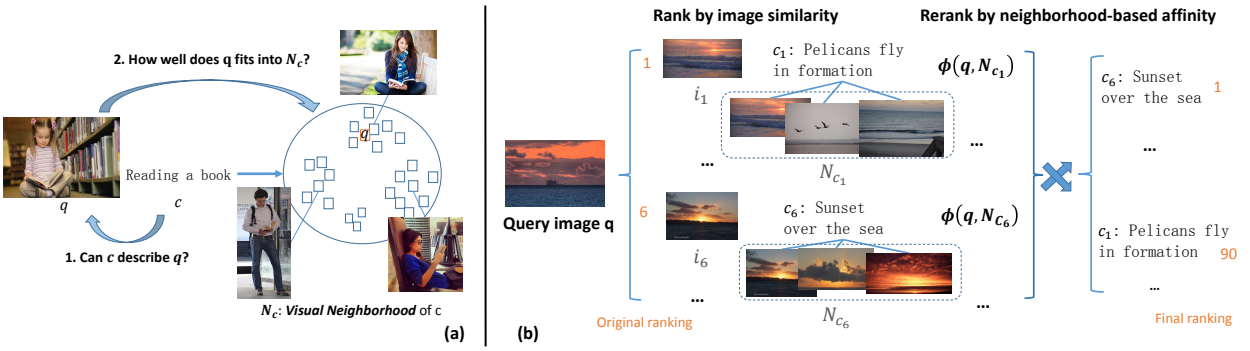

Figure 4: (a) Using the association structure, we retrieve a caption for which the query image is likely to be a *prototypical* visual rendering. We hypothesize that there can be multiple visual prototypes of a caption. (b) Reranking by visual neighborhood proximity.

and the visual information. Also, we hypothesize that there could be several diverse visual prototypes of any given textual description c, so we focus on only the top σ nearest members of $\mathcal{N}_c$.

We apply the neighborhood-based affinity for image captioning via reranking (Figure 4b): first we retrieve a pool of K candidate captions by finding top K closest images based on their direct visual similarity to the query image, then compute the neighborhood-based affinity to rerank the captions.[5] The proposed approach is similar in spirit to the non-parametric K nearest neighbor approach of (Boiman et al., 2008) in modeling image-to-concept similarity rather than image-to-image similarity, but differs in that our work is in the context of image description generation rather than classification.

4 Experiments: Association Structure Improves Image Captioning

Baselines: The proposed approach (to be referred as ASSOC) requires one-to-many mappings between captions and images *at scale* — a unique property of our dataset. We compare against two baselines: instance-based retrieval of (Ordonez et al., 2011) (INSTANCE) and Kernel Canonical Correlation Analysis (KCCA) (Hardoon et al., 2004; Hodosh et al., 2013). We implement KCCA with Hardoon's code[6]. We use a linear kernel since non-linear kernels like RBF showed worse performance.

[5]We set $K = 100$ and choose parameter σ using a held-out development set of 300 images. If there are less than σ available images, we use them all.

INSTANCE	*0.125*	*0.029*
KCCA	0.118	0.024**
ASSOC^{gi} w/ all	0.130	0.031
ASSOC^{g+t} w/ all	0.133	0.030
ASSOC^{ti} w/ all	0.126	0.029
ASSOC^{gi} w/ σ	0.172**	0.033*
ASSOC^{g+t} w/ σ	0.159**	0.033*
ASSOC^{ti} w/ σ	**0.184****	**0.034****

Table 6: Automatic evaluation for image captioning: The superscripts denote the image feature for reranking; gi: GIST; ti: Tinyimage; g+t:= gi + ti. We report the best setting (gt) for INSTANCE and KCCA. Results statistically significant compared to INSTANCE with two-tailed t-test are indicated with * ($p < 0.05$) and ** ($p < 0.005$).

Configurations: For image features, we follow (Ordonez et al., 2011) to experiment with two global image descriptors and their combination: a) the GIST feature that represents the dominant spatial structure of a scene (Oliva and Torralba, 2001); b) the Tinyimage feature that represents the overall color of an image (Torralba et al., 2008); c) a combination of the two. We compute the similarity as $sim(Q, I) = -\|Q - I\|^2$. The INSTANCE and the KCCA approaches use the feature combination. The ASSOC approach also use the combination for preparing candidate captions, but can use different features for reranking.

Dataset: We randomly sample 1000 images with unique captions as test set. The rest of the corpus is the pool of caption retrieval after *discarding*: (1) the original caption c and all of its associated images, to avoid potential unfair advantage toward ASSOC and (2) the 10K captions used for training KCCA and all

reranking feature	INSTANCE	ASSOC
gi	42%	58%
g+t	50%	50%
ti	46%	54%

Table 7: Human evaluation for image captioning: the % of cases judged as visually more *relevant*, in pairwise comparisons. gi: GIST; ti: Tinyimage; g+t:= gi+ti.

of their associated images (about 280K).

Evaluation. Automatic evaluation remains to be a challenge (Elliott and Keller, 2014). We report both BLEU (Papineni et al., 2002) at 1 without brevity penalty, and METEOR (Banerjee and Lavie, 2005) with balanced precision and recall. Table 6 shows the results: the ASSOC approach (w/ σ) significantly outperforms the two baselines. The largest improvement over INSTANCE is 60% higher in BLEU, and 44% higher in METEOR, demonstrating the benefit of the innate association structure of our corpus. Using *all* visual neighborhood (ASSOC w/ all) does not yield as strong results as selective neighborhood (ASSOC w/ σ), confirming our hypothesis that each visual concept can have diverse visual renderings.

We also compute crowd-sourced evaluation on a subset (200 images) randomly sampled out of the test set. For each query image, we present two captions generated by two competing methods in a random order. Turkers choose the caption that is more relevant to the visual content of the given image. We aggregate the choices of three turkers by majority voting. As shown in Table 7, ASSOC shows overall improvement over baselines, where the difference is more pronounced when reranking is based on feature sets that differ from the one used during the candidate retrieval.

5 Image Captioning using Visual Paraphrases

We present an exploration of *visually situated paraphrase* (or *visual paraphrase* in short hand), and demonstrate their utility for image captioning. Formally, given our corpus $G = (T, V, E)$, a visual paraphrase relation is a triple (i, c, p), where given an image $i \in V$ and its original caption $c \in T$ (i.e., $e(c, i, original) \in E$), $p \in T$ is a visual paraphrase for c situated in a visual context given by the image i (i.e, $e(p, i, paraphrase) \in E$). We collect visual paraphrases using both human annotation and an automatic algorithm.

(1) Visual Paraphrasing using Crowd-sourcing: We use Amazon Mechanical Turk to annotate visual paraphrases for a subset of images in our corpus. Given each image with its original caption, we showed 10 randomly sampled candidate captions from our dataset that share at least one physical-object noun[7] with the original caption. Turkers choose all candidate captions that could also describe the given image. We collect 7,570 (i, c, p) paraphrase triples in total.

(2) Visual Paraphrasing using Associative Structure: We also propose an algorithm for automatic visual paraphrasing by adapting the ASSOC algorithm for image captioning (§3) as follows: given an image-caption pair (i, c), it first prepares a set of candidate captions that share the largest number of physical-object nouns with c, which are likely to be semantically close to c; then we rerank the candidate captions using the same neighborhood-based affinity as described in §3.

We apply this algorithm to generate a large set of visual paraphrases. For each caption in our corpus, we randomly sample two of its associated images, and generate one visual paraphrase for each image-caption pair, which yields 353,560 (i, c, p) triples. See Figure 2 for example paraphrases.

5.1 Image Captioning using Visual Paraphrasing

We propose to utilize automatically-generated visual paraphrases to improve the ASSOC approach (§3) for image captioning. One potential limitation of the ASSOC approach is that for some captions, the number of associated images might be too small for reliable estimations of the neighborhood based affinity. We hypothesize that for a caption with a small visual neighborhood, merging its neighborhood with those associated with its *visual paraphrases* will give a more reliable estimation of the affinity between a query image and that caption. Thus we modify the ASSOC approach as follows.

After preparing a pool of K candidate captions $\{c_1, c_2, \ldots, c_K\}$, automatically generate a visual paraphrase (i_i, c_i, p_i) for each (i_i, c_i); then rerank the candidate captions by the following affinity function that merges the visual neighborhood from the

[7] under the WordNet "physical_entity.n.01" synset

method	BLEU	METEOR	AMT
INSTANCE	0.125	0.029	N/A
ASSOC^{gi}	0.172	0.033	45%
ASSOC$^{gi}_{para}$	**0.187**	**0.036**	55%
ASSOC^{ti}	0.184	0.034	45%
ASSOC$^{ti}_{para}$	**0.197**	**0.036**	55%

Table 8: Automatic and human evaluation of exploiting visual paraphrases for image captioning. The superscripts represent the image feature used in the reranking step; gi: GIST; ti: Tinyimage. The AMT column shows the percentages of captions preferred by human as of better visual relevance, in pairwise comparisons. The improvement of ASSOC$_{para}$ over ASSOC is significant at $p < 0.002$ for BLEU, and $p < 0.03$ for METEOR with two tailed *t*-test.

paraphrase,

$$\mathcal{A}(q, C_i) = \phi(q, \mathcal{N}_{c_i} \cup \mathcal{N}_{p_i}) \quad (3)$$

6 Experiments: Visual Paraphrasing Improves Image Captioning

The experimental configuration basically follows §4. We compare ASSOC$_{para}$, the visual-paraphrase augmented approach, to the vanilla ASSOC approach. The image feature setting is the one with which the ASSOC approach performs best. Both approaches use the GIST+Tinyimage feature to prepare candidate captions, then use either the GIST or Tinyimage feature for reranking.

Table 8 shows that the ASSOC$_{para}$ approach significantly improves the vanilla ASSOC method under both automatic and human evaluation. As a reference, the first row shows the performance of the INSTANCE method (§4). The ASSOC method significantly improves over the INSTANCE method. On a similar vein, the ASSOC$_{para}$ method further improves over the ASSOC method, as automatic paraphrases provide a better visual neighborhood. This improvement is remarkable since the paraphrasing association is added automatically without any supervised training. This demonstrates the usefulness of the bipartite association structure of our corpus.

7 Image Captioning with Creativity

Naturally existing captions reflect everyday narratives, which in turn reflect figurative language use such as metaphor, simile, and personification. To gain better insights, one of the authors manually categorized a set of 1000 random captions. About 17% are identified as figurative. Table 3 shows the distribution over different types of figurative captions.

Creative Language Classifier: Using the small set of labels described above, we train a simple binary classifier to identify captions with creative language.[8] Using this classifier, we can control the degree of literalness or creativity in generated captions. Based on 5-fold cross-validation, the classifier performs with 77% precision and 43% recall.

Importantly, a high-precision and low-recall classifier suffices our purpose. It is because in the context of creative captioning and creative paraphrasing presented below, we only need to detect *some* figurative captions, not *all*.

7.1 Creative Image Captioning

Given a query image q, we describe it with the most appropriate figurative caption. We propose the ASSOC$_{creative}$ approach that alters the ASSOC approach (§3) to return a *figurative* caption from the candidate pool, excluding *literal* captions.

7.2 Creative Visual Paraphrasing

Given a query image q and its *original* caption c, we rephrase c to a more creative and inspirational caption that still describes q. We use the PARA$_{creative}$ approach that changes our automatic visual paraphrasing algorithm (§5), by retrieving only figurative captions.

8 Experiments: Creative Image Captioning and Paraphrasing

8.1 Creative Captioning

We compare the ASSOC$_{creative}$ approach to the vanilla ASSOC approach. With the ASSOC approach, the top-rank caption is usually literal. Both approaches use the GIST+Tinyimage feature for preparing candidate captions, and the Tinyimage feature for reranking, which is the best setting for the ASSOC approach (§4).

Similarly to §4, we sample 200 test images from our corpus, and use AMT to compare two algorithms in terms of *visual relevance* and *creativity* separately. For creativity, we ask turkers to choose one

[8] We use a random forest classifier with features including words indicating reasoning (but, could, that), generality (never, always), caption length, abstract nouns (life, and hope), and whether the caption is a known idiom or quotation.

method	creativity	relevance
ASSOC	33%	41%
$\text{ASSOC}_{\text{creative}}$	67%	59%

Table 9: Human evaluation for creative captioning: % of captions preferred by judges in pairwise comparisons

of the two captions that is more creative and inspirational than the other to describe each given test image. Results are shown in Table 9.

(1) *Creativity*. For 2/3 of the query images, captions produced by the $\text{ASSOC}_{\text{creative}}$ method are judged as more creative than those produced by the ASSOC method. This result indirectly validates that the figurativeness classifier has a reasonable precision to control the literalness of the system caption.

(2) *Visual relevance*. Interestingly, not only the captions from the $\text{ASSOC}_{\text{creative}}$ method are favored as creative, they are also judged as visually more relevant than those from the ASSOC method, despite that each figurative caption has lower neighborhood-based affinity than the literal counterpart. We conjecture that it is easier for human judges to be imaginative and draw visual relevance between the query image and figurative captions than the literal counterparts. This result also suggests that figurative language may be of practical use in image caption applications as a means to smooth the potentially brittle system output. Figure 5 shows example system output.

8.2 Creative Visual Paraphrasing

We test 200 images that are associated with *literal* captions as predicted by the figurativeness classifier. The $\text{PARA}_{\text{creative}}$ approach competes against two baselines: 1) the ORIGINAL captions , and 2) a text-only variant of the $\text{PARA}_{\text{caption}}$ approach sans visual processing: it randomly chooses a figurative caption that shares the largest number of physical-object nouns with the original caption, without looking at the query image. This is for evaluating the effect of visual context.

In addition to the evaluations as in §8.1, we also use a *multiple-choice* setting that allows a turker to choose zero to two captions that are visually relevant to the query image. See Table 10 for results, and Figure 5 for example outputs.

method	creativity	relevance	
		single	*multiple*
ORIGINAL	32%	80%	87%
$\text{PARA}_{\text{creative}}$	68%	20%	60%
$\text{PARA}_{\text{caption}}$	56%	47%	63%
$\text{PARA}_{\text{creative}}$	44%	53%	74%

Table 10: Human eval for creative visual paraphrasing

I. Comparing original captions with creative paraphrases (ORIGINAL vs. $\text{PARA}_{\text{creative}}$): The paraphrases are preferred over the original literal captions as more creative most of the time. As for the visual relevance, the original captions are favored over the paraphrases most of the time in the single-choice competition. However, when we use a multiple-choice setting, paraphrases has a reasonable relevance rate (60%), despite the simplicity of the algorithm. The fact that the original captions has a high relevance rate (87%) shows that in our corpus the captions have high visual relevance to their associated images most of the time.

II. Creative paraphrasing with and without the visual context ($\text{PARA}_{\text{caption}}$ vs. $\text{PARA}_{\text{creative}}$): In terms of creativity, the $\text{PARA}_{\text{caption}}$ method is preferred over the $\text{PARA}_{\text{creative}}$ method. We conjecture that without conditioning on the visual content, $\text{PARA}_{\text{caption}}$ method tends to retrieve more unexpected captions that make turkers think they are more fun and creative. As for the visual relevance, by conditioning on the visual context given by query images, the $\text{PARA}_{\text{creative}}$ method significantly improves the visual relevance over the text-only counterpart, $\text{PARA}_{\text{caption}}$ method. This result highlights the pragmatic differences between visually-situated paraphrasing and text-based paraphrasing.

9 Related work

Image-caption corpus: Our work contributes to the line of research that makes use of internet web imagery and text (Ordonez et al., 2011; Berg et al., 2010) by detecting the visually relevant text (Dodge et al., 2012) and reducing the noise (Kuznetsova et al., 2013b; Kuznetsova et al., 2014). Compared to datasets with crowd-sourced captions (Hodosh et al., 2013; Lin et al., 2014), in which each image is annotated with several captions, our dataset presents several images for each caption, a subset of which also includes visually situated paraphrases. The as-

Figure 5: Examples of creative captioning and creative visual paraphrasing. The left column shows good examples in blue, and the right column shows bad examples in red. The captions marked with * are the original captions of the corresponding query images.

sociation structure of our dataset is analogous to that of ImageNet (Deng et al., 2009). Unlike ImageNet that is built for nouns (physical objects) listed under WordNet (Miller, 1995), our corpus is built for expressive phrases and full sentences and constructed without human curation. Our corpus has several unique properties to complement existing corpora. As explored in a very recent work of (Gong et al., 2014), we expect that it is possible to combine crowd-sourced and web-harvested datasets and achieve the best of both worlds.

Image captioning: Our work contributes to the increasing body of research on retrieval-based image captioning (Ordonez et al., 2011; Hodosh et al., 2013; Hodosh and Hockenmaier, 2013; Socher et al., 2014), by providing a new large-scale corpus with unique association structure between images and captions, by proposing an algorithm that exploits the structure, and by exploring two new dimensions: (i) visually situated paraphrasing (and its utility for retrieval-based image captioning), and (ii) creative image captioning.

Paraphrasing: Most previous studies in paraphrasing have focused exclusively on text, and the primary goal has been learning *semantic* equivalence of phrases that would be true out of context (e.g., (Barzilay and McKeown, 2001; Pang et al., 2003; Dolan et al., 2004; Ganitkevitch et al., 2013)), rather than targeting *situated* or *pragmatic* equivalence given a context. Emerging efforts began exploring paraphrases that are situated in video content (Chen and Dolan, 2011), news events (Zhang and Weld, 2013), and knowledge base (Berant and Liang, 2014). Our work is the first to introduce *visually situated paraphrasing* in which the task is to find paraphrases that are conditioned on both the input text as well as the visual context. (Chen and Dolan, 2011) collected situated paraphrases only through crowd sourcing, while we also explore automatic collection, and further test the quality of automatic paraphrases by using the learned paraphrases in an extrinsic evaluation setting.

Figurative language: There has been substantial work for detecting and interpreting figurative language (Shutova, 2010; Li et al., 2013; Kuznetsova et al., 2013a; Tsvetkov et al., 2014), while relatively less work on *generating* creative or figurative language (Veale, 2011; Ozbal and Strapparava, 2012). We probe data-driven approaches to creative language generation in the context of image captioning.

10 Conclusion

To conclude, we have provided insights into making a better use of multimodal web data in the wild, resulting in a large-scale corpus, *Deja Image-Captions*, with several unique properties to complement datasets with crowdsourced captions. To validate the usefulness of the corpus, we proposed new image captioning algorithms using the associative structure, which we extended to several related tasks ranging from visually situated paraphrasing to enhanced image captioning. In the process we have also explored several new tasks: visually situated paraphrasing, creative image captioning, and creative caption paraphrasing.

Abstract

Most of previous work in knowledge base (KB) completion has focused on the problem of relation extraction. In this work, we focus on the task of inferring missing entity type instances in a KB, a fundamental task for KB competition yet receives little attention.

Due to the novelty of this task, we construct a large-scale dataset and design an automatic evaluation methodology. Our knowledge base completion method uses information within the existing KB and external information from Wikipedia. We show that individual methods trained with a *global* objective that considers unobserved cells from both the entity and the type side gives consistently higher quality predictions compared to baseline methods. We also perform manual evaluation on a small subset of the data to verify the effectiveness of our knowledge base completion methods and the correctness of our proposed automatic evaluation method.

1 Introduction

There is now increasing interest in the construction of knowledge bases like *Freebase* (Bollacker et al., 2008) and *NELL* (Carlson et al., 2010) in the natural language processing community. KBs contain facts such as *Tiger Woods* is an *athlete*, and *Barack Obama* is the *president of USA*. However, one of the main drawbacks in existing KBs is that they are incomplete and are missing important facts (West et al., 2014), jeopardizing their usefulness in downstream tasks such as question answering. This has led to the task of completing the knowledge base entries, or Knowledge Base Completion (KBC) extremely important.

In this paper, we address an important subproblem of knowledge base completion— inferring missing entity type instances. Most of previous work in KB completion has only focused on the problem of relation extraction (Mintz et al., 2009; Nickel et al., 2011; Bordes et al., 2013; Riedel et al., 2013). Entity type information is crucial in KBs and is widely used in many NLP tasks such as relation extraction (Chang et al., 2014), coreference resolution (Ratinov and Roth, 2012; Hajishirzi et al., 2013), entity linking (Fang and Chang, 2014), semantic parsing (Kwiatkowski et al., 2013; Berant et al., 2013) and question answering (Bordes et al., 2014; Yao and Durme, 2014). For example, adding entity type information improves relation extraction by 3% (Chang et al., 2014) and entity linking by 4.2 F1 points (Guo et al., 2013). Despite their importance, there is surprisingly little previous work on this problem and, there are no datasets publicly available for evaluation.

We construct a large-scale dataset for the task of inferring missing entity type instances in a KB. Most of previous KBC datasets (Mintz et al., 2009; Riedel et al., 2013) are constructed using a single snapshot of the KB and methods are evaluated on a subset of facts that are hidden during training. Hence, the methods could be potentially evaluated by their ability to predict *easy* facts that the KB already contains. Moreover, the methods are not directly evaluated

* Most of the research conducted during summer internship at Microsoft.

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 515–525,
Denver, Colorado, May 31 – June 5, 2015.

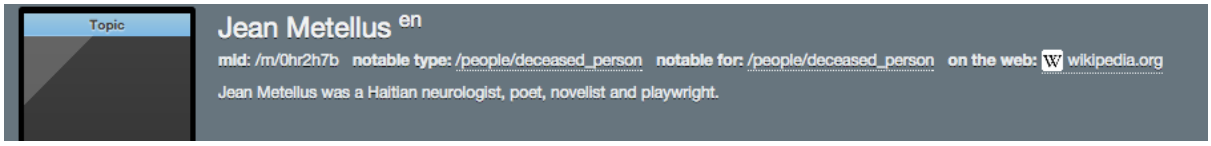

Figure 1: Freebase description of *Jean Metellus* can be used to infer that the entity has the type */book/author*. This missing fact is found by our algorithm and is still missing in the latest version of Freebase when the paper is written.

on their ability to predict missing facts. To overcome these drawbacks we construct the train and test data using two snapshots of the KB and evaluate the methods on predicting facts that are added to the more recent snapshot, enabling a more realistic and challenging evaluation.

Standard evaluation metrics for KBC methods are generally *type-based* (Mintz et al., 2009; Riedel et al., 2013), measuring the quality of the predictions by aggregating scores computed within a type. This is not ideal because: (1) it treats every entity type equally not considering the distribution of types, (2) it does not measure the ability of the methods to rank predictions across types. Therefore, we additionally use a global evaluation metric, where the quality of predictions is measured within and across types, and also accounts for the high variance in type distribution. In our experiments, we show that models trained with negative examples from the entity side perform better on type-based metrics, while when trained with negative examples from the type side perform better on the global metric.

In order to design methods that can rank predictions *both* within and across entity (or relation) types, we propose a *global objective* to train the models. Our proposed method combines the advantages of previous approaches by using negative examples from both the entity and the type side. When considering the same number of negative examples, we find that the linear classifiers and the low-dimensional embedding models trained with the global objective produce better quality ranking within and across entity types when compared to training with negatives examples only from entity or type side. Additionally compared to prior methods, the model trained on the proposed global objective can more reliably suggest confident entity-type pair candidates that could be added into the given knowledge base.

Our contributions are summarized as follows:

- We develop an evaluation framework comprising of methods for dataset construction and evaluation metrics to evaluate KBC approaches for missing entity type instances. The dataset and evaluation scripts are publicly available at `http://research.microsoft.com/en-US/downloads/df481862-65cc-4b05-886c-acc181ad07bb/default.aspx`.

- We propose a global training objective for KBC methods. The experimental results show that both linear classifiers and low-dimensional embedding models achieve best overall performance when trained with the global objective function.

- We conduct extensive studies on models for inferring missing type instances studying the impact of using various features and models.

2 Inferring Entity Types

We consider a KB Λ containing entity type information of the form (e, t), where $e \in E$ (E is the set of all entities) is an entity in the KB with type $t \in T$ (T is the set of all types). For example, e could be *Tiger Woods* and t could be *sports athlete*. As a single entity can have multiple types, entities in Freebase often miss some of their types. The aim of this work is to infer missing entity type instances in the KB. Given an unobserved fact (an entity-type pair) in the training data $(e, t) \notin \Lambda$ where entity $e \in E$ and type $t \in T$, the task is to infer whether the KB currently misses the fact, i.e., infer whether $(e, t) \in \Lambda$. We consider entities in the intersection of Freebase and Wikipedia in our experiments.

2.1 Information Resources

Now, we describe the information sources used to construct the feature representation of an entity to

infer its types. We use information in Freebase and external information from Wikipedia to complete the KB.

- **Entity Type Features**: The entity types observed in the training data can be a useful signal to infer missing entity type instances. For example, in our snapshot of *Freebase*, it is not uncommon to find an entity with the type */people/deceased_person* but missing the type */people/person*.

- **Freebase Description**: Almost all entities in *Freebase* have a short one paragraph description of the entity. Figure 1 shows the *Freebase* description of *Jean Metellus* that can be used to infer the type */book/author* which *Freebase* does not contain as the date of writing this article.

- **Wikipedia**: As external information, we include the *Wikipedia* full text article of an entity in its feature representation. We consider entities in Freebase that have a link to their Wikipedia article. The *Wikipedia* full text of an entity gives several clues to predict it's entity types. For example, Figure 2 shows a section of the *Wikipedia* article of *Claire Martin* which gives clues to infer the type */award/award_winner* that *Freebase* misses.

3 Evaluation Framework

In this section, we propose an evaluation methodology for the task of inferring missing entity type instances in a KB. While we focus on recovering entity types, the proposed framework can be easily adapted to relation extraction as well.

First, we discuss our two-snapshot dataset construction strategy. Then we motivate the importance of evaluating KBC algorithms globally and describe the evaluation metrics we employ.

3.1 Two Snapshots Construction

In most previous work on KB completion to predict missing relation facts (Mintz et al., 2009; Riedel et al., 2013), the methods are evaluated on a subset of facts from a *single* KB snapshot, that are hidden while training. However, given that the missing entries are usually selected randomly, the distribution of the selected unknown entries could be very different from the actual missing facts distribution. Also, since any fact could be potentially used for evaluation, the methods could be evaluated on their ability to predict easy facts that are already present in the KB.

To overcome this drawback, we construct our train and test set by considering *two* snapshots of the knowledge base. The *train* snapshot is taken from an earlier time without special treatment. The *test* snapshot is taken from a later period, and a KBC algorithm is evaluated by its ability of recovering newly added knowledge in the test snapshot. This enables the methods to be directly evaluated on facts that are missing in a KB snapshot. Note that the facts that are added to the test snapshot, in general, are more subtle than the facts that they already contain and predicting the newly added facts could be harder. Hence, our approach enables a more realistic and challenging evaluation setting than previous work.

We use manually constructed *Freebase* as the KB in our experiments. Notably, Chang et al. (2014) use a two-snapshot strategy for constructing a dataset for relation extraction using automatically constructed *NELL* as their KB. The new facts that are added to a KB by an automatic method may not have all the characteristics that make the two snapshot strategy more advantageous.

We construct our train snapshot Λ_0 by taking the *Freebase* snapshot on 3^{rd} September, 2013 and consider entities that have a link to their Wikipedia page. KBC algorithms are evaluated by their ability to predict facts that were added to the 1^{st} June, 2014 snapshot of *Freebase* Λ. To get negative data, we make a closed world assumption treating any unobserved instance in *Freebase* as a negative example. Unobserved instances in the *Freebase* snapshot on 3^{rd} September, 2013 and 1^{st} June, 2014 are used as negative examples in training and testing respectively.[1]

The positive instances in the test data ($\Lambda - \Lambda_0$) are facts that are newly added to the test snapshot Λ. Using the entire set of negative examples in the test data is impractical due to the large number of negative examples. To avoid this we only add the negative types

[1]Note that some of the negative instances used in training could be positive instances in test but we do not remove them during training.

Life and career [edit]

Martin was born in Wimbledon, London. She grew up in a house "full of music", and claims to have learned all of Judy Garland´s songs by the time she was 12. She cites Ella Fitzgerald´s *Song Books* as being the life changing influence which inspired her to attend stage school and later to study singing in both New York and London. Her professional career started with her first engagement, aboard the QE2, where she sang in the Theater Bar for two years.[1]

At the age of 21, Martin formed her own jazz quartet. In 1991, she was signed by the Scottish jazz label Linn Records, and her debut album, *The Waiting Game*, was released in 1992. The album was well reviewed and was selected by *The Times* as one of their "Albums of the Year". Later that year, she opened for Tony Bennett at the Glasgow International Jazz Festival.

Martin continued performing and recording, garnering numerous awards and rave reviews throughout the 1990s and early 2000s, including wins at the BBC Jazz Awards for Best Vocalist, and six wins at the British Jazz Awards. She has released a total of thirteen albums, all on the Linn label, and has collaborated with various prominent musicians including Martin Taylor, John Martyn, Stephane Grappelli, Mark Nightingale, Sir Richard Rodney Bennett, Jim Mullen and Nigel Hitchcock. In addition to her singing career, she is also a co-presenter for *Jazz Line Up* on BBC Radio 3.

Figure 2: A section of the *Wikipedia* article of *Claire Martin* which gives clues that entity has the type */award/award_winner*. This currently missing fact is also found by our algorithm.

of entities that have at least one new fact in the test data. Additionally, we add a portion of the negative examples for entities which do not have new fact in the test data and that were unused during training. This makes our dataset quite challenging since the number of negative instances is much larger than the number of positive instances in the test data.

It is important to note that the goal of this work is not to predict facts that emerged between the time period of the train and test snapshot[2]. For example, we do not aim to predict the type */award/award_winner* for an entity that won an award after 3^{rd} September, 2013. Hence, we use the *Freebase* description in the training data snapshot and *Wikipedia* snapshot on 3^{rd} September, 2013 to get the features for entities.

One might worry that the new snapshot might contain a significant amount of emerging facts so it could not be an effective way to evaluate the KBC algorithms. Therefore, we examine the difference between the training snapshot and test snapshot manually and found that this is likely not the case. For example, we randomly selected 25 */award/award_winner* instances that were added to the test snapshot and found that all of them had won at least one award before 3^{rd} September, 2013.

Note that while this automatic evaluation is closer to the real-world scenario, it is still not perfect as the new KB snapshot is still incomplete. Therefore, we also perform human evaluation on a small dataset to verify the effectiveness of our approach.

[2]In this work, we also do not aim to correct existing false positive errors in *Freebase*

3.2 Global Evaluation Metric

Mean average precision (MAP) (Manning et al., 2008) is now commonly used to evaluate KB completion methods (Mintz et al., 2009; Riedel et al., 2013). MAP is defined as the mean of *average precision* over all entity (or relation) types. MAP treats each entity type equally (not explicitly accounting for their distribution). However, some types occur much more frequently than others. For example, in our large-scale experiment with 500 entity types, there are many entity types with only 5 instances in the test set while the most frequent entity type has tens of thousands of missing instances. Moreover, MAP only measures the ability of the methods to correctly rank predictions within a type.

To account for the high variance in the distribution of entity types and measure the ability of the methods to correctly rank predictions across types we use global average precision (GAP) (similarly to micro-F1) as an additional evaluation metric for KB completion. We convert the multi-label classification problem to a binary classification problem where the label of an entity and type pair is true if the entity has that type in *Freebase* and false otherwise. GAP is the average precision of this transformed problem which can measure the ability of the methods to rank predictions both within and across entity types.

Prior to us, Bordes et al. (2013) use mean reciprocal rank as a global evaluation metric for a KBC task. We use average precision instead of mean reciprocal rank since MRR could be biased to the top predictions of the method (West et al., 2014)

While GAP captures global ordering, it would be

beneficial to measure the quality of the top k predictions of the model for bootstrapping and active learning scenarios (Lewis and Gale, 1994; Cucerzan and Yarowsky, 1999). We report G@k, GAP measured on the top k predictions (similarly to *Precision@k* and *Hits@k*). This metric can be reliably used to measure the overall quality of the top k predictions.

4 Global Objective for Knowledge Base Completion

We describe our approach for predicting missing entity types in a KB in this section. While we focus on recovering entity types in this paper, the methods we develop can be easily extended to other KB completion tasks.

4.1 Global Objective Framework

During training, only positive examples are observed in KB completion tasks. Similar to previous work (Mintz et al., 2009; Bordes et al., 2013; Riedel et al., 2013), we get negative training examples by treating the unobserved data in the KB as negative examples. Because the number of unobserved examples is much larger than the number of facts in the KB, we follow previous methods and sample few unobserved negative examples for every positive example.

Previous methods largely neglect the sampling methods on unobserved negative examples. The proposed global object framework allows us to systematically study the effect of the different sampling methods to get negative data, as the performance of the model for different evaluation metrics does depend on the sampling method.

We consider a training snapshot of the KB Λ_0, containing facts of the form (e, t) where e is an entity in the KB with type t. Given a fact (e, t) in the KB, we consider two types of negative examples constructed from the following two sets: $\mathcal{N}_E(e, t)$ is the "negative entity set", and $\mathcal{N}_T(e, t)$ is the "negative type set". More precisely,

$$\mathcal{N}_E(e, t) \subset \{e' | e' \in E, e' \neq e, (e', t) \notin \Lambda_0\},$$

and

$$\mathcal{N}_T(e, t) \subset \{t' | t' \in T, t' \neq t, (e, t') \notin \Lambda_0\}.$$

Let θ be the model parameters, $m = |\mathcal{N}_E(e, t)|$ and $n = |\mathcal{N}_T(e, t)|$ be the number of negative examples and types considered for training respectively. For each entity-type pair (e, t), we define the scoring function of our model as $s(e, t|\theta)$.[3] We define two loss functions one using negative entities and the other using negative types:

$$L_E(\Lambda_0, \theta) = \sum_{(e,t)\in\Lambda_0, e'\in\mathcal{N}_E(e,t)} [s(e', t) - s(e, t) + 1]_+^k,$$

and

$$L_T(\Lambda_0, \theta) = \sum_{(e,t)\in\Lambda_0, t'\in\mathcal{N}_T(e,t)} [s(e, t') - s(e, t) + 1]_+^k,$$

where k is the power of the loss function (k can be 1 or 2), and the function $[\cdot]_+$ is the hinge function.

The global objective function is defined as

$$\min_\theta Reg(\theta) + CL_T(\Lambda_0, \theta) + CL_E(\Lambda_0, \theta), \quad (1)$$

where $Reg(\theta)$ is the regularization term of the model, and C is the regularization parameter. Intuitively, the parameters θ are estimated to rank the observed facts above the negative examples with a margin. The total number of negative examples is controlled by the size of the sets $\mathcal{N}_E$ and $\mathcal{N}_T$. We experiment by sampling only entities or only types or both by fixing the total number of negative examples in Section 5.

The rest of section is organized as follows: we propose three algorithms based on the global objective in Section 4.2. In Section 4.3, we discuss the relationship between the proposed algorithms and existing approaches. Let $\Phi(e) \rightarrow R^{d_e}$ be the feature function that maps an entity to its feature representation, and $\Psi(t) \rightarrow R^{d_t}$ be the feature function that maps an entity type to its feature representation.[4] d_e and d_t represent the feature dimensionality of the entity features and the type features respectively. Feature representations of the entity types (Ψ) is only used in the embedding model.

[3] We often use $s(e, t)$ as an abbreviation of $s(e, t|\theta)$ in order to save space.

[4] This gives the possibility of defining features for the labels in the output space but we use a simple one-hot representation for types right now since richer features did not give performance gains in our initial experiments.

      AdaGradUpdate$(w_t, -\Phi(e))$
      AdaGradUpdate$(w_{t'}, \Phi(e))$.
    end if
  end for
end for

4.2 Algorithms

We propose three different algorithms based on the global objective framework for predicting missing entity types. Two algorithms use the linear model and the other one uses the embedding model.

Linear Model The scoring function in this model is given by $s(e,t|\theta = \{\mathbf{w}_t\}) = \mathbf{w}_t^T\Phi(e)$, where $\mathbf{w}_t \in R^{d_e}$ is the parameter vector for target type t. The regularization term in Eq. (1) is defined as follows: $R(\theta) = 1/2\sum_{t=1}\mathbf{w}_t^T\mathbf{w}_t$. We use $k = 2$ in our experiments. Our first algorithm is obtained by using the dual coordinate descent algorithm (Hsieh et al., 2008) to optimize Eq. (1), where we modified the original algorithm to handle multiple weight vectors. We refer to this algorithm as **Linear.DCD**.

While DCD algorithm ensures convergence to the global optimum solution, its convergence can be slow in certain cases. Therefore, we adopt an online algorithm, Adagrad (Duchi et al., 2011). We use the hinge loss function ($k = 1$) with no regularization ($Reg(\theta) = \emptyset$) since it gave best results in our initial experiments. We refer to this algorithm as **Linear.Adagrad**, which is described in Algorithm 1. Note that AdaGradUpdate(x, g) is a procedure which updates the vector x with the respect to the gradient g.

Embedding Model In this model, vector representations are constructed for entities and types using linear projection matrices. Recall $\Psi(t) \rightarrow R^{d_t}$ is the feature function that maps a type to its feature representation. The scoring function is given by

Algorithm 2 The training algorithm for the embedding model.

Initialize $\mathbf{V}, \mathbf{U}$ randomly.
for $(e,t) \in \Lambda_0$ **do**
  for $e' \in \mathcal{N}_E(e,t)$ **do**
    if $s(e,t) - s(e',t) - 1 < 0$ **then**
      $\mu \leftarrow \mathbf{V}^T\Psi(t)$
      $\eta \leftarrow \mathbf{U}^T(\Phi(e') - \Phi(e))$
      for $i \in 1 \dots d$ **do**
        AdaGradUpdate$(\mathbf{U}_i, \mu[i](\Phi(e') - \Phi(e)))$
        AdaGradUpdate$(\mathbf{V}_i, \eta[i]\Psi(t))$
      end for
    end if
  end for
  for $t' \in \mathcal{N}_T(e,t)$ **do**
    if $s(e,t) - s(e,t') - 1 < 0$ **then**
      $\mu \leftarrow \mathbf{V}^T(\Psi(t') - \Psi(t))$
      $\eta \leftarrow \mathbf{U}^T\Phi(e)$
      for $i \in 1 \dots d$ **do**
        AdaGradUpdate$(\mathbf{U}_i, \mu[i]\Phi(e))$
        AdaGradUpdate$(\mathbf{V}_i, \eta[i](\Psi(t') - \Psi(t)))$
      end for
    end if
  end for
end for

$$s(e,t|\theta = (\mathbf{U},\mathbf{V})) = \Psi(t)^T\mathbf{V}\mathbf{U}^T\Phi(e),$$

where $\mathbf{U} \in R^{d_e \times d}$ and $\mathbf{V} \in R^{d_t \times d}$ are projection matrices that embed the entities and types in a d-dimensional space. Similarly to the linear classifier model, we use the l1-hinge loss function ($k = 1$) with no regularization ($Reg(\theta) = \emptyset$). $\mathbf{U}_i$ and $\mathbf{V}_i$ denote the i-th column vector of the matrix $\mathbf{U}$ and $\mathbf{V}$, respectively. The algorithm is described in detail in Algorithm 2.

The embedding model has more expressive power than the linear model, but the training unlike in the linear model, converges only to a local optimum solution since the objective function is non-convex.

4.3 Relationship to Existing Methods

Many existing methods for relation extraction and entity type prediction can be cast as a special case under the global objective framework. For example, we can consider the work in relation extraction (Mintz et al., 2009; Bordes et al., 2013; Riedel et al., 2013) as models trained with $\mathcal{N}_T(e,t) = \emptyset$. These models are trained only using negative entities which we refer to as Negative Entity (NE) objective. The entity type prediction model in Ling and Weld (2012) is a linear model with $\mathcal{N}_E(e,t) = \emptyset$ which

	70 types	500 types
Entities	2.2M	2.2M
Training Data Statistics (Λ_0)		
positive example	4.5M	6.2M
max #ent for a type	1.1M	1.1M
min #ent for a type	6732	32
Test Data Statistics ($\Lambda - \Lambda_0$)		
positive examples	163K	240K
negative examples	17.1M	132M
negative/positive ratio	105.22	554.44

Table 1: Statistics of our dataset. Λ_0 is our training snapshot and Λ is our test snapshot. An example is an entity-type pair.

we refer to as the Negative Type (NT) objective. The embedding model described in Weston et al. (2011) developed for image retrieval is also a special case of our model trained with the NT objective.

While the NE or NT objective functions could be suitable for some classification tasks (Weston et al., 2011), the choice of objective functions for the KBC tasks has not been well motivated. Often the choice is made neither with theoretical foundation nor with empirical support. To the best of our knowledge, the global objective function, which includes both $\mathcal{N}_E(e,t)$ and $\mathcal{N}_T(e,t)$, has not been considered previously by KBC methods.

5 Experiments

In this section, we give details about our dataset and discuss our experimental results. Finally, we perform manual evaluation on a small subset of the data.

5.1 Data

First, we evaluate our methods on 70 entity types with the most observed facts in the training data.[5] We also perform large-scale evaluation by testing the methods on 500 types with the most observed facts in the training data.

Table 1 shows statistics of our dataset. The number of positive examples is much larger in the training data compared to that in the test data since the test set contains only facts that were added to the more recent snapshot. An additional effect of this is that most of the facts in the test data are about entities that are not very *w*ell-known or famous. The high negative to positive examples ratio in the test data makes this dataset very challenging.

[5] We removed few entity types that were trivial to predict in the test data.

5.2 Automatic Evaluation Results

Table 2 shows automatic evaluation results where we give results on 70 types and 500 types. We compare different aspects of the system on 70 types empirically.

Adagrad Vs DCD We first study the linear models by comparing Linear.DCD and Linear.AdaGrad. Table 2a shows that Linear.AdaGrad consistently performs better for our task.

Impact of Features We compare the effect of different features on the final performance using Linear.AdaGrad in Table 2b. Types are represented by boolean features while Freebase description and Wikipedia full text are represented using *tf-idf* weighting. The best MAP results are obtained by using all the information (T+D+W) while best GAP results are obtained by using the Freebase description and Wikipedia article of the entity. Note that the features are simply concatenated when multiple resources are used. We tried to use *idf* weighting on type features and on all features, but they did not yield improvements.

The Importance of Global Objective Table 2c and 2d compares global training objective with NE and NT training objective. Note that all the three methods use the same number of negative examples. More precisely, for each $(e,t) \in \Lambda_0$, $|\mathcal{N}_E(e,t)| + |\mathcal{N}_T(e,t)| = m + n = 2$. The results show that the global training objective achieves best scores on both MAP and GAP for classifiers and low-dimensional embedding models. Among NE and NT, NE performs better on the type-based metric while NT performs better on the global metric.

Linear Model Vs Embedding Model Finally, we compare the linear classifier model with the embedding model in Table 2e. The linear classifier model performs better than the embedding model in both MAP and GAP.

We perform large-scale evaluation on 500 types with the description features (as experiments are expensive) and the results are shown in Table 2f.

Features	Algorithm	MAP	GAP

Table 2: Automatic Evaluation Results. Note that $m = |\mathcal{N}_E(e,t)|$ and $n = |\mathcal{N}_T(e,t)|$.

One might expect that with the increased number of types, the embedding model would perform better than the classifier since they share parameters across types. However, despite the recent popularity of embedding models in NLP, linear model still performs better in our task.

5.3 Human Evaluation

To verify the effectiveness of our KBC algorithms, and the correctness of our automatic evaluation method, we perform manual evaluation on the top 100 predictions of the output obtained from two different experimental setting and the results are shown in Table 3. Even though the automatic evaluation gives pessimistic results since the test KB is also incomplete[6], the results indicate that the automatic evaluation is correlated with manual evaluation. More excitingly, among the 179 unique instances we manually evaluated, 17 of them are still[7] missing in Freebase which emphasizes the effectiveness of our approach.

[6]This is true even with existing automatic evaluation methods.

[7]at submission time.

Features	G@100	G@100-M	Accuracy-M
D + W	**87.68**	**97.31**	**97**
T + D + W	84.91	91.47	88

Table 3: Manual vs. Automatic evaluation of top 100 predictions on 70 types. Predictions are obtained by training a linear classifier using Adagrad with global training objective (m=1, n=1). G@100-M and Accuracy-M are computed by manual evaluation.

5.4 Error Analysis

- **Effect of training data**: We find the performance of the models on a type is highly dependent on the number of training instances for that type. For example, the linear classifier model when evaluated on 70 types performs 24.86 % better on the most frequent 35 types compared to the least frequent 35 types. This indicates bootstrapping or active learning techniques can be profitably used to provide more supervision for the methods. In this case, G@k would be an useful metric to compare the effectiveness of the different methods.

- **Shallow Linguistic features**: We found some of the false positive predictions are caused by the use of shallow linguistic features. For example, an entity who has acted in a movie and composes music only for television shows is wrongly tagged with the type /film/composer since words like "movie", "composer" and "music" occur frequently in the Wikipedia article of the entity (`http://en.wikipedia.org/wiki/J._J._Abrams`).

6 Related Work

Entity Type Prediction and Wikipedia Features Much of previous work (Pantel et al., 2012; Ling and Weld, 2012) in entity type prediction has focused on the task of predicting entity types at the sentence level. Yao et al. (2013) develop a method based on matrix factorization for entity type prediction in a KB using information within the KB and New York Times articles. However, the method was still evaluated only at the sentence level. Toral and Munoz (2006), Kazama and Torisawa (2007) use the first line of an entity's Wikipedia article to perform named entity recognition on three entity types.

Knowledge Base Completion Much of precious work in KB completion has focused on the problem of relation extraction. Majority of the methods infer missing relation facts using information within the KB (Nickel et al., 2011; Lao et al., 2011; Socher et al., 2013; Bordes et al., 2013) while methods such as Mintz et al. (2009) use information in text documents. Riedel et al. (2013) use both information within and outside the KB to complete the KB.

Linear Embedding Model Weston et al. (2011) is one of first work that developed a supervised linear embedding model and applied it to image retrieval. We apply this model to entity type prediction but we train using a different objective function which is more suited for our task.

7 Conclusion and Future Work

We propose an evaluation framework comprising of methods for dataset construction and evaluation metrics to evaluate KBC approaches for inferring missing entity type instances. We verified that our automatic evaluation is correlated with human evaluation, and our dataset and evaluation scripts are publicly available.[8] Experimental results show that models trained with our proposed global training objective produces higher quality ranking within and across types when compared to baseline methods.

In future work, we plan to use information from entity linked documents to improve performance and also explore active leaning, and other human-in-the-loop methods to get more training data.

Robust Morphological Tagging with Word Representations

Thomas Müller and **Hinrich Schütze**
Center for Information and Language Processing
University of Munich, Germany
muellets@cis.lmu.de

Abstract

We present a comparative investigation of word representations for part-of-speech (POS) and morphological tagging, focusing on scenarios with considerable differences between training and test data where a *robust* approach is necessary. Instead of adapting the model towards a specific domain we aim to build a robust model across domains. We developed a test suite for robust tagging consisting of six languages and different domains. We find that representations similar to Brown clusters perform best for POS tagging and that word representations based on linguistic morphological analyzers perform best for morphological tagging.

1 Introduction

Most natural language processing (NLP) tasks can be better solved if a preprocessor tags each word in the natural language input with a label like "noun, singular" or "verb, past tense" that gives some indication of the syntactic role that the word plays in its context. The most common form of such preprocessing is POS tagging. However, for morphologically rich languages, a large subset of the languages of the world, POS tagging in its original form – where labels are syntactic categories with little or no morphological information – does not make much sense. The reason is that POS and morphological properties are mutually dependent, so solving only one task or solving the tasks sequentially is inadequate. The most important dependence of this type is that POS can be read off morphology in many cases; e.g., the morphological suffix "-iste" is a reliable indicator of the informal second person singular preterite indicative form of a verb in Spanish. In what follows, we use the term "morphological tagging" to refer to "morphological and POS tagging" since morphological tags generally include POS information.

The importance of morphological tagging as part of the computational linguistics processing pipeline motivated us to conduct the research reported in this paper. The specific setting that we address is increasingly recognized as the setting in which most practical NLP takes place: We look at scenarios with considerable differences between the training data and the application data, i.e., between the data that the tagger is trained on and the data that it is applied to. This type of scenario is frequent because of the great diversity and variability of natural language and because of the high cost of annotation – which makes it impossible to create large training sets for each new domain. For this reason, we address morphological tagging in a setting in which training and application data differ.

The most common approach to this setting is domain adaptation. Domain adaptation has been demonstrated to have good performance in scenarios with differently distributed training/test data. However, it has two disadvantages. First, it requires the availability of data from the target domain. Second, we need to do some extra work in domain adaptation – consisting of taking target domain data and using it to adapt our NLP system to the target domain – and we end up with a number of different versions of our NLP system. The extra work required and the pro-

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 526–536,
Denver, Colorado, May 31 – June 5, 2015.

liferation of different versions increase the possibility of errors and increase the complexity of deploying NLP technology. Similar to other recent work (Zhang and Wang, 2009), we therefore take an approach that is different from domain adaptation. We build a system that is *robust across domains without any modification*. As a result, no extra work is required when the system is applied to a new domain: there is only one system and we can use it for all domains.

The key to making NLP components robust across domains is *the use of powerful domain-independent representations for words*. One of the main contributions of this paper is that we compare the performance of the most important representations that can be used for this purpose. We find that two of these are best suited for robust tagging. MarLiN (Martin et al., 1998) clusters – a derivative of Brown clusters – perform best for POS tagging. MarLiN clusters are also an order of magnitude more efficient to induce than the original Brown clusters. We provide an open source implementation of MarLiN clustering as part of this publication (Section 8). We compare the word representations to Morphological Analyzers (MAs), which are finite-state transducers that find the stems of a form and use them to derive all its possible morphological readings. MAs produce the best results in our experiments on morphological tagging. Our initial expectation was that domain differences and lack of coverage would put manually created MAs at a disadvantage when compared to learning algorithms that are run on very large text corpora. However, our results clearly show that MA-based representations are the best representations to use for robust morphological tagging.

The motivation for our work is that both morphological tagging and the "robust" application setting are important areas of research in NLP. To support this research, we created an extensive evaluation set for six languages. This involved identifying morphologically rich languages in which usable data sets with different distributional properties were available, designing mappings between different tag sets, organizing a manual annotation effort for one of the six languages and preparing large "general" (not domain-specific) data sets for unsupervised learning of word representations. The preparation and publication (Section 8) of this test suite is in itself a significant contribution.

The remainder of this paper is structured as follows. Section 2 discusses related work. Section 3 presents the representations we tested. Section 4 describes the data sets and the annotation and conversion efforts required to create the in-domain (ID) and out-of-domain (OOD) data sets. In Section 5, we describe the experiments and discuss our findings. In Section 6, we provide an analysis of our results. Section 7 summarizes our findings and contributions.

2 Related Work

Morphological tagging (Oflazer and Kuruöz, 1994; Hajič and Hladká, 1998) is the task of assigning a morphological reading to a token in context. The morphological reading consists of features such as case, gender, person and tense and is represented as a single tag. This allows for the application of standard sequence labeling algorithms such as Conditional Random Fields (CRFs) (Lafferty et al., 2001), but also puts an upper bound on the accuracy as only readings occurring in the training set can be produced. It is still the standard approach to morphological disambiguation as the number of readings that cannot be produced is usually small.

The related work can be divided in systems that try to exploit certain properties of a language (Habash and Rambow, 2005; Yuret and Türe, 2006) and language-independent systems (Hajič, 2000; Smith et al., 2005). In this paper, we adopt a language-independent approach.

Semi-supervised learning attempts to increase the accuracy of a machine learning system by using additional unlabeled data. Word representations, especially Brown clusters, have been extensively used for named entity recognition (NER) (Miller et al., 2004), parsing (Koo et al., 2008) and POS tagging (Collobert and Weston, 2008; Huang et al., 2009). In these papers, word representations were shown to yield consistent improvements and to often outperform traditional semi-supervised methods such as self-training. Prior work on semi-supervised training for morphological tagging includes Spoustová et al. (2009) and Chrupala (2011). In contrast to this earlier work on morphological tagging, we study a number of morphologically more complex and diverse languages. We also compare learned represen-

tations to representations obtained from MAs.

Domain adaptation (DA) attempts to adapt a model trained on a source domain to a target domain. DA can be broadly divided into supervised and unsupervised approaches depending on whether labeled target domain data is available or not. Among unsupervised approaches to DA, representation learning (Ando and Zhang, 2005; Blitzer et al., 2006) uses the unlabeled target domain data to induce a structure that is suitable for transferring information from the labeled source domain to the target domain. Similar to representation learning for DA, we attempt to include word representations into the model. However, we induce the representation from a *general domain* in an attempt to obtain a model that has robust high accuracy across domains, for the source domain as well as for the target domains, for which neither labeled nor unlabeled training data is available.

3 Representations

We survey the following distributional representations: (i) count vectors reduced by a Singular Value Decomposition (SVD), (ii) word clusters induced using the likelihood of a class-based language model, (iii) distributed embeddings trained using a neural network and (iv) accumulated tag counts, a task-specific representation obtained from an automatically tagged corpus.

Singular value decomposition of word-feature cooccurrence matrices (Schütze, 1995) has been found to be a fast and efficient way to obtain distributed embeddings. The approach selects a subset of the vocabulary as so-called feature words, usually by including words up to a certain frequency rank. Every word form can then be represented by the accumulated counts of feature words occurring to its left and right. Then an SVD is applied to the cooccurrence matrix as a form of dimension reduction and to reduce sparsity.

We also experimented with unreduced count vectors, but they did not give better results than SVD reduced count vectors. SVD-based representations have been used in English POS induction (Lamar et al., 2010) as well as as features in English POS tagging and syntactic chunking (Huang et al., 2009); they have a similar level of accuracy as unsupervised Hidden Markov Models (HMMs) in these studies.

Language model-based (LM-based) word clusters were introduced by Brown et al. (1992) and later found to be helpful in a range of NLP tasks. The basic idea is to find the optimal clustering with respect to the likelihood of a class-based language model:

$$g = \arg\max_{g} \prod_{i=1}^{|D|} p(g(x_i)|g(x_{i-1})) \cdot p(x_i|g(x_i))$$

where $g(x)$ is the cluster assignment function that maps a word form x to a cluster and $|D|$ denotes the length of the training set. Brown et al. (1992) propose a greedy bottom-up algorithm for the optimization that merges the pair of clusters that yields the smallest loss in likelihood; as well as a more efficient approximation of that algorithm that limits the number of clusters under consideration and still works well in practice. It is used by most work in the literature (Liang, 2005; Turian et al., 2010; Koo et al., 2008).

We, however, found the algorithm proposed by Martin et al. (1998) to be faster and to give slightly better results. The algorithm is similar to K-means in that it starts with an initial clustering and greedily improves the objective function by moving single words to their optimal cluster. In contrast to K-means, it updates the objective function immediately. The algorithm has also been shown to work well in unsupervised POS induction (Clark, 2003; Blunsom and Cohn, 2011). Our implementation of this algorithm is called MarLiN and has been made available as open-source software (Section 8). Miller et al. (2004) use tags of different granularity induced from unlabeled text to improve the performance of an averaged perceptron tagger (Collins, 2002) on an English NER task.

The Brown algorithm induces a tree where leaves represent a single word form and the root node the entire vocabulary. Intermediate nodes represent clusters of different sizes and can be addressed by a binary string specifying the path from the root node to the cluster. Brown clusters are also used by Koo et al. (2008) to improve dependency parsing for English and Czech. Chrupala (2011) compare Brown clusters to a Latent Dirichlet Allocation

(LDA) model on Spanish and French morphological tagging and find them to yield similar performance.[1]

Neural networks have been used by Collobert and Weston (2008) to train embeddings for POS tagging as well as other NLP tasks. These embeddings – henceforth *CW embeddings* – are trained by building a neural network that given contexts of a word as input is trained to discriminate between the correct center word and a random word. The proposed training algorithm is reported to need several days or even weeks, but has been reimplemented by Al-Rfou et al. (2013), who induced embeddings for the Wikipedias of more than 100 languages. Turian et al. (2010) find that the performance of Brown clusters is competitive with more training intensive embeddings like CW. In our experiments, we find that MarLiN clusters slightly outperform CW. We do not evaluate bag-of-words models such as WORD2VEC (Mikolov et al., 2013), because the ordering of words is essential for finding morphological properties.

Accumulated tag counts (ACT) are a form of task-specific sparse representation. The unlabeled corpus is first annotated by a tagger; for each occurring word form, the number of times a specific tag was assigned can then be used as a representation. Goldberg and Elhadad (2013) and (Szántó and Farkas, 2014) show that using such information in the word-preterminal emission probabilities of PCFGs can improve parsing accuracy. Specifically, Szántó and Farkas (2014) show that this approach performs as well as an MA in some cases. We find MAs to be more effective than the accumulated count embeddings; this is not a contradiction as we try to improve the performance of the tagger itself.

4 Data Preparation

Our test suite consists of data sets for six different languages: Czech (cs), English (en), German (de), Hungarian (hu), Spanish (es) and Latin (la). Czech, German, Hungarian and Latin are morphologically rich. We chose these languages because they represent different families: Germanic (English, German), Romance (Latin, Spanish), Slavic (Czech) and Finno-Ugric (Hungarian) and different degrees of morphological complexity and syncretism. For example, English and Spanish rarely mark case while the other languages do; and as an agglutinative language, Hungarian features a low number of possible readings for a word form while languages like German can have more than 40 different readings for a word form. An additional criterion was to have a sufficient amount of labeled OOD data. The data sets also feature an interesting selection of domain differences. For example, for Latin we have texts from different epochs while the English data contains canonical and non-canonical text.

Labeled Data. This section describes the annotation and conversion we performed to create consistent ID and OOD data sets.[2] No conversion was required for Hungarian, English and Latin as the data is already annotated in a consistent way.

For Hungarian we use the (multi-domain) Szeged Dependency Treebank (Vincze et al., 2010). We use the part that was used in the SPMRL 2013 shared task (Seddah et al., 2013) as ID data (news-wire) and an excerpt from the novel *1984* and a *Windows 2000* manual as OOD data.

For Latin we use the PROIEL treebank (Haug and Jøhndal, 2008). It consists of data from the *Vulgate* (bible text, $\approx$ 380 AD), *Commentarii de Bello Gallico* ($\approx$ 50 BC), Letters from Cicero to his friend Atticus ($\approx$ 50 BC) and *The Pilgrimage of Aetheria* ($\approx$ 380 AD). We use the biggest text source *(Vulgate)* as ID data and the remainder as OOD data.

For English we use the SANCL shared task data (Petrov and McDonald, 2012), which consists of Ontonotes 4.0 as ID data and five OOD domains from the Google Web treebank: Yahoo! Answers, weblogs, news groups, business reviews and emails. For Czech we use the part of the Prague Dependency Treebank (PDT) (Böhmová et al., 2003) that was used in the CoNLL 2009 shared tasks (Hajič et al., 2009) as ID data. We use the Czech part of the Multext East (MTE) corpus (Erjavec, 2010) as OOD data. MTE consists of translations of the

[1] The authors claim that LDA Gibbs sampling is faster than the induction of Brown clusters because it only depends linearly on the number of clusters. We, however, could not train their models on our bigger data sets as the sampling depends linearly on the number of tokens.

[2] Table 5 of the appendix provides a structured overview over the domains and resources used for each language. The appendix can be found at `http://cistern.cis.lmu.de/marmot/naacl2015/appendix.pdf`.

novel *1984* that have been annotated morphologically. PDT and MTE have been annotated using two different guidelines that without further annotation effort could only be merged by reducing them to a common subset. Specifically, we removed features such as sub POS tags as well as markers for (in)animacy. The PDT features a number of tags that are ambiguous and could not always be resolved. The gender feature Q for example can mean feminine or neuter. If we could not disambiguate such a tag, we removed it; this results in morphological tags that are not present in the MTE corpus and a relatively high number of unseen tags. Instead of describing the conversion process in greater detail we refer to our conversion scripts (Section 8).

For Spanish we use the part of the AnCora corpus (Taulé et al., 2008) of CoNLL 2009 and the IULA treebank (Marimon et al., 2012), which consists of five domains: law, economics, medicine, computer science and environment. We use the AnCora corpus as ID data set and IULA as OOD data set. The two treebanks have been annotated using the same annotation scheme, but slightly different guidelines. Similar to Czech we merged the data sets by deleting features that could not be merged or were not present in one of the treebanks. Again we refer to the conversion script for further details (Section 8).

For German we use the Tiger treebank (Brants et al., 2002) in the same split as Müller et al. (2013) as ID data and the Smultron corpus (Volk et al., 2010) as OOD data. Smultron consists of four parts: a description of Alpine hiking routes, a DVD manual, an excerpt of Sophie's World and economics texts. It has been annotated with POS and syntax, but not with morphological features. We annotated Smultron following the Tiger guidelines. The annotation process was similar to Marimon et al. (2012) in that the data sets were automatically tagged with the MORPH tagger MarMoT (Müller et al., 2013) and then manually corrected by two annotators. This tagger is a strong baseline as we could include features based on gold lemma, POS and syntax (Seeker and Kuhn, 2013). The agreement of the annotators was .9628 and the κ agreement .64.[3] As most of the differences between the annotators were cases where only one of the annotators had corrected an obvious error that the other had overlooked, the differences were resolved by the annotators themselves.

We used the provided segmentation if available and otherwise split ID data 8/1/1 into training, development and test sets and OOD data 1/1 into development and test sets if not mentioned otherwise. We thus have a classical setup of in-domain news paper text vs. prose, medical, law, economic or technical texts for Czech, German, Spanish and Hungarian. For English we have canonical vs. non-canonical data and for Latin data of different epochs (ca. 400 AD vs 50 BC). Additionally, for German one of the test domains is written in Swiss German.

Looking at some statistics of the labeled data sets,[4] we find that: Hungarian and Latin are the languages with the highest OOV rates (27% and 37%, which for reasons of consistency we will henceforth write as follows: .27 and .37); Hungarian has a very productive agglutinative morphology while the high number of Latin OOVs can be explained by the small training set (<60,000); Czech features the highest unknown tag rate (.05) as well as the highest unseen word-tag rate (.16). This can be explained by the limits of the conversion procedure we discussed above, e.g., ambiguous features like Q.

Unlabeled Data. As unlabeled data we use Wikipedia dumps from 2014 for all languages except for Latin for which we use the Patrologia Latina, a collection of clerical texts from ca. 100 AD to 1200 AD from Corpus Corporum (Roelli, 2014). We do not use the Latin version of Wikipedia because it is written by enthusiasts, not by native speakers, and contains many errors.

We preprocessed the Wikipedia dumps with WIKIPEDIAEXTRACTOR (Attardi and Fuschetto, 2013) and NLTK'S (Bird et al., 2009) implementation of PUNKT (Kiss and Strunk, 2006) to detect sentence boundaries. Tokenization was performed using MAGYARLANC (Hungarian, Zsibrita et al. (2013)), STANFORD TOKENIZER (English, Manning et al. (2014)), FREELING (Spanish, Padró and Stanilovsky (2012)) and CZECHTOK[5] (Czech). For

[3] For calculating κ, we assume that random agreement occurs when both annotators agree with the reading proposed by the tagger. We then estimate the probability of random agreement by multiplying the individual estimated probabilities of changing the proposed tagging. This yields a random agreement probability of .8965.

[4] Complete tables are in the appendix: Tables 1 and 2.

[5] http://sourceforge.net/projects/

Latin, we removed punctuation because PROIEL does not contain punctuation. We also split off the clitics *ne*, *que* and *ve* if the resulting token was accepted by LATMOR (Springmann et al. (2014)). Following common practice, we normalized the text by replacing digits with 0s.[6]

In our experiments, we extract representations for the 250,000 most frequent word types. This vocabulary size is comparable to other work; e.g., Turian et al. (2010) use 269,000 types. This threshold yields low fractions of uncovered tokens[7] for English and Latin (.009 and .02). For the other languages, this fraction rises to .04. We also extract the morphological readings of the words in this vocabulary using MAGYARLANC (Hungarian, Zsibrita et al. (2013)), FREELING (English and Spanish, Padró and Stanilovsky (2012)), SMOR (German, Schmid et al. (2004)), an MA from Charles University (Czech, Hajič (2001)) and LATMOR (Latin, Springmann et al. (2014)). Throughout this paper we extract one feature for each cluster id or MA reading of the current word form. For example, SMOR produces two readings for the German word form *erhielt* 'received': <1><SG><PAST><IND> and <2><SG><PAST><IND>, we thus fire two features representing the respective tags whenever *erhielt* is seen in the data. We also experimented with cluster indexes of neighboring uni/bigrams, but obtained no consistent improvement. For the dense embeddings we analogously extract the vector of the current word form.

5 Experiments

For all our experiments we use MarMoT (Müller et al., 2013) a joint POS and morphological tagger.[8] The CRF tagger employs a pruning strategy on forward-backward lattices to efficiently handle big tag sets and higher orders. Its feature set is similar to Ratnaparkhi (1996) and Toutanova et al. (2003) and includes prefixes, suffixes, immediate lexical context and shape features based on capitalization, special characters and digits. MarMoT was shown to be a competitive POS and morphological tagger across six languages (Müller et al., 2013). In order to make sure that it is also robust in an OOD setup we compare it to the two popular taggers SVMTool (Giménez and Marquez, 2004) and Morfette (Chrupała et al., 2008). The results are summarized in Table 1.

MarMoT uses stochastic gradient descent and produces different results in each training run. We therefore always report the average of five runs. The OOD numbers are macro-averages over the different OOD data sets of a language. [9] The tables in this paper are based on the development sets; the only exception to this is Table 5, which is based on the test set. MarMoT outperforms SVMTool and Morfette on every language and setup (ID / OOD) except for the Spanish OOD data set. For Czech, German and Latin the improvements over the best baseline are >1. Different orders of MarMoT behave as expected: higher-order models (order>1) outperform first-order models. The only exception to this is Latin. This suggests a drastic difference of the tag transition probabilities between the Latin ID and OOD data sets. Given the results in Table 1 and for simplicity we use an second-order MarMoT model in all subsequent experiments.

LM-based clustering. We first compare different implementations of LM-based clustering. The implementation of Brown clustering by Liang (2005) is most commonly used. Its hierarchical binary structure can be used to extract clusterings of varying granularity by selecting different prefixes of the path from the root to a specific word form. Following other work (Ratinov and Roth, 2009; Turian et al., 2010), we induce 1000 clusters and select path lengths 4, 6, 10 and 20. We call this representation Brown_path. We compare Brown_path to mkcls[10] (Och, 1999) and MarLiN. These implementations just induce flat clusterings of a certain size; we thus run them for cluster sizes 100, 200, 500 and 1000 to also obtain cluster ids of different sizes. The cluster sizes roughly resemble the granularity obtained in $\text{Brown}_{\text{path}}$. We call the corresponding mod-

czechtok/

[9] Throughout this paper we use the approximate randomization test (Yeh, 2000) to establish significance. To this end, we compare the output of the medians of the five independent models. We regard p-values $<.05$ as significant.

[10] mkcls implements a similar training algorithm as MarLiN, but uses simulated annealing, not greedy maximization.

Table 3: Tagging results for CW

els $\text{Brown}_{\text{flat}}$, mkcls and MarLiN. The runtime of the Brown algorithm depends quadratically on the number of clusters while mkcls and MarLiN have linear complexity. This is reflected in the training times: For German the Brown algorithm takes $\approx 5000\,\text{min}$, mkcls $\approx 2000\,\text{min}$ and MarLiN $\approx 500\,\text{min}$.

Table 2 shows that the absolute differences between systems are small, but overall MarLiN and mkcls are better.[11] We conclude that systems based on the algorithm of Martin et al. (1998) are slightly more accurate for tagging and are several times faster than the more frequently used version of Brown et al. (1992). We thus use MarLiN for the remainder of this paper.

Neural Network Representations. We compare MarLiN with the implementation of CW by Al-Rfou et al. (2013). They extracted 64-dimensional representations for only the most frequent 100,000 word forms. To make the comparison fair, we use the intersection of our and their representation vocabularies.[12] The results in Table 3 show that MarLiN is best in 15 out of 22 cases and significantly better in eight. CW is best in 9 out of 22 cases and significantly better in two. We conclude that LM-based representations are more suited for tagging as they can be induced faster, are smaller and give better results.

SVD and ACT Representations. For the SVD-based representation we use feature ranks out of $\{500, 1000\}$ and dimensions out of $\{50, 100, 200, 500\}$. We found that l1-normalizing the vectors before and after the SVD improved results slightly. For the accumulated tag counts (ACT) we annotate the data with our baseline model and extract word-tag probabilities. The probabilities are then used as sparse real-valued features. Table 4 shows that all representations outperform the baseline. Improvements are biggest for Latin. Overall, SVD outperforms ACT and is outperformed by MarLiN and MA. MarLiN gives the best representations for POS tagging while MA outperforms MarLiN in MORPH tagging. Table 5 shows that the findings for the baseline, MarLiN and MA also hold for the test set.

[11] $\text{Brown}_{\text{path}}$ reaches the same performance as MarLiN in one case: pos/es/OOD.

[12] We also use representations from Wikipedia (instead of Corpus Corporum) for Latin to increase the similarity of the training data.

Table 7: Improvement compared to the baseline for different features

6 Analysis

We now analyze why MarLiN and MA perform better than the baseline. First we compare the improvements in absolute error rate over the baseline by grouping word forms by their training set frequency f. The number are shown in Table 6. We find that most of the improvement comes from OOV words. Rare words (frequency <10) show a smaller, but still important contribution while the contribution of frequent words can be almost neglected for four languages. The exception is German where frequent words contribute more to the error reduction than rare words. This could be caused by syncretisms such as in plural noun phrases where the gender is not marked in determiner and adjective and can only be derived from the head noun; e.g., the adjectives in *schwere Schulfächer* 'difficult school subjects' and *verdächtige Personen* 'suspect persons' are unmarked for gender and the correct genders (neuter vs. feminine) cannot be inferred from distributional information or suffixes for the nouns (although gender is easy to infer distributionally for singular forms of nouns).

Looking at the morphological features with the highest improvement in absolute error rate (Table 7) we find, that the features with the highest improvement are POS, SUB-POS (a finer division of POS, e.g., nouns are split into proper / common nouns), gender, case and number. For all languages POS and – if part of the annotation – SUB-POS are among the

three features with the highest improvements. Gender is also always among the three features with the highest improvements for the four languages that have gender (es, de, la, cs). We just discussed an example for German where gender could not be derived from context or inflectional suffixes. Other languages also have word forms that do not mark gender, e.g., Spanish masculine *ave* 'bird' vs. feminine *llave* 'key'. The gender can, however, easily be derived if the word representation encodes whether a word form has been seen with a specific determiner or adjective on its right or left.

Lastly, we use Jaccard similarity[13] to compare the sets of gold and predicted morphological features. Jaccard can be interpreted as a soft variant of accuracy: If the two tags are identical it yields 1 and otherwise it corresponds to the number of correctly predicted features divided by the size of the union of gold and predicted features.

morph		cs	de	es	hu	la
	accuracy	79.41	85.72	95.43	91.14	73.23
	Jaccard	89.89	90.71	96.77	93.52	83.68

This table demonstrates that the evaluation measure we have used throughout this paper – a tag counts as completely wrong if a single feature was misidentified even though all others are correct – is conservative. On a feature-by-feature basis accuracy would be much higher. The difference is largest for Czech and Latin.

7 Conclusion

We have presented a test suite for morphological tagging consisting of in-domain (ID) and out-of-domain (OOD) data sets for six languages: Czech, English, German, Hungarian, Latin and Spanish. We converted some of the data sets to obtain a reasonably consistent annotation and manually annotated the German part of the Smultron treebank. We surveyed four different word representations: SVD-reduced count vectors, LM-based clusters, accumulated tag counts and CW embeddings. We found that the LM-based clusters outperformed the other representations for POS and MORPH tagging, ID and OOD data sets and all languages. We also showed that our implementation of MarLiN (Martin et al., 1998) is an order-of-magnitude more efficient and performs slightly better than the implementation by Liang (2005). We also compared the learned representations to manually created Morphological Analyzers (MAs). We found that MarLiN outperforms MAs in POS tagging, but that it is substantially worse in morphological tagging. In our analysis of the results, we showed that both MarLiN and MAs decrease the error most for out-of-vocabulary words and for the features POS and gender.

[13] $\text{Jaccard}(U, V) = |U \cap V|/|U \cup V|$

8 Resources

As part of this publication we also release the following resources at `http://cistern.cis.lmu.de/marmot/`: (i) our implementation of MarLiN as open-source (ii) the morphological layer of the German part of the SMULTRON corpus. For easier reproducibility, we also made (iii) the preprocessed Wikipedia dumps and the induced representation dictionaries available. (iv) Morphological dictionaries were released to the extent this was compatible with the usage agreement. (v) We also published the conversion code for unifying the Spanish and Czech annotations.

Acknowledgments

We would like to thank the anonymous reviewers for their comments. The first author is a recipient of the Google Europe Fellowship in Natural Language Processing, and this research is supported by this Google Fellowship. The annotation of the SMULTRON data was supported by Deutsche Forschungsgemeinschaft (grant DFG 2246/2, Wordgraph).

English orthography is not "close to optimal"

Garrett Nicolai and **Grzegorz Kondrak**
Department of Computing Science
University of Alberta
{nicolai,gkondrak}@ualberta.ca

Abstract

In spite of the apparent irregularity of the English spelling system, Chomsky and Halle (1968) characterize it as "near optimal". We investigate this assertion using computational techniques and resources. We design an algorithm to generate word spellings that maximize both phonemic transparency and morphological consistency. Experimental results demonstrate that the constructed system is much closer to optimality than the traditional English orthography.

1 Introduction

English spelling is notorious for its irregularity. Kominek and Black (2006) estimate that it is about 3 times more complex than German, and 40 times more complex than Spanish. This is confirmed by lower accuracy of letter-to-phoneme systems on English (Bisani and Ney, 2008). A survey of English spelling (Carney, 1994) devotes 120 pages to describe phoneme-to-letter correspondences, and lists 226 letter-to-phoneme rules, almost all of which admit exceptions. Numerous proposals have been put forward for spelling reforms over the years, ranging from small changes affecting a limited set of words to complete overhauls based on novel writing scripts (Venezky, 1970).

In spite of the perceived irregularity of English spellings, Chomsky and Halle (1968) assert that they remarkably well reflect abstract underlying forms, from which the surface pronunciations are generated with "rules of great generality and wide applicability". They postulate two principles of an optimal orthographic system: (1) it should have "one representation for each lexical entry" (*consistency*); and, (2) "phonetic variation is not indicated where it is predictable by a general rule" (*predictability*). They conclude that "conventional orthography is [...] a near optimal system for the lexical representation of English words" (page 49), which we refer to as the *optimality claim*.

Chomsky and Halle's account of English orthography is not without its detractors. Steinberg (1973) argues against the idea that speakers store abstract underlying forms of separate morphemes and apply sequences of phonological rules during composition. Sampson (1985) cites the work of Yule (1978) in asserting that many common English word-forms provide counter-evidence to their vowel alternation observations. Derwing (1992) maintains that the observations only hold for five vowel alternations that can be predicted with simple spelling rules. According to Nunn (2006), the idea that spelling represents an abstract phonological level has been abandoned by most linguists. Sproat (2000) notes that few scholars of writing systems would agree with Chomsky and Halle, concluding that the evidence for a consistent morphological representation in English orthography is equivocal.

It is not our goal to formulate yet another proposal for reforming English orthography, nor even to argue that there is a need for such a reform. Furthermore, we refrain from taking into account other potential advantages of the traditional orthography, such as reflecting archaic pronunciation of native words, preserving the original spelling of loanwords, or maintaining orthographic similarity to cognates in other languages. Although these may be valid concerns, they are not considered as such by Chomsky and Halle. Instead, our primary objective is a deeper understanding of how the phono-

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 537–545,
Denver, Colorado, May 31 – June 5, 2015.

logical and morphological characteristics of English are reflected in its traditional orthography, which is currently the dominant medium of information exchange in the world.

In this paper, we investigate the issue of orthographic optimality from the computational perspective. We define metrics to quantify the degree of optimality of a spelling system in terms of phonemic transparency and morphological consistency. We design an algorithm to generate an orthography that maximizes both types of optimality, and implement it using computational tools and resources. We show experimentally that the traditional orthography is much further from optimality than our constructed system, which contradicts the claim of Chomsky and Halle.

2 Optimality

In this section, we define the notions of phonemic and morphemic optimality, and our general approach to quantifying them. We propose two theoretical orthographies that are phonemically and morphologically optimal, respectively. We argue that no orthographic system for English can be simultaneously optimal according to both criteria.

2.1 Phonemic optimality

A purely phonemic system would have a perfect one-to-one relationship between graphemes and phonemes. Rogers (2005) states that no standard writing system completely satisfies this property, although Finnish orthography comes remarkably close. For our purposes, we assume the International Phonetic Alphabet (IPA) transcription to be such an ideal system. For example, the IPA transcription of the word *viscosity* is [vɪskɑsəti]. We obtain the transcriptions from a digital dictionary that represents the General American pronunciation of English.

Phonemic transparency can be considered in two directions: from letters to phonemes, and vice versa. The pronunciation of Spanish words is recoverable from the spelling by applying a limited set of rules (Kominek and Black, 2006). However, there is some ambiguity in the opposite direction; for example, the phoneme [b] can be expressed with either 'b' or 'v'. As a result, it is not unusual for native Spanish speakers to make spelling mistakes. On the other hand, the orthography of Serbo-Croatian was originally created according to the rule "write as you speak", so that the spelling can be unambiguously produced from pronunciation. This does not mean that the pronunciation is completely predictable from spelling; for example, lexical stress is not marked (Sproat, 2000).

In this paper, we measure phonemic transparency by computing average perplexity between graphemes and phonemes. Roughly speaking, phonemic perplexity indicates how many different graphemes on average correspond to a single phoneme, while graphemic perplexity reflects the corresponding ambiguity of graphemes. We provide a formal definition in Section 5.

2.2 Morphological optimality

A purely morphemic writing system would have a unique graphemic representation for each morpheme. Chinese is usually given as an example of a near-morphemic writing system. In this paper, we construct an abstract morphemic spelling system for English by selecting a single alphabetic form for each morpheme, and simply concatenating them to make up words. For example, the morphemic spelling of *viscosity* could be 'viscous·ity'.[1]

We define morphemic optimality to correspond to the consistency principle of Chomsky and Halle. The rationale is that a unique spelling for each morpheme should allow related words to be readily identified in the mental lexicon. Sproat (2000) distinguishes between morpheme-oriented "deep" orthographies, like Russian, and phoneme-oriented "shallow" orthographies, like Serbo-Croatian.

We propose to measure morphemic consistency by computing the average edit distance between morpheme representations in different word-forms. The less variation morpheme spellings exhibit in a writing system, the higher the corresponding value of the morphemic transparency will be. We define the measure in Section 5.

It is impossible to achieve complete phonemic and morphemic optimality within one system designed for English spelling. For example, the stem morpheme of verb forms *hearing* and *heard* is

[1] Non-traditional spellings are written within single quotes. Morphemes may be explicitly separated by the centered dot character.

spelled identically but pronounced differently. If we changed the spellings to indicate the difference in pronunciation, we would move towards phonemic optimality, but away from morphemic optimality. Apart from purely phonographic or logographic variants, any English spelling system must be a compromise between phonemic and morphemic transparency. In this paper, we attempt to algorithmically create an orthography that simultaneously approaches the optimality along both dimensions.

3 Algorithm

In this section, we describe our algorithm for generating English spellings (Figure 1), which serves as a constructive proof that the traditional orthography is not optimal. Our objective is to find the best compromise between phonemic transparency and morphemic consistency. Section 3.1 explains how we derive a unique representation for each morpheme. Section 3.2 shows how the morpheme representations are combined into word spellings. Without a loss of generality, the generated spellings are composed of IPA symbols.

3.1 Morpheme representations

We start by identifying all morphemes in the lexicon, and associating each morpheme with sets of words that contain it (lines 1–3 in Figure 1). An example word set that corresponds to the morpheme *atom* is shown in Table 1. Words may belong to more than one set. For example, the word *atomic* will also be included in the word set that corresponds to the morpheme *-ic*. We make no distinction between bound and free morphemes.

As can be seen in Table 1, English morphemes often have multiple phonemic realizations. The objective of the second step (lines 4–11) is to follow the consistency principle by establishing a single representation of each morpheme. They suggest that orthographic representations should reflect the underlying forms of morphemes as much as possible. Unfortunately, underlying forms are not attested, and there is no commonly accepted algorithm to construct them. Instead, our algorithm attempts to establish a sequence of phonemes that is maximally similar to the attested surface allomorphs.

Table 1 shows an example of generating the common representation for a morpheme. We extract the phonemic representation of each allomorph in the word set, and perform a multi-alignment of the representations by pivoting on the longest representation of the morpheme (lines 5–8). For each position in the multi-alignment, we identify the set of phonemes corresponding to that position. If there is no variation within a position, we simply adopt the common phoneme. Otherwise, we choose the phoneme that is most preferred in a fixed hierarchy of phonemes. In this case, since [æ] and [ɑ] are preferred to [ə], the resulting morpheme representation is 'ætɑm'.

For selecting between variant phonemes, we follow a manually-constructed hierarchy of phonemes (Table 2), which roughly follows the principle of least effort. The assumption is that the phonemes requiring more articulatory effort to produce are more likely to represent the underlying phoneme. Within a single row, phonemes are listed in the order of preference. For example, alveolar fricatives like [s]

```
   // Create word sets
 1: for each word w in lexicon L do
 2:     for each morpheme m in w do
 3:         add w to word set S_m
   // Generate morpheme representations
 4: for each word set S_m do
 5:     m_0 := longest representation of m
 6:     for each word w in S_m do
 7:         a_w := alignment of m_0 and w
 8:         add a_w to multi-alignment A
 9:     for each position i in A do
10:         select representative phoneme r[i]
11:     r_m := r[1..|m_0|]
   // Adopt a surface phoneme predictor
12: Pronounce := Predictor (L)
   // Generate word representations
13: for each word w = m_1 ... m_k do
14:     r := r_{m_1} · ... · r_{m_k}
15:     for each phoneme r[i] in r do
16:         if Pronounce(r[i]) ≠ w[i] then
17:             r[i] := w[i]
18:     r_w := r[1..|w|]
```

are preferred to post-alveolar ones like [ʃ], in order to account for palatalization. Since our representations are not intended to represent actual underlying forms, the choice of a particular phoneme hierarchy affects only the shape of the generated word spellings.

3.2 Word representations

Ideally, polymorphemic words should be represented by a simple concatenation of the corresponding morpheme representations. However, for languages that are not purely concatenative, this approach may produce forms that are far from the phonemic realizations. For example, assuming that the words *deceive* and *deception* share a morpheme, a spelling 'deceive·ion' would fail to convey the actual pronunciation [dəsɛpʃən]. The predictability principle of Chomsky and Halle implies that phonetic variation should only be indicated where it is not predictable by general rules. Unfortunately, the task of establishing such a set of general rules, which we discuss in Section 7, is not at all straightforward. Instead, we assume the existence of an oracle (line 12 in Figure 1) which predicts the surface pronunciation of each phoneme found in the concatenation of the morphemic forms.

In our algorithm (lines 13–18), the default spelling of the word is composed of the representations of its constituent morphemes conjoined with a separator character. If the predicted pronunciation matches the actual surface phoneme, the "underlying" phoneme is preserved; otherwise, it is substituted by the surface phoneme. This modification helps to maintain the resulting word spellings reasonably close to the surface pronunciation.

For example, consider the word *sincerity*. Suppose that our algorithm derives the representations of the two underlying morphemes as 'sɪnsir' and 'ɪti'. If, given the input 'sɪnsir·ɪti', the predictor correctly generates the surface pronunciation [sɪnsɛrəti], we adopt the input as our final spelling. However, if the prediction is [sɪnsirəti] instead, our final spelling becomes 'sɪnsɛr·ɪti', in order to avoid a potentially misleading spelling. Since the second vowel was incorrectly predicted, we determine it to be unpredictable, and thus represent it with the surface phoneme, rather than the underlying one. The choice of the predictor affects only the details of the generated spellings.

4 Implementation

In this section, we describe the specific data and tools that we use in our implementation of the algorithm described in the previous section.

4.1 Data

For the implementation of our spelling generation algorithm, we require a lexicon that contains morphological segmentation of phonemic representations of words. Since we have been been unsuccessful in finding such a lexicon, we extract the necessary information from two different resources: the CELEX lexical database (Baayen et al., 1995), which includes morphological analysis of words, and the Combilex speech lexicon (Richmond et al., 2009), which contains high-quality phonemic transcriptions. After intersecting the lexicons, and pruning it of proper nouns, function words, duplicate forms, and multi-word entries, we are left with approximately 51,000 word-forms that are annotated both morphologically and phonemically.

In order to segment phonemic representations into constituent morphemes, we apply a high-precision phonetic aligner (Kondrak, 2000) to link letters and phonemes using the procedure described in (Dwyer and Kondrak, 2009). In rare cases where the phonetic aligner fails to produce an alignment, we back-off to alignment generated with *m2m-aligner* (Jiampojamarn et al., 2007), an unsupervised EM-based algorithm. We found that this approach worked better for our purposes than relying on the alignments provided in Combilex. We use the same approach to align variant phonemic representations of morphemes as described in Section 3.1.

The morphological information contained in CELEX is incomplete for our purposes, and requires further processing. For example, the word *amputate* is listed as monomorphemic, but in fact contains the suffix *-ate*. However, *amputee* is analyzed as

$$amputee = amputate - ate + ee.$$

This allows us to identify the stem as *amput*, which in turn implies the segmentations *amput·ee*, *amput·ate*, and *amput·at·ion*.

Another issue that requires special handling in CELEX involves recovering reduced geminate consonants. For example, the word *interrelate* is pronounced with a single [r] phoneme at the morpheme boundary. However, when segmenting the phoneme sequence, we need to include [r] both at the end of *inter-* and at the beginning of *relate*.

4.2 Predictor

The role of the predictor mentioned in Section 3.2 is performed by DIRECTL+ (Jiampojamarn et al., 2010), a publicly available discriminative string transducer. It takes as input a sequence of common morpheme representations, determined using the method described above, and produces the predicted word pronunciation. Since DIRECTL+ tends to make mistakes related to the unstressed vowel reduction phenomenon in English, we refrain from replacing the "underlying" phonemes with either [ə] or [ɪ].

An example derivation is shown in Table 3, where the *Underlying* string represents the input to DIRECTL+, *Predicted* is its output, *Surface* is the actual pronunciation, and *Respelling* is the spelling generated according to the algorithm in Figure 1.

Underlying:	foto	+	græf	+	ər	+	z
Predicted:	fotə		græf		ər		z
Surface:	fətɑ		grəf		ər		z
Respelling:	fotɑ	·	græf	·	ər	·	z

Table 3: Deriving the spelling of the word *photographers*.

Since DIRECTL+ requires a training set, we split the lexicon into two equal-size parts with no morpheme overlap, and induce two separate models on each set. Then we apply each model as the predictor on the other half of the lexicon. This approach simulates the human ability to guess pronunciation from the spelling. Jiampojamarn et al. (2010) report that DIRECTL+ achieves approximately 90% word accuracy on the letter-to-phoneme conversion task on the CELEX data.

5 Evaluation measures

In this section, we define our measures of phonemic transparency and morphemic consistency.

5.1 Phonemic transparency

Kominek and Black (2006) measure the complexity of spelling systems by calculating the average perplexity of phoneme emissions for each letter. The total perplexity is the sum of each letter's perplexity weighted by its unigram probability. Since their focus is on the task of inducing text-to-speech rules, they also incorporate letter context into this definition. Thus, a system that is completely explained by a set of rules has a perplexity of 1.

The way we compute perplexity differs in several aspects. Whereas Kominek and Black (2006) calculate the perplexity of single letters, we take as units substrings derived from many-to-many alignment, with the length limited to two characters. Some letter bigrams, such as ph, th, and ch, are typically pronounced as a single phoneme, while the letter x often corresponds to the phoneme bigram [ks]. By considering substrings we obtain a more realistic estimate of spelling perplexity.

We calculate the average orthographic perplexity using the standard formulation:

$$P_{ave} = \sum_c P_c e^{-\sum_i P_i log P_i} \quad (1)$$

System	*viscous*	*viscosity*
T.O.	viscous	viscosity
IPA	vɪskəs	vɪskɑsəti
M-CAT	viscous	viscous·ity
ALG	vɪskɑs	vɪskɑs·ɪti
SR	viscous	viscosity
SS	viscus	viscosity

Table 4: Example spellings according to various systems.

System	Orth	Phon	Morph
T.O.	2.32	2.10	96.11
IPA	1.00	1.00	93.94
M-CAT	2.51	2.36	100.00
ALG	1.33	1.72	98.90
SR	2.27	2.15	96.57
SS	1.60	1.72	94.72

Table 5: Orthographic, phonemic and morphemic optimality of spelling systems.

where P_c is the probability of a grapheme substring in the dictionary, and P_i is the probability that the grapheme substring is pronounced as the phoneme substring *i*. Note that this formulation is not contingent on any set of rules.

In a similar way, we compute the phonemic perplexity in the opposite direction, from phonemes to letters. The orthographic and the phonemic perplexity values quantify the transparency of a spelling system with respect to reading and writing, respectively.

5.2 Morphemic consistency

Little (2001) proposes to calculate the morphemic optimality of English spellings by computing the average percentage of "undisturbed letters" in the polymorphemic words with respect to the base form. For example, four of five letters of the base form *voice* are present in *voicing*, which translates into 80% optimal. The examples given in the paper allow us to interpret this measure as a function of edit distance normalized by the length of the base form.

We make three modifications to the original method. First, we compute the average over all words in the lexicon rather than over word sets, which would give disproportionate weight to words in smaller word sets. Second, we normalize edit distance by the number of phonemes in a word, rather than by the number of letters in a spelling, in order to avoid penalizing systems that use shorter spellings. Finally, we consider edit operations to apply to substrings aligned to substrings of phonemes, rather than to individual symbols. In this way, the maximum number of edit operations is equal to the number of phonemes. The modified measure yields a score between 0 and 100%, with the latter value representing morphemic optimality.

As an example, consider the word set consisting of six word-forms: *snip*, *snips*, *snipped*, *snipping*, *snippet*, and *snippets*. The first two words, which represent the base morpheme as *snip*, receive a perfect score of 1 for morphemic consistency. The remaining four words, which have the morpheme as *snipp*, obtain the score of 75% because one of the four phonemes is spelled differently from the base form. For free morphemes, the base form is simply the spelling of the morpheme, but for bound morphemes, we take the majority spelling of the morpheme.

6 Quantitative comparison

We compare the traditional English orthography (T.O.) to three hypothetical systems: phonemic transcription (IPA), morpheme concatenation (M-CAT), and the orthography generated by the algorithm described in Section 3 (ALG). In addition, we consider two proposals submitted to the English Spelling Society: a minimalist spelling reform (SR) of Gibbs (1984), and the more comprehensive SoundSpel (SS) of Rondthaler and Edward (1986). Table 4 lists the spellings of the words *viscous* and *viscosity* in various orthographies.

Table 5 shows the values of orthographic and phonemic transparency, as well as morphemic consistency for the evaluated spelling systems. By definition, phonemic transcription obtains the optimal transparency scores of 1, while simple morphological concatenation receives a perfect 100% in terms of morphemic consistency.

The results in Table 5 indicate that traditional orthography scores poorly according to all three measures. Its low orthographic and phonemic transparency is to be expected, but its low morphemic

Rule	Input	Output
e-deletion	voic**e**·ing	voicing
y-replacement	industr**y**·al	industr**i**al
k-insertion	panic·ing	panic**k**ing
e-insertion	church·s	church**e**s
consonant doubling	get·ing	ge**t**ting
f-voicing	kni**f**e·s	kni**v**es

Table 6: Common English spelling rules with examples.

Rule	Writing	Reading
e-deletion	98.8	67.1
y-replacement	93.5	95.8
k-insertion	100.0	1.0
e-insertion	100.0	98.7
consonant doubling	96.3	36.3
f-voicing	33.3	14.7

Table 7: Applicability of common spelling rules.

consistency is striking. Traditional orthography is not only far from optimality, but overall seems no more optimal than any other of the evaluated systems.

Searching for the explanation of this surprising result, we find that much of the morphemic score deduction can be attributed to small changes like dropping of the silent *e*, as in 'make' + 'ing' = 'making'. These types of inconsistencies counter-weigh the high marks that traditional orthography gets for maintaining consistent spelling in spite of unstressed vowel reductions.

The prevalence of silent e's in traditional orthography undeniably diminishes its morphemic consistency. Nor is the device necessary to represent the pronunciation of the preceding vowel; for example, SoundSpel has those words as 'maek' and 'maeking'. However, one can argue that such minor alterations should not be penalized because English speakers subconsciously take them into account while reading. In the next section, we describe an experiment in which we pre-process words with such orthographic rules, in order to determine how much they influence the optimality picture.

7 Spelling rules

Table 6 lists six common English spelling rules that affect letters at morpheme boundaries, of which the first five are included in the textbook account of Jurafsky and Martin (2009, page 63). We conducted an experiment to determine the applicability of these rules by computing how often they fired when triggered by the correct environment.[2] We tested the rules in both directions, with respect to both writing and reading applicability. Writing rules are applied to morphemes when they are in the correct environment. For example, the *k-insertion* rule fires if the morpheme ends in a c and the next morpheme begins with e or i, as in *panic·ing*. On the other hand, reading may involve recovering the morphemes from the surface forms. For example, if the stem ends in a tt and the affix begins with an i, the *consonant doubling* rule implies that the free form of the morpheme ends in a single t, as in *getting*.

The results in Table 7 show that the rules, with the exception of the *f-voicing* rule, have high applicability in writing. Most rules, however, cannot be trusted to recover the morpheme spellings from the surface form. For example, following the consonant doubling rule would cause the reader to incorrectly infer from the word *butted* that the spelling of the verb is *but*. This is significant considering that Chomsky and Halle define orthography as a system for *readers* (page 49).

Notwithstanding the unreliability of the spelling rules, we incorporate them into the computation of the morphemic consistency of the traditional orthography. We apply the rules from a reading perspective, but assume some morphemic knowledge of a reader. Whereas we consider a rule to misfire if it does not apply in the correct environment when calculating applicability, as in Table 7, when calculating morphemic consistency, we allow the rules to be more flexible. We consider a morpheme to match the prototype if either the observed form or the form modified by the spelling rule matches the prototype.

8 Discussion

Figure 2 shows a two-dimensional plot of orthographic perplexity vs. morphemic consistency. The (unattainable) optimality is represented by the lower

[2]The conditioning environments of the rules were implemented according to the guidelines provided at *http://www.phonicslessons.co.uk/englishspellingrules.html*.

left corner of the plot. The effect of accommodating the spelling rules within the traditional orthography is illustrated by an arrow, which indicates an increase in morphemic consistency from 96.11 to 98.90.

The ALG(L) system represents a version of the ALG system in which the IPA symbols are respelled using combinations of the 26 letters of the Roman alphabet, with the morpheme boundary symbol removed. This change, which is intended to make the comparison with the traditional orthography more interpretable, increases the orthographic perplexity from 1.33 to 1.58. Furthermore, we ensure that ALG(L) contains no homographs (which consitute 2.6% of the lexicon in ALG) by reverting to a traditional spelling of a morpheme if necessary. Since the respelling applies to all instances of that morpheme, it has no effect on the morphemic consistency, but results in a small increase of the orthographic perplexity to 1.61.

The plot in Figure 2 shows that, even after accounting for the orthographic rules, traditional orthography does not surpass the level of morphemic consistency of ALG. With the same writing script and no homographs, ALG(L) is less than half the distance from the orthographic optimality. On the other hand, neither of the spelling reform proposals is substantially better overall than the traditional orthography.

Inspection of the spellings generated by our algorithm reveals that it generally maintains consistent spellings of morphemes. In fact, it only makes a change from the underlying form in 3660 cases, or 7.2% of the words in the dictionary. Consider the morpheme *transcribe*, which is traditionally spelled as 'transcrip' in *transcription*. Even if we disregard the final 'e' by invoking the *e-deletion* spelling rule, the morphemic consistency in the traditional orthography is still violated by the 'b'/'p' alternation. Our predictor, however, considers this a predictable devoicing assimilation change, which occurs in a number of words, including *subscription* and *absorption*. Consequently, the spellings generated by the algorithm preserve the morpheme's 'b' ending in all words that contain it. In addition, the algorithm avoids spurious idiosyncrasies such as *four/forty*, which abound in traditional orthography.

The spellings generated by the algorithm are also much more phonemically transparent, particularly for vowels. Phonemically, ALG(L) improves on the traditional orthography mostly by making the spelling more predictable, For example, 'a' represents the phoneme [æ] in 91.7% of the cases in the generated spellings, as opposed to only 36.5% in traditional orthography.

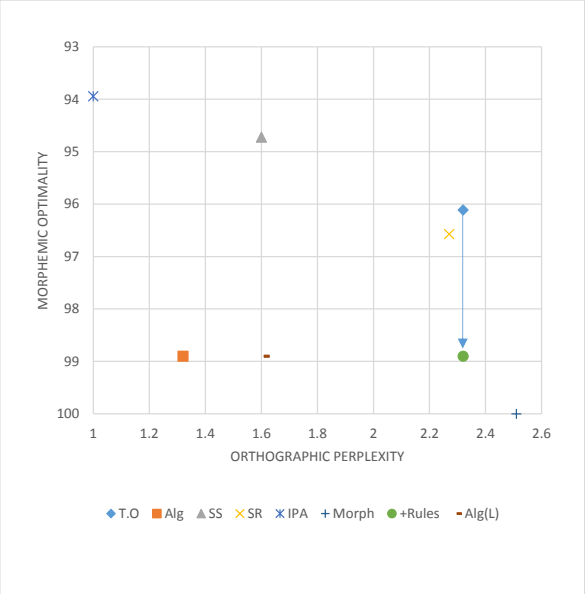

Figure 2: Morphemic and orthographic optimality of various spelling systems.

9 Conclusion

We have analyzed English orthography in terms of morphemic consistency and phonemic transparency. According to the strict interpretation of morphemic consistency, traditional orthography is closer to the level of a phonemic transcription than to that of a morphemic concatenation. Even if orthographic rules are assumed to operate cost-free as a preprocessing step, the orthographic perplexity of traditional orthography remains high.

While phonemic transparency and morphemic consistency are at odds with each other, we have provided a constructive proof that it is possible to create a spelling system for English that it is substantially closer to theoretical optimality than the traditional orthography, even when it is constrained by the traditional character set. This contradicts the claim that English orthography is near optimal.

Abstract

Analyzing public opinions towards products, services and social events is an important but challenging task. An accurate sentiment analyzer should take both lexicon-level information and corpus-level information into account. It also needs to exploit the domain-specific knowledge and utilize the common knowledge shared across domains. In addition, we want the algorithm being able to deal with missing labels and learning from incomplete sentiment lexicons. This paper presents a LCCT (**L**exicon-based and **C**orpus-based, **C**o-**T**raining) model for semi-supervised sentiment classification. The proposed method combines the idea of lexicon-based learning and corpus-based learning in a unified co-training framework. It is capable of incorporating both domain-specific and domain-independent knowledge. Extensive experiments show that it achieves very competitive classification accuracy, even with a small portion of labeled data. Comparing to state-of-the-art sentiment classification methods, the LCCT approach exhibits significantly better performances on a variety of datasets in both English and Chinese.

1 Introduction

Due to the popularity of opinion-rich resources (e.g., online review sites, forums, blogs and the microblogging websites), people express their opinions all over the Internet. Motivated by the demand of gleaning insights from such valuable data, a flurry of research devotes to the task of extracting people's opinions from online reviews. Such opinions could be expressed on products, services or policies, etc (Pang and Lee, 2008). Existing sentiment analysis approaches can be divided into two categories based on the source of information they use: the lexicon-based approach (Turney, 2002; Dave et al., 2003) and the corpus-based approach (Pang et al., 2002; Blitzer et al., 2007; Wan, 2009). The lexicon-based approach counts positive and negative terms in a review based on the sentiment dictionary and classifies the document as positive if it contains more positive terms than negative ones. On the contrary, the corpus-based approach uses supervised learning algorithms to train a sentiment classifier.

Further study (Kennedy and Inkpen, 2006; Andreevskaia and Bergler, 2008; Qiu et al., 2009) shows that corpus-based and lexicon-based approaches have complementary performances. Specifically, the corpus-based approach has high precision but low recall on positive instances, while the lexicon-based approach has high recall but low precision on positive instances. In fact, corpus-based approaches are over conservative in classifying instances as positive, because positive reviews usually contain many neutral statements. In contrast, the lexicon-based approaches tend to classify negative or neutral instances as positive when there are a few positive words appear in the document. It motivates us to develop a new approach that achieves good performance on both precision and recall evaluations.

Besides reviews on products and services, another rich source of opinion data are social reviews in forums, blogs and microblogging websites. Different from product reviews, the social reviews are not associated with numerical ratings, making it difficult to perform supervised classification. Since manual labeling is time consuming and expensive, it is

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 546–555,
Denver, Colorado, May 31 – June 5, 2015.

preferable to label a small portion of social reviews to perform semi-supervised learning, leveraging information from both labeled and unlabeled data.

In this paper, we propose a novel approach to handle the above two challenges. We presents the LCCT Model (**L**exicon-based and **C**orpus-based, **C**o-**T**raining Model), which treats the lexicon-based information and the corpus-based information as two views, and combine them via co-training (Blum and Mitchell, 1998). The algorithm naturally incorporates the framework of semi-supervised learning, as missing labels in each view can be estimated by the classifier trained from the other view. The proposed LCCT model exploits the complementary performance associated with the lexicon-based and the corpus-based approaches, taking the best of each side to improve the overall performance. We present a novel semi-supervised sentiment-aware LDA approach to build the lexicon-based classifier, which uses a minimal set of seed words (e.g., "good","happy" as positive seeds) as well as document sentiment labels to construct a domain-specific sentiment lexicon. This model reflects the domain-specific knowledge. We employ the stacked denoising auto-encoder (Vincent et al., 2008; Glorot et al., 2011) to build the corpus-based classifier. As Glorot et al. (Glorot et al., 2011) point out, the intermediate abstractions extracted in this way tend to reflect the domain-independent knowledge, unifying information across all domains. Finally, we use a co-training algorithm to combine the corpus-based and lexicon-based classifiers and to combine the domain-specific knowledge and the domain-independent knowledge.

The main contributions of our approach are three-folded. First, we propose a method that exploits both general domain-independent knowledge and specific domain-dependent knowledge, behaving like a human being when she analyzes the text. Second, we complement the lexicon-based approach and the corpus-based approach to overcome their respective classification biases. Third, our approach is capable of levering labeled and unlabeled data, unifying them into a semi-supervised learning framework. We conduct extensive experiments to verify the effectiveness of the proposed approach on real-world social reviews. The experiment results show that our model substantially outperforms the state-of-the-art methods in analyzing sentiments in online reviews.

2 Related Works

Sentiment analysis of natural language texts is an active research field. The papers by Pang and Lee (Pang and Lee, 2008) and Liu (Liu, 2012) describe most of the existing techniques for sentiment analysis and opinion mining. Sentiment analysis approaches can be categorized into lexicon-based approaches (Turney, 2002; Kennedy and Inkpen, 2006; Andreevskaia and Bergler, 2008) and corpus-based approaches (Pang et al., 2002; Blitzer et al., 2007; Wan, 2009). The lexicon-based approach uses a dictionary of opinion words (e.g., "good" and "bad") to identify the sentiment of a text. In contrast, the corpus-based approach can be seen as a statistical learning approach (Pang et al., 2002; Whitelaw et al., 2005; Wiebe and Riloff, 2005; Ye et al., 2009). The performance of corpus-based methods often degenerates when the labeled training data is insufficient.

As we have discussed earlier, corpus-based algorithms are overly conservative on positive reviews, while lexicon-based approaches are overly aggressive on positive reviews. There are several literature integrating both methods (Kennedy and Inkpen, 2006; Andreevskaia and Bergler, 2008; Qiu et al., 2009; Zhang et al., 2011). These methods require either a complete lexicon or a fully labeled corpus being available, which might not be true in practice. The method in this paper, in contrast, uses incomplete lexicon and partially labeled corpus as training examples.

On the other hand, there are semi-supervised methods in sentiment analysis which handle incomplete data (Wan, 2009; Dasgupta and Ng, 2009; Li et al., 2010; Zhou et al., 2010; Biyani et al., 2013). Nevertheless, none of them combines the lexicon-based and corpus-based approaches and thus they do not solve the bias problem in sentiment classification.

3 LCCT Model

In the LCCT model, we use a novel semi-supervised sentiment-aware LDA model to build the lexicon-based model. We use stacked denoising auto-encoder (Vincent et al., 2008; Glorot et al., 2011) to build the corpus-based model. Finally, a co-training algorithm is employed for semi-supervised

sentiment classification, and the two classifiers from corpus-based method and lexicon-based method are combined. The overall structure of the model is illustrated by Figure 1.

3.1 Lexicon-based Approach

For building the lexicon-based model, the key challenge is that a single word can carry multiple sentiment meanings in different domains, so that a general-purpose sentiment lexicon is less accurate than domain-specific lexicons. To solve this problem, we build a domain-specific sentiment lexicon by semi-supervised sentiment-aware LDA (ssLDA). The ssLDA method takes semi-supervised data as input.

3.1.1 Semi-supervised Sentiment-aware LDA

In this section, we describe how each word of the corpus is generated by the ssLDA model, then illustrate its inference method. Each document has three classes of topics: $K^{(p)}$ positive sentiment topics, $K^{(n)}$ negative sentiment topics, and $K^{(u)}$ neutral sentiment topics. Each document is a mixture of the three classes of topics. Each topic is associated with a multinomial distribution over words. To prevent conceptual confusion, we use a superscript "(p)" and "(n)" to indicate variables relating to positive and negative sentiment topics, and a superscript "(u)" to indicate variables relating to neutral sentiment topics. In addition, we assume that the vocabulary consists of V distinct words indexed by $\{1, \ldots, V\}$.

For each word w, there is a multinomial distribution determining which class of topics that w belongs to. This prior distribution is sampled from a Dirichlet distribution $\mathrm{Dir}(\lambda)$, where $\lambda = (\lambda^{(p)}, \lambda^{(n)}, \lambda^{(u)})$ is a vector of three scalars. For documents with different sentiment labels, we choose different values of λ, so that words in the document with a positive label has a higher probability belonging to positive topics, and vice versa. In the semi-supervised setting, a document usually doesn't have a sentiment label. In that case, the value of λ is equal to $(\frac{1}{3}, \frac{1}{3}, \frac{1}{3})$.

Given the class of topics, there is another multinomial distribution indicating the particular topic that the word belongs to. If it turns out that the word belongs to a positive sentiment class, then its topic distribution is drawn from a biased Dirichlet prior $\phi_w^{(p)} \sim \mathrm{Dir}(\beta_w^{(p)})$. The vector $\beta_w^{(p)} \in \mathbb{R}^V$ is constructed by

$$\beta_{w,k}^{(p)} := \gamma_0(1 - \omega_w) + \gamma_1\omega_w \quad \text{for } k \in \{1, \ldots, K\} \tag{1}$$

We set $\omega_w = 1$ if the word w is a positive seed word, otherwise, we set $\omega_w = 0$. The scalars γ_0 and γ_1 are hyperparameters. Intuitively, the biased prior enforces a positive seed word more probably drawn from a positive sentiment topic. The distributions $\phi_{\mathrm{w}}^{(\mathrm{n})} \sim \mathrm{Dir}(\beta_w^{(n)})$ and $\phi_w^{(u)} \sim \mathrm{Dir}(\beta_w^{(u)})$ for negative and neutral sentiment topics are similarly constructed. Once the topic is determined, the word is generated from a multinomial distribution that associates with the topic. We summarize the generative process of the ssLDA model as below:

1. For each word w in the vocabulary, draw the distributions of topics for three sentiment classes: $\phi_w^{(p)} \sim \mathrm{Dir}(\beta_w^{(p)})$, $\phi_w^{(n)} \sim \mathrm{Dir}(\beta_w^{(n)})$ and $\phi_w^{(u)} \sim \mathrm{Dir}(\beta_w^{(u)})$.

2. For each topic k, draw the distribution over words: $\theta_k^{(p)} \sim \mathrm{Dir}(\alpha)$, $\theta_k^{(n)} \sim \mathrm{Dir}(\alpha)$ and $\theta_k^{(u)} \sim \mathrm{Dir}(\alpha)$.

3. For each document in the corpus
   (a) Draw sentiment class distribution p from either $\mathrm{Dir}(\lambda^{(p)})$, $\mathrm{Dir}(\lambda^{(n)})$ or $\mathrm{Dir}(\lambda^{(u)})$ based on the document's sentiment label.
   (b) For each word in document, Draw sentiment class indicator $c \sim \mathrm{Mult}(p)$, then generate the word's topic z from $\mathrm{Mult}(\phi_w^{(c)})$, and generate the word w from $\mathrm{Mult}(\theta_z^{(c)})$.

Given hyper-parameters α, λ, and $\{\beta^{(s)}, \beta^{(n)}, \beta^{(u)}\}$, our goal is to estimate the latent variables in the ssLDA model. We present a collapsed Gibbs-sampling algorithm, which iteratively takes a word w from the corpus and samples the topic that the word belongs to. The reader may refer to (Yang et al., 2014) for a detailed derivation of the sampling procedure. Let the whole corpus excluding the current word be denoted by D. Let $n_{i,w}^{(p)}$ (or $n_{j,w}^{(n)}$, or $n_{k,w}^{(u)}$) indicate the number of occurrences of positive sentiment topic $i^{(p)}$ (or negative sentiment topic $j^{(n)}$, or neutral sentiment topic $k^{(u)}$) with word w in

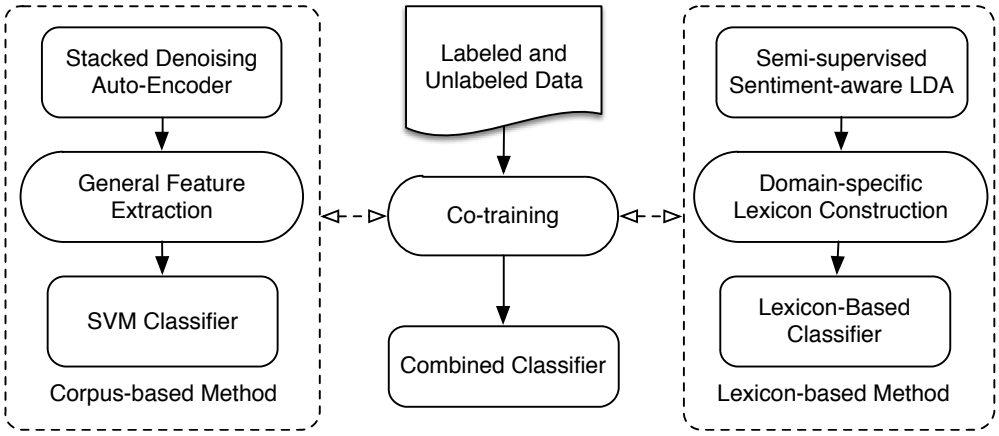

Figure 1: Algorithm Overview

the whole corpus. Let $m_i^{(p)}$ (or $m_j^{(n)}$, or $m_k^{(u)}$) indicate the number of occurrence of positive sentiment topic $i^{(p)}$ (or negative sentiment topic $j^{(n)}$, or neutral sentiment topic $k^{(u)}$) in the current document. Then, the posterior probability that the current word w belongs to a specific topic is presented as follow

$$\Pr\left(z = i^{(p)}|D\right) \propto (\lambda^{(p)} + \sum_{i=1}^{K^{(p)}} m_i^{(p)}) \cdot \frac{\alpha + m_i^{(p)}}{K^{(p)}\alpha + \sum_{i'=1}^{K^{(p)}} m_{i'}^{(p)}} \cdot \frac{\beta_{i,w}^{(p)} + n_{i,w}^{(p)}}{\sum_{w'=1}^{V}\left(\beta_{i,w'}^{(p)} + n_{i,w'}^{(p)}\right)} \quad (2)$$

$$\Pr\left(z = j^{(n)}|D\right) \propto (\lambda^{(p)} + \sum_{i=1}^{K^{(p)}} m_i^{(p)}) \cdot \frac{\alpha + m_j^{(n)}}{K^{(n)}\alpha + \sum_{j'=1}^{K^{(n)}} m_{j'}^{(n)}} \cdot \frac{\beta_{j,w}^{(n)} + n_{i,w}^{(n)}}{\sum_{w'=1}^{V}\left(\beta_{j,w'}^{(n)} + n_{j,w'}^{(n)}\right)} \quad (3)$$

$$\Pr\left(z = k^{(u)}|D\right) \propto (\lambda^{(p)} + \sum_{i=1}^{K^{(p)}} m_i^{(p)}) \cdot \frac{\alpha + m_k^{(u)}}{K^{(u)}\alpha + \sum_{k'=1}^{K^{(u)}} m_{u'}^{(n)}} \cdot \frac{\beta_{k,w}^{(u)} + n_{k,w}^{(u)}}{\sum_{w'=1}^{V}\left(\beta_{k,w'}^{(u)} + n_{k,w'}^{(u)}\right)} \quad (4)$$

By equations (2), (3), and (4), we can sample the topic z for each word. In the Gibbs sampling procedure, we only need to maintain the counters $n^{(p)}$, $n^{(n)}$, $n^{(u)}$, $m^{(p)}$, $m^{(n)}$ and $m^{(u)}$, which takes $O(1)$ time to update for each iteration.

3.1.2 Lexicon Construction and Sentiment Classification

Once we obtain the topic of each word, we obtain the value of hidden variables $p^{(c)}, \theta^{(c)}, \phi^{(c)}$, where $c \in \{p, n, u\}$. The goal is to use these values to construct a sentiment lexicon, which assigns sentiment scores to each word. In particular, we need the probability that each word w appears in a certain sentiment class, i.e. we want to calculate $\Pr(c \in \{p, n, u\}|w)$ for the sentiment indicator c. We use $\gamma_w^{(p)}$, $\gamma_w^{(n)}$, $\gamma_w^{(u)}$ to represent these probabilities. By the ssLDA's model specification, we define

$$\gamma_w^{(p)} := \Pr(c = p|w) \propto p^{(p)} \cdot \sum_{i=1}^{K^{(p)}} \theta_{i,w}^{(p)} \phi_{w,i}^{(p)} \quad (5)$$

$$\gamma_w^{(n)} := \Pr(c = n|w) \propto p^{(n)} \cdot \sum_{j=1}^{K^{(n)}} \theta_{i,w}^{(n)} \phi_{w,j}^{(n)} \quad (6)$$

$$\gamma_w^{(u)} := \Pr(c = u|w) \propto p^{(u)} \cdot \sum_{k=1}^{K^{(u)}} \theta_{i,w}^{(u)} \phi_{w,k}^{(u)} \quad (7)$$

We construct the sentiment lexicon for each word w by comparing $\gamma_w^{(p)}$, $\gamma_w^{(n)}$ and $\gamma_w^{(u)}$. If $\gamma_w^{(p)}$ is the greatest value, then the word w is considered to convey positive sentiment, and is added to the positive sentiment lexicon with weight $\gamma_w^{(p)}$. If $\phi_{1,w}^{(s)}$ is the greatest, then the word w is added to the negative sentiment lexicon with weight $-\gamma_w^{(n)}$. Otherwise, the word w is considered neutral and not included in the sentiment lexicon.

It remains to classify the sentiment for each document. We aggregate the weights for each word, so that the document is classified as "positive" if the accumulated weight is larger than zero; Otherwise,

it is classified as "negative". The proposed model is a semi-supervised method since it is capable of processing documents without the sentiment label. This property makes the proposed method suitable for co-training.

3.2 Corpus-based Method

The deep learning approach, especially Stacked Denoising Auto-encoders (SDA), has been shown highly beneficial for extracting domain-independent knowledge (Glorot et al., 2011). Thus, we use SDA to construct the corpus-based sentiment classifier. The stacked autoencoder method was introduced by Rumelhart, Hinton and Williams (Rumelhart et al., 1985) and its denoising variant was proposed by Vincent et al. (Vincent et al., 2010). Recently, it has become an essential building block in deep learning architectures. A basic denoising autoencoder consists of an input layer, a hidden layer and an output layer. The procedure can be interpreted into two phases, i.e., encode and decode. In the encoding phrase, an encoder function is employed to map input data into a feature vector h. For each sample x from input dataset $\{x^{(1)}, \ldots, x^{(N)}\}$, we have

$$h = f(U^T(x + \epsilon) + b) \tag{8}$$

where $f(x)$ is sigmoid activation function, U is the weight matrix between input layer and hidden layer, b_h is the bias of each input layer neuron and ϵ is a random Gaussian noise. In the decoding phrase, a decoder function is deployed to remap the feature vector in the feature space back to the input space, producing a reconstruction $\hat{x}$. The decoder function takes the following form

$$\hat{x} = f(V^T h + b') \tag{9}$$

where $f(x)$ is also a sigmoid function, V is the weight matrix between the hidden layer and the output layer, and b' is the bias. The parameters of the SDA models, namely $\theta = \{U, V, b, b'\}$, are learned by minimizing the reconstruction error $L(x, \hat{x})$ over all training instances:

$$J(\theta) = \sum_{x^{(t)}} L(x^{(t)}, \hat{x}^{(t)}) \tag{10}$$

where $L(\cdot, \cdot)$ is measure of discrepancy. Popular choices of L include squared error and Kullback-Liebler divergence. By iteratively adding autoencoders on top of a trained denoising autoencoder, we obtain the stacked denoising autoencoder (SDA). Once trained, their parameters can be used to initialize a supervised learning algorithm. In this paper, SDA is learnt in a greedy layer-wise fashion using stochastic gradient descent. For the first layer, the decoder is activated by a sigmoid function, and the Kullback-Liebler divergence is used as the reconstruction error. For the remaining layers, we use the softplus function for activation. After the SDA parameters are trained (on both labeled and unlabeled data) and the high-level representation of each data instance is obtained, a SVM classifier is employed using the resulting representation (of labeled data) to train a sentiment classifier.

3.3 Combining two Methods with Co-training

Algorithm 1 Co-training with corpus-based and lexicon-based methods

- Inputs: labeled training data $\boldsymbol{L}$, unlabeled training data $\boldsymbol{U}$
- Create a pool $\boldsymbol{U}'$ of examples by choosing u unlabeled examples at random, then loop for k iterations
  - use $\boldsymbol{L}$ and $\boldsymbol{U}$ to train a corpus-based classifier f_1, then use f_1 to label samples from $\boldsymbol{U}'$. Let $\boldsymbol{A}_1$ be the set of p positive and n negative most confidently labeled examples.
  - use $\boldsymbol{L}$ and $\boldsymbol{U}$ to train a lexicon-based classifier f_2, then use f_2 to label samples from $\boldsymbol{U}'$. Let $\boldsymbol{A}_2$ be the set of p positive and n negative most confidently labeled examples.
  - Add f_1 and f_2 to the set $\boldsymbol{C}$ of classifiers and add the self-labeled examples $\boldsymbol{A}_1 \cup \boldsymbol{A}_2$ to the labeled dataset $\boldsymbol{L}$. Randomly choose $2p + 2n$ examples from $\boldsymbol{U}$ to replenish $\boldsymbol{U}'$
- For testing, run all classifiers in $\boldsymbol{C}$ and output the majority vote.

We employ a variant of co-training algorithm to train the classifier with a small number of labeled data and a large number of unlabeled data. The co-training approach is well known for semi-supervised approach (Blum and Mitchell, 1998). For our problem, the two views of co-training are lexicon-based method (domain-specific knowledge) and corpus-based method (domain-independent knowledge). Initially, both classifiers are trained with the partially available labels, as described by the above two subsections. Then, we use one of the two classifiers to label the unlabeled documents, adding its labels to

the pool of labeled data, re-training the other classifier using the new labeled data. The procedure is performed iteratively. After a sufficient number of iterations, we obtain a set of classifiers and we combine them using a majority-voting scheme to predict the sentiment label for test data. The details of the algorithm are summarized in Algorithm 1.

4 Experiments

In this section, we compare the proposed LCCT model with state-of-the-art methods in sentiment classification. The experiment demonstrates the superior performance of our approach.

4.1 Datasets

We conduct experiments on English and Chinese reviews from three datasets. In this subsection, we describe the datasets.

Movie Review (MR) dataset in English The movie reviews are selected if the rating was stars or a numerical score. In this paper, we use the Movie Review dataset containing 1000 positive examples and 1000 negative examples (Pang and Lee, 2004). Positive labels were assigned to reviews that had a rating above 3.5 stars and negative labels were assigned to the rest (Pang and Lee, 2004).

SemEval-2013 (SemEval) dataset in English This dataset is constructed for the Twitter sentiment analysis task (Task 2) in the Semantic Evaluation of Systems challenge (SemEval-2013). All the tweets were manually annotated by 5 Amazon Mechanical Turk workers with negative, positive and neutral labels. SemEval contains 13,975 tweets with 2,186 negative, 6,440 neutrals and 5,349 positives tweets. We collect the 2,186 negative tweets and 5,349 positive tweets as the training data.

COAE-2009 (COAE) dataset in Chinese This dataset is provided by COAE 2009 [1] (Task 4). The corpus consists of 39,976 documents and 50 topics. The topics cover education, entertainment, finance, computer, etc. In this paper, we select the 2202 negative and 1248 positive documents as our dataset.

In all experiments, data preprocessing is performed. For English dataset, the texts are first tokenized using the natural language toolkit NLTK[2].

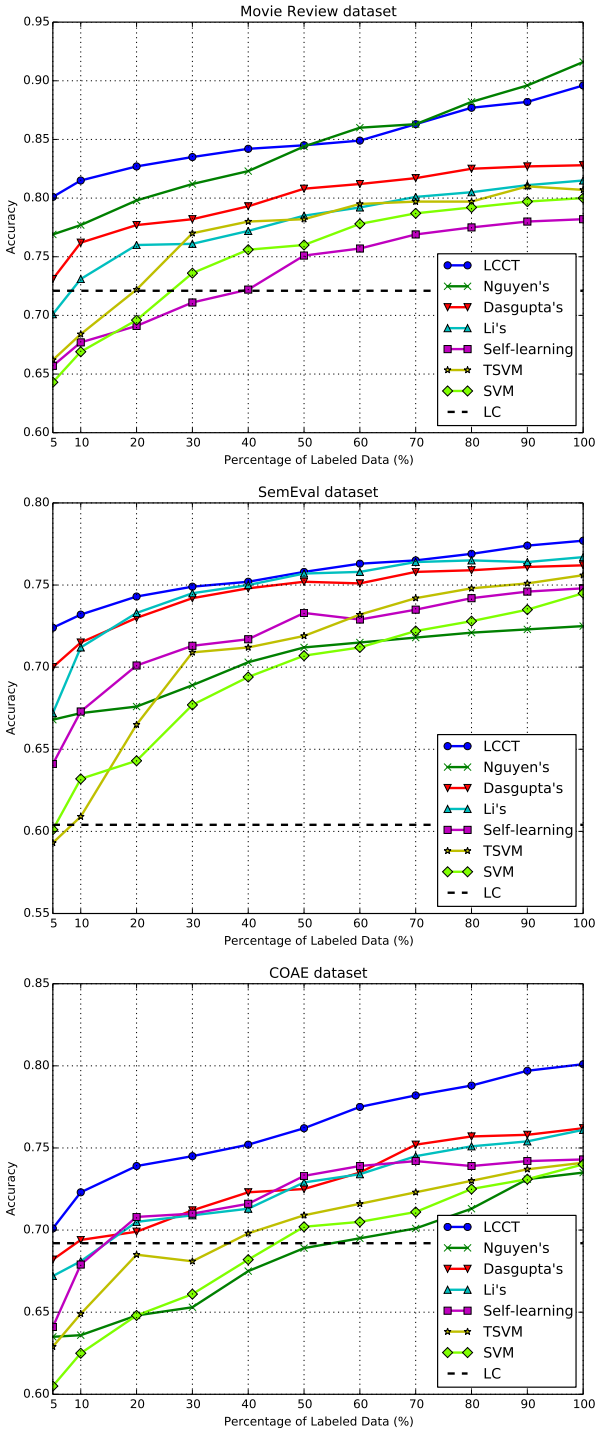

Figure 2: Comparing classification accuracy by varying the percentage of labeled data from 5% to 100%. The LCCT model is robust to incomplete data.

[1] http://ir-china.org.cn/coae2009.html
[2] http://www.nltk.org

Then, we remove non-alphabet characters, numbers, pronoun, punctuation and stop words from the text. Finally, the WordNet stemmer[3] is applied to reduce the vocabulary size and settle the issue of data sparseness. For Chinese dataset, we first perform Chinese word segmentation with a popular Chinese auto-segmentation system ICTCLAS[4]. Then, the words about time, numeral words, pronoun and punctuation are removed as they are unrelated to the sentiment analysis task.

4.2 Implementation Details

We specify the hyper-parameters we use for the experiments. For all datasets, we choose $\alpha = 0.5$, $\lambda^{(p)} = (0.95, 0.25, 0.4)$, $\lambda^{(n)} = (0.25, 0.95, 0.4)$, $\lambda^{(u)} = (0.6, 0.6, 0.4)$ and $(\gamma_0, \gamma_1) = (0.25, 0.75)$. We use cross-validation to set the number of topics on datasets MR, SemEval and COAE as 20, 10 and 20, respectively. The seed words used to construct English and Chinese lexicons are the same as in previous literatures (Xie and Li, 2012) and (Yang et al., 2014). For the corpus-based method, each document is transformed into binary vectors which encodes the presence/absence of the terms. The autoencoder is constructed with 500 input neurons and 200 hidden neurons. Each autoencoder is trained by back propagation with 400 iterations.

For all datasets, we set the iteration number of co-training to be $k = 50$. Other parameters of co-training are chosen by cross-validation: u is set to be 10% of all unlabeled data, the sum of p and n are 0.8% of all unlabeled data, while their ratio are determined by the ratio of positive and negative samples in labeled training data.

4.3 Baseline Methods

In this paper, we evaluate and compare our approach with an unsupervised method, two supervised methods and a variety of semi-supervised methods:

SVM: 5000 words with greatest information gain are chosen as features. In our experiment, we use the LibLinear[5] implementation of SVM.

Lexical Classifier (LC): This method calculates the number of positive words and negative words contained in the Opinion Lexicon (Hu and Liu, 2004) for English texts or the HowNet[6] lexicon for Chinese texts. If the positive sentiment words are more than negative words, then the document is classified as positive, and vice versa.

Self-learning: Following the idea of (Zhu, 2006), this method uses the unlabeled data in a bootstrapping way. The SVM classifier is used to select most confident unlabeled samples in each iteration.

Transductive SVM (TSVM) : Following the idea of (Joachims, 1999), this method seeks the largest separation between labeled and unlabeled data through regularization. We implement it with the SVM-light toolkit [7].

Dasgupta's method: This is a popular semi-supervised approach to automatic sentiment classification proposed by Dasgupta and Ng (Dasgupta and Ng, 2009). The unambiguous reviews are first mined using spectral techniques, then classified by a combination of active learning, transductive learning, and ensemble learning.

Li's method: This method is proposed in (Li et al., 2010). An unsupervised bootstrapping method is adopted to automatically split documents into personal and impersonal views. Then, two views are combined by an ensemble of individual classifier generated by each view. The co-training algorithm is utilized to incorporate unlabeled data.

Nguyen's method: This method is proposed in (Nguyen et al., 2014), which achieves the state-of-the-art results in supervised sentiment classification. We follow all the settings in (Nguyen et al., 2014). For the document with no associated score, we predict a score for the document as the values of the rating-based features using a regression model learned from SRA14[8] dataset.

4.4 Experiment Results

For each dataset, we use 80% instances as the training data and the remaining are used for testing. To test the performance of semi-supervised learning, we randomly select 10% of the training instances as labeled data and treat the remaining as unlabeled. For fair comparison, the fully supervised SVM and Nguyen's method use the 10% labeled data for training.

Dataset	SVM	LC	Self-learning	TSVM	Dasgupta's	Li's	Nguyen's	LCCT
MR	0.669	0.721	0.677	0.684	0.762	0.731	0.769	0.815
SemEval	0.632	0.604	0.675	0.609	0.735	0.702	0.652	0.775
COAE	0.625	0.706	0.679	0.649	0.709	0.692	0.642	0.713

Table 1: Comparing classification accuracy with 10% labeled data. The LCCT model performs significantly better

We summarize the experiment results in Table 1. According to Table 1, the proposed LCCT method substantially and consistently outperforms other methods on all the three datasets. This verifies the effectiveness of the proposed approach and demonstrates its advantage in semi-supervised sentiment analysis where reviews are from different domains and different language. For example, the overall accuracy of our algorithm is 5.3% higher than Dasgupta's method and 13.1% higher than TSVM on Movie Reviews dataset. On other datasets, we observe the similar results. To verify that unlabeled data improves the performance, we compare the SVM and Nguyen's classifier trained on 10% of the labeled data with other semi-supervised classifiers. Table 1 shows that the semi-supervised learning methods greatly benefit from using unlabeled data, especially on the Movie Reviews and on the SemEval dataset. Surprisingly, on the COAE dataset, lexicon-based method turns out to outperform SVM, self-learning and TSVM. The reason might be that the topics in the COAE dataset are pretty diverse. Without sufficient labeled data or prior knowledge such as sentiment lexicon, the corpus-based classifiers tend to separate the documents into topical sub-clusters as opposed to sentiment classes.

To understand the performance of our algorithm with respect to different portions of labeled data, we compare our algorithm with baseline methods by varying the percentage of labeled data from 5% to 100%. Figure 2 shows that our approach is robust and achieves excellent performance on different labeling percentages. As expected, having more labeled data improves the performance. The LCCT method achieves a relative high accuracy with 10% of the reviews labeled, better than SVM, TSVM and Self-learning with 100% of the reviews labeled. On the other hand, when all the training data are labeled, LCCT is still significantly more accurate than all the competitors except Nguyen's method. Although, the accuracy of Nguyen's method is slightly better than ours on Movie Reviews dataset, it dosen't perform well on SemEval and COAE datasets since the rating-based features learned from score-associated product reviews cannot significantly benefit the social reviews in forums and blogs, etc. The main advantage of our model comes from its capability of exploiting the complementary information from the lexicon-based approach and the corpus-based approach. Another reason for the effectiveness of our approach is the way that we combine the domain-independent knowledge and the domain-specific knowledge.

It is known that both the corpus-based approach and the lexicon-based approach have classification biases (Kennedy and Inkpen, 2006; Andreevskaia and Bergler, 2008; Qiu et al., 2009). To evaluate the effectiveness of our algorithm in reducing the bias, we compare it with the classifier that only uses one view of the LCCT model: either using the corpus-based view or using the lexicon-based view. The comparison is conducted on the Movie Review dataset. As Table 2 shows, our algorithm achieves good performance on both precision and recall. In contrast, the baseline methods either have high precision but low recall, or have high recall but low precision. The experiment result suggests that combining the two views is essential in eliminating the classification bias.

Data	Corpus-based		Lexicon-based		LCCT	
	Prec.	Rec.	Prec.	Rec.	Prec.	Rec.
MR pos.	0.92	0.79	0.67	0.86	0.90	0.86
MR neg.	0.78	0.90	0.80	0.58	0.88	0.89

Table 2: Precision and recall on Movie reviews

5 Conclusions

We have proposed the LCCT model for semi-supervised sentiment classification, combining the idea of lexicon-based learning and corpus-based learning in a unified co-training framework. It is capable of incorporating both domain-specific and domain-independent knowledge. Comparing to state-of-the-art sentiment classification methods, the LCCT approach exhibits significantly better performances on a variety of datasets in both English and Chinese, even with a small portion of labeled data.

Multiview LSA: Representation Learning via Generalized CCA

Pushpendre Rastogi[1] and **Benjamin Van Durme**[1,2] and **Raman Arora**[1]

Johns Hopkins University

Abstract

Multiview LSA (MVLSA) is a generalization of Latent Semantic Analysis (LSA) that supports the fusion of arbitrary views of data and relies on Generalized Canonical Correlation Analysis (GCCA). We present an algorithm for fast approximate computation of GCCA, which when coupled with methods for handling missing values, is general enough to approximate some recent algorithms for inducing vector representations of words. Experiments across a comprehensive collection of test-sets show our approach to be competitive with the state of the art.

1 Introduction

Winograd (1972) wrote that: *"Two sentences are paraphrases if they produce the same representation in the internal formalism for meaning"*. This intuition is made soft in vector-space models (Turney and Pantel, 2010), where we say that expressions in language are paraphrases if their representations are *close* under some distance measure.

One of the earliest linguistic vector space models was Latent Semantic Analysis (LSA). LSA has been successfully used for Information Retrieval but it is limited in its reliance on a single matrix, or *view*, of term co-occurrences. Here we address the single-view limitation of LSA by demonstrating that the framework of Generalized Canonical Correlation Analysis (GCCA) can be used to perform Multiview LSA (MVLSA). This approach allows for the use of an arbitrary number of views in the induction process, including embeddings induced using other algorithms. We also present a fast approximate method for performing GCCA and approximately recover the objective of (Pennington et al., 2014) while accounting for missing values.

Our experiments show that MVLSA is competitive with state of the art approached for inducing vector representations of words and phrases. As a methodological aside, we discuss the (in-)significance of conclusions being drawn from comparisons done on small sized datasets.

2 Motivation

LSA is an application of Principal Component Analysis (PCA) to a term-document cooccurrence matrix. The principal directions found by PCA form the basis of the vector-space in which to represent the input terms (Landauer and Dumais, 1997). A drawback of PCA is that it can leverage only a single source of data and it is sensitive to scaling.

An arguably better approach to representation learning is Canonical Correlation Analysis (CCA) that induces representations that are maximally *correlated* across two views, allowing the utilization of two distinct sources of data. While an improvement over PCA, being limited to only two views is unfortunate in light of the fact that many sources of data (perspectives) are frequently available in practice. In such cases it is natural to extend CCA's original objective of maximizing correlation between two views by maximizing some measure of the matrix Φ that contains all the pairwise correlations between linear projections of the *covariates*. This is how Generalized Canonical Correlation Analysis (GCCA) was first derived by Horst (1961). Recently these intuitive ideas about benefits of leveraging multiple sources of data have received strong theoretical backing due to the work by Sridharan and

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 556–566,
Denver, Colorado, May 31 – June 5, 2015.

Kakade (2008) who showed that learning with multiple views is beneficial since it reduces the complexity of the learning problem by restricting the search space. Recent work by Anandkumar et al. (2014) showed that at least three views are necessary for recovering hidden variable models.

Note that there exist different variants of GCCA depending on the measure of Φ that we choose to maximize. Kettenring (1971) enumerated a variety of possible measures, such as the spectral-norm of Φ. Kettenring noted that maximizing this spectral-norm is equivalent to finding linear projections of the *covariates* that are most amenable to rank-one PCA, or that can be best explained by a single term factor model. This variant was named *MAX-VAR GCCA* and was shown to be equivalent to a proposal by Carroll (1968), which searched for an auxiliary orthogonal representation G that was maximally correlated to the linear projections of the covariates. Carroll's objective targets the intuition that representations leveraging multiple views should correlate with all provided views as much as possible.

3 Proposed Method: MVLSA

Let $X_j \in \mathbb{R}^{N \times d_j}\ \forall j \in [1, \ldots, J]$ be the mean centered matrix containing data from view j such that row i of X_j contains the information for word w_i. Let the number of words in the vocabulary be N and number of contexts (columns in X_j) be d_j. Following standard notation (Hastie et al., 2009) we call $X_j^\top X_j$ the scatter matrix and $X_j(X_j^\top X_j)^{-1}X_j^\top$ the projection matrix.

The objective of *MAX-VAR GCCA* can be written as the following optimization problem: Find $G \in \mathbb{R}^{N \times r}$ and $U_j \in \mathbb{R}^{d_j \times r}$ that solve:

$$\begin{aligned} &\underset{G,U_j}{\arg\min} \sum_{j=1}^{J} \left\| G - X_j U_j \right\|_F^2 \\ &\text{subject to } G^\top G = I. \end{aligned} \tag{1}$$

The matrix G that solves problem (1) is our vector representation of the vocabulary. Finding G reduces to spectral decomposition of sum of projection matrices of different views: Define

$$P_j = X_j(X_j^\top X_j)^{-1}X_j^\top, \tag{2}$$

$$M = \sum_{j=1}^{J} P_j. \tag{3}$$

Then, for some positive diagonal matrix Λ, G and U_j satisfy:

$$MG = G\Lambda, \tag{4}$$

$$U_j = \left(X_j^\top X_j\right)^{-1} X_j^\top G. \tag{5}$$

Computationally storing $P_j \in \mathbb{R}^{N \times N}$ is problematic owing to memory constraints. Further, the scatter matrices may be non-singular leading to an ill-posed procedure. We now describe a novel scalable GCCA with ℓ_2-regularization to address these issues.

Approximate Regularized GCCA: GCCA can be regularized by adding $r_j I$ to scatter matrix $X_j^\top X_j$ before doing the inversion where r_j is a small constant e.g. 10^{-8}. Projection matrices in (2) and (3) can then be written as

$$\widetilde{P}_j = X_j(X_j^\top X_j + r_j I)^{-1}X_j^\top, \tag{6}$$

$$M = \sum_{j=1}^{J} \widetilde{P}_j. \tag{7}$$

Next, to scale up GCCA to large datasets, we first form a rank-m approximation of projection matrices (Arora and Livescu, 2012) and then extend it to an eigendecomposition for M following ideas by Savostyanov (2014). Consider the rank-m SVD of X_j:

$$X_j = A_j S_j B_j^\top,$$

where $S_j \in \mathbb{R}^{m \times m}$ is the diagonal matrix with m-largest singular values of X_j and $A_j \in \mathbb{R}^{N \times m}$ and $B_j \in \mathbb{R}^{m \times d_j}$ are the corresponding left and right singular vectors. Given this SVD, write the j^{th} projection matrix as

$$\begin{aligned} \widetilde{P}_j &= A_j S_j^\top (r_j I + S_j S_j^\top)^{-1} S_j A_j^\top, \\ &= A_j T_j T_j^\top A_j^\top, \end{aligned}$$

where $T_j \in \mathbb{R}^{m \times m}$ is a diagonal matrix such that $T_j T_j^\top = S_j^\top (r_j I + S_j S_j^\top)^{-1} S_j$. Finally, we note

that the sum of projection matrices can be expressed as $M = \tilde{M}\tilde{M}^\top$ where

$$\tilde{M} = [A_1 T_1 \dots A_J T_J] \in \mathbb{R}^{N \times mJ}.$$

Therefore, eigenvectors of matrix M, i.e. the matrix G that we are interested in finding, are the left singular vectors of $\tilde{M}$, i.e. $\tilde{M} = GSV^\top$. These left singular vectors can be computed by using Incremental PCA (Brand, 2002) since $\tilde{M}$ may be too large to fit in memory.

3.1 Computing SVD of mean centered X_j

Recall that we assumed X_j to be mean centered matrices. Let $Z_j \in \mathbb{R}^{N \times d_j}$ be sparse matrices containing mean-uncentered cooccurrence counts. Let $f_j = n_j \circ t_j$ be the preprocessing function that we apply to Z_j:

$$Y_j = f_j(Z_j), \tag{8}$$
$$X_j = Y_j - 1(1^\top Y_j). \tag{9}$$

In order to compute the SVD of mean centered matrices X_j we first compute the partial SVD of uncentered matrix Y_j and then update it (Brand (2006) provides details). We experimented with representations created from the uncentered matrices Y_j and found that they performed as well as the mean centered versions but we would not mention them further since it is computationally efficient to follow the principled approach. We note, however, that even the method of mean-centering the SVD produces an approximation.

3.2 Handling missing rows across views

With real data it may happen that a term was not observed in a view at all. A large number of missing rows can corrupt the learnt representations since the rows in the left singular matrix become zero. To counter this problem we adopt a variant of the "missing-data passive" algorithm from Van De Velden and Bijmolt (2006) who modified the GCCA objective to counter the problem of missing rows.[1] The objective now becomes:

$$\begin{aligned} &\arg\min_{G,U_j} \sum_{j=1}^{J} \left\| K_j(G - X_j U_j) \right\|_F^2 \\ &\text{subject to } G^\top G = I, \end{aligned} \tag{10}$$

where $[K_j]_{ii} = 1$ if row i of view j is observed and zero otherwise. Essentially K_j is a diagonal row-selection matrix which ensures that we optimize our representations only on the observed rows. Note that $X_j = K_j X_j$ since the rows that K_j removed were already zero. Let, $K = \sum_j K_j$ then the optima of the objective can be computed by modifying equation (7) as:

$$M = K^{-\frac{1}{2}} (\sum_{j=1}^{J} P_j) K^{-\frac{1}{2}}. \tag{11}$$

Again, if we regularize and approximate the GCCA solution we get G as the left singular vectors of $K^{-\frac{1}{2}}\tilde{M}$. We mean center the matrices using only the observed rows.

Also note that other heuristic weighting schemes could be used here. For example if we modify our objective as follows then we would approximately recover the objective of Pennington et al. (2014):

$$\begin{aligned} &\underset{G,U_j}{\text{minimize:}} \quad \sum_{j=1}^{J} \left\| W_j K_j(G - X_j U_j) \right\|_F^2 \\ &\text{subject to:} \quad G^\top G = I \end{aligned} \tag{12}$$

where

$$[W_j]_{ii} = \left(\frac{w_i}{w_{\max}} \right)^{\frac{3}{4}} \text{ if } w_i < w_{\max} \text{ else } 1,$$
$$\text{and } w_i = \sum_k [X_j]_{ik}.$$

4 Data

Training Data We used the English portion of the *Polyglot* Wikipedia dataset released by Al-Rfou et

[1] A more recent effort, by van de Velden and Takane (2012), describes newer iterative and non-iterative (Test-Equating Method) approaches for handling missing values. It is possible that using one of those methods could improve performance.

al. (2013) to create 15 *irredundant* views of cooccurrence statistics where element $[z]_{ij}$ of view Z_k represents that number of times word w_j occurred k words behind w_i. We selected the top 500K words by occurrence to create our vocabulary for the rest of the paper.

We extracted cooccurrence statistics from a large bitext corpus that was made by combining a number of parallel bilingual corpora as part of the ParaPhrase DataBase (PPDB) project: Table 1 gives a summary, Ganitkevitch et al. (2013) provides further details. Element $[z]_{ij}$ of the *bitext* matrix represents the number of times English word w_i was automatically aligned to the foreign word w_j.

We also used the dependency relations in the *Annotated Gigaword Corpus* (Napoles et al., 2012) to create 21 views[2] where element $[z]_{ij}$ of view Z_d represents the number of times word w_j occurred as the governor of word w_i under dependency relation d.

We combined the knowledge of paraphrases present in FrameNet and PPDB by using the dataset created by Rastogi and Van Durme (2014) to construct a *FrameNet* view. Element $[z]_{ij}$ of the *FrameNet* view represents whether word w_i was present in frame f_j. Similarly we combined the knowledge of morphology present in the *CatVar* database released by Habash and Dorr (2003) and *morpha* released by Minnen et al. (2001) along with *morphy* that is a part of WordNet. The morphological views and the frame semantic views were especially sparse with densities of 0.0003% and 0.03%. While the approach allows for an arbitrary number of distinct sources of semantic information, such as going further to include cooccurrence in WordNet synsets, we considered the described views to be representative, with further improvements possible as future work.

Test Data We evaluated the representations on the word similarity datasets listed in Table 2. The first 10 datasets in Table 2 were annotated with different rubrics and rated on different scales. But broadly they all contain human judgements about how similar two words are. The "AN-SYN" and "AN-SEM" datasets contain 4-tuples of analogous words and the task is to predict the missing word given the first three. Both of these are open vocabulary tasks while TOEFL is a closed vocabulary task.

4.1 Significance of comparison

While surveying the literature we found that performance on word similarity datasets is typically reported in terms of the Spearman correlation between the gold ratings and the cosine distance between normalized embeddings. However researchers do not report measures of significance of the difference between the Spearman Correlations even for comparisons on small evaluation sets.[3] This motivated our defining a method for calculating the *Minimum Required Difference for Significance (MRDS)*.

Minimum Required Difference for Significance (MRDS): Imagine two lists of ratings over the same

[3]For example, the comparative difference by competing algorithms reported by Faruqui et al. (2014) could not be significant for the Word Similarity test set released by Finkelstein et al. (2001), even if we assumed a correlation between competing methods as high as 0.9, with a p value threshold of 0.05. Similar such comparisons on small datasets are performed by Hill et al. (2014a).

Table 2: List of test datasets used. The columns headed $\sigma^r_{p_0}$ contain *MRDS* values. The rows for accuracy based test sets contain σ_{p_0} which does not depend on r. See § 4.1 for details.

items, produced respectively by algorithms A and B, and then a list of gold ratings T. Let r_{AT}, r_{BT} and r_{AB} denote the Spearman correlations between $A:T$, $B:T$ and $A:B$ respectively. Let $\hat{r}_{AT}, \hat{r}_{BT}, \hat{r}_{AB}$ be their empirical estimates and assume that $\hat{r}_{BT} > \hat{r}_{AT}$ without loss of generality.

For word similarity datasets we define $\sigma^r_{p_0}$ as the MRDS, such that it satisfies the following proposition:

$$(r_{AB} < r) \wedge (|\hat{r}_{BT} - \hat{r}_{AT}| < \sigma^r_{p_0}) \Longrightarrow \textit{pval} > p_0$$

. Here *pval* is the probability of the test statistic under the null hypothesis that $r_{AT} = r_{BT}$ found using the Steiger's test (Steiger, 1980). The above constraint ensures that as long as the correlation between the competing methods is less than r and the difference between the correlations of the scores of the competing methods to the gold ratings is less than $\sigma^r_{p_0}$, then the pvalue of the null hypothesis will be greater than p_0. We can then ask what we consider a reasonable upper bound on the agreement of ratings produced by competing algorithms: for instance two algorithms correlating above 0.9 might not be considered meaningfully different. That leaves us with the second part of the predicate which ensures that as long as the difference between the correlations of the competing algorithms to the gold scores is less than $\sigma^r_{p_0}$ then the null hypothesis is more likely than p_0.

We can find $\sigma^r_{p_0}$ as follows: Let *stest* denote Steiger's test predicate which satisfies the following:

$$\textit{stest-p}(\hat{r}_{AT}, \hat{r}_{BT}, r_{AB}, p_0, n) \Longrightarrow \textit{pval} < p_0$$

Once we define this predicate then we can use it to set up an optimistic problem where our aim is to find $\sigma^r_{p_0}$ by solving the following:

$$\sigma^r_{p_0} = \min\{\sigma | \forall\, 0 < r' < 1\ \textit{stest-p}(r', \min(r'+\sigma, 1), r, p_0, n)\}$$

Note that MRDS is a liberal threshold and it only guarantees that differences in correlations below that threshold can never be statistically significant (under the given parameter settings). MRDS might optimistically consider some differences as significant when they are not, but it is at least useful in reducing some of the noise in the evaluations. The values of $\sigma^r_{p_0}$ are shown in Table 2.

For the accuracy based test-sets we found MRDS$=\sigma_{p_0}$ that satisfied the following:

$$0 < (\hat{\theta}_B - \hat{\theta}_A) < \sigma_{p_0} \Longrightarrow \mathrm{p}(\theta_B \leq \theta_A) > p_0$$

Specifically, we calculated the posterior probability $\mathrm{p}(\theta_B \leq \theta_A)$ with a flat prior of $\beta(1,1)$ to solve the following:[4] $\sigma_{p_0} = \min\{\sigma | \forall\, 0 < \theta < \min(1-\sigma, 0.9)$ $\mathrm{p}(\theta_B \leq \theta_A | \hat{\theta}_A = \theta, \hat{\theta}_B = \theta + \sigma, n) < p_0\}$ Here θ_A and θ_B

[4] This instead of using McNemar's test (McNemar, 1947) since the Bayesian approach is tractable and more direct. A calculation with $\beta(0.5, 0.5)$ as the prior changed $\sigma_{0.5}$ from 6.63 to 6.38 for the TOEFL dataset but did not affect MRDS for the AN-SEM and AN-SYN datasets.

are probability of correctness of algorithms A, B and $\hat{\theta}_A$, $\hat{\theta}_B$ are observed empirical accuracies.

Unfortunately there are no widely reported train-test splits of the above datasets, leading to potential concerns of *soft supervision* (hyper-parameter tuning) on these evaluations, both in our own work and throughout the existing literature. We report on the resulting impact of various parameterizations, and our final results are based on a single set of parameters used across all evaluation sets.

5 Experiments and Results

We wanted to answer the following questions through our experiments: (1) How do hyper-parameters affect performance? (2) What is the contribution of the multiple sources of data to performance? (3) How does the performance of MVLSA compare with other methods? For brevity we show tuning runs only on the larger datasets. We also highlight the top performing configurations in bold using the small threshold values in column $\sigma_{0.05}^{0.09}$ of Table 2.

Effect of Hyper-parameters f_j: We modeled the preprocessing function f_j as the composition of two functions, $f_j = n_j \circ t_j$. n_j represents nonlinear preprocessing that is usually employed with LSA. We experimented by setting n_j to be: identity; logarithm of count plus one; and the fourth root of the count. t_j represents the truncation of columns and can be interpreted as a type of regularization of the raw counts themselves through which we prune away the noisy contexts. Decrease in t_j also reduces the influence of views that have a large number of context columns and emphasizes the sparser views. Table 3 and Table 4 show the results.

Test Set	Log	Count	Count$^{\frac{1}{4}}$
MEN	67.5	59.7	**70.7**
RW	31.1	25.3	**37.8**
SCWS	64.2	58.2	**66.6**
AN-SYN	45.7	21.1	**53.6**
AN-SEM	25.4	15.9	**38.7**

Table 3: Performance versus n_j, the non linear processing of cooccurrence counts. $t = 200K,\ m = 500,\ v = 16,\ k = 300$. All the top configurations determined by $\sigma_{0.05}^{0.09}$ are in bold font.

Test Set	6.25K	12.5K	25K	50K	100K	200K
MEN	70.2	**71.2**	**71.5**	**71.6**	**71.2**	**70.7**

SCWS	**67.1**	**67.3**	**67.1**	**67.0**	**66.9**	**66.6**
AN-SYN	59.2	**60.0**	**59.5**	58.4	56.1	53.6
AN-SEM	37.7	**38.6**	**39.4**	**39.2**	38.4	**38.7**

Table 4: Performance versus the truncation threshold, t, of raw cooccurrence counts. We used $n_j = \text{Count}^{\frac{1}{4}}$ and other settings were the same as Table 3.

m: The number of left singular vectors extracted after SVD of the preprocessed cooccurrence matrices can again be interpreted as a type of regularization, since the result of this truncation is that we find cooccurrence patterns only between the top left singular vectors. We set $m_j = max(d_j, m)$ with $m = [100, 300, 500]$. See table 5.

Test Set	100	200	300	500
MEN	65.6	68.5	**70.1**	**71.1**
RW	34.6	**36.0**	**37.2**	**37.1**

AN-SYN	50.5	**56.2**	**56.4**	**56.4**
AN-SEM	24.3	31.4	34.3	**40.6**

Table 5: Performance versus m, the number of left singular vectors extracted from raw cooccurrence counts. We set $n_j = \text{Count}^{\frac{1}{4}},\ t = 100K,\ v = 25,\ k = 300$.

k: Table 6 demonstrates the variation in performance versus the dimensionality of the learnt vector representations of the words. Since the dimensions of the MVLSA representations are orthogonal to each other therefore creating lower dimensional representations is a trivial matrix slicing operation and does not require retraining.

Test Set	10	50	100	200	300	500

Table 6: Performance versus k, the final dimensionality of the embeddings. We set $m = 300$ and other settings were same as Table 5.

v: Expression 12 describes a method to set W_j. We experimented with a different, more global,

heuristic to set $[W_j]_{ii} = (K_{ww} \geq v)$, essentially removing all words that did not appear in v views before doing GCCA. Table 7 shows that changes in v are largely inconsequential for performance.

Test Set	16	17	21	25	29
MEN	**70.4**	**70.4**	**70.2**	**70.1**	**70.0**
RW	**39.9**	**38.8**	**39.7**	37.2	33.5

AN-SEM	**34.6**	**34.3**	**34.0**	**34.3**	**34.3**

Table 7: Performance versus minimum view support threshold v, The other hyperparameters were $n_j = \text{Count}^{\frac{1}{4}}$, $m = 300$, $t = 100K$. Though a clear best setting did not emerge, we chose $v = 25$ as the middle ground.

r_j: The regularization parameter ensures that all the inverses exist at all points in our method. We found that the performance of our procedure was invariant to r over a large range from 1 to 1e-10. This was because even the 1000th singular value of our data was much higher than 1.

Contribution of different sources of data Table 8 shows an ablative analysis of performance where we remove individual views or some combination of them and measure the performance. It is clear by comparing the last column to the second column that adding in more views improves performance. Also we can see that the Dependency based views and the Bitext based views give a larger boost than the morphology and FrameNet based views, probably because the latter are so sparse.

Comparison to other word representation creation methods There are a large number of methods of creating representations both multilingual and monolingual. There are many new methods such as by Yu and Dredze (2014), Faruqui et al. (2014), Hill and Korhonen (2014), and Weston et al. (2014) that are performing multiview learning and could be considered here as baselines: however it is not straightforward to use those systems to handle the variety of data that we are using. Therefore, we directly compare our method to the Glove and the SkipGram model of Word2Vec as the performance of those systems is considered state of the art. We trained these two systems on the English portion of the *Polyglot* Wikipedia dataset.[5] We also combined their outputs using MVLSA to create *MV-G-WSG)* embeddings.

We trained our best MVLSA system with data from all views and by using the individual best settings of the hyper-parameters. Specifically the configuration we used was as follows: $n_j = \text{Count}^{\frac{1}{4}}, t = 12.5K, m = 500, k = 300, v = 16$. To make a fair comparison we also provide results where we used only the views derived from the *Polyglot* Wikipedia corpus. See column *MVLSA (All Views)* and *MVLSA (Wiki)* respectively. It is clearly visible that MVLSA on the monolingual data itself is competitive with Glove but worse than Word2Vec on the word similarity datasets and it is substantially worse than both the systems on the AN-SYN and AN-SEM datasets. However with the addition of multiple views MVLSA makes substantial gains, shown in column *MV Gain*, and after consuming the Glove and WSG embeddings it again improves performance by some margins, as shown in column *G-WSG Gain*, and outperforms the original systems. Using GCCA itself for system combination provides closure for the MVLSA algorithm since multiple distinct approaches can now be simply fused using this method. Finally we contrast the Spearman correlations r_s with Glove and Word2Vec before and after including them in the GCCA procedure. The values demonstrate that including Glove and WSG during GCCA actually increased the correlation between them and the learnt embeddings, which supports our motivation for performing GCCA in the first place.

6 Previous Work

Vector space representations of words have been created using diverse frameworks including Spectral methods (Dhillon et al., 2011; Dhillon et al., 2012), [6] Neural Networks (Mikolov et al., 2013b; Collobert and Lebret, 2013), and Random Projections (Ravichandran et al., 2005; Bhagat and Ravichan-

[5] We explicitly provided the vocabulary file to Glove and Word2Vec and set the truncation threshold for Word2Vec to 10. Glove was trained for 25 iterations. Glove was provided a window of 15 previous words and Word2Vec used a symmetric window of 10 words.

The r_s columns demonstrate that GCCA increased pearson correlation.

dran, 2008; Chan et al., 2011). [7] They have been trained using either one (Pennington et al., 2014) [8] or two sources of cooccurrence statistics (Zou et al., 2013; Faruqui and Dyer, 2014; Bansal et al., 2014; Levy and Goldberg, 2014) [9] or using multi-modal data (Hill and Korhonen, 2014; Bruni et al., 2012).

Dhillon et al. (2011) and Dhillon et al. (2012) were the first to use CCA as the primary method to learn vector representations and Faruqui and Dyer (2014) further demonstrated that incorporating bilingual data through CCA improved performance. More recently this same phenomenon was reported by Hill et al. (2014a) through their experiments over neural representations learnt from MT systems. Various other researchers have tried to improve the performance of their paraphrase systems or vector space models by using diverse sources of information such as bilingual corpora (Bannard and Callison-Burch, 2005; Huang et al., 2012; Zou et al., 2013),[10] structured datasets (Yu and Dredze, 2014; Faruqui et al., 2014) or even tagged images (Bruni

[10] An example of complementary views: Chan et al. (2011) observed that monolingual distributional statistics are susceptible to conflating antonyms, where bilingual data is not; on the other hand bilingual statistics are susceptible to noisy alignments, where monolingual data is not.

et al., 2012). However, most previous work[11] did not adopt the general, simplifying view that all of these sources of data are just cooccurrence statistics coming from different sources with underlying latent factors.[12]

Bach and Jordan (2005) presented a probabilistic interpretation for CCA. Though they did not generalize it to include GCCA we believe that one could give a probabilistic interpretation of *MAX-VAR GCCA*. Such a probabilistic interpretation would allow for an online-generative model of lexical representations, which unlike methods like Glove or LSA would allows us to naturally perplexity or generate sequences. We also note that Vía et al. (2007) presented a neural network model of GCCA and adaptive/incremental GCCA. To the best of our knowledge both of these approaches have not been used for word representation learning.

CCA is also an algorithm for multi-view learning (Kakade and Foster, 2007; Ganchev et al., 2008) and when we view our work as an application of multi-view learning to NLP, this follows a long chain of effort started by Yarowsky (1995) and continued with *Co-Training* (Blum and Mitchell, 1998), *CoBoosting* (Collins and Singer, 1999) and *2 view perceptrons* (Brefeld et al., 2006).

7 Conclusion and Future Work

While previous efforts demonstrated that incorporating two views is beneficial in word-representation learning, we extended that thread of work to a logical extreme and created *MVLSA* to learn distributed representations using data from 46 views![13] Through evaluation of our induced representations, shown in Table 9, we demonstrated that the MVLSA algorithm is able to leverage the information present in multiple data sources to improve performance on a battery of tests against state of the art baselines. In order to perform MVLSA on large vocabularies with up to 500K words we presented a fast scalable algorithm. We also showed that a close variant of the Glove objective proposed by Pennington et al. (2014) could be derived as a heuristic for handling missing data under the MVLSA framework. In order to better understand the benefit of using multiple sources of data we performed MVLSA using views derived only from the monolingual Wikipedia dataset thereby providing a more principled alternative of LSA that removes the need for heuristically combining word-word cooccurrence matrices into a single matrix. Finally, while surveying the literature we noticed that not enough emphasis was being given towards establishing the significance of comparative results and proposed a method, *(MRDS)*, to filter out insignificant comparative gains between competing algorithms.

Future Work Column *MVLSA Wiki* of Table 9 shows us that MVLSA applied to monolingual data has mediocre performance compared to the baselines of Glove and Word2Vec on word similarity tasks and performs surprisingly worse on the ANSEM dataset. We believe that the results could be improved by (1) either using recent methods for handling missing values mentioned in footnote 1 or by using the heuristic count dependent non-linear weighting mentioned by Pennington et al. (2014) and that sits well within our framework as exemplified in Expression 12 (2) by using even more views, which look at the future words as well as views that contain PMI values. Finally, we note that Table 8 shows that certain datasets can actually degrade performance over certain metrics. Therefore we are exploring methods for performing discriminative optimization of weights assigned to views, for purposes of task-based customization of learned representations.

This material is based on research sponsored by the Defense Advanced Research Projects Agency (DARPA) under the Deep Exploration and Filtering of Text (DEFT) Program, agreement number FA8750-13-2-001, as well as the National Science Foundation (NSF), agreement number BCS-1344269. We also thank Juri Ganitkevitch for providing the word aligned bitext corpus.

[11] Ganitkevitch et al. (2013) did employ a rich set of diverse cooccurrence statistics in constructing the initial PPDB, but without a notion of "training" a joint representation beyond random projection to a binary vector subspace (bit-signatures).

[12] Note that while Faruqui et al. (2014) performed belief propagation over a graph representation of their data, such an undirected weighted graph can be viewed as an adjacency matrix, which is then also a cooccurrence matrix.

NASARI: a Novel Approach to a Semantically-Aware Representation of Items

José Camacho-Collados, Mohammad Taher Pilehvar and **Roberto Navigli**
Department of Computer Science
Sapienza University of Rome
{collados,pilehvar,navigli}@di.uniroma1.it

Abstract

The semantic representation of individual word senses and concepts is of fundamental importance to several applications in Natural Language Processing. To date, concept modeling techniques have in the main based their representation either on lexicographic resources, such as WordNet, or on encyclopedic resources, such as Wikipedia. We propose a vector representation technique that combines the complementary knowledge of both these types of resource. Thanks to its use of explicit semantics combined with a novel cluster-based dimensionality reduction and an effective weighting scheme, our representation attains state-of-the-art performance on multiple datasets in two standard benchmarks: word similarity and sense clustering. We are releasing our vector representations at http://lcl.uniroma1.it/nasari/.

1 Introduction

Obtaining accurate semantic representations of individual word senses or concepts is vital for several applications in Natural Language Processing (NLP) such as, for example, Word Sense Disambiguation (Navigli, 2009; Navigli, 2012), Entity Linking (Bunescu and Paşca, 2006; Rao et al., 2013), semantic similarity (Budanitsky and Hirst, 2006), Information Extraction (Banko et al., 2007), and resource linking and integration (Pilehvar and Navigli, 2014). One prominent semantic representation approach is the distributional semantic model, which represents lexical items as vectors in a semantic space. The weights in these vectors were traditionally computed on the basis of co-occurrence statistics (Salton et al., 1975; Turney and Pantel, 2010; Dinu and Lapata, 2010; Lappin and Fox, 2014), whereas for the more recent generation of distributional models weight computation is viewed as a context prediction problem, often to be solved by using neural networks (Collobert and Weston, 2008; Turian et al., 2010; Mikolov et al., 2013). Unfortunately, unless they are provided with large amounts of sense-annotated data these corpus-based techniques cannot capture polysemy in their representations, as they conflate different meanings of a word into a single vector. Therefore, most sense modeling techniques tend to base their computation on the knowledge obtained from various lexical resources. However, these techniques mainly utilize the knowledge derived from either WordNet (Banerjee and Pedersen, 2002; Budanitsky and Hirst, 2006; Pilehvar et al., 2013) or Wikipedia (Medelyan et al., 2009; Mihalcea, 2007; Dandala et al., 2013; Gabrilovich and Markovitch, 2007; Strube and Ponzetto, 2006), which are, respectively, the most widely-used lexicographic and encyclopedic resources in lexical semantics (Hovy et al., 2013). This restriction to a single resource brings about two main limitations: (1) the sense modeling does not benefit from the complementary knowledge of different resources, and (2) the obtained representations are resource-specific and cannot be used across settings.

In this paper we put forward a novel concept representation technique, called NASARI, which exploits the knowledge available in both types of resource in order to obtain effective representations of arbitrary concepts. The contributions of this paper are threefold. First, we propose a novel technique

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 567–577,
Denver, Colorado, May 31 – June 5, 2015.

for rich semantic representation of arbitrary WordNet synsets or Wikipedia pages. Second, we provide improvements over the conventional *tf-idf* weighting scheme by applying lexical specificity (Lafon, 1980), a statistical measure mainly used for term extraction, to the task of computing vector weights in a vector representation. Third, we propose a semantically-aware dimensionality reduction technique that transforms a lexical item's representation from a semantic space of words to one of WordNet synsets, simultaneously providing an implicit disambiguation and a distribution smoothing. We demonstrate that our representation achieves state-of-the-art performance on two different tasks: (1) word similarity on multiple standard datasets: MC-30, RG-65, and WordSim-353 similarity, and (2) Wikipedia sense clustering, in which our unsupervised system surpasses the performance of a state-of-the-art supervised technique that exploits knowledge available in Wikipedia in several languages.

2 Semantic Representation of Concepts

Lexical resources and concepts. The gist of our approach lies in its combination of knowledge from two different lexical resources: (1) the expert-based lexicographic WordNet, whose basic constituents are synsets, i.e., concepts expressed by sets of synonymous words (Miller et al., 1990), and (2) the collaboratively-constructed encyclopedic Wikipedia, whose articles can be considered as individual concepts. Throughout the paper, by a concept we mean a tuple $b = (p, s)$ where p is a Wikipedia page and s is the corresponding WordNet synset. As a bridge between the two resources we use the synset-to-article mappings provided by BabelNet[1] (Navigli and Ponzetto, 2012), a high coverage multilingual encyclopedic dictionary and semantic network that merges, among other resources, Wikipedia and WordNet. Note that the concept b can also contain a Wikipedia page or a WordNet synset only, if a mapping is not provided by BabelNet.

Semantic representation: NASARI. Our concept modeling approach consists of two phases. First, for a given concept, we collect a set of relevant Wikipedia pages by leveraging the structural information in Wikipedia and WordNet (Section 2.1).

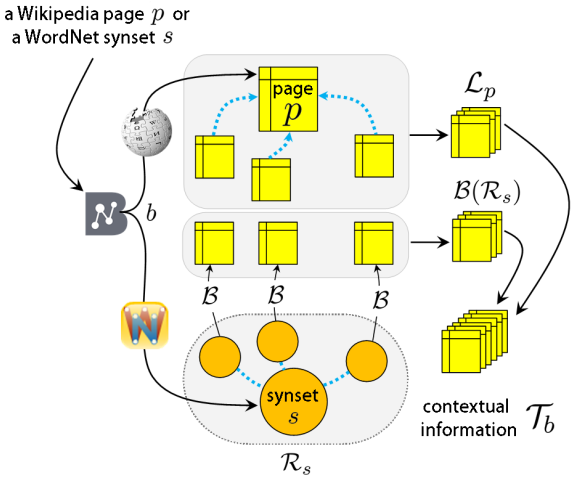

Figure 1: The process of obtaining contextual information for a WordNet synset or a Wikipedia article.

Then, we analyze the obtained contextual information and construct two vector representations of the concept (Section 2.2).

2.1 Collecting contextual information

Figure 1 illustrates the process of obtaining a set of relevant Wikipedia pages $\mathcal{T}_b$ as contextual information for a given concept $b = (p, s)$. Let $\mathcal{L}_p$ be the set containing p and all the Wikipedia pages having an outgoing link to p, and $\mathcal{R}_s$ be the set consisting of s and all other synsets that are in its direct neighbourhood. We further enrich $\mathcal{R}_s$ by including the coordinate synsets of s and the related synsets from its disambiguated gloss[2]. Let $\mathcal{B}$ be a function mapping each WordNet synset s' to its corresponding Wikipedia page p, if such mapping exists in BabelNet, and to the empty set otherwise. Hence, $\mathcal{B}(\mathcal{R}_s) = \cup_{s' \in \mathcal{R}_s} \mathcal{B}(s')$. Then, our contextual information is the set of Wikipedia pages $\mathcal{T}_b = \mathcal{L}_p \cup \mathcal{B}(\mathcal{R}_s)$. In the case either p or s is not present in the concept b, we take the contextual information as $\mathcal{T}_b = \mathcal{B}(\mathcal{R}_s)$ or $\mathcal{T}_b = \mathcal{L}_p$, respectively.

2.2 Vector construction

By processing the collected contextual information $\mathcal{T}_b$, NASARI represents the concept b as two vectors in two semantic spaces: (1) word-based and (2) synset-based. Let $\mathcal{W}_b$ be the bag of words of all the Wikipedia pages in $\mathcal{T}_b$ after lemmatization and stop-

[1] http://www.babelnet.org/

[2] http://wordnet.princeton.edu/glosstag.shtml

word removal. We use lexical specificity in order to extract the most representative words (Section 2.2.1) and synsets (Section 2.2.2) of $\mathcal{W}_b$.

Lexical specificity. Lexical specificity (Lafon, 1980) is a statistical measure that has been used in a wide range of NLP applications, such as textual data analysis (Lebart et al., 1998), term extraction (Drouin, 2003), and domain disambiguation (Camacho Collados et al., 2014). However, to our knowledge, it has never heretofore been used to calculate weights in a vector-based representation (Turney and Pantel, 2010). Lexical specificity is based on the hypergeometric distribution over word frequencies. This statistical measure is particularly suitable for extracting an accurate set of representative terms for a given subcorpus of a reference corpus (Lafon, 1980). Unlike the conventional term frequency-inverse document frequency weighting scheme (Jones, 1972, *tf-idf*), lexical specificity is not especially sensitive to different text lengths.

Assume a reference corpus of T words and a t-words subcorpus of that corpus. The goal is to find a set of terms that are peculiar to the subcorpus, but not to the whole reference corpus. Formally, given a word w that occurs f and k times in the corpus and subcorpus, respectively, positive specificity computes the relevance of w to the subcorpus as $P(X \geq k)$ if $k \geq \frac{ft}{T}$, where X is a random variable following a hypergeometric distribution with parameters f, t and T, and $\frac{ft}{T}$ is the expected value of X. In our setting we are only interested in the positive specificity, i.e., the set of most relevant words appearing in the contextual information. We apply the standard procedure of applying log_{10} and then inverting the sign of the specificity probabilities in order to re-scale them to the real line, which is more easily interpretable (Drouin, 2003; Camacho Collados et al., 2014). We only retain words with specificity greater than two, which is equal to $-log_{10}(0.01)$. This threshold leads to a set of representative words that are relevant to the context with a confidence of at least 99%, i.e., $P(X \geq k) \leq 0.01$ (Billami et al., 2014).

2.2.1 Word-based representation

This word-based representation models the concept b in a conventional semantic space whose dimensions are individual words. We leverage lexical specificity to compute a weighted set of most representative words for $\mathcal{W}_b$ with respect to the reference corpus, i.e., the whole Wikipedia. As an example, the obtained word-based vector for the *edge of water* sense of *shore* has *water*, *ocean*, *lake*, *beach* and *sea* among its most relevant dimensions.

2.2.2 Synset-based representation

Given that the amount of contextual information gathered for a concept can be small, the resulting word-based vector can be sparse and as a consequence prone to noise, especially in the case of less frequent concepts. Therefore, we put forward a method that tackles the issue, providing rich semantically-aware representations. To this end, we group - and thereby generalize - similar dimensions in the obtained word-based vector, to produce a smaller vector in which dimensions are WordNet synsets and weights are computed on the basis of the combined information of the individual words in the group. The generalization procedure can be summarized in two main steps.

First, for each word w in $\mathcal{W}_b$, we obtain from WordNet the set $\mathcal{H}_w$ of all the direct hypernyms of all the synsets containing w. For each synset $h \in \mathcal{H}_w$ we check whether there exists another word w' from the contextual information that is a hyponym of h, i.e., $h \in \mathcal{H}_w \cap \mathcal{H}_{w'}$. When such is the case, letting $\mathcal{Y}_h$ be the set of all words in the hyponym synsets of h, we combine w, w' and all the other words in $\mathcal{Y}_h$ into a single dimension represented by their common hypernym h. Thus for our earlier example, the three words *ocean*, *lake*, and *sea* are grouped into a single dimension represented by their hypernym, i.e., the synset containing the *body of water* sense of *water* (*water*^2_n in WordNet 3.0)[3].

Then, we compute the weight associated with the new dimension by calculating the lexical specificity of the word cluster. Formally, we calculate the lexical specificity of h by setting the parameters k and f as the total number of times the words in $\mathcal{Y}_h$ occur in $\mathcal{W}_b$ and the whole Wikipedia, respectively. The values of t and T remain unchanged.

Our generalization procedure is similar to the dimensionality reduction that is performed using singular value decomposition in Latent Semantic Analysis (Landauer and Dumais, 1997, LSA). However,

[3]We denote the i^{th} sense of word w with POS p as w^i_p.

LSA is not applicable to our setting because, due to the usage of lexical specificity, our vectors are relatively small in size and different vectors usually have few overlapping dimensions. Moreover, unlike LSA, in which the size-reduced vectors have opaque conflations of multiple words as their dimensions, our new semantic space has human- and machine-readable synsets as its dimensions. Our generalization procedure produces three advantages: (1) it maps the vectors from a word-based semantic space to a lower-dimensional space of synsets, (2) while merging multiple words into a single synset an implicit disambiguation of context words takes place, providing better means for sense distinction, and (3) the dimensionality reduction tackles the potential noise and sparsity, resulting in smoother vectors.

3 NASARI for Semantic Similarity

So far we have explained how NASARI constructs two types of representations, i.e., word-based and synset-based, for arbitrary WordNet synsets and Wikipedia pages. In this section we provide a method that leverages NASARI representations for effective measurement of concept and word similarity. Semantic similarity between a pair of lexical items (e.g., words or concepts) lies at the core of many applications in NLP and hence it has received a considerable amount of research interest, leading to a wide range of semantic similarity measures (Mohammad and Hirst, 2012).

3.1 Concept similarity

Given a pair of concepts, we first use the procedure described in Section 2 to obtain for each concept the two corresponding vector representations, i.e., word-based and synset-based. For each representation type, we then compute the similarity of the two concepts by comparing their corresponding vectors. This results in two similarity scores, one for each representation type. The final similarity is computed as the average of the two similarity scores. We use Weighted Overlap for comparing vectors.

Weighted Overlap. Proposed by Pilehvar et al. (2013), Weighted Overlap (WO) first sorts the elements of each vector v_i and then harmonically weights the overlaps between the two vectors:

$$WO(v_1, v_2) = \frac{\sum_{q \in O}(r_q^1 + r_q^2)^{-1}}{\sum_{i=1}^{|O|}(2i)^{-1}} \qquad (1)$$

where O is the set of overlapping dimensions between the two vectors and r_q^j is the rank of dimension q in the vector v_j. Given that our vectors are significantly smaller than those in the original setting of WO, the overlaps are also generally smaller in size. Hence, we apply a square root operation to the computed value in order to obtain a more uniformly-distributed range of scores across the similarity scale, i.e., [0, 1]. In our experiments we show the advantage we gain by using WO in comparison to the conventional cosine measure.

Algorithm 1 NASARI-based word similarity

Input: words w_1 and w_2
Output: *Sim*, similarity score

for each synonym set $H \in \mathcal{S}$
  if $w_1 \in H$ & $w_2 \in H$ **then**
    return $Sim = 1$
for each word $w_i \in \{w_1, w_2\}$
  $\mathcal{C}_{w_i} \leftarrow \emptyset$, set of concepts associated with w_i
  if $w_i \in$ *WordNet* & w_i *not* Named Entity **then**
    for each sense $s \in$ *WordNet senses* (w_i)
      $\mathcal{C}_{w_i} \leftarrow \mathcal{C}_{w_i} \cup \{s\}$
  else
    for each page $p \in$ *piped links* (w_i)
      $\mathcal{C}_{w_i} \leftarrow \mathcal{C}_{w_i} \cup \{p\}$
  $V_i \leftarrow \emptyset$, set of representations for concepts in $\mathcal{C}_{w_i}$
  for each concept $c \in \mathcal{C}_{w_i}$
    $v_{wrd} \leftarrow$NASARI word-based rep. of c
    $v_{syn} \leftarrow$NASARI synset-based rep. of c
    $v \leftarrow (v_{wrd}, v_{syn})$
    $V_i \leftarrow V_i \cup \{v\}$
$Sim \leftarrow \max_{v \in V_1, v' \in V_2} \frac{WO(v_{wrd}, v'_{wrd}) + WO(v_{syn}, v'_{syn})}{2}$
return *Sim*

3.2 Word similarity

Algorithm 1 shows the procedure we devised for measuring semantic similarity between two words. There are three main steps:

1. Given a pair of words w_1 and w_2 the algorithm first checks whether they are synonymous according to our synonym set collection $\mathcal{S}$. In Section 3.2.1, we explain how we obtain this set. If the words are defined as synonyms in $\mathcal{S}$,

the algorithm returns the maximum similarity score of one (lines 1-3).

2. If the words are not defined as synonyms, we proceed by obtaining, for each word w_i, its set of possible senses ($\mathcal{C}_{w_i}$, lines 5-11). We accordingly obtain the set of their respective NASARI vector representations (V_i, lines 13-17), two (word-based and synset-based) for each concept in $\mathcal{C}_{w_i}$. Section 3.2.2 describes the concept extraction process.

3. Finally, the algorithm returns the similarity score *Sim* (line 19), calculated as the similarity of the closest senses of w_1 and w_2. In our default setting, we linearly combine our two vector representations by averaging them (line 18).

3.2.1 Wiktionary synonyms $\mathcal{S}$

Wiktionary is a rich collaboratively-constructed lexical resource that provides a considerable amount of multilingual lexical information for a large number of words. We use this resource in order to obtain sets of synonymous words $\mathcal{S}$. To this end, we first extract all the pre-specified synonymy relations in the English Wiktionary. This results in 17K sets with an average size of 2.8 synonyms.

In order to enrich the set we introduce a method that exploits the multilinguality of Wiktionary to extract synonymous words. Our approach utilizes translations of words in other languages as bridges between synonymous words in English. Specifically, for each sense s of word w in Wiktionary, we first get all the available translations. Assume that the sense s of w translates into the word t_l in language l. If there is another word sense s' of another word w' in Wiktionary that is also translated to t_l in language l, we hypothesize that w and w' are synonyms. In order to avoid ambiguity, as t_l we only consider words that are monosemous according to language l.

This procedure results in around 9K additional synonymous sets with an average size of 2.1. For instance, the Finnish noun *ammatti*, which is monosemous according to Wiktionary, links seven English words into a single set of synonyms: *career*, *business*, *profession*, *occupation*, *trade*, *calling*, and *vocation*. The final synonym set collection $\mathcal{S}$ contains 25K sets, each having, on average, 2.6 words.

3.2.2 Concept extraction

If the two input words w_1 and w_2 are not found in the same synonym set in $\mathcal{S}$, we proceed by obtaining their sets of senses $\mathcal{C}_{w_1}$ and $\mathcal{C}_{w_2}$, respectively. Depending on the type of w_i, we use two different resources for obtaining $\mathcal{C}_{w_i}$: the WordNet sense inventory and Wikipedia.

WordNet words. When the word w_i is defined in the WordNet sense inventory and is not a named entity (line 6 in Algorithm 1), we set $\mathcal{C}_{w_i}$ as all the WordNet synsets that contain w_i, i.e., $\mathcal{C}_{w_i} = \{\textit{synset } s \in \textit{WordNet} : w_i \in s\}$. We use Stanford Named Entity Recognizer (Finkel et al., 2005) in our experiments.

WordNet OOV and named entities. For named entities and words that do not exist in WordNet's vocabulary (OOV) we construct the set $\mathcal{C}_{w_i}$ by exploiting Wikipedia's piped links (line 10 in Algorithm 1). To this end, we take as elements of $\mathcal{C}_{w_i}$ the Wikipedia pages of the hyperlinks which have w_i as their surface form, i.e., *piped-links* (w_i). If $|\mathcal{C}_{w_i}| > 5$, we prune $\mathcal{C}_{w_i}$ to its top-5 pages in terms of their number of ingoing links. Our choice of Wikipedia as a source for named entities is due to its higher coverage in comparison to WordNet.

4 Experiments

We evaluated NASARI on two different tasks that require the computation of semantic similarity between words or concepts: word similarity (Section 4.1) and sense clustering (Section 4.2).

4.1 Word similarity

4.1.1 Datasets

We took as benchmark for our word similarity experiments three standard datasets that are widely used in the literature: RG-65 (Rubenstein and Goodenough, 1965), MC-30 (Miller and Charles, 1991), and WordSim-353 (Finkelstein et al., 2002; Agirre et al., 2009). WordSim-353 originally conflated similarity and relatedness, leading to high similarity scores for pairs such as *computer-keyboard* despite the dissimilarity in their meanings. To correct the conflation, Agirre et al. (2009) partitioned the dataset into two subsets: relatedness and similarity. Given that our similarity measure is targeted at semantic similarity, we took the similarity subset of

WordSim-353 (WS-Sim) as test bed for our evaluations. The subset comprises 203 word pairs.

4.1.2 Experimental setup

In this task, we assess the performance of different systems in terms of Pearson correlation. We compare our system against six similarity measures that have reported best performance on the three datasets. Lin (Lin, 1998) and ADW (Pilehvar et al., 2013) are WordNet-based approaches that leverage the structural information of WordNet for the computation of semantic similarity. Most similar to our work are Explicit Semantic Analysis (Gabrilovich and Markovitch, 2007, ESA), which represents a word in a high-dimensional space of Wikipedia articles, and Salient Semantic Analysis (Hassan and Mihalcea, 2011, SSA), which leverages the linking of concepts within Wikipedia articles for generating *semantic profiles* of words. Word2Vec (Mikolov et al., 2013) and PMI-SVD are the best predictive and co-occurrence models obtained by Baroni et al. (2014) on a 2.8 billion-token corpus that also includes the English Wikipedia.[4] Word2Vec is based on neural network context prediction models (Mikolov et al., 2013), whereas PMI-SVD is a traditional co-occurrence based vector wherein weights are calculated by means of Pointwise Mutual Information (PMI) and the vector's dimension is reduced to 500 by singular value decomposition (SVD). We use the DKProSimilarity (Bär et al., 2013) implementation of Lin and ESA in order to evaluate these measures on the WS-Sim dataset.

4.1.3 Results

Table 1 shows the Pearson correlation of the different similarity measures on the three datasets considered. NASARI proves to be highly reliable on the task of word similarity, providing state-of-the-art performance on RG-65 and MC-30, and competitive results on WS-Sim. Importantly, the improvement we attain over measures that utilize as their knowledge base either WordNet (i.e., ADW, Lin) or Wikipedia (i.e., ESA and SSA) shows that our usage of the complementary information of the two types of resource has been helpful. We note that our Wiktionary module detects four additional synonymous pairs (i.e., similarity = 1.0) in MC-30 (13%), eight in RG-65 (12%), and thirteen in WS-Sim (6%) that are not defined as synonyms in WordNet. We also obtain competitive results according to the Spearman correlation (a setting in which the absolute similarity scores do not play a role and it is solely their ranking that matters) on all the three datasets: MC-30 (0.89), RG-65 (0.88), and WS-Sim (0.73).

Measure	RG-65	MC-30	WS-Sim
NASARI	**0.91**	**0.91**	0.74
SSA	0.86	0.88	NA
Word2Vec	0.84$^{\diamond}$	0.83‡	**0.76**‡
Lin	0.83	0.82	0.66
ADW	0.81	0.79	0.63
PMI-SVD	0.74$^{\diamond}$	0.76‡	0.68‡
ESA	0.72	0.74	0.45

Table 1: Pearson correlation of different similarity measures on RG-65, MC-30, and WordSim-353 similarity (WS-Sim) datasets. Results for Lin and ESA on RG-65 and MC-30 are taken from (Hassan and Mihalcea, 2011). We show the best performance obtained by Baroni et al. (2014) out of 48 configurations specifically tested on RG-65 (highlighted by $\diamond$) and across different datasets including WS-Sim (highlighted by $\ddagger$).

WS-Sim is the only dataset on which we do not report state-of-the-art performance. An analysis of the outputs of our system on the WS-Sim dataset revealed that there are pairs in this subset of WordSim-353 that are not assigned proper scores according to the similarity scale. Hill et al. (2014) had previously pointed out this deficiency of WS-Sim, mainly due to its original relatedness-based scoring scale. For instance, word pairs that are barely related (e.g., *street-children*) or antonyms (e.g., *profit-loss* and *smart-stupid*) are assigned relatively high similarity values (respectively, 4.9 for the former and 7.3 and 5.8 for the latter case, in the 0-10 scale). In all these cases our system produces more appropriate judgements according to the similarity scale. On the other hand, there are highly similar pairs in the dataset with relatively low gold scores. Examples include *school-center*[5] and *term-life*[6] with the respective gold similarity scores of 3.4 and 4.5, whereas

[4] clic.cimec.unitn.it/composes/semantic-vectors.html

[5] *School* and *center* have a pair of highly similar senses in WordNet 3.0: *center*$^{3}_{n}$*: "a building dedicated to a particular activity"* and *school*$^{2}_{n}$*: "a building where young people receive education."*

[6] *Term* and *life* are in coordinate synsets (with *time period* as their common hypernym) in WordNet 3.0.

Measure	System type	500-pair	SemEval
NASARI	unsupervised	**84.6%**	**88.4%**
Dan-mono	supervised	77.4%	83.5%
Dan-multi	supervised	84.4%	85.5%
Baseline	-	71.4%	82.5%

Table 2: Accuracy of different systems on two manually-annotated English datasets for sense clustering in Wikipedia. Dan-mono and Dan-multi are the monolingual and multilingual systems of Dandala et al. (2013).

NASARI computes their similarities as 8.4 and 9.6.

4.2 Sense clustering

Our second set of experiments focuses on sense clustering of the Wikipedia sense inventory. Wikipedia can be considered as a sense inventory wherein the different meanings of a word are denoted by the articles listed in its disambiguation page (Mihalcea and Csomai, 2007). Given the high granularity of this inventory, clustering of senses can be highly beneficial to tasks that take this encyclopedic resource as their sense inventory (Hovy et al., 2013), such as Wikipedia-based Word Sense Disambiguation (Mihalcea, 2007; Dandala et al., 2013).

4.2.1 Datasets

For the sense clustering task, we take as our benchmark the two datasets created by Dandala et al. (2013). In these datasets, clustering has been viewed as a binary classification problem in which all possible pairings of senses of a word are annotated whether they ought to be clustered or not. The first dataset contains 500 pairs, 357 of which are set to *clustered* and the remaining 143 to *not clustered*. The second dataset, referred to as the SemEval dataset, is based on a set of highly ambiguous words taken from SemEval evaluations (Mihalcea, 2007) and consists of 925 pairs, 162 of which are positively labeled, i.e., clustered.

4.2.2 Experimental setup

In this task we use the procedure explained in Section 3.1 for measuring the similarity of concepts. A pair of pages is set to belong to the same cluster if their similarity exceeds the middle point in our similarity scale, i.e., 0.5 in the scale of [0, 1]. We compare our results with the state-of-the-art systems of Dandala et al. (2013) that perform clustering by exploiting the structure and content of an English page (monolingual variant), or several pages in different languages (multilingual variant that uses English, German, Spanish and Italian pages). These systems are essentially multi-feature Support Vector Machine classifiers that use an automatically-labeled dataset for their training.

4.2.3 Results

Table 2 lists the results of NASARI as well as the state-of-the-art systems of Dandala et al. (2013). We also report the results for a baseline system that sets all pairs as *not clustered*. As can be seen from the table, our system proves to be highly robust and competitive by outperforming, in an unsupervised setting, the supervised monolingual and multilingual systems of Dandala et al. (2013) on both datasets. As regards the F1, we obtain 72.0% and 64.2% on the 500-pair and SemEval datasets, respectively, a measure that is not reported by Dandala et al. (2013).

4.3 Analysis

Recall from Section 2 that our system has two vector representations, for each of which we compute vectors based on lexical specificity. We also mentioned in Section 3 that we opt for Weighted Overlap as our vector comparison method. In order to analyze the impact of each of these elements, we carried out a series of experiments with the conventional logarithmically-scaled *tf-idf* weighting scheme and the cosine vector comparison technique. For a word w, we calculate the *tf-idf* by taking *tf* as the frequency of w in the corresponding contextual information, and $idf = log(|D|/|\{p \in D : w \in p\}|)$, where D is the set of all pages in Wikipedia.

Table 3 shows the performance of the NASARI-based similarity system and its individual vector representations for different weight computation schemes, i.e., lexical specificity and *tf-idf*, and for different vector comparison techniques, i.e., cosine and WO, on word similarity and sense clustering datasets. As can be seen from the Table, the performance of the word-based representation consistently improves on both tasks when combined with the additional information from the synset-based vectors, demonstrating that the sense distinctions offered by the generalization process have been beneficial.

Between the two vector comparison methods, WO proves to better suit our specificity-based vec-

Vector representation	Weighting scheme	Vector comparison	Word similarity			Sense clustering	
			MC-30	RG-65	WS-Sim	500-pair	SemEval
Combined	specificity	WO	⋆**0.91**	⋆**0.91**	⋆0.74	⋆**84.6%**	⋆**88.4%**
		cosine	0.88	0.89	**0.75**	76.2%	83.6%
	tf-idf	WO	0.85	0.87	0.73	60.4%	67.8%

		cosine	0.90	0.88	**0.75**	**79.8%**	**85.0%**
	tf-idf	WO	0.86	0.85	0.73	37.2%	41.1%
		cosine	0.71	0.80	0.66	79.4%	**85.0%**
Word-based	specificity	WO	†0.86	†0.87	†0.71	†80.0%	†85.1%

Table 3: Performance of NASARI and its individual vector representations for different weight computation schemes, i.e., lexical specificity and *tf-idf*, and for different vector comparison techniques, i.e., cosine and Weighted Overlap (WO), in terms of Pearson correlation (word similarity) and accuracy (sense clustering). The scores highlighted by ⋆ are the ones obtained using our default NASARI setting, and the ones highlighted by † correspond to the setting of our system using Wikipedia as its only knowledge source.

tors by outperforming cosine in most cases. The reason behind the lower performance of WO for the synset-based vectors on the task of sense clustering can be explained by the nature of the corresponding datasets. Since the synset-based vectors and their overlapping dimensions are small, their cosine similarity scores also tend to be relatively low, unlike WO whose range of values is not affected by the number of overlapping dimensions. Given that in the experiments the threshold is fixed to the middle point of the scale (cf. Section 4.2.2), generally low similarity values lead to a high-precision, low-recall system, which is rewarded by higher accuracy performance in datasets in which a large portion of instances are negative. In fact, for the synset-based vector representation weighted using specificity, the F1 performance of the cosine is significantly lower than WO. On the SemEval dataset the F1 performance of WO is 60.1%, whereas cosine attains 37.1%. Similarly, on the 500-pair dataset, WO leads cosine by 16.8%: 68.5% vs. 51.7%.

As far as the weighting scheme is concerned, lexical specificity outperforms *tf-idf* on both tasks, irrespective of the vector comparison technique and representation. We attribute the better performance of lexical specificity to the probabilistic nature of weights in its vectors. The *tf-idf* weighting scheme, in contrast, suffers from insensitivity to the relative size of the contextual information. Thus, subsequently, specificity-based vectors provide the advantage of accurately reducing the vectors' dimension, unlike the *tf-idf* scheme in which the size-insensitive weights are not comparable across vectors. As a result, the specificity-based vectors are substantially smaller in size, bringing about better space utilization and faster running time. In our experiments the vectors obtained by using lexical specificity were, on average, almost nine times (2505 vs. 21825) and four times (335 vs. 1311) smaller than the *tf-idf*-based vectors for the word-based and synset-based vector representations, respectively.

We were also interested in verifying the advantage gained by combining the complementary knowledge of Wikipedia and WordNet. To this end, we carried out an experiment in which NASARI uses Wikipedia as its only knowledge source (i.e., without using WordNet). The last row in the Table (highlighted by †) shows the results for this setting. Note that since WordNet is not used in this setting, we are constrained to the word-based vector representation only. The results show that the combination of the types of resource leads to a consistent performance

improvement across tasks and datasets, with the average improvement being 5%.

5 Related Work

Given that in this work we focused mainly on similarity for the evaluation of our semantic representation, in addition to concept representation, we also briefly discuss related works for semantic similarity.

Concept representation. Distributional semantic models are usually the first choice for representing textual items such as words or sentences (Turney and Pantel, 2010). These models have attracted considerable research interest, resulting in various co-occurrence based representations (Salton et al., 1975; Evert, 2005; Pado and Lapata, 2007; Erk and Padó, 2008) or predictive models (Collobert and Weston, 2008; Turian et al., 2010; Mikolov et al., 2013; Baroni et al., 2014). Although there have been approaches proposed in the literature for learning sense-specific embeddings (Weston et al., 2013; Huang et al., 2012; Neelakantan et al., 2014), their coverage is limited only to those senses that are covered in the underlying corpus. Moreover, the obtained sense representations are usually not linked to any sense inventory, and therefore such linking has to be carried out, either manually, or with the help of sense-annotated data. Hence, unless they are provided with large amounts of sense-annotated data, these techniques cannot furnish an effective representation of word senses in an existing standard sense inventory.

Consequently, most sense modeling techniques have based their representation on the knowledge derived from resources such as WordNet (Mihalcea and Moldovan, 1999; Agirre and Lopez, 2003; Agirre and de Lacalle, 2004; Pilehvar et al., 2013), or Wikipedia (Gabrilovich and Markovitch, 2007; Mihalcea, 2007). None of these techniques, however, combine knowledge from multiple types of resource, making their representations resource-specific and also prone to sparsity. In contrast, our method is based on the complementary knowledge of two different resources and their interlinking, leading to richer semantic representations that are also applicable across resources. Most similar to our combination of complementary knowledge is the work of Franco-Salvador et al. (2014) for cross-lingual document retrieval.

Concept similarity. Concept similarity techniques are mainly limited to the knowledge that their underlying lexical resources provide. For instance, methods designed for measuring semantic similarity of WordNet synsets (Banerjee and Pedersen, 2002; Budanitsky and Hirst, 2006; Pilehvar et al., 2013) usually leverage lexicographic or structural information in this lexical resource. Similarly, Wikipedia-based approaches (Hassan and Mihalcea, 2011; Strube and Ponzetto, 2006; Milne and Witten, 2008) do not usually benefit from the expert-based lexico-semantic knowledge provided in WordNet. In contrast, our approach combines knowledge from both resources, providing two advantages: (1) more effective measurement of similarity based on rich semantic representations, and (2) the possibility of measuring cross-resource semantic similarity, i.e., between Wikipedia pages and WordNet synsets.

6 Conclusions

In this paper we presented a novel semantic approach, called NASARI, for effective vector representation of arbitrary WordNet synsets and Wikipedia pages. The strength of our approach lies in its combination of complementary knowledge from different types of resource, while at the same time it also benefits from an effective vector representation with two novel features: lexical specificity for the calculation of vector weights and a semantically-aware dimensionality reduction. NASARI attains state-of-the-art performance on multiple standard benchmarks in word similarity as well as Wikipedia sense clustering. We release the representations obtained for all the Wikipedia pages and WordNet synsets in http://lcl.uniroma1.it/nasari/. As future work we plan to integrate NASARI into BabelNet and apply our representation to a multilingual setting, enabling the comparison of pairs of concepts across languages. We also intend to use our approach on the task of multilingual Word Sense Disambiguation.

Towards a standard evaluation method for grammatical error detection and correction

Mariano Felice and **Ted Briscoe**

Abstract

We present a novel evaluation method for grammatical error correction that addresses problems with previous approaches and scores systems in terms of improvement on the original text. Our method evaluates corrections at the token level using a globally optimal alignment between the source, a system hypothesis, and a reference. Unlike the M^2 Scorer, our method provides scores for both detection and correction and is sensitive to different types of edit operations.

1 Introduction

A range of methods have been applied to evaluation of grammatical error correction, but no entirely satisfactory method has emerged as yet. Standard metrics (such as accuracy, precision, recall and F-score) have been used, but they can lead to different results depending on the criteria used for their computation (Leacock et al., 2014; Chodorow et al., 2012).

Accuracy, for example, can only be computed in cases where we can enumerate all true negatives, which is why it has been mostly used for article and preposition errors (De Felice and Pulman, 2008; Rozovskaya and Roth, 2010). Extending this approach to other error types involves the identification of all *relevant instances* or positions where an error can occur, which is not always easy and renders the evaluation process costly, language-dependent, and possibly inexact. Accuracy has also been criticised as being a poor indicator of predictive power, especially on unbalanced datasets (Manning and Schütze, 1999).

Source:	You have missed word.
System hypothesis:	You have missed a word.
System edits:	($\epsilon \rightarrow$ a)
Gold edits:	(word $\rightarrow$ a word) or (word $\rightarrow$ words)

Figure 1: Mismatch between system and gold standard edits producing the same corrected sentence.

Alternatively, we can compute precision (P), recall (R) and F-score by comparing system edits to gold-standard edits and thus circumvent the problem of counting true negatives. This was the official evaluation scheme adopted for the HOO 2011 (Dale and Kilgarriff, 2011) and HOO 2012 (Dale et al., 2012) shared tasks. However, these metrics can fail when edits are not identical and therefore underestimate system performance (see Figure 1).

This problem was later addressed by the *Max-Match* or *M^2 Scorer* (Dahlmeier and Ng, 2012), which is able to identify equivalent edits by applying a transitive rule (e.g. ($\epsilon \rightarrow$ a) + (word $\rightarrow$ word) $\Rightarrow$ (word $\rightarrow$ a word)). The scorer also allows for multiple gold standard annotations of each sentence, choosing the ones that maximise overall F-score. So far, the M^2 Scorer has been the most reliable tool for evaluating error correction systems and has been used as the official scorer in the subsequent CoNLL 2013 (Ng et al., 2013), CoNLL 2014 (Ng et al., 2014) and EMNLP 2014 (Mohit et al., 2014) shared tasks. In 2014, system ranking was based on $F_{0.5}$-score, weighting precision twice as highly as recall.

Nevertheless, this method also suffers from a number of limitations:

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 578–587,
Denver, Colorado, May 31 – June 5, 2015.

Source	**Annotator 1**	**Annotator 2**

System hypothesis	**System edits**	**P**	**R**	**$F_{0.5}$**
These machines are designed to help people .	(This → These), (is → are), (for → to)	0.67	0.67	0.67

Table 1: The M^2 Scorer is unable to mix and match corrections from different annotators.

Source	**Gold edits**			
Machine is design to help people .	(Machine → Machines), (is design → are designed)			
System hypothesis	**System edits**	**P**	**R**	**$F_{0.5}$**
Machine is designed to help people .	(design → designed)	0.00	0.00	0.00

Table 2: Partial matches are ignored by the M^2 Scorer.

(a) There is a limit to the number of unchanged words allowed in an edit (2 by default), whose value affects final results.

(b) Given that the computed metrics rely on true positive counts, a baseline system that does not propose any correct edits will not produce informative results ($P = 1$ by definition, $R = 0$ and $F = 0$). The actual error rate and consequent potential for text improvement are not taken into account.

(c) It is not possible to discriminate between a 'do-nothing' baseline system and other systems that only propose wrong corrections, as they will all yield $F = 0$.

(d) System performance is underestimated when using multiple annotations for a sentence, since the scorer will choose the one that maximises F-score instead of mixing and matching all the available annotations (see Table 1).

(e) Partial matches are ignored (see Table 2).

(f) Phrase-level edits can produce misleading results, as they may not always reflect effective improvements (see Table 3).

(g) The lack of a true negative count (i.e. the number of non-errors) precludes the computation of accuracy, which is useful for discriminating between systems with $F = 0$.

(h) There is no clear indicator of improvement on the original text after applying the suggested corrections, since an increase in P, R or F does not imply a reduction in the error rate (see Section 2.3.3).

(i) It is not clear how values of F should be interpreted (especially for $F_{0.5}$), as there is no known threshold that would signal improvement. Ranking by F-score does not guarantee that the top systems make the source text better.

(j) Detection scores are not computed.

In addition, Leacock et al. (2014) discuss key issues concerning system evaluation, such as the estimation of true negatives and good practices for reporting results, which are currently not addressed by the M^2 scorer.

2 Designing a new evaluation method

A better evaluation method should address the issues described above and use a metric that is meaningful and easy to interpret. We examine these and other related problems, showing how they can be resolved.

The proposed method uses tokens as the unit of evaluation (instead of phrase-level edits), which provides a stable unit of comparison and facilitates the computation of true negatives. In turn, this provides a solution for problems 1.(a), 1.(e), 1.(f) and 1.(g).

Source	**Gold edits**			
Machine is design to help people .	(Machine → Machines), (is → are), (design → designed)			
System hypothesis	**System edits**	**P**	**R**	**$F_{0.5}$**
The machine is designed for helping people .	(Machine is → The machine is), (design → designed), (to help people → for helping people)	0.33	0.33	0.33
Machines is a design on the helping of the people .	(Machine → Machines), (is design to help → is a design on the helping of the)	0.50	0.33	0.45

Table 3: The M^2 Scorer evaluates systems based on the number of edits, regardless of their length and their effect on the final corrected sentence. The first hypothesis is better than the second despite having a lower $F_{0.5}$-score.

The following sections describe the three pillars of our method: a new annotation scheme, sentence alignment and metrics.

2.1 Annotation

We define a gold standard format where each sentence is annotated with a set of errors and their possible corrections. A sentence can contain zero or more errors, each of which includes information such as type, a flag indicating whether a correction is required, and a list of alternative corrections corresponding to each of the annotators. An error is required to be corrected when all annotators provide a correction for it.

Unlike in other annotation schemes, each error is defined by its locus (regardless of the position of the incorrect tokens in the sentence) and all its alternative corrections must be mutually exclusive. In other words, corrections are grouped whenever they refer to the same underlying error, even if the tokens involved are not contiguous. Listing 1 shows a sample XML annotation for the sentence in Table 1.

Because all the correction alternatives are mutually exclusive, we can directly combine them to generate all possible valid gold standard references. The annotation in Listing 1 would produce the following list of references:

These machines *are* designed for *helping* people .

These machines *are* designed *to* help people .

This *machine* is designed for *helping* people .

This *machine* is designed *to* help people .

```
<sentence id="1" numann="2">
  <text>
    This machines is designed for help
    people .
  </text>
  <error-list>
    <error id="1" req="yes" type="SVA">
      <alt ann="0">
        <c start="0" end="1">These</c>
        <c start="2" end="3">are</c>
      </alt>
      <alt ann="1">
        <c start="1" end="2">machine</c>
      </alt>
    </error>
    <error id="2" req="yes" type="Vform">
      <alt ann="0">
        <c start="5" end="6">helping</c>
      </alt>
      <alt ann="1">
        <c start="4" end="5">to</c>
      </alt>
    </error>
  </error-list>
</sentence>
```

Listing 1: An example annotated sentence.

By mixing and matching corrections from different annotators, we avoid the performance underestimation described in 1.(d).

2.2 Alignment

In order to compute matches for detection and correction, we generate a token-level alignment between a source sentence, a system's hypothesis, and a gold standard reference. Three-way alignments

are a special case of *multiple sequence alignment*, a well-known string matching problem in computational biology (Mount, 2004).

We generate an exact (globally optimal) alignment using a dynamic programming implementation of the Sum of Pairs (SP) alignment (Carrillo and Lipman, 1988), shown in Listing 2. Under this model, the score of a multiple alignment is the sum of the scores of each pairwise alignment, so that a globally optimal alignment has minimum SP score. Time and space complexity of the dynamic programming implementation for k strings of length n is $O(n^k)$, which is acceptable for three average-length sentences but can quickly become impractical for a larger number of sequences.

In computational biology, edit costs are defined in terms of mutation probabilities, which are irrelevant to our task. However, we can find new optimal costs by defining a set of constraints that are meaningful for error correction:

(a) Matches have zero cost ($c_{\text{match}} = 0$).

(b) Gaps (insertions or deletions) are more costly than matches ($c_{\text{gap}} > c_{\text{match}}$).

(c) Mismatches (substitutions) are set to be more costly than gaps (insertions or deletions) so as to maximise matches ($c_{\text{mis}} > c_{\text{gap}}$).

Given these constraints, we can set $c_{\text{gap}} = 1$ and $c_{\text{mis}} = 2$; however, they will not necessarily keep gaps aligned (see Table 4). To ensure this, we must place a new constraint on the SP algorithm so that a gap-aligned version (desired alignment) has a lower cost than a gap-unaligned version (initial alignment):

$$\text{cost(A,–)} + \ldots + \text{cost(B,–)} > \text{cost(A,C)} + \ldots + \text{cost(B,–)}$$
$$c_{\text{gap}} + \ldots + c_{\text{gap}} > c_{\text{mis}} + \ldots + c_{\text{gap}}$$
$$4c_{\text{gap}} + c_{\text{mis}} > 2c_{\text{mis}} + 2c_{\text{gap}}$$
$$2c_{\text{gap}} > c_{\text{mis}}$$

Therefore $2c_{\text{gap}} > c_{\text{mis}} > c_{\text{gap}} > c_{\text{match}}$. For our implementation, we adopted $c_{\text{gap}} = 2$ and $c_{\text{mis}} = 3$.

There can be more than one optimal alignment for a given set of strings. Some of these alignments will look more intuitive than others (see Table 5) but they are equally optimal for our evaluation method and will produce the same final results.

Initial alignment		Desired alignment	
A	B	A	B
–	C	C	–
A	–	A	–

Table 4: Initial and desired alignments showing differences in the distribution of gaps.

```
/* Initialisation */

c_match := cost of match
c_mis := cost of mismatch

Listing 2: The Sum of Pairs dynamic programming algorithm for the alignment of three sequences, S_1, S_2 and S_3 (adapted from Gusfield (1997)).

2.3 Metrics

Once we have an optimal alignment between a source, a hypothesis and a reference, we compute a number of metrics that measure different aspects of performance and can be used for ranking systems.

Their	is	wide	spread	usage	of	technology	.		A	A	A	A	A	A	A	A
There	is	widespread	use		of	technology	.	⇔	B	A	B	B	-	A	A	A
There	is	widespread	use		of	technology	.		B	A	B	B	-	A	A	A
Their	is	wide	spread	usage	of	technology	.		A	A	A	A	A	A	A	A
There	is	widespread		use	of	technology	.	⇔	B	A	B	-	B	A	A	A
There	is	widespread		use	of	technology	.		B	A	B	-	B	A	A	A

Table 5: Two equally optimal alignments under the SP alignment model.

Tokens			Classification	
Source	**Hypothesis**	**Reference**	**Detection**	**Correction**
a	a	a	TN	TN
a	a	b	FN	FN
a	a	-	FN	FN
a	b	a	FP	FP
a	b	b	TP	TP
a	b	c	TP	FP, FN, FPN
a	b	-	TP	FP, FN, FPN
a	-	a	FP	FP
a	-	b	TP	FP, FN, FPN
a	-	-	TP	TP
-	a	a	TP	TP
-	a	b	TP	FP, FN, FPN
-	a	-	FP	FP
-	-	a	FN	FN

Table 6: Our extended WAS evaluation scheme.

The limitation in 1.(j) is addressed by computing these metrics for both detection and correction.

We adopt an extended version of the Writer-Annotator-System (WAS) evaluation scheme (Chodorow et al., 2012) where each token alignment is classified as a true positive (TP), true negative (TN), false positive (FP) or false negative (FN). As noted by Chodorow et al. (2012), cases where *source* $\neq$ *hypothesis* $\neq$ *reference*[1] are both a FP and a FN for correction,[2] so we introduce a new FPN class to count such cases and adjust our metrics accordingly. Our extended WAS scheme is shown in Table 6.

With these counts, we can compute P, R and F_β using their standard definitions:

$$P = \frac{\text{TP}}{\text{TP} + \text{FP}} \qquad R = \frac{\text{TP}}{\text{TP} + \text{FN}}$$

$$F_\beta = (1 + \beta^2) \cdot \frac{P \cdot R}{(\beta^2 \cdot P) + R}$$

[1]Note that we use different terminology where *source* = *writer*, *hypothesis* = *system* and *reference* = *annotator*.

[2]From a correction perspective, an alignment where $a \neq b \neq c$ generates a FP for the b class and a FN for the c class.

As mentioned in Section 1, the F measure does not shed light on the error rates in the data and is unable to discriminate between a 'do-nothing' baseline and other systems unless TP > 0. However, because we now have a TN count, we can address problems 1.(b) and 1.(c) by computing accuracy (*Acc*) as follows:

$$Acc = \frac{\text{TP} + \text{TN}}{\text{TP} + \text{TN} + \text{FP} + \text{FN} - \text{FPN}}$$

Unlike in information retrieval, for example, where the whole document collection is usually unknown to the user so TNs are perhaps less relevant, the sentences fed into an error correction system will be provided by users. In this context, TNs are relevant because they indicate what parts of the text are already correct, allowing users to focus on problematic regions. For this reason, accuracy seems a more appropriate measure of text quality than F-score.

2.3.1 Weighted accuracy

Accuracy treats all counts equally, which has two main side effects. A system that introduces the same number of TPs and FPs will have the same accuracy as the 'do-nothing' baseline, in which case we would prefer to keep the original text and rank the system lower, in accord with the choice of $F_{0.5}$ for evaluating the 2014 shared task. Accuracy is also unable to discriminate between systems with different TP and TN counts if their sum is the same.

It is clear that for error correction these counts should be weighted differently. In particular, we would like to:

- Reward correction more than preservation (i.e. $weight_{\text{TP}} > weight_{\text{TN}}$).
- Penalise unnecessary corrections more than uncorrected errors (i.e. $weight_{\text{FP}} > weight_{\text{FN}}$).

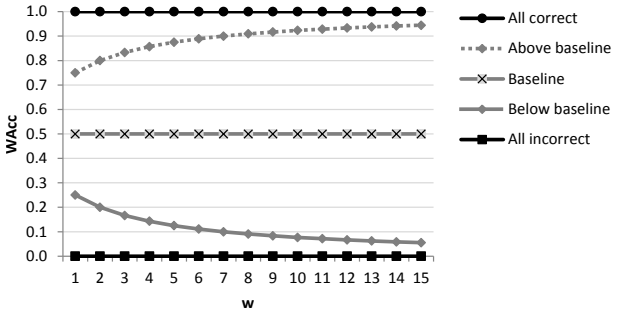

Figure 2: Effect of w on weighted accuracy (WAcc).

We can reformulate accuracy to satisfy these conditions by including a weight factor $w > 1$:

$$\begin{aligned} \mathit{WAcc} &= \frac{w \cdot \text{TP} + \text{TN}}{w \cdot \text{TP} + \text{TN} + w \cdot \left(\text{FP} - \frac{\text{FPN}}{2}\right) + \left(\text{FN} - \frac{\text{FPN}}{2}\right)} \\ &= \frac{w \cdot \text{TP} + \text{TN}}{w \cdot \text{TP} + \text{TN} + w \cdot \text{FP} - w \cdot \frac{\text{FPN}}{2} + \text{FN} - \frac{\text{FPN}}{2}} \\ &= \frac{w \cdot \text{TP} + \text{TN}}{w \cdot (\text{TP} + \text{FP}) + \text{TN} + \text{FN} - (w+1) \cdot \frac{\text{FPN}}{2}} \end{aligned}$$

Higher values of w will reward and penalise systems more heavily, bringing those below the baseline closer to the lower bound and those above the baseline closer to the upper bound (see Figure 2). As w increases, differences between $\mathit{WAcc}_{\text{sys}}$ and its bounds become less pronounced, which is why we adopt $w = 2$. Regardless of w, *WAcc* will always reduce to *Acc* for the 'do-nothing' baseline.

2.3.2 Metric behaviour

Before we set out to evaluate and compare systems, we must understand how metrics behave and to what extent they are comparable.

Table 6 indicates that the metrics will always produce the same results for detection and correction unless *source* $\neq$ *hypothesis* $\neq$ *reference* for at least one position in the alignment. A 'do-nothing' baseline will always produce the same results for both aspects, since *source* $=$ *hypothesis* for all positions.

Whenever a gold standard allows for alternative corrections, references that maximise the target metric should be chosen. Nevertheless, we note that the (maximum) score obtained by a system only applies to a given set of chosen references and is therefore only directly comparable to results on the same reference set.

System	Chosen references	P	R	$F_{0.5}$
S_1	**1.2, 2.1, 3.1**	**0.60**	**0.20**	**0.43**
S_2	1.2, 2.1, 3.1	0.80	0.05	0.20
S_1	1.1, 2.1, 3.2	0.30	0.30	0.30
S_2	**1.1, 2.1, 3.2**	**0.30**	**0.40**	**0.32**

Table 7: S_1 outperforms S_2 in terms of overall $F_{0.5}$ but S_2 outperforms S_1 when evaluated on different references.

To illustrate this, consider two systems (S_1 and S_2) evaluated on a gold standard containing 3 sentences with 2 correction alternatives each (i.e. six possible references: 1.1, 1.2, 2.1, 2.2, 3.1 and 3.2 respectively). Table 7 shows that, while S_1 achieves a higher maximum score than S_2, comparing their $F_{0.5}$ scores directly is not possible as they are computed on a different set of references. In fact, S_2 could outperform S_1 on other reference sets.

2.3.3 Measuring improvement

We know that whenever $P > 0.5$, the error rate decreases (and therefore *Acc* increases) so the text is improved.[3] However, an increase in P, R or F alone does not necessarily imply an increase in *Acc* or *WAcc*, as illustrated in Table 8.

In order to determine whether a system improves on the source text, we must compare its performance ($\mathit{WAcc}_{\text{sys}}$) with that of the baseline ($\mathit{WAcc}_{\text{base}}$). Because each $\mathit{WAcc}_{\text{sys}}$ is computed from a different set of references, we must compute $\mathit{WAcc}_{\text{base}}$ individually for each system using its chosen references. This is done by using the source sentence as the hypothesis in the existing alignment. Once we have $\mathit{WAcc}_{\text{sys}}$ and $\mathit{WAcc}_{\text{base}}$ for each system, we can compare them to determine if the text has improved. When these two values are equal, there is no benefit to deploying the system.

If we want to compare and rank systems, we need to measure how much the text has been improved or degraded. This can be done using a baseline-normalised metric that measures relative coverage of the area between the baseline and *WAcc* bounds (see Figure 3). This metric, henceforth *Improvement* or

[3] In theory, applying more correct edits than incorrect edits will yield a positive balance. However, in practice, this depends on the edits, especially if they are variable-length phrases. The $P > 0.5$ criterion also only holds for *Acc* and not *WAcc*, as the latter modifies the original proportions by introducing weights.

System	TP	FP	TN	FN	P	R	$F_{0.5}$	Acc	WAcc
Baseline	0	0	6	4	1.00	0.00	0.00	0.60	0.60
S_1	4	1	5	0	0.80	1.00	0.83	0.90	0.87
S_2	1	0	6	3	1.00	0.25	0.62	0.70	0.73
S_3	1	1	5	3	0.50	0.25	0.42	0.60	0.58
S_4	4	6	0	0	0.40	1.00	0.45	0.40	0.40

Table 8: An increase in P, R or F does not necessarily translate into an increase in *Acc*, assuming all systems are evaluated on the same set of references.

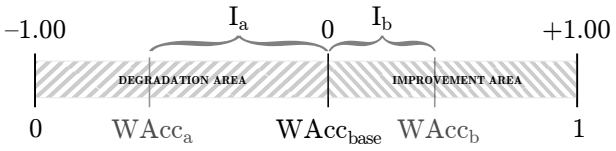

Figure 3: Graphical representation of improvement for two hypothetical systems, a and b. Values of I are shown at the top while values of *WAcc* are shown at the bottom.

Value	Interpretation
1	100% improvement (100% correct text).
> 0	Relative improvement.
0	Baseline performance (no change).
< 0	Relative degradation.
-1	100% degradation (100% incorrect text).

Table 9: Interpretation of I values.

I, is defined as:

$$I = \begin{cases} \lfloor WAcc_{\text{sys}} \rfloor & \text{if } WAcc_{\text{sys}} = WAcc_{\text{base}} \\ \dfrac{WAcc_{\text{sys}} - WAcc_{\text{base}}}{1 - WAcc_{\text{base}}} & \text{if } WAcc_{\text{sys}} > WAcc_{\text{base}} \\ \dfrac{WAcc_{\text{sys}}}{WAcc_{\text{base}}} - 1 & \text{otherwise} \end{cases}$$

Values of I lie in the $[-1; 1]$ interval and should be interpreted as per Table 9. The use of this metric provides a solution to problems 1.(h) and 1.(i).

The I-measure should be computed after maximising system *WAcc* at the sentence level, so as to ensure all the evaluated hypotheses are paired with their highest scoring references.

3 Experiments and results

We tested our evaluation method by re-ranking systems in the CoNLL 2014 shared task on grammatical error correction. Re-ranking was limited to the 12 participating teams that made their system's output publicly available.

For the gold standard, we used the shared task test set containing corrections from the two official annotators as well as alternative corrections provided by three participating teams. This version allowed us to generate many more references than the original test set and thus reduce annotator bias.

The corrections extracted from the gold standard were automatically clustered into groups of independent errors based on token overlap. This means that overlapping corrections from different annotators are considered to be mutually exclusive (i.e. alternative) corrections of the same error and are therefore grouped together (the *error* elements in Listing 1). Provided the original annotations are correct, the combination of alternatives will generate all possible valid references. Sentences containing corrections that could not be automatically clustered because they require human knowledge were excluded, leaving a subset of 711 sentences (out of 1,312).

We restrict our analysis to correction, since that is the only aspect reported by the M^2 Scorer. Table 10 shows the results of the M^2 Scorer using the original annotations as well as a modified version containing mixed-and-matched corrections. Results of our proposed evaluation method are included in Table 11.

As expected, rankings are clearly distinct between the two methods, as they use different units of evaluation (phrase-level edits vs tokens) and maximising metrics ($F_{0.5}$ vs *WAcc*). Results show that only the UFC system is able to beat the baseline (by a small but statistically significant margin), being also the one with consistently highest P (much higher than the rest).

These rankings are affected by the fact that systems were probably optimised for $F_{0.5}$ during development, as it was the official evaluation metric

System	TP	TN	FP	FN	FPN	P	R	$F_{0.5}$	Acc	WAcc	$WAcc_{base}$	I ↓

Table 10: M^2 Scorer results (in percentages).

for the shared task. Rankings by $F_{0.5}$ are almost identical for the two methods (Spearman's rank correlation is 0.9835 with $p < 0.01$), suggesting that there is a statistically significant difference between phrase-level edits and tokens, despite phrases being only 1.12 tokens on average in this dataset.

Spearman's ρ between both scorers ($F_{0.5}$ vs I) is -0.5330, which suggests they generally produce inverse rankings. Pearson's correlation between token-level $F_{0.5}$ and I is -0.5942, confirming the relationship between rankings and our intuition that $F_{0.5}$ is not a good indicator of overall correction quality. While the I-measure reflects improvement, $F_{0.5}$ indicates error manipulation. We argue that I is better suited to the needs of end-users (as it indicates whether the output of the system is better than the original text) whereas $F_{0.5}$ is more relevant to system developers (since they need to analyse P and R in order to tune their systems).

Lastly, we verify that mixing and matching corrections from different annotators improves R (see Table 10) and ensures systems are always assigned the maximum possible score.

4 Discussion

Automatic evaluation metrics that are based on comparisons with a gold standard are inherently limited by the number of available references. Although this does not pose much problem for tasks such as part-of-speech tagging, it does constrain evaluation for text generation tasks (such as error correction, machine translation or summarisation), where the number of 'correct answers' goes beyond a few collected references.

Sentences can be corrected in many different ways and the fact that a given correction is not matched by any of the references does not necessarily mean that it is not valid. Therefore, we must accept that any metric used in such scenarios will not be perfect. However, it is worth noting that this limitation does not extend to evaluation of error detection *per se* using such metrics.

Finding independent evidence to support one correction over another is also difficult, since the notion of sentence quality is somewhat subjective. Evaluation metrics that rely on a gold standard are es-

System hypotheses		Best

Table 12: Example hypotheses produced by two error correction systems (a and b). The last two columns indicate the highest-scoring hypothesis from each pair according to each evaluation metric.

sentially distance metrics, but judging between hypotheses without looking at the source or reference sentences is a distinct task, which is more similar to *sentence quality estimation* for machine translation output.

Our evaluation method overcomes many of the limitations of previous approaches by using a stable unit of evaluation, weighting edit operations in line with the goals of grammatical error correction and making the most of the available annotations. Values of F are always positive, with no clear interpretation or threshold that would indicate improvement of the original text whereas the I-measure provides meaningful indicators ($I < 0$ for degradation, $I = 0$ for no change and $I > 0$ for improvement). Table 12 shows a few examples where the M^2 Scorer differs from our method, revealing how the I-measure is able to pick hypotheses in accord with (at least our) intuitions.

5 Conclusion

We have presented a new evaluation method for grammatical error detection and correction that overcomes many of the limitations of previous approaches and provides more meaningful indicators of system performance.

The method is designed to evaluate improvement in correction of the input text by analysing post-system error rate. Improvement is measured using a reformulation of accuracy where TPs and FPs are weighted higher than TNs and FNs, in an attempt to model desirable aspects of correction. We also combine individual corrections from different annotators, as this improves R and ensures systems get the maximum possible score from the available annotations.

Experiments show I and $F_{0.5}$ are inversely correlated and account for different aspects of system performance. Choosing one metric over the other poses a fundamental question about the aims of error correction, whether we prefer a system that tackles few errors but improves the original text or one that handles many more errors but degrades the original. We believe that, from a user perspective, a system that reliably improves text is more desirable.

Future work might usefully explore automated sentence quality estimation, as a component both of grammatical error correction systems and of their evaluation, in order to ameliorate the issue that any set of gold standard references will underspecify the set of possible corrections.

An open-source implementation of our evaluation method is available for download at `https://github.com/mfelice/imeasure`.

Abstract

Research on ranked retrieval of spoken content has assumed the existence of some automated (word or phonetic) transcription. Recently, however, methods have been demonstrated for matching spoken terms to spoken content without the need for language-tuned transcription. This paper describes the first application of such techniques to ranked retrieval, evaluated using a newly created test collection. Both the queries and the collection to be searched are based on Gujarati produced naturally by native speakers; relevance assessment was performed by other native speakers of Gujarati. Ranked retrieval is based on fast acoustic matching that identifies a deeply nested set of matching speech regions, coupled with ways of combining evidence from those matching regions. Results indicate that the resulting ranked lists may be useful for some practical similarity-based ranking tasks.

1 Introduction

Despite new methods of interaction, speech continues to be a dominant modality for information exchange, particularly among the half of the world's almost five billion mobile phone users who currently lack text-based Internet access. Recording speech poses no particular problems, but retrieval of spoken content using spoken queries is presently available only for the approximately two dozen languages in which there is an established path to market; English, German, or Chinese, for example. However, many of the mobile-only users who could benefit most from such systems speak only one of the several hundred other languages that each have at least a million speakers;[1] Balochi, Mossi or Quechua, for example. Addressing this challenge in a scalable manner requires an integration of speech processing and information retrieval techniques that can be effectively and affordably extended to a large number of languages.

To this end, the experiments in this paper were conducted in a conventional ranked retrieval framework consisting of spoken queries, spoken "documents" (*responses*, hereafter), graded relevance judgments, and standard evaluation measures. As with other information retrieval tasks, there is an element of uncertainty in our best representations of what was said. Our focus on speech processing techniques that are language-agnostic creates the potential for explosive growth in the uncertainty that our search techniques must accommodate. The design and evaluation of such techniques is therefore the central focus of the work explored in this paper.

Our results are both heartening and disconcerting. On the positive side, useful responses can often be found. As one measure of success, we show that a Mean Reciprocal Rank near 0.5 can be achieved when more than one relevant response exists; this corresponds to a relevant response appearing in the second position of a ranked list, on average (by the harmonic mean). On the negative side, the zero-resource speech processing technique that we rely on to generate indexing terms has quadratic time complexity, making even the hundred-hour scale of

[1] There are 393 languages with at least one million speakers according to Ethnologue.

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 588–597,
Denver, Colorado, May 31 – June 5, 2015.

the collection on which we have run our experiments computationally strenuous. We believe, however, that by demonstrating the utility of the techniques introduced in this paper we can help to motivate further work on even more affordable scalable language-agnostic techniques for generating indexable terms from speech.

2 Motivation and Related Work

Extending spoken language processing to low-resource languages has been a longstanding goal of the Spoken Web Search task of MediaEval. In this task, research teams are challenged to identify instances of specific spoken terms that are provided as queries in a few hours of speech. Between 2011 and 2013, the task was run three times on a total of 16 different languages (Rajput and Metze, 2011; Metze et al., 2012; Anguera et al., 2013).[2] Two broad classes of techniques over this span proved to be practical: one based on phonetic recognition followed by phonetic matching; the other based on direct matching of acoustic features. Of the two approaches, phonetic recognition was, at the time, slightly more accurate. Directly matching acoustic features, the focus of this paper, potentially offers easier extensibility to additional languages.

From the perspective of information retrieval, the principal limitation of the "spoken term detection" design of the MediaEval task was the restriction to single-term queries. While single-term queries are common in Web search (Spink et al., 2001), the best reported Actual Term Weighted Value (ATWV) from any MediaEval Spoken Web Search participant was 0.4846 (Abad and Astudillo, 2012). This corresponds to a system that correctly detects 48 per cent of all instances of the spoken query terms, while producing at most ten false alarms for every missed detection (Fiscus et al., 2007). Thus, if users are willing to tolerate low precision, moderate levels of recall are possible. Speech search arguably demands higher precision than does Web search, however, since browsing multiple alternatives is easier in text than in speech. One way of potentially improving retrieval performance is to encourage a searcher to speak at length about what they are looking for (Oard, 2012). Such an approach, however, introduces the new challenge of properly leveraging the additional matching potential of verbose multi-term queries (White et al., 2013).

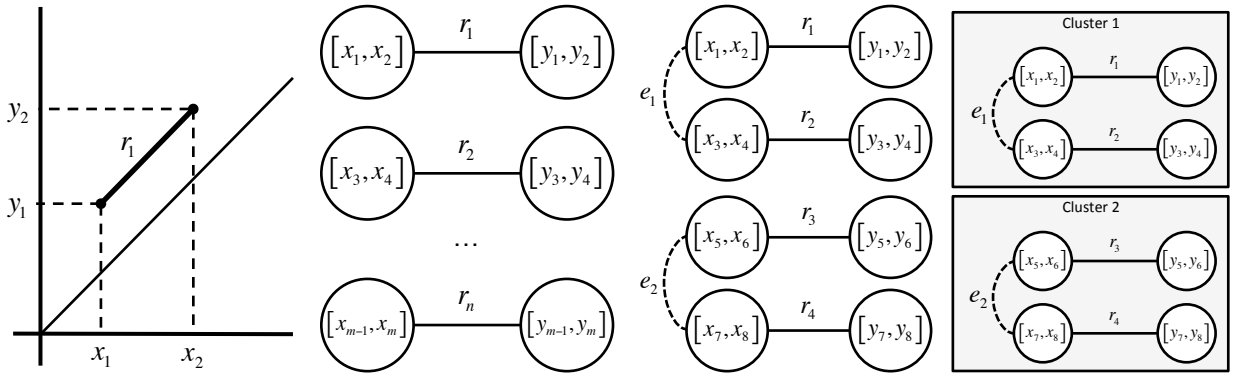
To this end, our work builds on two components: a term matching system, and a test collection. As a term matching system, we used our zero-knowledge speech matching system. In MediaEval 2012, this system achieved an ATWV of 0.321 in the Spoken Web Search task (Jansen et al., 2012). A version of this system has previously been evaluated in an example-based topic classification task using English speech, achieving a classification accuracy of 0.8683 (Drezde et al., 2010). Ranked retrieval using naturally occurring queries is more challenging, however, both because topics in information retrieval are often not easily separable, and because the form of a query may be unlike the form of the responses that are sought. Our goal now, therefore, is to use an information retrieval evaluation framework to drive the development of robust techniques for accommodating representational uncertainty.

Traditional spoken term detection (STD) tries to address uncertainty by learning speech-signal to language-model mappings; using neural networks (Cui et al., 2013; Gales et al., 2014) or Markov models (Chan et al., 2013), for example. From a broad perspective, the method utilized in our work does not use an acoustic model for its analysis. More fundamentally, however, speech signals in our collection map to dozens of smaller terms that are not necessarily the same across utterances of the same word. Thus, it is more accurate to think of the work herein as matching signal features rather than linguistic features.

For this reason, widely used techniques such as stemming, spelling correction, and stopword removal that rely to some extent on linguistic features do not apply in our setting. We therefore rely on term and corpus statistics. Even here there are limitations, since our lexical items are not easily aligned with those found in other collections. For this reason, we can not leverage external corpus statistics from, for example, Google or Wikipedia (Bendersky et al., 2011; Bendersky et al., 2010; Bendersky and Croft, 2008; Lease, 2009), or phrases from search logs (Svore et al., 2010).

Evaluation of ranked retrieval for spoken content

[2] For example, Gujarati, isiNdebele, isiXhosa, Sepedi, Setswana, Telugu, Tshivenda, and Xitsonga.



(a) Term discovery. (b) Term extraction. (c) Term overlap. (d) Term clustering.

Figure 1: Overview of the pseudo-term creation process. The term discovery system is run over the audio. A threshold, δ, dictates the acceptable length, r, and thus the number of regions extracted. Extracted regions are then made into a graph structure, where vertices are regions of speech, and edges denote a connection between those regions. A second edge set is added based on region overlap. Resulting connected components are then clustered; these clusters are known as *pseudo-terms*.

in low-resource languages has to date been hampered by a lack of suitable test collections. We have therefore made our new test collection freely available for research use in recent shared-task information retrieval evaluations (Oard et al., 2013; Joshi and White, 2014).

3 Zero-Resource Term Discovery

In traditional speech retrieval applications, document-level features are derived from the outputs of supervised phonetic or word recognizers. Recent term discovery systems automatically identify repeating words and phrases in large collections of audio (Park and Glass, 2008; Jansen et al., 2010), providing an alternative means of extracting lexical features for retrieval tasks. Critically, this discovery is performed without the assistance of any supervised speech tools by instead resorting to a search for repeated trajectories in a suitable acoustic feature space (for example, Mel Frequency Cepstrum Coefficients (MFCC) and Perceptual Linear Prediction (PLP)) followed by a graph clustering procedure. We refer to the discovered units as *pseudo-terms* (by analogy to the terms built from character sequences that are commonly used in text retrieval), and we can represent each query and response as a set of pseudo-term offsets and durations. We summarize each step in the subsections below. Complete specifications can be found in the literature (Drezde et al., 2010; Jansen and Van Durme, 2011).

3.1 Repetition and Clustering

Our test collection consists of nearly 100 hours of speech audio. Term discovery is inherently an $O(n^2)$ search problem, and application to a corpus of this size is unprecedented in the literature. We applied the scalable system described by Jansen and Van Durme (2011), which employs a pure-to-noisy strategy to achieve a very substantial (orders-of-magnitude) speedup over its predecessor state-of-the-art system (Park and Glass, 2008). The system functions by constructing a sparse (thresholded) distance matrix across the frames of the entire corpus and then searching for approximately diagonal line structures in that matrix, as such structures are indicative that a word or phrase has been repeated (Figure 1a).

To cluster the individual acoustic repetitions into pseudo-term categories we apply a simple graph-based procedure. First, we construct an unweighted acoustic similarity graph, where each segment of speech involved in a discovered repetition becomes a vertex, and each match provides an edge (Figure 1b). Since we construct an unweighted graph and employ a simple connected-components clustering, it is es-

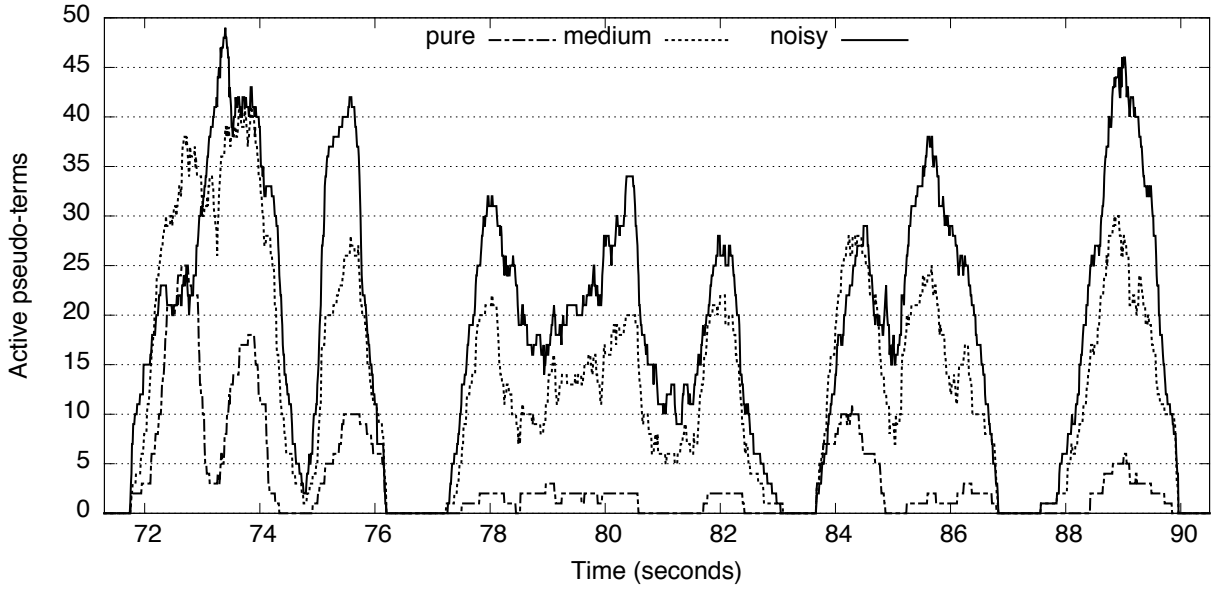


Figure 2: Different pseudo-term nesting structures for various settings of the speech-to-term extraction model. The y-axis represents the number of terms extracted at a given period in time. This figure represents an approximately twenty second interval of Query 42.

sential some DTW distance threshold δ is applied before a repetition is passed along to the clustering procedure. This produces a graph consisting of a set of disconnected "dumbbells."

Finally, the original edge list is augmented with a set of "overlap" edges between corresponding nodes in different dumbbells (Figure 1c); these overlap edges indicate that two nodes correspond to essentially the same segment of speech. For two nodes (two segments of speech) to be considered essentially the same, we require a minimal fractional overlap of 0.97, which is set less than unity to allow some noise in the segment end points. These overlap edges act to effectively merge vertexes across the dumbbells, enabling transitive matches between acoustic segments that did not match directly. The pseudo-terms are defined to be the resulting connected components of the graph, each consisting of a set of corresponding acoustic segments that can occur anywhere in the collection (Figure 1d).

In the experiments described in this paper, three pseudo-term feature variants arising from three settings of the DTW distance threshold are considered. Lower thresholds imply higher fidelity matches that yield fewer and purer pseudo-term clusters. These are referred to as *pure clustering* ($\delta = 0.06$, producing 406,366 unique pseudo-terms), *medium clustering* ($\delta = 0.07$, producing 1,213,223 unique pseudo-terms) and *noisy clustering* ($\delta = 0.075$, producing 1,503,169 unique pseudo-terms).

3.2 Nested Pseudo-Terms

Each pseudo-term cluster consists of a list of occurrences. A term is denoted using start and end offsets, in units of 10 milliseconds, from the beginning of the file. It is thus a simple matter of bookkeeping to construct a bag-of-pseudo-terms representation for each query and response. Moreover, because we have start and end offsets for each pseudo-term, we can also construct more sophisticated representations that are based on filtering or grouping the pseudo-terms based on the ways in which they overlap temporally.

One interesting effect of pseudo-term creation is that the pseudo-terms are often "nested," and they are often nested quite deeply. This sort of nesting has previously been explored for phrase indexing, where a longer term contains a shorter term that might also be used independently elsewhere in the collection. As an English text analogy, if we index "White House spokesman" we might well also want to index "White House" and "spokesman"

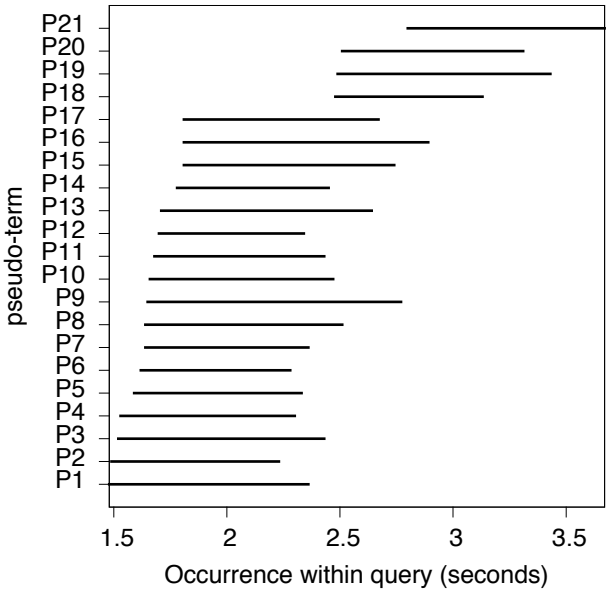

Figure 3: Example of overlapping pseudo-terms within Query 42 under medium clustering. Terms are presented as horizontal bars denoting their start and end time.

separately to support partial matching. Because pseudo-term detection can find any pair of matching regions, we could, continuing the analogy, not only get pseudo-terms for "White House Spokesman" and "White House," but also for parts of those words such as "Whit" and "Whi". Indeed, nesting to depth 50 has been observed in practice for noisy clustering, as displayed in Figure 2. This is a fairly typical pseudo-term nesting graph, in which noisy clustering yields deeper nesting than medium clustering, and much deeper nesting than pure clustering.

Figure 3 shows a collection of pseudo-terms within an overlapping region; in this case a medium clustering representation of the 1.48 second to 3.67 second region of Query 42.[3] As can be seen, calling this "nesting" is somewhat of an oversimplification, the region is actually a set of pseudo-terms that generally overlap to some degree, although not all pseudo-term pairs in one of these "nested" regions actually overlap—pseudo-terms P1 and P21, for example. What gives a nested region its depth is the overlap between pseudo-terms that have adjacent start times. Although in this case, as is typical, there is no one dominating pseudo-term for the entire nested region, there are some cases in which one pseudo-terms is entirely subsumed by another; pseudo-terms P5 and P6, for example. This trait can be leveraged during term matching.

[3]Figure 2 shows the same query between 70 and 90 seconds.

4 Retrieval Models

The development of ranking functions, referred to as "retrieval models," proceeded in three stages. To establish a baseline, we first implemented a standard bag-of-words approach. We then looked to techniques from Cross-Language Information Retrieval (CLIR) for inspiration, since CLIR techniques must accommodate some degree of translation ambiguity and for which robust techniques have been established. Our zero-resource pseudo-term discovery techniques result in representations that differ from the CLIR case in two key ways, however: 1) in CLIR the translation relationship is normally represented such that one side (query or document) exhibits no ambiguity, whereas we have ambiguity on both sides; and 2) in CLIR the typical scope of all translation alternatives are aligned, whereas we have complex nested units that contain terms with differing temporal extents. We therefore developed a new class of techniques that leverage the temporal extent of a pseudo-term as a measure of specificity (Figure 2) and the fraction of a nested unit covered by a pseudo-term as a measure of descriptiveness (Figure 3). This section describes each of these three types of retrieval models in turn.

Indri (Strohman et al., 2004) indexes were built using pseudo-terms from pure, medium or noisy clustering; in each case, stemming and stopword removal were disabled. Indri's query language provides operators that make it possible to implement all of our retrieval models using query-time processing from a single index.

4.1 Types of Retrieval Models

To explore the balance between specificity and descriptiveness, retrieval models were developed that primarily differed along three dimensions: structured versus unstructured, selective versus inclusive, and weighted versus unweighted. Structured mod-

els (*S*) treat nested pseudo-terms with varying levels of synonymy. Unstructured models (*U*) treat nested pseudo-terms as independent. Selective models retain only a subset (1 or n) of the pseudo-terms from each nested region; inclusive models retain them all (*a*). Finally, weighted models (*W*) include a heuristic adjustment to give some pseudo-terms (in our experiments, longer ones) greater influence; unweighted models treat each pseudo-term in the same manner. Table 1 illustrates the weights given to each term by each of the retrieval models defined below. Unweighted models implicitly take a binary approach to term weighting—with unweighted selective models omitting many pseudo-terms—while structured and weighted models yield real values between zero and one. Note that both weighted and unweighted models reward term repetition (term frequency) and term specificity (inverse collection frequency).

4.2 Bag-of-Words Baseline (Ua)

Our first set of experiments had three goals: 1) to serve as a dry run for system development, as we had no prior experience with indexing or ranked retrieval based on pseudo-terms; 2) to gain experience with performing relevance judgments using only the audio responses; and 3) to understand the feasibility of speech retrieval based on pseudo-terms. For these initial experiments, each pseudo-term was treated as a "word" in a bag-of-words representation (coded Ua). No consideration was given to term length or nesting. Although this set of runs was largely exploratory, it provided a good baseline for comparison to other methods considered.

4.3 Terms as Synonyms (Sa, U1)

Moving beyond the bag of words method of term selection involves various forms of term analysis within an overlapping region. The first family of methods treats terms in each overlapping group as synonymous. Aside from being straightforward, treating terms as unweighted synonyms has been a successful technique in cross-language IR. There are generally two methods that can be used in such cases. The first is to treat all overlapping pseudo-terms as synonyms of a single term. This is accomplished in Indri by placing each pseudo-term in an overlapping region within the `syn` operator. This model is coded Sa.

	Retrieval Model					
P. Term	Ua	Sa	U1	Un	UaW	SaW
P21	1.00	0.05		1.00	0.45	0.45
P20	1.00	0.05			0.43	0.22
P19	1.00	0.05			0.48	0.48
P18	1.00	0.05			0.36	0.36
P17	1.00	0.05			0.45	0.06
P16	1.00	0.05		1.00	0.53	0.53
P15	1.00	0.05			0.48	0.11
P14	1.00	0.05			0.37	0.12
P13	1.00	0.05			0.48	0.22
P12	1.00	0.05			0.36	0.02
P11	1.00	0.05			0.41	0.22
P10	1.00	0.05			0.43	0.24
P9	1.00	0.05	1.00		0.54	0.54
P8	1.00	0.05			0.45	0.45
P7	1.00	0.05			0.39	0.04
P6	1.00	0.05			0.37	0.03
P5	1.00	0.05			0.40	0.13
P4	1.00	0.05			0.41	0.08
P3	1.00	0.05			0.47	0.47
P2	1.00	0.05			0.40	0.22
P1	1.00	0.05		1.00	0.46	0.46

Table 1: Weights assigned to pseudo-terms in Figure 3 by each retrieval model (zero values shown as blank).

One risk with the Sa model is that including shorter terms may add more noise than signal. Another method of dealing with alternatives in the cross-language IR literature is to somehow select a single term from the set. For our experiments with this technique, only the longest pseudo-term from an overlapping set is retained; all other ("nested") pseudo-terms are simply deleted from the query. The thinking behind this is that the longest term should contain the greatest amount of information. This method is coded U1.

4.4 Length Measure of Specificity (UaW, SaW)

The U1 and Sa models are two extremes on a spectrum of possibilities; thus, models in which some pseudo-terms receive less weight, rather than being ignored entirely, were also explored. Care must be

taken, however, to do so in a way that emphasizes coverage rather than nesting depth: more weight should not be given to some region in a query or a response just because it is deeply nested (indicating extreme uncertainty). Both the U1 and Sa models do this, but in a rather unnuanced manner. For a more nuanced approach, inspiration can be found in techniques from cross-language IR that give more weight to some term choices than to others.

Our basic approach is to downweight terms that are dominated temporally by several other terms, where the amount of downweighting is proportional to the number of terms that cover it. This is implemented by adjusting the contribution of each pseudo-term based on the extent of its overlap with other pseudo-terms. This could be done in a way that would give the greatest weight to either the shortest or the longest nested pseudo-term.

Formally, let $T = \{t_1, t_2, \ldots, t_n\}$ be the nested term class, ordered by term length. Let $l(t_i)$ denote the length of term t_i, in seconds. Further, let

$$w(t_i) = \frac{\alpha \times l(t_i)}{1 + \alpha \times l(t_i)}$$

be the weight of term t_i, where α is a free parameter. For our experiments, $\alpha = 0.5$. The *discounted weight* is

$$d(t_i) = \begin{cases} w(t_i) & i = 1 \\ w(t_i) \times \prod_{j=1}^{i-1} (1 - w(t_j)) & \text{otherwise,} \end{cases}$$

where t_j refers, implicitly, to other members of T. The factor $1 - w(t_i)$ is used to discount the weight of t_i due to the contribution made by the previous term(s). We assume T to be in descending order and define two heuristics: *total weight discounted* (UaW) and *longest weight discounted* (SaW). The former uses Indri's `weight` operator to specify term weights at query time; the latter uses `wsyn`.

4.5 Coverage Measure of Descriptiveness (Un)

Recall Figure 3, a visual display of pseudo-term overlap within an arbitrary region of speech. Outside of the bounds of that figure there is either silence—no terms to describe a particular segment of time—or a region of terms that describe some other utterance within the overall speech. Of particular note, however, is that within the bounds there are a potentially large number of terms that can be used to *describe* a region of speech. Thus, the larger the number of terms present, the larger the amount of redundancy in the segment of speech each term describes. This observation motivates our final query methodology: removing redundancy within a region by extracting a seemingly descriptive subset of terms from that region. Here we begin to move beyond the ideas inspired by cross-language IR.

Specifically, we posit that an optimal subset contains the beginning and ending terms of the region, along with a series of intra-terms that connect the two. It is with this logic that the *unweighted shortest path* (coded Un) was conceived. Un attempts to find the subset that captures the most information using the smallest number of terms. Formally, consider a directed graph in which the set of vertexes is the set of pseudo-terms within an overlapping region. For an arbitrary pair of vertexes, $u, v \in V$, there is an outgoing edge from u to v if $y(u) \geq x(v)$, where $x(\cdot)$ and $y(\cdot)$ denote the start and end time, respectively, of a given pseudo-term. Further, the weight of such an edge is the difference between these times: $w(u, v) = y(u) - x(v)$. Note that an edge between u and v does not exist if they have the same start time, $x(u) = x(v)$.

Let $\hat{u}$ and $\hat{v}$ be the endpoints of the graph; that is, for all $u, v \in P$, $x(\hat{u}) \leq x(u)$, and $y(\hat{v}) \geq y(v)$. Our objective is to find the shortest path from $\hat{u}$ to $\hat{v}$ that minimizes the standard deviation of the edge weights. Minimizing standard deviation results in a set of terms with more uniform overlaps.

5 Building a Test Collection

The test collection was built using actual spoken content from the Avaj Otalo (Patel et al., 2010) "speech forum," an information service that was regularly used by a select group of farmers in Gujarat. These farmers spoke Gujarati, a language native to western parts of India and spoken by more than 65 million people worldwide. Most of the farmers knew no other language, and approximately 30 per cent were unable to read or write. The idea was to provide a resource for the local farming community to exchange ideas and have their questions an-

swered. To this end, farmers would call into an Interactive Voice Response (IVR) system and peruse answers to existing questions, or would pose their own questions for the community. Other farmers would call into the system to leave answers to those questions. On occasion, there were also a small group of system administrators who would periodically call in to leave announcements that they expected would be of interest to the broader farming community. The system was completely automated—no human intervention or call center was involved.

Avaj Otalo's recorded speech was divided into 50 *queries* and 2,999 *responses*. Queries were statements on a particular topic, sometimes phrased as a question, sometimes phrased as an announcement. Responses were sometimes answers to questions, sometimes they were related announcements, and sometimes they were questions on a similar topic. This represented approximately two-thirds of the total audio present in the system. Very short recordings were omitted, as were those in which little speech activity was automatically detected. The average length of a query is approximately 70 seconds ($SD = 14.40$s), or approximately 61 seconds ($SD = 15.76$s) after automated silence removal. Raw response lengths averaged 110 seconds ($SD = 88.80$s), and 96.52 seconds ($SD = 82.75$s) after silence was removed.

5.1 Relevance Judgments and Evaluation

Pools for judgment were formed by combining the results from every system reported in our results section below, along with several other systems that yielded less interesting results that we omit for space reasons. Three native speakers of Gujarati performed relevance assessment; none of the three had any role in system development. Relevance assessment was performed by listening to the audio and making a graded relevance judgment. Assessors could assign one of the following judgments for each response: 1) unable to assess, 2) not relevant, 3) relevant, and 4) highly relevant.

For evaluation measures that require binary judgments, and for computing inter-annotator agreement, the relevance judgments were subsequently binarized by removing all the unassessable cases. Highly relevant and relevant responses were then collapsed into a single relevant category. To compute NDCG, relevant and highly relevant categories were assigned the scores 1 and 2, respectively, while non-relevant judgments retained a score of 0. Three rounds of relevance assessments were conducted as query models were developed and assessor agreement was characterized.

	Retrieval Model					
	U1	Un	Ua	UaW	Sa	SaW
MRR	0.447	0.281	0.169	0.204	0.235	0.432
	0.139	0.071	0.081	0.089	0.242	0.075
	0.188	0.104	0.109	0.193	0.252	0.105
MAP	0.106*	0.057	0.047	0.060*	0.058	0.111
	0.023	0.011	0.015	0.018	0.050	0.010
	0.045	0.013	0.018	0.050	0.058	0.022
NDCG	0.237	0.216	0.206	0.219	0.214	0.284*
	0.122	0.098*	0.187	0.195	0.243	0.194
	0.142	0.089*	0.219	0.191	0.285	0.230

Table 2: Results for pure (top), medium (middle) and noisy (bottom) clustering for the 10 queries for which more than one relevant response is known. Shaded cells are best-performers, per measure; starred values indicate NDCG or MAP is significantly better or worse than same-row Ua (two-sided paired t-test, $p < 0.05$).

6 Results

Each retrieval model was run for each of the three clustering results. For each method, there were three metrics of interest: normalized discounted cumulative gain (NDCG), mean reciprocal rank (MRR), and mean average precision (MAP). Results are outlined in Table 2. To limit the effect of quantization noise on the evaluation measures, results are reported for queries having three or more relevant documents. There were a total of 10 such queries, having a total of 61 relevant documents and yielding an average of 6.10 documents per query ($SD = 2.13$).

Low baselines for each evaluation were established—as there were none in prior existence—by randomly sampling 60 documents from the test collection. For each of the six randomly selected topics, 10 of the 60 randomly selected documents were add to the judgment pool without replacement.

Relevance judgments were performed in an order that obscured, from the assessor, the source of the response being judged. The 10 random selections were then evaluated for each of the six topics as if they had been a system run. None of the 60 randomly selected documents were judged by assessors to be relevant to their respective randomly selected topic; thus the random baseline for each of our measures is zero. Without multiple draws, confidence intervals on this value cannot be established. However, we are confident that random baselines even as high as 0.1 for any of our measures would be surprising.

Pure clustering produced the best results with respect to other clustering domains. SaW was, generally, the best performing retrieval model. Although SaW did not produce the highest pure cluster MRR numbers, it was within 0.015 of U1, the best performing method. This is notable given that the difference between U1 and the third best method was 0.166. Further, given the highly quantized nature of MRR, a difference of 0.015 says little about any overall difference between the rankings. In the case of NDCG, SaW was the best performer with pure clustering, significantly better than BoW with pure clustering and second best overall. Sa with noisy clustering was best numerically with NDCG, but the difference is minuscule (1/1000th).

Under pure clustering, Ua was generally the worst performer. Thus, query refinement using the temporal extent of pseudo-terms is a good idea. Further, the MRR of U1 and SaW both approach one-half. Since MRR is the inverse of the harmonic mean of the rank, we can interpret this as meaning that it is likely that a user will get a relevant document somewhere in the first three positions of the result set. Such a result is encouraging, as it means that, under the correct conditions, a retrieval system built using zero-resource term detection is a potentially useful tool in practice. We should note, however, that this result was obtained for result-rich queries in which three or more relevant responses were known to exist; MRR results on needle-in-a-haystack queries for which only a single relevance response exists would likely be lower. As with all search, precision-biased measures benefit from collection richness.

7 Conclusions and Future Work

Recent advances in zero-resource term discovery have facilitated spoken document retrieval without the need for traditional transcription or ASR. There are still open questions, however, as to best practices around building useful IR systems on top of these tools. This work has been a step in filling that void. The results show that these zero-resource methods can be used to find relevant responses, and that in some cases such relevant responses can also be highly ranked. Retrieval results vary depending on how much redundancy exists in the transcribed data, and how that redundancy is handled within the query. One common theme, at least for the techniques that we have explored, is that pure clustering seems to be the best overall choice when ranked retrieval is the goal. A promising next step is to look to techniques from speech retrieval for insights that might be applicable to the zero-resource setting. One possibility in this regard is to explore extending the zero-resource term matching techniques to generate a lattice representation from which expected pseudo-term counts could be computed.

Constraint-Based Models of Lexical Borrowing

Abstract

Linguistic borrowing is the phenomenon of transferring linguistic constructions (lexical, phonological, morphological, and syntactic) from a "donor" language to a "recipient" language as a result of contacts between communities speaking different languages. Borrowed words are found in all languages, and—in contrast to cognate relationships—borrowing relationships may exist across unrelated languages (for example, about 40% of Swahili's vocabulary is borrowed from Arabic). In this paper, we develop a model of morpho-phonological transformations across languages with features based on universal constraints from Optimality Theory (OT). Compared to several standard—but linguistically naïve—baselines, our OT-inspired model obtains good performance with only a few dozen training examples, making this a cost-effective strategy for sharing lexical information across languages.

1 Introduction

We may imagine that globalization is a modern phenomenon, but the lexicons of the world's languages attest to the fact that robust interaction between communities of speakers of different languages is widespread throughout history. Language contact breeds *linguistic borrowing*—a phenomenon as old as language itself—adoption and nativization of phonemes, morphemes, words, and syntactic constructions from another language (Thomason and Kaufman, 2001).

Contact-induced borrowing is a fundamental research topic in linguistics; however, in computational linguistics, very limited work has addressed modeling this phenomenon. The problem we address is the identification of plausible donor words (in the donor language) given a loanword (in the recipient language), and vice versa, identification of loanwords given a donor. For example, given a Swahili loanword *safari* 'journey', our model identifies its Arabic donor سفريه (*sfryh*)[1] 'journey' (§2). Although at a high level, this is an instance of the well-known problem of modeling string transductions, our interest is being able to identify correspondences across languages with minimal supervision, so as to make the technique applicable in low-resource settings. To reduce the supervision burden, we propose a model that includes awareness of the morpho-phonological repair strategies that native speakers of a language subconsciously employ to adapt a loanword to phonological constraints of the recipient language (§3). To this end, we use constraint-based theories of phonology, as exemplified by Optimality Theory (OT) (Prince and Smolensky, 2008; McCarthy, 2009), which non-computational linguistic work has demonstrated to be particularly well suited to account for phonologically complex borrowing processes (Kang, 2011). We operationalize OT constraints as features in our borrowing model (§4).

We conduct a case study on Arabic and Swahili, two unrelated languages with a long history of contact; we then apply the model to additional language pairs (§5). The proposed approach significantly outperforms transliteration and cognate discovery models (§6).

[1] We use Buckwalter notation to write Arabic glosses.

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 598–608,
Denver, Colorado, May 31 – June 5, 2015.

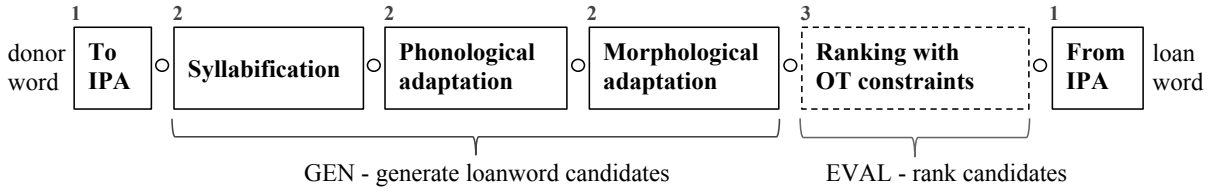

Figure 1: Our morpho-phonological borrowing model conceptually has three main parts: (1) conversion of orthographic word forms to pronunciations in IPA format; (2) generation of loanword pronunciation candidates; (3) ranking of generated candidates using Optimality-Theoretic constraints. Part (1) and (2) are rule-based, (1) uses pronunciation dictionaries, (2) is based on prior linguistic studies; part (3) is learned. In (3) we learn OT constraint weights from a few dozen automatically extracted training examples.

2 Methodology

Our task is to identify plausible donor–loan word pairs in a language pair. While modeling string transductions is a well-studied problem in NLP, we wish to be able to learn the cross-lingual correspondences from minimal amounts of data, so we propose a linguistically-motivated approach: we formulate a scoring model inspired by Optimality Theory (OT; discussed below), in which borrowing candidates are ranked by universal constraints posited to underly the human faculty of language, and the candidates are determined by transduction processes articulated in prior studies of contact linguistics.

As shown in figure 1, our model is conceptually divided into three main parts: (1) mapping of orthographic word forms in two languages into a common space of their phonetic representation; (2) generation of loanword pronunciation candidates from a donor word; (3) ranking of generated loanword candidates, based on linguistic constraints of the donor and recipient languages. Parts (1) and (2) are rule-based; whereas (3) is learned. Each component of the model is discussed in detail in the following sections.

The model is implemented within a finite-state cascade. Parts (1) and (2) amount to unweighted string transformation operations. In (1), we convert orthographic word forms to their pronunciations in the International Phonetic Alphabet (IPA), these are pronunciation transducers. In (2) we syllabify donor pronunciations, then perform insertion, deletion, and substitution of phonemes and morphemes (affixes), to generate multiple loanword candidates from a donor word. Although string transformation transducers in (2) can generate loanword candidates that are not found in a recipient language vocabulary, such candidates are filtered out due to composition with the recipient language lexicon acceptor.

We perform string transformations from donor to recipient (recapitulating the historical process). However, the resulting relation (i.e., the final composed transducer) is a bidirectional model which can just as well be used to reason about underlying donor forms given recipient forms. To employ the model in a specific direction, one needs to optimize parameters—weights on transitions—to generate a desired set of outputs from a specific input. Our model is trained to discriminate a donor word given a loanword. In part (3), candidates are "evaluated" (i.e., scored) with a weighted sum of universal constraint violations. The non-negative weights, which we call "cost vector", constitute our model parameters and are learned using a small training set of donor–recepient pairs. We use a shortest path algorithm to find the path with the minimal cost.

OT: constraint-based evaluation Our decision to evaluate borrowing candidates by weighting counts of "constraint violations" is based on Optimality Theory, which has shown that complex surface phenomena can be well-explained as the interaction of constraints on the form of outputs and the relationships of inputs and outputs (Kager, 1999). Although our linear scoring scheme departs from OT's standard evaluation assumptions (namely, the assumption of an ordinal constraint ranking and strict dominance rather than constraint "weighting"), we are still able to obtain effective models.

Although originally a theory of monolingual phonology, OT has been adapted to account for borrowing by treating the donor language word as the underlying form for the recipient language; that is,

the phonological system of the recipient language is encoded as a system of constraints, and these constraints account for how the donor word is adapted when borrowed. There has been substantial prior work in linguistics on borrowing in the OT paradigm (Yip, 1993; Davidson and Noyer, 1997; Jacobs and Gussenhoven, 2000; Kang, 2003; Broselow, 2004; Adler, 2006; Rose and Demuth, 2006; Kenstowicz and Suchato, 2006; Kenstowicz, 2007; Mwita, 2009), but none of it has led to computational realizations.

3 Generating loanword candidates

In this section, we use the Arabic–Swahili language-pair to describe the prototypical linguistic adaptation processes that words undergo when borrowed. Then, we describe how we model these processes.[2]

3.1 Case study: Arabic–Swahili borrowing

The Swahili lexicon has been influenced by Arabic due to a prolonged period of language contact in the Indian Ocean trading (800 A.D.–1920), as well as the influence of Islam (Rothman, 2002). According to several independent studies, Arabic loanwords constitute from 18% (Hurskainen, 2004) to 40% (Johnson, 1939) of Swahili word types.

Despite a strong susceptibility of Swahili to borrowing and a large fraction of Swahili words originating from Arabic, the two languages are typologically distinct with profoundly dissimilar phonological and morpho-syntactic systems. Therefore, Arabic loanwords have been substantially adapted to conform to Swahili phonotactics, which we survey briefly. First, Arabic has five syllable patterns:[3] CV, CVV, CVC, CVCC, and CVVC (McCarthy, 1985, pp. 23–28), whereas Swahili (like other Bantu languages) is characterized by the syllable ending with a vowel and CV or V syllable structure. At the segment level, Swahili loanword adaptation thus involves extensive vowel epenthesis in consonant clusters and at a syllable final position if the syllable ends with a consonant, e.g., : كتاب (*ktAb*) → *kitabu* 'book' (Polomé, 1967; Schadeberg, 2009; Mwita, 2009). Second, phonological adaptation in Swahili loanwords includes shortening of vowels (unlike Arabic, Swahili does not have phonemic length); substitution of consonants that are found in Arabic but not in Swahili (e.g., emphatic (pharyngealized) /tˤ/→/t/, voiceless velar fricative /x/→/k/, dental fricatives /θ/→/s/, /ð/→/z/, and the voiced velar fricative /ɣ/→/g/); adoption of Arabic phonemes that were not originally present in Swahili /θ/, /ð/, /ɣ/ (e.g., تحذير (*tH*yr*)→ *tahadhari* 'warning'); degemination of Arabic geminate consonants (e.g., شرّ (*$r~*)→ *shari* 'evil'). Finally, adapted loanwords can freely undergo Swahili inflectional and derivational processes, e.g., الوزير (*Alwzyr*) → *waziri* 'minister', *mawaziri* 'ministers', *kiuwaziri* 'ministerial' (Zawawi, 1979; Schadeberg, 2009).

3.2 Arabic–Swahili borrowing transducers

We describe unweighted transducers for pronunciation, syllabification, and morphological and phonological adaptation. An example that illustrates some of the possible string transformations by individual components of the model is shown in figure 2. The goal of these transducers is to minimally overgenerate Swahili adapted forms of Arabic words, based on the adaptations described above.

Pronunciation. Based on the IPA, we assign shared symbols to sounds that exist in both sound systems of Arabic and Swahili (e.g., nasals /n/, /m/; voiced stops /b/, /d/), and language-specific unique symbols to sounds that are unique to the phonemic inventory of Arabic (e.g., pharyngeal voiced and voiceless fricatives /ħ/, /ʕ/) or Swahili (e.g., velar nasal /ŋ/). For Swahili, we construct a pronunciation dictionary based on the Omniglot grapheme-to-IPA mapping.[4] In Arabic, we use the CMU Arabic vowelized pronunciation dictionary containing about 700K types which has an average of four pronunciations per word (Metze et al., 2010).[5] We then design four transducers—Arabic and Swahili word-to-IPA and IPA-to-word transducers—each as a union of linear chain transducers, as well as one acceptor per pronunciation dictionary listing.

[2]For simplicity, we subsume Omani Arabic and other historical dialects of Arabic under the label "Arabic"; similarly, we subsume Swahili, its dialects and protolanguages under "Swahili".

[3]C stands for consonant, and V for vowel.

[4]www.omniglot.com

[5]Since we are working at the level of word types which have no context, we cannot disambiguate the intended form, so we include all options. For example, for the input word كتابا (*ktAbA*) 'book.sg.indef', we use both pronunciations /kitabɑ/ and /kuttɑbɑ/.

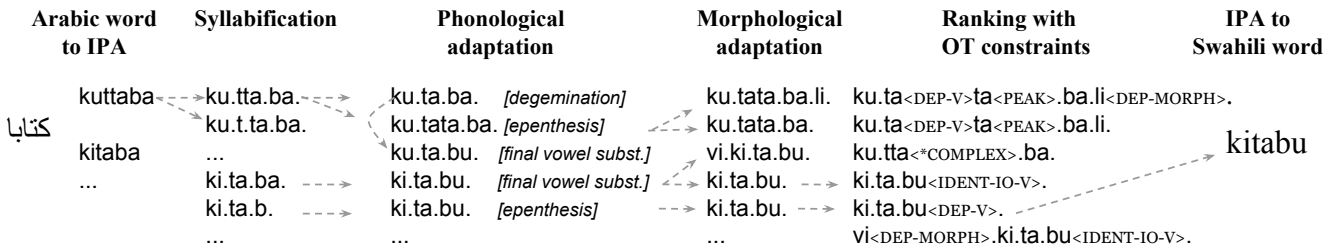

Figure 2: An example of an Arabic word كتابا (*ktAbA*) 'book.sg.indef' transformed by our model into a Swahili loanword *kitabu*.

Syllabification. Arabic words borrowed into Swahili undergo a repair of violations of the Swahili segmental and phonotactic constraints, for example via vowel epenthesis in a consonant cluster. Importantly, *repair depends upon syllabification*. To simulate plausible phonological repair processes, we generate multiple syllabification variants for input pronunciations. The syllabification transducer optionally inserts syllable separators between phones. For example, for an input phonetic sequence /kuttɑbɑ/, the output strings include /ku.t.tɑ.bɑ/, /kut.tɑ.bɑ/, and /ku.ttɑ.bɑ/ as syllabification variants; each variant violates different constraints and consequently triggers different phonological adaptation.

Phonological adaptation. Phonological adaptation of syllabified phone sequences is the crux of the loanword adaptation process. We implement phonological adaptation transducers as a composition of plausible context-dependent insertions, deletions, and substitutions of phone subsets, based on prior studies summarized in §3.1. In what follows, we list phonological adaptation components in the order of transducer composition in the borrowing model. The **vowel deletion** transducer shortens Arabic long vowels and vowel clusters. The **consonant degemination** transducer shortens Arabic geminate consonants, e.g., it degeminates /tt/ in /ku.ttɑ.bɑ/, outputting /ku.tɑ.bɑ/. The **substitution of similar phonemes** transducer substitutes similar phonemes and phonemes that are found in Arabic but not in Swahili (Polomé, 1967, p. 45). For example, the emphatic /tˤ/, /dˤ/, /sˤ/ are replaced by the corresponding non-emphatic segments [t], [d], [s]. The **vowel epenthesis** transducer inserts a vowel between pairs of consonants (/ku.ttɑ.bɑ/ → /ku.tatɑ.bɑ/), and at the end of a syllable, if the syllable ends with a consonant (/ku.t.tɑ.bɑ/ → /ku.ta.tɑ.bɑ/). Sometimes it is possible to predict the final vowel of a word, depending on the word-final coda consonant of its Arabic counterpart: /u/ or /o/ added if an Arabic donor ends with a labial, and /i/ or /e/ added after coronals and dorsals (Mwita, 2009). Following these rules, the **final vowel substitution** transducer complements the inventory of final vowels in loanword candidates.

Morphological adaptation. Both Arabic and Swahili have significant morphological processes that alter the appearance of lemmas. To deal with morphological variants, we construct morphological adaptation transducers that optionally strip Arabic concatenative affixes and clitics, and then optionally append Swahili affixes, generating a superset of all possible loanword hypotheses. We obtain the list of Arabic affixes from the Arabic morphological analyzer SAMA (Maamouri et al., 2010); the Swahili affixes are taken from a hand-crafted Swahili morphological analyzer (Littell et al., 2014).

4 Learning constraint weights

Due to the computational problems of working with OT (Eisner, 1997; Eisner, 2002), we make simplifying assumptions by (1) bounding the theoretically infinite set of underlying forms with a small linguistically-motivated subset of allowed transformations on donor pronunciations, as described in §3; (2) imposing a priori restrictions on the set of the surface realizations by intersecting the candidate set with the recipient pronunciation lexicon; (3) assuming that the set of constraints is finite and regular (Ellison, 1994); and (4) assigning linear weights to constraints, rather than learning an ordinal constraint ranking (Boersma and Hayes, 2001; Goldwater and

Faithfulness constraints	
MAX-IO-MORPH	no (donor) affix deletion
MAX-IO-C	no consonant deletion
MAX-IO-V	no vowel deletion
DEP-IO-MORPH	no (recipient) affix epenthesis
DEP-IO-V	no vowel epenthesis
IDENT-IO-C	no consonant substitution
IDENT-IO-C-M	no subst. in manner of pronunciation
IDENT-IO-C-A	no subst. in place of articulation
IDENT-IO-C-S	no subst. in sonority
IDENT-IO-C-P	no pharyngeal consonant substitution
IDENT-IO-C-G	no glottal consonant substitution
IDENT-IO-C-E	no emphatic consonant substitution
IDENT-IO-V	no vowel substitution
IDENT-IO-V-O	no subst. in vowel openness
IDENT-IO-V-R	no subst. in vowel roundness
IDENT-IO-V-F	no subst. in vowel frontness
IDENT-IO-V-FIN	no final vowel substitution

Table 1: Faithfulness constraints prefer pronounced realizations completely congruent with their underlying forms.

Markedness constraints	
NO-CODA	syllables must not have a coda
ONSET	syllables must have onsets
PEAK	there is only one syllabic peak
SSP	complex onsets rise in sonority, complex codas fall in sonority
*COMPLEX-S	no consonant clusters on syllable margins
*COMPLEX-C	no consonant clusters within a syllable
*COMPLEX-V	no vowel clusters

Table 2: Markedness constraints impose language-specific structural well-formedness of surface realizations.

Johnson, 2003).

OT distinguishes "markedness" constraints (McCarthy and Prince, 1995), which detect dispreferred phonetic patterns in the language, and "faithfulness" constraints (Prince and Smolensky, 2008), which ensure correspondences between the underlying form and the surface candidates.[6] The implemented constraints are listed in tables 1 and 2. Faithfulness constraints are integrated in phonological transformation components as transitions following each insertion, deletion, or substitution. Markedness constraints are implemented as standalone identity transducers: inputs are equal outputs, but path weights representing candidate evaluation with respect to violated constraints are different.

The final "loanword transducer" is the composition of all transducers described in §3 and OT constraint transducers. A path in the transducer represents a syllabified phonemic sequence along with (weighted) OT constraints it violates, and shortest path outputs are those, whose cumulative weight of violated constraints is minimal.

OT constraints are realized as features in our linear model, and feature weights are learned in a discriminative training to maximize the accuracy obtained by the loanword transducer on a small development set of donor–recipient pairs. For parameter estimation, we employ the Nelder–Mead algorithm (Nelder and Mead, 1965), a heuristic derivative-free method that iteratively optimizes, based on an objective function evaluation, the convex hull of $n+1$ simplex vertices.[7] The objective function is the "soft accuracy" of the development set, defined as the proportion of correctly identified donor words in the total set of 1-best outputs.

5 Adapting the model to a new language

Although we conduct a thorough case study on the Arabic–Swahili language pair, our methodology can easily be generalized to other language pairs. String transformation operations, as well as OT constraints are language-universal. The only adaptation required is a linguistic analysis to identify plausible morphophonological repair strategies for the new language pair (i.e., a subset of allowed insertions, deletions and substitutions of phonemes and morphemes). Since we need only to overgenerate candidates (the OT constraints will filter bad outputs), the effort is minimal relative to many other grammar engineering exercises. The second language-specific component is the grapheme-to-IPA converter. While this can be a non-

[6] To clarify the distinction between faithfulness and markedness constraint groups to the NLP readership, we can draw the following analogy to the components of machine translation or speech recognition: faithfulness constraints are analogical to the translation model or acoustic model (reflecting input), while markedness constraints are analogical to the language model (requiring well-formedness of the output). Without faithfulness constraints, the optimal surface form could differ arbitrarily from the underlying form.

[7] The decision to use Nelder–Mead rather than more conventional gradient-based optimization algorithms was motivated by practical limitations of the finite-state toolkit we used that made computing derivatives with latent structure impractical.

trivial problem in some cases, the problem is well studied, and many under-resourced languages have "phonographic" systems where orthography corresponds to phonology, rather than organically evolved written forms, which makes the mapping problem trivial.

To illustrate the ease with which a language pair can be engineered, we applied our borrowing model to the French–Romanian language pair. Although French and Romanian are sister languages (both descending from Latin), about 12% of Romanian types are true French borrowings that came into the language in the past few centuries (Schulte, 2009). We employ the GLOBALPHONE pronunciation dictionary for French (Schultz and Schlippe, 2014) (we convert it to IPA), and automatically construct a Romanian pronunciation dictionary using Omniglot grapheme-to-IPA conversion rules.

6 Experiments

Our experimental setup is defined as follows. The input to the borrowing model is a loanword candidate in Swahili/Romanian,[8] the outputs are plausible donor words in the Arabic/French monolingual lexicon (i.e., any word in pronunciation dictionary). We train the borrowing model using a small set of training examples, and then evaluate it using a held-out test set. In the rest of this section we describe in detail our datasets, tools, and experimental results.

Resources We employ Arabic–English and Swahili–English bitexts to extract a training set (corpora of sizes 5.4M and 14K sentence pairs, respectively), using a cognate discovery technique (Kondrak, 2001). Phonetically and semantically similar strings are classified as cognates; phonetic similarity is the string similarity between phonetic representations, and semantic similarly is approximated by translation.[9] We thereby extract Arabic and Swahili pairs $\langle a, s \rangle$ that are phonetically similar ($\frac{\Delta(a,s)}{\min(|a|,|s|)} < 0.5$) where $\Delta(a, s)$ is the Levenshtein distance between a and s and that are aligned to the same English word e. FastAlign (Dyer et al., 2013) is used for word alignments. Given an extracted word pair $\langle a, s \rangle$, we also extract word pairs $\{\langle a', s \rangle\}$ for all proper Arabic words a' which share the same lemma with a producing on average 33 Arabic types per Swahili type. We use MADA (Habash et al., 2009) for Arabic morphological expansion.

From the resulting dataset of 490 extracted Arabic–Swahili borrowing examples,[10] we set aside randomly sampled 73 examples (15%) for evaluation,[11] and use the remaining 417 examples for model parameter optimization. For French–Romanian language pair, we use an existing small annotated set of borrowing examples,[12] with 282 training and 50 (15%) randomly sampled test examples.

We use `pyfst`—a Python interface to OpenFst (Allauzen et al., 2007)—for the borrowing model implementation.[13]

Baselines We compare our model to several baselines. In the Levenshtein (L) distance baselines we chose the closest word (either surface or pronunciation-based). In the Levenshtein-weighted (L-W) baselines, we evaluate a variant of the Levenshtein distance tuned to identify cognates (Mann and Yarowsky, 2001; Kondrak and Sherif, 2006); this method was identified by Kondrak and Sherif (2006) among the top three cognate identification methods. In the CRF baselines we generate plausible "transliterations" of the input Swahili (or Romanian) words in the donor lexicon using the model of Ammar et al. (2012), with multiple references in a lattice and without reranking. The CRF transliteration model is a linear-chain CRF where we label each source character with a sequence of target characters. The features are label unigrams, label bigrams, and label

[8] Our model does not provide a mechanism for identifying loanwords in the recipient language; we only model the borrowing process. Classifying loanwords in the recipient language is an interesting but ultimately different problem: the ontological status of words in a lexicon is a difficult problem, even for human experts, however, knowledge of cross-lingual correspondences is a valuable feature, and as such, our work can be understood as enabling this.

[9] This cognate discovery technique is sufficient to extract a small training set, but is not generally applicable, as it requires parallel corpora or manually constructed dictionaries to measure semantic similarity. Large parallel corpora are unavailable for most language pairs, including Swahili–English.

[10] In each training/test example one Swahili word corresponds to all extracted Arabic donor words.

[11] We manually verified that our test set contains clear Arabic–Swahili borrowings. For example, we extract Swahili *kusafiri, safari* and Arabic السفر, يسفر, سفر (*Alsfr, ysAfr, sfr*) all aligned to 'travel'.

[12] `http://wold.clld.org/vocabulary/8`

[13] `https://github.com/vchahun/pyfst`

conjoined with a moving window of source characters. In the OT-uniform baseline, we evaluate the accuracy of the borrowing model with uniform weights, thus shortest paths in the loanwords transducer will be forms violating the fewest constraints.

Evaluation In addition to predictive accuracy on all models (if a model produces multiple hypotheses with the same 1-best weight, we count the proportion of correct outputs in this set), we evaluate two particular aspects of our proposed model: (1) appropriateness of the model family, and (2) the quality of the learned OT constraint weights. The first aspect is designed to evaluate whether the morpho-phonological transformations implemented in the model are required *and* sufficient to generate loanwords from the donor inputs. We report two evaluation measures: model *reachability* and *ambiguity*. Reachability is a percentage of test samples that are reachable (i.e., there is a path from the input test example to a correct output) in the loanword transducer. A naïve model which generates all possible strings would score 100% reachability, but it will be hard to set the model parameters such that it discriminates between good and bad candidates. In order to capture this trade-off, we also report the inherent *ambiguity* of our model, which is the average number of outputs potentially generated per input. A generic Arabic–Swahili transducer, for example, has an ambiguity of 786,998—the size of the Arabic pronunciation lexicon.

Results The borrowing model reachability and ambiguity are listed in table 3. The model obtains high reachability, while significantly reducing the average number of possible outputs per input: in Arabic from 787K to 857 words, in French from 62K to 12. This result shows that the loanword transducer design, based on the prior linguistic analysis, is a plausible model of word borrowing. Yet, there are on average 33 correct Arabic words out of the possible 857 outputs, thus the second part of the model—OT constraint weights optimization—is crucial.

The accuracy results in table 4 show how challenging the task of modeling lexical borrowing between two distinct languages is, and importantly, that orthographic and phonetic baselines including the state-of-the-art generative model of transliteration are not suitable for this task. Phonetic baselines for Arabic–Swahili perform better than orthographic ones, but substantially worse than OT-based models, even if OT constraints are not weighted. Crucially, the performance of the borrowing model with the learned OT weights corroborates the assumption made in numerous linguistic accounts that OT is an adequate analysis of the lexical borrowing phenomenon.

	AR–SW	FR–RO
Reachability	87.7%	82.0%
Ambiguity	857	12

Table 3: The evaluation of the borrowing model design. Reachability is a percentage of donor–recipient pairs that are reachable from a donor to a recipient language. Ambiguity is an average number of outputs that the model generates per one input.

		Accuracy (%)	
		AR–SW	FR–RO
Orthographic	L	8.9	38.0
	CRF	16.4	36.0
Phonetic	L	19.8	26.3
	L-W	19.7	30.7
OT	OT-U	29.3	58.5
	OT	**48.4**	**75.6**

Table 4: The evaluation of the borrowing model accuracy. The baselines are orthographic (surface) and phonetic (based on pronunciation lexicon) Levenshtein distance (L), heuristic Levenshtein distance with lower penalty on vowel updates and similar letter/phone substitutions (L-W), CRF transliteration, and our model with uniform (OT-U) and learned OT constraint weights assignment.

Qualitative evaluation The constraint ranking learned by the borrowing model (constraints are listed in tables 1, 2) is in line with prior linguistic analysis. Space precludes a thorough discussion, but we highlight a few points. In Swahili NO-CODA dominates all other markedness constraints, as expected. Both *COMPLEX-S and *COMPLEX-C, restricting consonant clusters, dominate *COMPLEX-V, confirming that Swahili is more permissive to vowel clusters. SSP—sonority-based constraint—captures a common pattern of consonant clustering, found across languages, and is also learned by our model as undominated by most competitors in Swahili, and as a dominating markedness constraint in Romanian. Finally, vowel epenthesis DEP-IO-V is the most common strategy in Arabic loanword adaptation, and is ranked lower according to the model; however, it is ranked

EN	AR gloss	AR pronunciation	SW syllabification	Violated OT constraints
book	ktAb	kitAb	ki.ta.bu.	IDENT-IO-C-G$\langle A, a\rangle$, DEP-IO-V$\langle \epsilon, u\rangle$
palace	AlqSr	AlqaSr	ka.sri	MAX-IO-MORPH$\langle Al, \epsilon\rangle$, IDENT-IO-C-S$\langle q, k\rangle$, IDENT-IO-C-E$\langle S, s\rangle$, *COMPLEX-C$\langle sr\rangle$, DEP-IO-V$\langle \epsilon, i\rangle$
wage	Ajrh	Aujrah	u.ji.ra.	MAX-IO-V$\langle A, \epsilon\rangle$, ONSET$\langle u\rangle$, DEP-IO-V$\langle \epsilon, i\rangle$, MAX-IO-C$\langle h, \epsilon\rangle$

Table 5: Examples of syllabification and OT constraint violations produced by our borrowing model.

highly in the French–Romanian model, where vowel insertion is rare.

A second interesting by-product of our model is an inferred syllabification. While we did not conduct a systematic quantitative evaluation, higher-ranked Swahili outputs tend to contain linguistically plausible syllabifications, although the syllabification transducer inserts optional syllable boundaries between every pair of phones. This result further attests to the plausible constraint ranking learned by the model. Example Swahili syllabifications[14] along with the OT constraint violations produced by the borrowing model are depicted in table 5.

7 Discussion

The task of modeling borrowing is unexplored in computational linguistics. In this section we first situate the task with respect to two most closely related research directions: modeling transliteration and cognate forms. We then motivate the new line of research proposed in this work: modeling borrowing.

Borrowing vs. transliteration Borrowing is not transliteration. Transliteration refers to writing in a different *orthography*, whereas borrowing refers to *expanding a language* to include words adapted from another language. Unlike borrowing, transliteration is more amenable to orthographic—rather than morpho-phonological—features, although see (Knight and Graehl, 1998). Borrowed words might have begun as transliterations, but a characteristic of borrowed words is that they become assimilated in the linguistic system of the recipient language, and became regular content words, e.g., 'orange' and 'sugar' are English words borrowed from Arabic نارنج (*nArnj*) and السكر (*Alskr*), respectively.

[14]We chose examples from the Arabic–Swahili system because this is a more challenging case due to linguistic discrepancies.

Borrowing vs. inheritance Cognates are words in related languages inherited from one word in a common ancestral language (the proto-language). Loanwords, on the other hand, can occur between any languages, either related or not, that historically came into contact. Theoretical analysis of cognates has tended to be concerned with a diachronic point of view, i.e., modeling word changes across time. While of immense scientific interest, language processing applications are arguably better served by models of synchronic processes, peculiar to loanword analysis.

Why borrowing? Borrowing is a distinctive and pervasive phenomenon: *all* languages borrowed from other languages at some point in their lifetime, and borrowed words constitute a large fraction of most language lexicons. Another important property of borrowing is that in adaptation of borrowed items, changes in words are systematic, knowledge of morphological and phonological patterns in a language can be used to predict how borrowings will be realized in that language, without having to list them all. Therefore, modeling of borrowing is a task well-suited for computational approaches.

Our suggestion in this work is that we can identify borrowing relations between resource-limited languages and resource-rich donor languages, such as English, French, Spanish, Arabic, Chinese, and Russian. For example, 30–70% of the vocabulary in Vietnamese, Cantonese, and Thai—relatively resource-limited languages spoken by hundreds of millions of people—are borrowed from Chinese and English. Similarly, African languages have been greatly influenced by Arabic, Spanish, English, and French—widely spoken languages such as Swahili, Zulu, Malagasy, Hausa, Tarifit, Yoruba contain up to 40% of loanwords. Indo-Iranian languages—Hindustani, Hindi, Urdu, Bengali, Persian, Pashto—spoken by 860 million, also extensively borrowed from Arabic and English (Haspelmath and Tadmor, 2009). In

short, at least a billion people are speaking resource-scarce languages whose lexicons are heavily borrowed from resource-rich languages.

Why is this important? Lexical translations or alignments extracted from large parallel corpora have been widely used to project annotations from high- to low-resource languages (Hwa et al., 2005; Täckström et al., 2013; Ganchev et al., 2009; Tsvetkov et al., 2014, *inter alia*). Unfortunately, parallel resources are unavailable for the majority of resource-limited languages. Loanwords can be used as a source of cross-lingual links complementary to lexical alignments. This holds promise for applying existing cross-lingual methods and bootstrapping linguistic resources in languages where no parallel data is available.

8 Related work

With the exception of a study conducted by Blair and Ingram (2003) on generation of borrowed phonemes in English–Japanese language pair (the method does not generalize from borrowed phonemes to borrowed words, and does not rely on linguistic insights), we are not aware of any prior work on computational modeling of lexical borrowing. Few papers only mention or tangentially address borrowing, we briefly list them here. Daumé III (2009) focuses on areal effects on linguistic typology, a broader phenomenon that includes borrowing and genetic relations across languages. This study is aimed at discovering language areas based on typological features of languages. Garley and Hockenmaier (2012) train a maxent classifier with character n-gram and morphological features to identify anglicisms (which they compare to loanwords) in an online community of German hip hop fans. List and Moran (2013) have published a toolkit for computational tasks in historical linguistics but remark that "Automatic approaches for borrowing detection are still in their infancy in historical linguistics."

Two related lines of research are transliteration and cognate identification. Knight and Graehl (1998), Al-Onaizan and Knight (2002) developed a finite-state generative model of transliteration, and successfully applied it to Arabic–English named entity translation. Mann and Yarowsky (2001) and Kondrak (2001) identify cognate pairs, based on the learned surface and phonetic similarities, respectively. As our experiments confirm, orthographic and phonetic transliteration and string edit distance methods are not adequate models for the complex borrowing phenomena.

9 Conclusion

Given a loanword, our model identifies plausible donor words in a contact language. We show that a discriminative model with Optimality Theoretic features effectively models systematic phonological changes in Arabic–Swahili loanwords. We also found that the model and methodology is generally applicable to other language pairs with minimal engineering effort.

This paper makes two contributions: (1) To the best of our knowledge, this is the first computational model of lexical borrowing. (2) While there are implementations of OT (Hayes et al., 2013), they are used chiefly to facilitate linguistic analysis.

There are numerous research questions that we would like to explore further. Is it possible to monolingually identify borrowed words in a language? Can we automatically identify a donor language (or its phonological properties) for a borrowed word? Since languages may borrow from many sources, can jointly modeling this process lead to better performance? Can we reduce the amount of language-specific engineering required to deploy our model? Can we integrate knowledge of borrowing in downstream NLP applications? We intend to address these questions in future work.

Abstract

We present Model Invertibility Regularization (MIR), a method that jointly trains two directional sequence alignment models, one in each direction, and takes into account the invertibility of the alignment task. By coupling the two models through their parameters (as opposed to through their inferences, as in Liang et al.'s Alignment by Agreement (ABA), and Ganchev et al.'s Posterior Regularization (PostCAT)), our method seamlessly extends to all IBM-style word alignment models as well as to alignment *without* parallel data. Our proposed algorithm is mathematically sound and inherits its convergence guarantees from EM. We evaluate MIR on two tasks: (1) On word alignment, applying MIR on fertility based models we attain higher F-scores than ABA and PostCAT. (2) On Japanese-to-English back-transliteration without parallel data, applied to the decipherment model of Ravi and Knight, MIR learns sparser models that close the gap in whole-name error rate by 33% relative to a model trained on parallel data, and further, beats a previous approach by Mylonakis et al.

1 Introduction

The transfer of information between languages is a common natural language phenomenon that is intuitively invertible. For example, in transliteration, a source-language word is mapped to a target language's writing system under a sound preserving mapping (for example, "computer" to Japanese Romaji, "konpyutaa"). The original word should then be recoverable from its transliterated version. Similarly, in translation, the back-translation of the translation of a word is likely to be that same word itself.

In NLP, however, commonly-used generative models describing such phenomena are directional, only concerned with the transfer of source-language symbols to target-language symbols or vice versa, but not both directions. Left unchecked, independently training two such directional models (source-to-target and target-to-source) often yields two models that diverge from this invertibility intuition.

In word alignment, this can lead to disagreements between alignments inferred by a model trained in one direction and those inferred by a model trained in the reverse direction. To remedy this disparity (and other shortcomings), it is common to turn to alignment symmetrization techniques such as grow-diag-final-and (Koehn et al., 2003) which heuristically combines alignments from both directions.

Liang et al. (2006) suggest a more fundamental approach they call Alignment by Agreement (ABA), which jointly trains two word alignment models by maximizing their data-likelihoods along with a regularizer that rewards agreement between their alignment posteriors (computed over each parallel sentence pair). Although their EM-like optimization procedure is heuristic, it proves effective at jointly training bidirectional models. Ganchev et al. (2008) propose another approach for agreement between the directed models by adding constraints on the alignment posteriors. Unlike ABA, their optimization is exact, but it can be computationally expensive, requiring multiple forward-backward inferences in each E-step.

In this paper we develop a different approach for jointly training general bidirectional sequence alignment models called Model Invertibility Regularization, or MIR (Section 3). Our approach has two key benefits over ABA and PostCAT: First, MIR can

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 609–618,
Denver, Colorado, May 31 – June 5, 2015.

be applied to sequence alignment without parallel data. Second, a single implementation seamlessly extends to all IBM models, including the fertility based models. Furthermore, since MIR follows the MAP-EM framework, it inherits its desirable convergence guarantees.

The key idea facilitating the easy extension to complex models and to non-parallel data settings is in our regularizer, which operates on the model parameters as opposed to their inferences. Specifically, MIR was designed to reward model pairs whose translation tables respect the invertibility intuition.

We tested MIR against competitive baselines on two sequence alignment tasks: word alignment (with parallel data) and back-transliteration decipherment (without parallel data).

On Czech-English and Chinese-English word alignment (Section 5), restricted to the HMM model, MIR attains F- and B score improvements that are comparable to those of ABA and PostCAT. We further apply MIR beyond HMM, on the fertility-based IBM Models, showing further gains in F-score compared to the baseline, ABAandPostCAT. Interestingly, the HMM alignments obtained by ABA and MIR are qualitatively different, so that combining the two yields additive gains over each method by itself.

On English-Japanese back-transliteration decipherment (Section 6), we apply MIR to the cascade of wFSTs approach proposed by Ravi and Knight (2009). Using MIR, we are able to reduce the whole-name error-rate relative to a model trained on parallel data by 33%, as well as significantly outperform the joint model proposed by Mylonakis et al. (2007).

2 Background

We are concerned with learning generative models that describe transformations of a source-language sequence $\mathbf{e} = (e_1, \ldots, e_I)$ to a target-language sequence $\mathbf{f} = (f_1, \ldots, f_J)$. We consider two different data scenarios.

In the parallel data setting, each sample in the observed data consists of a pair $(\mathbf{e}, \mathbf{f})$. The generative story assigns the following probability to the event that $\mathbf{f}$ arises from $\mathbf{e}$:

$$p(\mathbf{f} \mid \mathbf{e}; \Theta) = \sum_{\mathbf{a}} p(\mathbf{a}, \mathbf{f} \mid \mathbf{e}; \Theta) \qquad (1)$$

where Θ denotes the model parameters and $\mathbf{a}$ denotes a hidden variable that corresponds to unknown choices taken in the generative process.

In the non-parallel data setting, only the target sequence $\mathbf{f}$ is observed and the source sequence $\mathbf{e}$ is hidden. The model assigns the following probability to the observed data:

$$p(\mathbf{f}; \Theta) = \sum_{\mathbf{e}} p(\mathbf{e}) \sum_{\mathbf{a}} p(\mathbf{a}, \mathbf{f} \mid \mathbf{e}). \qquad (2)$$

That is, the sequence $\mathbf{f}$ can arise from any sequence $\mathbf{e}$ by first selecting $\mathbf{e} \sim p(\mathbf{e})$ and then proceeding according to the parallel-data generative story (Eq. 1).

Unsupervised training of such models entails maximizing the data log-likelihood $L(\Theta)$:

$$\arg\max_{\Theta} \; L(\Theta) = \arg\max_{\Theta} \sum_{x \in X} \log p(\mathbf{x}; \Theta)$$

where $X = \{(\mathbf{e}^n, \mathbf{f}^n)\}_n$ in the parallel data setting and $X = \{(\mathbf{f}^n)\}_n$ in the non-parallel data setting.

Although the structure of Θ is unspecified, in practice, most models that follow these generative stories contain a word translation table (t-table) denoted t, with each parameter $t(f \mid e)$ representing the conditional probability of mapping a given source symbol e to a target symbol f.

3 Model Invertibility Regularization

In this section we propose a method for jointly training two word alignment models, a source-to-target model Θ_1 and a target-to-source model Θ_2, by regularizing their parameters to respect the invertibility of the alignment task. We therefore name our method *Model Invertibility Regularization* (MIR).

3.1 Regularizer

Our regularizer operates on the t-table parameters t_1, t_2 of the two models, as follows: Let matrices T_1, T_2 denote the t-tables t_1, t_2 in matrix form and consider their multiplication $T = T_1 T_2$. The resulting matrix T is a stochastic square matrix of dimension $|V_1| \times |V_1|$ where $|V_1|$ denotes the size of the source-language vocabulary. Each entry T_{ij} represents the total probability mass mapped from source word e_i to source word e_j by first applying the source-to-target mapping T_1 and then the target-to-source mapping T_2.

In particular, each diagonal entry T_{ii} holds the probability of mapping a source symbol back onto itself, a quantity we intuitively believe should be high. We therefore (initially) consider maximizing the trace of T:

$$\mathrm{Tr}[T] = \sum_i T_{ii} = \sum_e \sum_f t_1(f \mid e)\, t_2(e \mid f).$$

We further note that $\mathrm{Tr}[T] = \mathrm{Tr}[T_1 T_2] = \mathrm{Tr}[T_2 T_1]$, so that the trace captures equally well how much the target symbols map onto themselves.

Since T is stochastic, setting it to the identity matrix I maximizes its trace. In other words, the more T_1 and T_2 behave as (pseudo-)inverses of each other, the higher the trace is. This exactly fits with our intuition regarding invertibility.

Unfortunately, the trace is not concave in both T_1 and T_2, a property which will become desirable in optimization. We therefore modify the trace regularizer by applying the entrywise square root operator on T_1, T_2 and denote the new term R:

$$\begin{aligned} R(t_1, t_2) &= \mathrm{Tr}\left[\sqrt{T_1}\,\sqrt{T_2}\right] \\ &= \sum_e \sum_f \sqrt{t_1(f \mid e)\, t_2(e \mid f)}. \end{aligned} \tag{3}$$

Note that R is maximized when $\sqrt{T_1}\,\sqrt{T_2} = I$.

Concavity of R in both t_1, t_2 (or equivalently T_1, T_2) follows by observing that it is a sum of concave functions – each term in the summation is a geometric mean, which is concave in its parameters.

3.2 Joint Objective Function

We apply `MIR` in two data scenarios: In the parallel data setting, we observe N sequence pairs $\{\mathbf{x}_1^n\}_n = \{(\mathbf{e}^n, \mathbf{f}^n)\}_n$ or, equivalently, $\{\mathbf{x}_2^n\}_n = \{(\mathbf{f}^n, \mathbf{e}^n)\}_n$.

In the non-parallel setting, two monolingual datasets are observed: N_1 source sequences $\{\mathbf{x}_1^n\}_n = \{\mathbf{e}^n\}_n$ and N_2 target sequences $\{\mathbf{x}_2^n\}_n = \{\mathbf{f}^n\}_n$.

The probability of the nth sample under the kth model Θ_k (for $k \in \{1, 2\}$) is denoted $p_k(\mathbf{x}_k^n; \Theta_k)$. Specifically, in the parallel data setting, the probability of $\mathbf{x}_k^n$ under its model is:[1]

$$\begin{aligned} p_1(\mathbf{x}_1^n; \Theta_1) &= p(\mathbf{f}^n \mid \mathbf{e}^n; \Theta_1) \\ p_2(\mathbf{x}_2^n; \Theta_2) &= p(\mathbf{e}^n \mid \mathbf{f}^n; \Theta_2) \end{aligned}$$

[1]This slight notational abuse helps represent both data scenarios succinctly.

whereas in the non-parallel data setting, the probability is defined as:

$$\begin{aligned} p_1(\mathbf{x}_1^n; \Theta_1) &= p(\mathbf{f}^n; \Theta_1) \\ p_2(\mathbf{x}_2^n; \Theta_2) &= p(\mathbf{e}^n; \Theta_2). \end{aligned}$$

Using the above definitions and the `MIR` regularizer R (Eq. 3), we formulate an optimization program for maximizing the regularized log-likelihoods of the observed data:

$$\max_{\Theta_1, \Theta_2} \; \lambda R(t_1, t_2) + \sum_{k \in \{1,2\}} \sum_{n=1}^{N_k} \log p_k(\mathbf{x}_k^n; \Theta_k) \tag{4}$$

where $\lambda \geq 0$ is a tunable hyperparameter (note that, in the parallel case, $N = N_1 = N_2$).

We defer discussion on the relationship and merits of our approach with respect to `ABA` (Liang et al., 2006) and `PostCAT` (Ganchev et al., 2008) to Section 4.

3.3 Optimization Procedure

Using our concave regularizer, `MIR` optimization (Eq. 4) neatly falls under the MAP-EM framework (Dempster et al., 1977) and inherits the convergence properties of the underlying algorithms. MAP-EM follows the same structure as standard EM: The E-step remains identical to the standard E-step, while the M-step maximizes the complete-data log-likelihood plus the regularization term. In the case of `MIR`, the E-step can be carried out independently for each model. The only extra work is in the M-step, which optimizes a single (concave) objective function.

Specifically, let $\mathbf{z}_n$ denote the missing data, where, in the parallel data setting, only the alignment is missing ($\mathbf{z}_k^n = \mathbf{a}_k^n$) and in the non-parallel data setting, both alignment and source symbol are missing ($\mathbf{z}_1^n = (\mathbf{a}_1^n, \mathbf{e}^n), \mathbf{z}_2^n = (\mathbf{a}_2^n, \mathbf{f}^n)$).

In the E-step, each model Θ_k (for $k \in \{1, 2\}$) is held fixed and its posterior distribution over the missing data $\mathbf{z}_k^n$ is computed per each observation, $\mathbf{x}_k^n$:

$$q_k(\mathbf{z}_k^n, \mathbf{x}_k^n) := p_k(\mathbf{z}_k^n \mid \mathbf{x}_k^n; \Theta_k).$$

In the M-step, the computed posteriors are used to define a convex optimization program that max-

imizes the regularized sum of expected complete-data log-likelihoods:

$$\max_{\Theta_1,\Theta_2} \lambda R(t_1, t_2) + \sum_{k\in\{1,2\}} \sum_{n=1}^{N_k} q_k(\mathbf{z}_k^n, \mathbf{x}_k^n) \log p_k(\mathbf{x}_k^n, \mathbf{z}_k^n)$$

where n ranges over the appropriate sample set.

Operationally, for models Θ_k that can be encoded as wFSTs (such as the IBM1, IBM2 and HMM word alignment models), the E-step can be carried out efficiently and exactly using dynamic programming (Eisner, 2002). Other models resort to approximation techniques – for example, the fertility-based word alignment models apply hill-climbing and sampling heuristics in order to efficiently estimate the posteriors (Brown et al., 1993)

From the computed posteriors q_k we collect expected counts for each event, used to construct the M-step optimization objective. Since the `MIR` regularizer couples only the t-table parameters, the update rule for any remaining parameter is left unchanged (that is, one can use the usual closed-form count-and-divide solution).

Now, let $\mathsf{C}_1^{e,f}$ and $\mathsf{C}_2^{e,f}$ denote the expected counts for the t-table parameters. That is, $\mathsf{C}_k^{e,f}$ denotes the expected number of times a source-symbol type e is seen aligned to a target-symbol type f according to the posterior q_k. In the M-step, we maximize the following objective with respect to t_1 and t_2:

$$\arg\max_{t_1,t_2} \sum_{e,f} \mathsf{C}_1^{e,f} \log t_1(f \mid e) + \sum_{e,f} \mathsf{C}_2^{e,f} \log t_2(e \mid f) + \lambda R(t_1, t_2) \quad (5)$$

which can be efficiently solved using convex programming techniques due to the concavity of R and the complete-data log-likelihoods in both t_1 and t_2.

In our implementation, we applied Projected Gradient Descent (Bertsekas, 1999; Schoenemann, 2011), where at each step, the parameters are updated in the direction of the M-step objective gradient at (t_1, t_2) and then projected back onto the probability simplex. We used simple stopping conditions based on objective function value convergence and a bounded number of iterations.

4 Baselines

4.1 Parallel Data Baseline: `ABA` and `PostCAT`

Our approach is most similar to Alignment by Agreement (Liang et al., 2006) which uses a single joint objective for two word alignment models. The difference between our objective (Eq. 4) and theirs lies in their proposed regularizer, which rewards the per-sample agreement of the two models' alignment posteriors:

$$\sum_n \log \sum_{\mathbf{z}} p_1(\mathbf{z} \mid \mathbf{x}^n) \cdot p_2(\mathbf{z} \mid \mathbf{x}^n)$$

where $\mathbf{x}^n = (\mathbf{e}^n, \mathbf{f}^n)$ and where $\mathbf{z}$ ranges over the possible alignments between $\mathbf{e}^n$ and $\mathbf{f}^n$ (practically, only over 1-to-1 alignments, since each model is only capable of producing one-to-many alignments).

Liang et al. (2006) note that proper EM optimization of their regularized joint objective leads to an intractable E-step. Unable to exactly and efficiently compute alignment posteriors, they resort to a product-of-marginals heuristic which breaks EM's convergence guarantees, but has a closed-form solution and works well in practice.

`MIR` regularization has both theoretical and practical advantages compared to `ABA`, which make our method more convenient and broadly applicable:

1. By regularizing for posterior agreement, `ABA` is restricted to a parallel data setting, whereas `MIR` can be applied even without parallel data.

2. The posteriors of more advanced word alignment models (such as fertility-based models) do not correspond to alignments, and furthermore, are already estimated with approximation techniques. Thus, even if we somehow adapt `ABA`'s product-of-marginals heuristic to such models, we run the risk of estimating highly inaccurate posteriors (specifically, zero-valued posteriors). In contrast, `MIR` extends to all IBM-style word alignment models and does not add heuristics. The M-step computation can be done exactly and efficiently with convex optimization.

3. `MIR` provides the same theoretical convergence guarantees as the underlying algorithms.

Ganchev et al. (2008) propose `PostCAT` which uses Posterior Regularization (Ganchev et al., 2010)

to enforce posterior agreement between the two models. Specifically, they add a KL-projection step after the E-step of the EM algorithm which returns the posterior $q(z \mid x)$ closest in KL-Divergence to an E-step posterior, but which also upholds certain constraints. The particular constraints they suggest encode alignment agreement *in expectation* between the two models' posteriors. For details, the reader can refer to (Ganchev et al., 2008).

Similarly to ABA, with their suggested alignment agreement constraints PostCAT cannot be applied without parallel data and it is unclear how to extend it to fertility based models (however, it does seems possible to apply other constraints using the general posterior regularization framework).

We compare MIR against ABA and PostCAT in Section 5.

4.2 Non-Parallel Data Baseline: bi-EM

Mylonakis et al. (2007) cast the two directional models as a single joint model by reparameterization and normalization. That is, both directional models, consisting of a t-table only, are reparameterized as:

$$t_1(f \mid e) = \frac{\beta_{e,f}}{\sum_f \beta_{e,f}} \qquad t_2(e \mid f) = \frac{\beta_{e,f}}{\sum_e \beta_{e,f}} \tag{6}$$

They then maximize the likelihood of observed *monolingual* sequences from both languages:

$$\max_{\beta} L_1(\{\mathbf{f}^n\};\beta) + L_2(\{\mathbf{e}^n\};\beta) \tag{7}$$

where, for example:

$$\begin{aligned} L_1(\{\mathbf{f}^n\};\beta) &= \log \prod_n p(\mathbf{f}^n) \\ &= \log \prod_n \sum_{\mathbf{e}} p(\mathbf{f}^n \mid \mathbf{e}) p(\mathbf{e}) \\ &= \log \prod_n \sum_{\mathbf{e}} p(\mathbf{e}) \prod_m t_1(f_m^n \mid \mathbf{e}) \end{aligned}$$

Here, $p(\mathbf{e})$ denotes the probability of $\mathbf{e}$ according to a fixed source language model.

Once training of β is complete, we can decode an observed target sequence $\mathbf{f}$, by casting β back in terms of t_1 and apply the Viterbi decoding algorithm.

To solve for β in Eq. 7, Mylonakis et al. (2007) propose bi-EM, an iterative EM-style algorithm. The objective function in their M-step is not concave, hinting that a closed-form solution for the maximizer is unlikely. The probability estimate that they use in the M-step appears to maximize an approximation of their M-step objective which omits the normalization factors in Eq. 7.

Nevertheless, bi-EM attains improved results compared to standard EM on both POS-tagging and monotone noun sequence translation without parallel data. We compare MIR against bi-EM in Sec. 6.

5 Experiments with Parallel Data

In this section, we compare MIR against standard EM training and ABA on Czech-English and Chinese-English word alignment and translation.

5.1 Implementation and Code

For ABA[2] and PostCAT[3] training we used the authors' implementation, which supports the HMM model. Vanilla EM training was done using GIZA++,[4] which supports all IBM models as well as HMM. Our method MIR was implemented on top of GIZA++.[5]

5.2 Data

We used the following parallel data to train the word alignment models:

Chinese-English: 287K sentence pairs from the NIST 2009 Open MT Evaluation constrained task consisting of 5.3M and 6.6M tokens, respectively.

Czech-English: 85K sentence pairs from the News Commentary corpus, consisting of 1.6M and 1.8M tokens, respectively.

Sentence length was restricted to at most 40 tokens.

5.3 Word Alignment Experiments

We obtained HMM alignments by running either 5 or 10 iterations (optimized on a held-out validation set) of both IBM Model 1 and HMM. We obtained IBM Model 4 alignments by continuing with 5 iterations of IBM Model 3 and 10 iterations of IBM

Method	Chi-Eng **Align F1**	Cze-Eng **Align F1**
EM-HMM	64.6	65.0
PostCAT-HMM	69.8	69.6
ABA-HMM	70.8	70.4
MIR-HMM	70.9	69.6
EM-IBM4	68.4	67.3
MIR-IBM4	72.9	70.7

Table 1: Word alignment F1 scores.

Model 4. We then extracted symmetrized alignments in the following manner: For all HMM models, we used the *posterior decoding* technique described in Liang et al. (2006) as implemented by each package. For IBM Model 4, we used the standard grow-diag-final-and (gdfa) symmetrization heuristic (Koehn et al., 2003).

We tuned MIR's λ parameter to maximize alignment F-score on a validation set of 460 hand-aligned Czech-English and 1102 Chinese-English sentences.

Alignment F-scores are reported in Table 1. In particular, the best results were obtained by MIR, when applied to the fertility based IBM4 model - we obtained gains of +2.1% (Chinese-English) and +0.3% (Czech-English) compared to the best competitor.

5.4 MT Experiments

We ran MT experiments using the Moses (Koehn et al., 2007) phrase-based translation system.[6] The feature weights were trained discriminatively using MIRA (Chiang et al., 2008), and we used a 5-gram language model trained on the Xinhua portion of English Gigaword (LDC2007T07). All other parameters remained with their default settings. The development data used for discriminative training were: for Chinese-English, data from the NIST 2004 and NIST 2006 test sets; for Czech-English, 2051 sentences from the WMT 2010 shared task. We used case-insensitive IBM B (closest reference length) as our metric.

On both language pairs, ABA, PostCAT and MIR outperform their respective EM baseline with comparable gains overall. However, we noticed that ABA and MIR are not producing the same alignments.

[6] http://www.statmt.org/moses/

Method	Chi-Eng **NIST08**	Cze-Eng **WMT09**	Cze-Eng **WMT10**
EM-HMM	23.6	16.7	17.1
PostCAT-HMM	24.6	16.9	17.4
MIR-HMM	24.0	17.1	17.6
ABA-HMM	24.4	17.1	17.7
EM-IBM4	24.2	16.8	17.2
MIR-IBM4	24.6	17.2	17.5
ABA + MIR-HMM	25.1	17.4	17.9

Table 2: B scores. Combining ABA and MIR HMM alignments improves B score significantly over all other methods.

For example, by combining their HMM alignments (simply concatenating aligned bitexts) the total improvement reaches +1.5 B on the Chinese-to-English task, a statistically significant improvement ($p < 0.05$) according to a bootstrap resampling significance test (Koehn, 2004)). Table 5.4 summarizes our MT results.

6 Experiments without Parallel Data

Ravi and Knight (2009) consider the challenging task of learning a Japanese-English back-transliteration model without parallel data. The goal is to correctly decode a list of 100 US senator names written in katakana script, without having access to parallel data. In this section, we reproduce their decipherment experiment and show that applying MIR to their baseline model significantly outperforms both the baseline and the bi-EM method.

6.1 Phonetic-Based Japanese Decipherment

Ravi and Knight (2009) construct a English-to-Japanese transliteration model as a cascade of wFSTs (depicted in Figure 1, top). According to their generative story, any word in katakana is generated by re-writing an English word in its English phonetic representation, which is then transformed to a Japanese phonetic representation and finally re-written in katakana script. For example, the word "computer" is mapped to a sequence of 8 English phonemes (k, ah, m, p, y, uw, t, er), which is mapped to a sequence of 9 Japanese phonemes (K, O, N, P, Y, U, T, A, A) and finally to Katakana.

They apply their trained transliteration model to decode a list of 100 US senator names and report a

whole-name error-rate (WNER)[7] of 40% with parallel data (trained over 3.3k word pairs), compared to 73% WNER without parallel data (trained over 9.5k Japanese words only), demonstrating the weakness of methods that do not use parallel data.

6.2 Forward Pipeline

We reproduced the English-to-Japanese transliteration pipeline of Ravi and Knight (2009) by constructing each of the cascade wFSTs as follows:

1. A unigram language model (LM) of English terms, estimated over the top 40K most frequent capitalized words found in the Gigaword corpus (without smoothing).

2. An English pronunciation wFST from the CMU pronunciation dictionary.[8]

3. An English-to-Japanese phoneme mapping wFST that encodes a phoneme t-table t_1 which was designed according to the best setting reported by Ravi and Knight (2009). Specifically, t_1 is restricted to either 1-to-1 or 1-to-2 phoneme mappings and maintains consonant parity. See further details in their paper.

4. A hand-built Japanese pronunciation to Katakana wFST (Ravi and Knight, 2009).

6.3 Backward Pipeline

`MIR` requires a pipeline in the reverse direction, transliteration of Japanese to English. We constructed a unigram LM of Katakana terms over the top 25K most frequent Katakana words found in the Japanese `2005-2008-news` dictionary from the Leipzig corpora.[9]

The remaining required wFSTs were obtained by inverting the forward model wFSTs (that is, wFSTs 2,3,4 above), and the cascade was composed in the reverse direction. In particular, by inverting t_1, we obtained the Japanese-to-English t-table t_2 that allows only 2-to-1 or 1-to-1 phoneme mappings.

[7] The percentage of names where any error occurs anywhere in either the first or last name.

[8] `http://www.speech.cs.cmu.edu/cgi-bin/cmudict`

[9] `http://corpora.uni-leipzig.de/`

6.4 Training Data

For training data, we used the top 50% most frequent terms from the monolingual data over which we constructed the LM wFSTs. This resulted in a set of 20K English terms (denoted `ENG`) and a set of 13K Japanese terms in Katakana (denoted `KTKN`).

Taking the entire set of monolingual terms led to poor baseline results, probably since uncommon English terms are not transliterated, and uncommon Katakana terms may be borrowed from languages other than English.

In any case, it is important to note that `ENG` and `KTKN` are unrelated, since both were collected over non-parallel corpora.

6.5 Training and Tuning

We train and tune 4 models:

`baseline`: the model proposed by Ravi and Knight (2009), which maximizes the likelihood (Eq. 2) of the observed Japanese terms `KTKN`.

`MIR`: Our bidirectional, regularized model, which maximizes the regularized likelihoods (Eq. 4) of both monolingual corpora `ENG`, `KTKN`.

`bi-EM`: The joint model proposed by Mylonakis et al. (2007), which maximizes the likelihoods (Eq. 7) of both monolingual corpora `ENG`, `KTKN`.

`Oracle`: As an upper bound, we train the model of Ravi and Knight (2009) as if it was given the correct English origin for each Japanese term. (over 4.2K *parallel* English-Japanese phoneme sequences).

We train each method for 15 EM iterations, while keeping the LM and pronunciation wFSTs fixed.

Training was done using the Carmel finite-state toolkit.[10] Specifically, `baseline` and `oracle` rely on Carmel exclusively, while for `MIR` and `bi-EM`, we manipulated Carmel to output the E-step posteriors, which we then used to construct and solve the M-step objective using our own implementation.

The different models were tuned over a development set consisting of 50 frequent Japanese terms and their English origin. For each method, we chose the so-called stretch-factor $\alpha \in \{1, 2, 3\}$ used to exponentiate the model parameters before decoding

[10] `http://www.isi.edu/licensed-sw/carmel/`

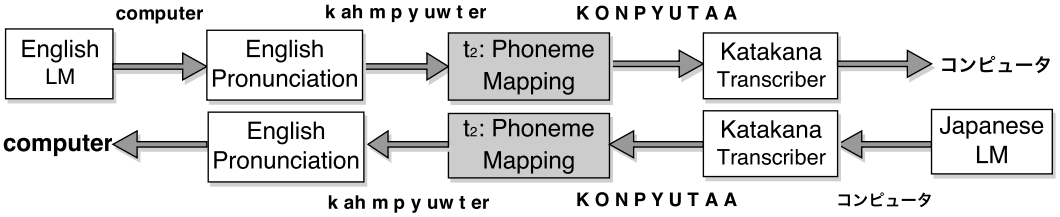

Figure 1: The transliteration generative story as a cascade of wFSTs. Each box represents a transducer. **Top:** transliteration of the word "computer" to Japanese Katakana. **Bottom:** the reverse process. `MIR` jointly trains the two cascades by maximizing the regularized data log-likelihood with respect to the two (shaded) phoneme mapping models t_1, t_2.

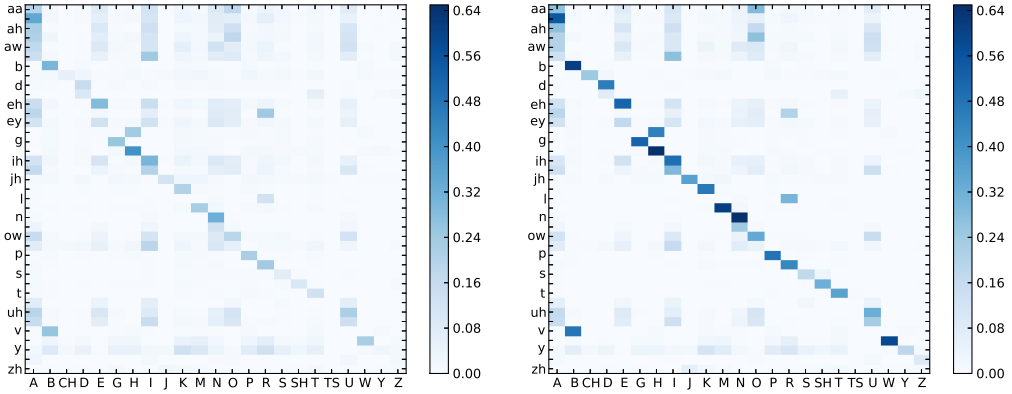

Figure 2: The 1-to-1 mapping submatrix of the t_1 transliteration table for independent training (left) and `MIR` (right). `MIR` learns sparser, peaked models compared to those learned by independent training.

(see Ravi and Knight (2009)), our model's hyperparameter $\lambda \in \{1, 2, 3, 4\}$, and the number of iterations (up to 15) to minimize WNER on the development set.

We decoded Japanese terms using the Viterbi algorithm, applied on the selected t_1 model (using Eq. 6 to convert the `bi-EM` model β back to to t_1). Finally, note that `ABA` training and symmetrization decoding heuristics are inapplicable, since they rely on parallel data.

6.6 Senator Name Decoding Results

We compiled our own test set, consisting of 100 US senator names (first and last), and compared the performance of the four algorithms. Table 3 reports WNER, average normalized edit distance (NED) and the number of model parameters (t_1) with value greater than 0.01 as an indication of sparsity. Figure 2 further compares the 1-to-1 portions of the best model learned by the `baseline` method with the best model learned by `MIR`, showing the difference in parameter sparsity.

	WNER	NED	$t_1 > 0.01$
`baseline`	67%	23.2	649
`bi-EM`	66%	21.8	600
`MIR`	**59%**	**17.3**	**421**
`Oracle`	43%	10.8	152

Table 3: `MIR` reduces error rates (WNER, NED) and learns sparser models (number of t_1 parameters greater than 0.01) compared to the other models.

Using `MIR`, we obtained significant reduction in error rates, closing the gap between the `baseline` method and `Oracle`, which was trained on parallel data, by 33% in WNER and nearly 50% in NED. This error reduction clearly demonstrates the efficacy of `MIR` in the non-parallel data setting.

7 Conclusion

We presented Model Invertibility Regularization (MIR), an unsupervised method for jointly training bidirectional sequence alignment models with or without parallel data. Our formulation is based on the simple observation that the alignment tasks at hand are inherently invertible and encourages the translation tables in both models to behave like pseudo-inverses of each other.

We derived an efficient MAP-EM algorithm and demonstrated our method's effectiveness on two different alignment tasks. On word alignment, applying MIR on the IBM4 model yielded the highest F scores and the resulting B scores were comparable to that of Alignment by Agreement (Liang et al., 2006) and PostCAT (Ganchev et al., 2008). Our best MT results (up to +1.5 B improvement) were obtained by combining alignments from both MIR and ABA, indicating that the two methods learn complementary alignments. On Japanese-English back-transliteration with no parallel data, we obtained a significant error reduction over two baseline methods (Ravi and Knight, 2009; Mylonakis et al., 2007).

As future work, we plan to apply MIR on large-scale MT decipherment (Ravi and Knight, 2011; Dou and Knight, 2013), where, so far, only a single directional model has been used. Another promising direction is to encourage invertibility not only between words, but between their senses and synonyms.

Acknowledgements

We would like to thank Markos Mylonakis and Khalil Sima'an for their help in understanding the derivation of their bi-EM method. This work was partially supported by DARPA grants DOI/NBC D12AP00225 and HR0011-12-C-0014 and a Google Faculty Research Award to Chiang.

Jointly Modeling Inter-Slot Relations by Random Walk on Knowledge Graphs for Unsupervised Spoken Language Understanding

Yun-Nung Chen, William Yang Wang, and Alexander I. Rudnicky
School of Computer Science, Carnegie Mellon University
5000 Forbes Avenue, Pittsburgh, PA 15213-3891, USA
{yvchen, yww, air}@cs.cmu.edu

Abstract

A key challenge of designing coherent semantic ontology for spoken language understanding is to consider inter-slot relations. In practice, however, it is difficult for domain experts and professional annotators to define a coherent slot set, while considering various lexical, syntactic, and semantic dependencies. In this paper, we exploit the typed syntactic dependency theory for unsupervised induction and filling of semantics slots in spoken dialogue systems. More specifically, we build two knowledge graphs: a slot-based semantic graph, and a word-based lexical graph. To jointly consider word-to-word, word-to-slot, and slot-to-slot relations, we use a random walk inference algorithm to combine the two knowledge graphs, guided by dependency grammars. The experiments show that considering inter-slot relations is crucial for generating a more coherent and compete slot set, resulting in a better spoken language understanding model, while enhancing the interpretability of semantic slots.

1 Introduction

An important requirement for building a successful spoken dialogue system (SDS) is to define a coherent slot set and the corresponding slot-fillers for the spoken language understanding (SLU) component. Unfortunately, since the semantic slots are often mutually-related, it is non-trivial for domain experts and professional annotators to design a such slot set for semantic representation of SLU.

Considering a restaurant domain (Henderson et al., 2012), "*restaurant*" is the target slot, and important adjective modifiers such as "*Asian*" (the restaurant type) and "*cheap*" (the price of the restaurant) should be included in the slot set, so that the semantic representation of SLU can be more coherent and complete. In this case, it is challenging to design such a coherent and complete slot set manually, while considering various lexical, syntactic, and semantic dependencies.

Instead of considering slots independently, this paper takes a data-driven approach to model word-to-word relations via syntactic dependencies and further infer slot-to-slot relations. To do this, we incorporate the typed dependency grammar theory (De Marneffe and Manning, 2008) in a state-of-the-art frame-semantic driven unsupervised slot induction framework (Chen et al., 2013b). In particular, we build two knowledge graphs: a slot-based semantic knowledge graph, and a word-based lexical knowledge graph. Using typed dependency triples, we then study the stochastic relations between slots and words, using a mutually-reinforced random walk inference procedure to combine the two knowledge graphs. In evaluations, we use the jointly learned inter-slot relations to induce a coherent slot set in an unsupervised fashion. Our contributions are three-fold:

- We are among the first to consider unsupervised spoken language understanding combining semantic and lexical knowledge graphs;
- We propose a novel typed syntactic dependency grammar driven random walk model for relation discovery;

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 619–629,
Denver, Colorado, May 31 – June 5, 2015.

- Our experimental results suggest that jointly considering inter-slot relations helps obtain a more coherent and complete semantic slot set.

2 Related Work

With the recent success of commercial dialogue systems and personal assistants (e.g., Microsoft's Cortana[1], Google Now[2], Apple's Siri[3], and Amazon's Echo[4]), a key focus on developing spoken understanding techniques is the scalability issue.

From the knowledge management perspective, empowering the system with a large knowledge base is of crucial significance to modern spoken dialogue systems. On this end, our work clearly aligns with recent studies on leveraging semantic knowledge graphs for SLU modeling (Heck et al., 2013; Hakkani-Tür et al., 2013; Hakkani-Tür et al., 2014; El-Kahky et al., 2014; Chen et al., 2014a). While leveraging external knowledge is the trend, efficient inference algorithms, such as random walk, are still less-studied for direct inference on knowledge graphs of the spoken contents.

In the natural language processing literature, Lao et al. (2011) used a random walk algorithm to construct inference rules on large entity-based knowledge bases, and leveraged syntactic information for reading the Web (Lao et al., 2012). Even though this work has important contributions, the proposed algorithm cannot learn mutually-recursive relations, and does not to consider lexical items—in fact, more and more studies show that, in addition to semantic knowledge graphs, lexical knowledge graphs (Inkpen and Hirst, 2006; Song et al., 2011; Li et al., 2013b) that model surface-level natural language realization, multiword expressions, and context (Li et al., 2013a), are also critical for short text understanding (Song et al., 2011; Wang et al., 2014).

From the engineering perspective, quick and easy development turnaround time for domain-specific dialogue applications is also critical (Chen and Rudnicky, 2014). Prior work shows that it is possible to use the frame-semantics theory to automatically induce and fill semantic slots (Chen et al., 2013b), and that leveraging distributional semantics helps improving the performance (Chen et al., 2014b). However, prior works treat each slot independently and have not considered the inter-slot relations when inducing the semantic slots. To the best of our knowledge, we are the first to use syntactically-informed random walk algorithms to combine the semantic and lexical knowledge graphs, and not individually but globally inducing the semantic slots for building better unsupervised SLU components.

3 The Proposed Framework

We build our approach on top of the recent success of an unsupervised frame-semantic parsing approach (Chen et al., 2013b). The main motivation of prior work is to use a FrameNet-trained statistical probabilistic semantic parser to generate initial frame-semantic parses from automatic speech recognition (ASR) decodings of the raw audio conversation files, and then adapt the FrameNet-style frames to the semantic slots in the target semantic space, so that they can be used practically in the SDSs. Chen et al. formulated the semantic mapping and adaptation problem as a ranking problem to differentiate generic semantic concepts from target semantic space for task-oriented dialogue systems. This paper improves the adaptation process by leveraging distributed word embeddings associated with typed syntactic dependencies between words to infer inter-slot relations (Mikolov et al., 2013b; Mikolov et al., 2013c; Levy and Goldberg, 2014). The proposed framework is shown in Figure 1. In the remainder of the section, we first introduce frame-semantic parsing to obtain slot candidates. With slot candidates, then we train the independent semantic decoders. The adaptation process, which is the main focus of this paper, is performed to decide outputted slots. Finally we can build an SLU model based on the learned semantic decoders and induced slots.

3.1 Probabilistic Semantic Parsing

FrameNet is a linguistically-principled semantic resource that offers annotations of predicate-argument semantics, and associated lexical units for English (Baker et al., 1998). FrameNet is developed based on a semantic theory, Frame Semantics (Fill-

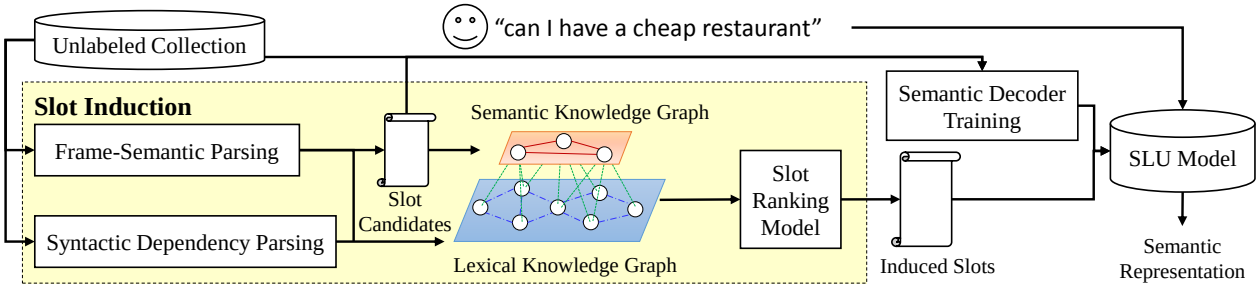

Figure 1: The proposed framework

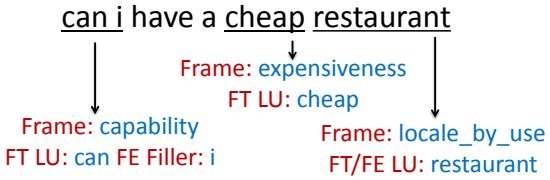

Figure 2: An example of probabilistic frame-semantic parsing on ASR output. FT: frame target. FE: frame element. LU: lexical unit.

more, 1976), which holds that the meaning of most words can be expressed on the basis of semantic frames, which encompass three major components: frame (F), frame elements (FE), and lexical units (LU). For example, the frame "food" contains words referring to items of food. A descriptor frame element within the food frame indicates the characteristic of the food. For example, the phrase "*low fat milk*" should be analyzed with "*milk*" evoking the food frame and "*low fat*" filling the descriptor FE of that frame.

In our approach, we parse all ASR-decoded utterances in our corpus using SEMAFOR[5], a state-of-the-art semantic parser for frame-semantic parsing (Das et al., 2010; Das et al., 2013), and extract all frames from semantic parsing results as slot candidates, where the LUs that correspond to the frames are extracted for slot filling. For example, Figure 2 shows an example of an ASR-decoded text output parsed by SEMAFOR. SEMAFOR generates three frames (capability, expensiveness, and locale_by_use) for the utterance, which we consider as slot candidates for training the SLU model. Note that for each slot candidate, SEMAFOR also includes the corresponding lexical unit (*can i*, *cheap*, and *restaurant*), which we consider as possible slot-fillers.

[5] http://www.ark.cs.cmu.edu/SEMAFOR/

3.2 Independent Semantic Decoder

With outputted semantic parses, we extract the frames with the top 50 highest frequency as our slot candidates for training SLU. The features for training are generated by word confusion network, where confusion network features are shown to be useful in developing more robust systems for SLU (Hakkani-Tür et al., 2006; Henderson et al., 2012). We build a vector representation of an utterance as $\mathbf{u} = [x_1, ..., x_j, ...]$.

$$x_j = \mathbb{E}[C_u(n\text{-gram}_j)]^{1/|n\text{-gram}_j|}, \quad (1)$$

where $C_u(n\text{-gram}_j)$ counts how many times n-gram$_j$ occurs in the utterance u, $\mathbb{E}(C_u(n\text{-gram}_j))$ is the expected frequency of n-gram$_j$ in u, and $|n\text{-gram}_j|$ is the number of words in n-gram$_j$.

For each slot candidate s_i, we generate a pseudo training data $\mathcal{D}^i$ to train a binary classifier $\mathcal{M}^i$ for predicting the existence of s_i given an utterance, $\mathcal{D}^i = \{(\mathbf{u_k}, l_k^i) \mid \mathbf{u_k} \in \mathbb{R}^+, l_k^i \in \{-1, +1\}\}_{k=1}^K$, where $l_k^i = +1$ when the utterance u_k contains the slot candidate s_i in its semantic parse, $l_k^i = -1$ otherwise, and K is the number of utterances.

3.3 Adaptation Process and SLU Model

Since SEMAFOR was trained on FrameNet annotation, which has a more generic frame-semantic context, not all the frames from the parsing results can be used as the actual slots in the domain-specific dialogue systems. For instance, in Figure 2, we see that the frames "expensiveness" and "locale_by_use" are essentially the key slots for the purpose of understanding in the restaurant query domain, whereas

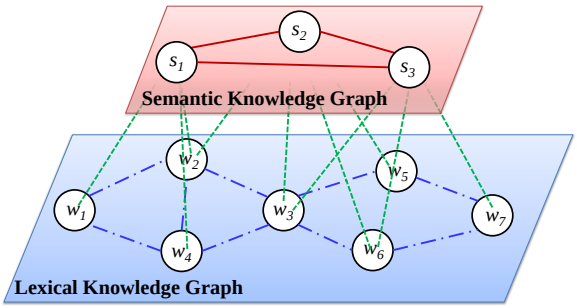

Figure 3: A simplified example of the two knowledge graphs, where a slot candidate s_i is represented as a node in a semantic knowledge graph and a word w_j is represented as a node in a lexical knowledge graph.

the "capability" frame does not convey particular valuable information for SLU. With the trained independent semantic decoders for all slot candidates, adaptation process computes the prominence of slot candidates for ranking and then selects a list of induced slots associated with their corresponding semantic decoders for use in domain-specific dialogue systems, where the detail is described in Section 4.

Then with each induced slot s_i and its corresponding trained semantic decoder $\mathcal{M}^i$, an SLU model can be built to predict whether the semantic slot occurs in the given utterance in a fully unsupervised way. In other words, the SLU model is able to transform the testing utterance into semantic representations without human involvement.

4 Slot Ranking Model

The purpose of the ranking model is to distinguish between generic semantic concepts and domain-specific concepts that are relevant to an SDS. To induce meaningful slots for the purpose of SDS, we compute the prominence of the slot candidates using a slot ranking model described below.

With the semantic parses from SEMAFOR, where each frame is viewed independently, so inter-slot relations are not included, the model ranks the slot candidates by integrating two information: (1) the frequency of each slot candidate in the corpus, since slots with higher frequency may be more important. (2) the relations between slot candidates. Assuming that domain-specific concepts are usually related to each other, globally considering inter-slot relations induces a more coherent slot set. Here for baseline

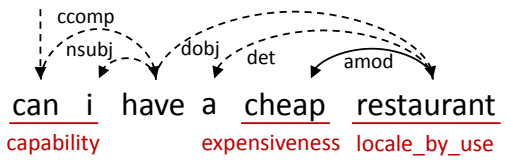

Figure 4: The dependency parsing result on an utterance.

scores, we only use the frequency of each slot candidate as its prominence.

First we construct two knowledge graphs, one is a slot-based semantic knowledge graph and another is a word-based lexical knowledge graph, both of which encode the typed dependency relations in their edge weights. We also connect two graphs to model the relations between slot-filler pairs.

4.1 Knowledge Graphs

We construct two undirected graphs, semantic and lexical knowledge graphs. Each node in the semantic knowledge graph is a slot candidate s_i outputted by the frame-semantic parser, and each node in the lexical knowledge graph is a word w_j.

- **Slot-based semantic knowledge graph** is built as $G_s = \langle V_s, E_{ss} \rangle$, where $V_s = \{s_i\}$ and $E_{ss} = \{e_{ij} \mid s_i, s_j \in V_s\}$.
- **Word-based lexical knowledge graph** is built as $G_w = \langle V_w, E_{ww} \rangle$, where $V_w = \{w_i\}$ and $E_{ww} = \{e_{ij} \mid w_i, w_j \in V_w\}$.

With two knowledge graphs, we build the edges between slots and slot-fillers to integrate them as shown in Figure 3. Thus the combined graph can be formulated as $G = \langle V_s, V_w, E_{ss}, E_{ww}, E_{ws} \rangle$, where $E_{ws} = \{e_{ij} \mid w_i \in V_w, s_j \in V_s\}$. E_{ss}, E_{ww}, and E_{ws} correspond to slot-to-slot relations, word-to-word relations, and word-to-slot relations respectively (Chen and Metze, 2012; Chen and Metze, 2013).

4.2 Edge Weight Estimation

Considering the relations in the knowledge graphs, the edge weights for E_{ww} and E_{ss} are measured based on the dependency parsing results. The example utterance "*can i have a cheap restaurant*" and its dependency parsing result are illustrated in Figure 4. The arrows denote the de-

	Typed Dependency Relation	Target Word	Contexts
Word	⟨*restaurant*, AMOD, *cheap*⟩	*restaurant* *cheap*	*cheap*/AMOD *restaurant*/AMOD^{-1}
Slot	⟨locale_by_use, AMOD, expensiveness⟩	locale_by_use expansiveness	expensiveness/AMOD locale_by_use/AMOD^{-1}

Table 1: The contexts extracted for training dependency-based word/slot embeddings from the utterance of Fig. 2.

pendency relations from headwords to their dependents, and words on arcs denote types of the dependencies. All typed dependencies between two words are encoded in triples and form a word-based dependency set $\mathcal{T}_w = \{\langle w_i, t, w_j\rangle\}$, where t is the typed dependency between the headword w_i and the dependent w_j. For example, Figure 4 generates ⟨*restaurant*, AMOD, *cheap*⟩, ⟨*have*, DOBJ, *restaurant*⟩, etc. for $\mathcal{T}_w$. Similarly, we build a slot-based dependency set $\mathcal{T}_s = \{\langle s_i, t, s_j\rangle\}$ by transforming dependencies between slot-fillers into ones between slots. For example, ⟨*restaurant*, AMOD, *cheap*⟩ from $\mathcal{T}_w$ is transformed into ⟨locale_by_use, AMOD, expensiveness⟩ for building $\mathcal{T}_s$, because both sides of the non-dotted line are parsed as slot-fillers by SEMAFOR.

For the edges within a single knowledge graph, we assign a weight of the edge connecting nodes x_i and x_j as $\hat{r}(x_i, x_j)$, where x is either s or w. Since the weights are measured based on the relations between nodes regardless of the directions, we combine the scores of two directional dependencies:

$$\hat{r}(x_i, x_j) = r(x_i \rightarrow x_j) + r(x_j \rightarrow x_i), \quad (2)$$

where $r(x_i \rightarrow x_j)$ is the score estimating the dependency including x_i as a head and x_j as a dependent. In Section 4.2.1 and 4.2.2, we propose two scoring functions for $r(\cdot)$, frequency-based as $r_1(\cdot)$ and embedding-based as $r_2(\cdot)$ respectively.

For the edges in E_{ws}, we estimate the edge weights based on the frequency that the slot candidates and the words are parsed as slot-filler pairs. In other words, the edge weight between the slot-filler w_i and the slot candidate s_j, $\hat{r}(w_i, s_j)$, is equal to how many times the filler w_i corresponds to the slot candidate s_j in the parsing results.

4.2.1 Frequency-Based Measurement

Based on the dependency set $\mathcal{T}_x$, we use $t^*_{x_i \rightarrow x_j}$ to denote the most frequent typed dependency with x_i as a head and x_j as a dependent.

$$t^*_{x_i \rightarrow x_j} = \arg\max_t C(x_i \underset{t}{\rightarrow} x_j), \quad (3)$$

where $C(x_i \underset{t}{\rightarrow} x_j)$ counts how many times the dependency $\langle x_i, t, x_j\rangle$ occurs in the dependency set $\mathcal{T}_x$.

Then the scoring function that estimates the dependency $x_i \rightarrow x_j$ is measured as

$$r_1(x_i \rightarrow x_j) = C(x_i \underset{t^*_{x_i \rightarrow x_j}}{\longrightarrow} x_j), \quad (4)$$

which equals to the highest observed frequency of the dependency $x_i \rightarrow x_j$ among all types from $\mathcal{T}_x$.

4.2.2 Embedding-Based Measurement

Most neural embeddings use linear bag-of-words contexts, where a window size is defined to produce contexts of the target words (Mikolov et al., 2013c; Mikolov et al., 2013b; Mikolov et al., 2013a). However, some important contexts may be missing due to smaller windows, while larger windows capture broad topical content. A dependency-based embedding approach was proposed to derive contexts based on the syntactic relations the word participates in for training embeddings, where the embeddings are less topical but offer more functional similarity compared to original embeddings (Levy and Goldberg, 2014).

Table 1 shows the extracted dependency-based contexts for each target word from the example in Figure 4, where headwords and their dependents can form the contexts by following the arc on a word in the dependency tree, and -1 denotes the directionality of the dependency. After replacing original bag-of-words contexts with dependency-based contexts, we can train dependency-based embeddings for all target words (Yih et al., 2014; Bordes et al., 2011; Bordes et al., 2013).

For training dependency-based word embeddings, each word w is associated with a word vector $\mathbf{v_w} \in$

$\mathbb{R}^d$ and each context c is represented as a context vector $\mathbf{v_c} \in \mathbb{R}^d$, where d is the embedding dimensionality. We learn vector representations for both words and contexts such that the dot product $\mathbf{v_w} \cdot \mathbf{v_c}$ associated with "good" word-context pairs belonging to the training data $\mathcal{D}$ is maximized, leading to the objective function:

$$\arg\max_{\mathbf{v_w},\mathbf{v_c}} \sum_{(w,c)\in\mathcal{D}} \log \frac{1}{1+\exp(-\mathbf{v_c}\cdot\mathbf{v_w})}, \quad (5)$$

which can be trained using stochastic-gradient updates (Levy and Goldberg, 2014). Then we can obtain the dependency-based slot and word embeddings using $\mathcal{T}_s$ and $\mathcal{T}_w$ respectively.

With trained dependency-based embeddings, we estimate the probability that x_i is the headword and x_j is its dependent via the typed dependency t as

$$P(x_i \underset{t}{\rightarrow} x_j) = \frac{Sim(x_i, x_j/t) + Sim(x_j, x_i/t^{-1})}{2}, \quad (6)$$

where $Sim(x_i, x_j/t)$ is the cosine similarity between the slot/word embeddings $\mathbf{v_{x_i}}$ and the context embeddings $\mathbf{v_{x_j/t}}$ after normalizing to $[0, 1]$. Then we can measure the scoring function $r_2(\cdot)$ as

$$r_2(x_i \rightarrow x_j) = C(x_i \xrightarrow[t^*_{x_i\rightarrow x_j}]{} x_j) \cdot P(x_i \xrightarrow[t^*_{x_i\rightarrow x_j}]{} x_j), \quad (7)$$

which is similar to (4) but additionally weighted by the estimated probability. The estimated probability smooths the observed frequency to avoid overfitting due to a smaller dataset.

4.3 Random Walk Algorithm

We first compute $L_{ww} = [\hat{r}(w_i, w_j)]_{|V_w|\times|V_w|}$ and $L_{ss} = [\hat{r}(s_i, s_j)]_{|V_s|\times|V_s|}$, where $\hat{r}(w_i, w_j)$ and $\hat{r}(s_i, s_j)$ are either from frequency-based ($r_1(\cdot)$) or embedding-based measurements ($r_2(\cdot)$). Similarly, $L_{ws} = [\hat{r}(w_i, s_j)]_{|V_w|\times|V_s|}$ and $L_{sw} = [\hat{r}(w_i, s_j)]^T_{|V_w|\times|V_s|}$, where $\hat{r}(w_i, s_j)$ is the frequency that s_j and w_i are a slot-filler pair computed in Section 4.2. Then we only keep the top N highest weights for each row in L_{ww} and L_{ss} ($N = 10$), which means that we filter out the edges with smaller weights within the single knowledge graph. Column-normalization are performed for L_{ww}, L_{ss}, L_{ws}, L_{sw} (Shi and Malik, 2000). They can be viewed as word-to-word, slot-to-slot, and word-to-slot relation matrices.

4.3.1 Single-Graph Random Walk

Here we run random walk only on the semantic knowledge graph to propagate the scores based on inter-slot relations through the edges E_{ss}.

$$R_s^{(t+1)} = (1-\alpha)R_s^{(0)} + \alpha L_{ss} R_s^{(t)}, \quad (8)$$

where $R_s^{(t)}$ denotes the importance scores of the slot candidates V_s in t-th iteration. In the algorithm, the score is the interpolation of two scores, the normalized baseline importance of slot candidates ($R_s^{(0)}$), and the scores propagated from the neighboring nodes in the semantic knowledge graph based on slot-to-slot relations via L_{ss}. The algorithm will converge when $R_s^{(t+1)} = R_s^{(t)} = R_s^*$ and (9) can be satisfied.

$$R_s^* = \left((1-\alpha)R_s^{(0)}e^T + \alpha L_{ss}\right) R_s^* = M_1 R_s^*, \quad (9)$$

where $e = [1, 1, ..., 1]^T$. It has been shown that the closed-form solution R_s^* of (9) is the dominant eigenvector of M_1 (Langville and Meyer, 2005), the eigenvector corresponding to the largest absolute eigenvalue of M_1. The solution of R_s^* denotes the updated importance scores for all utterances. Similar to the PageRank algorithm (Brin and Page, 1998), the solution can also be obtained by iteratively updating $R_s^{(t)}$.

4.3.2 Double-Graph Random Walk

Here we borrow the idea from two-layer mutually reinforced random walk to propagate the scores based on not only internal importance propagation within the same graph but external mutual reinforcement between different knowledge graphs (Chen and Metze, 2012; Chen and Metze, 2013).

$$\begin{cases} R_s^{(t+1)} = (1-\alpha)R_s^{(0)} + \alpha L_{ss} L_{sw} R_w^{(t)} \\ R_w^{(t+1)} = (1-\alpha)R_w^{(0)} + \alpha L_{ww} L_{ws} R_s^{(t)} \end{cases} \quad (10)$$

In the algorithm, they are the interpolations of two scores, the normalized baseline importance ($R_s^{(0)}$ and $R_w^{(0)}$) and the scores propagated from another graph. For the semantic knowledge graph, $L_{sw}R_w^{(t)}$ is the score from the word set weighted by slot-to-word relations, and then the scores are propagated based on slot-to-slot relations via L_{ss}. Similarly, nodes of the lexical knowledge graph also include

the scores propagated from the semantic knowledge graph. Then $R_s^{(t+1)}$ and $R_w^{(t+1)}$ can be mutually updated by the latter parts in (10) iteratively. When the algorithm converges, we have R_s^* as follows.

$$\begin{aligned} R_s^* &= (1-\alpha)R_s^{(0)} \\ &+ \alpha L_{ss}L_{sw}\left((1-\alpha)R_w^{(0)} + \alpha L_{ww}L_{ws}R_s^*\right) \\ &= \Big((1-\alpha)R_s^{(0)}e^T + \alpha(1-\alpha)L_{ss}L_{sw}R_w^{(0)}e^T \\ &+ \alpha^2 L_{ss}L_{sw}L_{ww}L_{ws}\Big)R_s^* = M_2 R_s^*. \end{aligned} \tag{11}$$

The closed-form solution R_s^* of (11) is the dominant eigenvector of M_2.

5 Experiments

We evaluate our approach in two ways. First, we examine the slot induction accuracy by comparing the ranked list of induced slots with the reference slots created by system developers (Young, 2007). Secondly, with the ranked list of induced slots and their associated semantic decoders, we can evaluate the SLU performance. For the experiments, we evaluate both on ASR transcripts of the raw audio, and on the manual transcripts.

5.1 Experimental Setup

In this experiment, we used the Cambridge University SLU corpus, previously used on several other SLU tasks (Henderson et al., 2012; Chen et al., 2013a). The domain of the corpus is about restaurant recommendation in Cambridge; subjects were asked to interact with multiple SDSs in an in-car setting. The corpus contains a total number of 2,166 dialogues, including 15,453 utterances (10,571 for self-training and 4,882 for testing). The data is gender-balanced, with slightly more native than non-native speakers. The vocabulary size is 1868. An ASR system was used to transcribe the speech; the word error rate was reported as 37%. There are 10 slots created by domain experts: addr, area, food, name, phone, postcode, price range, signature, task, and type.

For parameter setting, the damping factor for random walk α is empirically set as 0.9 for all experiments. For training the semantic decoders, we use SVM with a linear kernel to predict each semantic slot. We use Stanford Parser to obtain the collapsed typed syntactic dependencies (Socher et al., 2013) and set the dimensionality of embeddings $d = 300$ in all experiments.

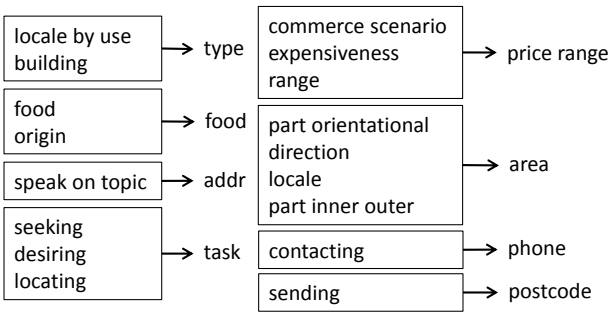

Figure 5: The mappings from induced slots (within blocks) to reference slots (right sides of arrows).

5.2 Evaluation Metrics

To eliminate the influence of threshold selection when choosing induced slots, in the following metrics, we take the whole ranking list into account and evaluate the performance by the metrics that are independent of the selected threshold.

5.2.1 Slot Induction

To evaluate the accuracy of the induced slots, we measure their quality as the proximity between induced slots and reference slots. Figure 5 shows the mappings that indicate semantically related induced slots and reference slots (Chen et al., 2013b). For example, "expensiveness → price", "food → food", and "direction → area" show that these induced slots can be mapped into the reference slots defined by experts and carry important semantics in the target domain for developing the task-oriented SDS. Since we define the adaptation task as a ranking problem, with a ranked list of induced slots and associated scores, we can use the standard average precision (AP) and the area under the precision-recall curve (PR-AUC) as our metrics, where the induced slot is counted as correct when it has a mapping to a reference slot.

5.2.2 SLU Model

While semantic slot induction is essential for providing semantic categories and imposing semantic constraints, we are also interested in understanding the performance of our unsupervised SLU models.

Approach			ASR				Manual			
			Slot Induction		SLU Model		Slot Induction		SLU Model	
			AP	PR-AUC	WAP	AF	AP	PR-AUC	WAP	AF
(a)	Baseline (Frequency)		56.69	54.67	35.82	43.28	53.01	50.80	36.78	44.20
(b)	Single	Frequency	63.88	62.05	41.67	47.38	63.02	61.10	43.76	48.53
(c)		Embedding	69.04	68.25	**46.29**	**48.89**	75.15	74.50	**54.50**	**50.86**
(d)	Double	Frequency	56.83	55.31	32.64	44.91	52.12	50.54	34.01	45.05
(e)		Embedding	**71.48**	**70.84**	44.06	47.91	**76.42**	**75.94**	52.89	50.40

Table 2: The performance of induced slots and corresponding SLU models (%)

For each induced slot with the mapping to a reference slot, we can compute an F-measure of the corresponding semantic decoder, and weight the average precision with corresponding F-measure as weighted average precision (WAP) to evaluate the performance of slot induction and SLU tasks together. The metric scores the ranking result higher if the induced slots corresponding to better semantic decoders are ranked higher. Another metric is the average F-measure (AF), which is the average micro F-measure of SLU models at all cut-off positions in the ranked list. Compared to WAP, AF additionally considers the slot popularity in the dataset.

5.3 Evaluation Results

Table 5.1 shows the results on both ASR and manual transcripts. Rows (a) is the baseline only considering the frequency of each slot candidate for ranking (Chen et al., 2013b). Rows (b) and (c) show performance after leveraging a semantic knowledge graph through random walk. Rows (d) and (e) are the results after combining two knowledge graphs. We find almost all results are improved by additionally considering inter-slot relations in terms of single- and double-graph random walk for both ASR and manual transcripts.

5.3.1 Slot Induction

For both ASR and manual transcripts, almost all results outperform the baseline, showing that inter-slot relations significantly influence the performance of slot induction. The best performance is from the results of double-graph random walk with the embedding-based measurement, which integrate a semantic knowledge graph and a lexical knowledge graph together and jointly consider slot-to-slot, word-to-word, and word-to-slot relations when scoring the prominence of slot candidates to generate a coherent slot set.

5.3.2 SLU Model

For both ASR and manual transcripts, almost all results outperform the baseline, which shows the practical usage for training dialogue systems. The best performance is from the results of single-graph random walk with the embedding-based measurement, which only use the semantic knowledge graph to involve the inter-slot relations. The semantic knowledge graph is not as precise as the lexical one and may be influenced by the performance of the semantic parser more. Although the row (e) does not show better performance than the row (c), double-graph random walk may be more robust because it additionally includes the word relations to avoid only relying on the relations tied with the slot candidates.

5.4 Discussion and Analysis

5.4.1 Comparing Frequency- and Embedding-Based Measurements

Table 5.1 shows that all results with the embedding-based measurement perform better than those with the frequency-based measurement. The frequency-based measurement also brings large improvement for single-graph approaches, but does not for double-graph ones. The reason is probably that using observed frequencies in the lexical knowledge graph may result in overfitting issues due to the smaller dataset. Additionally including embedding information can smooth the edge weights and deal with data sparsity to improve the performance, especially for the lexical knowledge graph.

5.4.2 Comparing Single- and Double-Graph Approaches

Considering that the embedding-based measurement performs better, we only compare the results of single- and double-graph random walk using this measurement (rows (c) and (e)). It can be seen that the difference between them is not consistent in terms of slot induction and SLU model.

For evaluating slot induction (AP and PR-AUC), the double-graph random walk (row (e)) performs better on both ASR and manual results, which implies that additionally integrating the lexical knowledge graph helps decide a more coherent and complete slot set since we can model the score propagation more precisely (not only slot-level but word-level information). However, for SLU evaluation (WAP and AF), the single-graph random walk (row (c)) performs better, which may imply that the slots carrying the coherent relations from the row (e) may not have good semantic decoder performance so that the performance is decreased a little. For example, double-graph random walk scores the slots local_by_use and expensiveness higher than the slot contacting, while the single-graph method ranks the latter higher. local_by_use and expensiveness are more important on this domain but contacting has very good performance of its semantic decoder, so the double-graph approach does not show the improvement when evaluating SLU models. This allows us to try an improved method of jointly optimizing the slot coherence and SLU performance in the future.

5.4.3 Relation Discovery Analysis

To interpret the inter-slot relations, we output the slot-to-slot relations with highest scores from the best results (row (e) in Table 5.1) in Table 3, and the automatically constructed ontology is shown in Figure 6. It can be shown that the outputted inter-slot relations are reasonable and usually connect two important semantic slots in this restaurant domain. This proves that inter-slot relations help decide a coherent and complete slot set and enhance the interpretability of semantic slots. Therefore, from a practical perspective, developers are able to design the framework of dialogue systems more easily, and the development of SDS can be speeded up with less human effort.

Rank	Relation

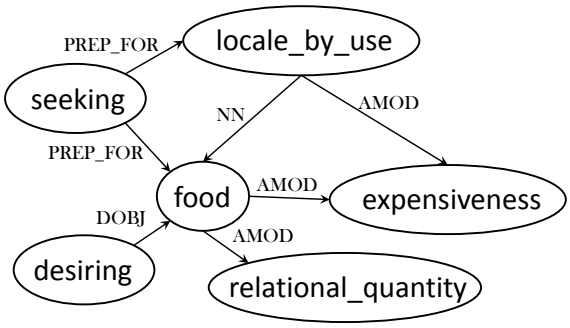

Figure 6: The automatically constructed domain-specific ontology based on Table 3.

6 Conclusion

The paper proposes an approach of jointly considering inter-slot relations for slot induction to output a more coherent slot set, where two knowledge graphs, a slot-based semantic knowledge graph and a word-based lexical knowledge graph, are built and combined by a random walk algorithm. The automatically induced slots carry coherent and interpretable relations and can be used for training better SLU models of SDSs in an unsupervised fashion.

Abstract

This study tackles the problem of paraphrase acquisition: achieving high coverage as well as accuracy. Our method first induces paraphrase patterns from given seed paraphrases, exploiting the generality of paraphrases exhibited by pairs of lexical variants, e.g., "amendment" and "amending," in a fully empirical way. It then searches monolingual corpora for new paraphrases that match the patterns. This can extract paraphrases comprising words that are completely different from those of the given seeds. In experiments, our method expanded seed sets by factors of 42 to 206, gaining 84% to 208% more coverage than a previous method that generalizes only identical word forms. Human evaluation through a paraphrase substitution test demonstrated that the newly acquired paraphrases retained reasonable quality, given substantially high-quality seeds.

1 Introduction

One of the characteristics of human languages is that the same semantic content can be expressed using several different linguistic expressions, i.e., paraphrases. Dealing with paraphrases is an important issue in a broad range of natural language processing (NLP) tasks (Madnani and Dorr, 2010; Androutsopoulos and Malakasiotis, 2010).

To adequately and robustly deal with paraphrases, a large-scale knowledge base containing words and phrases having approximately the same meaning is indispensable. Thus, the task of automatically creating such large-scale **paraphrase lexicons** has been drawing the attention of many researchers (see Section 2 for details). The challenge is to ensure substantial coverage along with high accuracy despite the natural tension between these factors. Among the different types of language resources, monolingual corpora[1] offer the largest coverage, but the quality of the extracted candidates is generally rather low. The difficulty lies in the manner of distinguishing paraphrases from expressions that stand in different semantic relations, e.g., antonyms and sibling words, using only the statistics estimated from such corpora. In contrast, highly accurate paraphrases can be extracted from parallel or comparable corpora, but their coverage is limited owing to the limited availability of such corpora for most languages.

This study aims to improve coverage while maintaining accuracy. To that end, we propose a method that exploits the generality exhibited by pairs of **lexical variants**. Given a seed set of paraphrase pairs, our method first induces paraphrase patterns by generalizing not only identical word forms (Fujita et al., 2012) but also pairs of lexical variants. For instance, from a seed pair (1a), a pattern (1b) is acquired, where the pair of lexical variants ("amendment", "amending") and the shared word form "regulation" are generalized.

(1) a. amendment of regulation
$\Leftrightarrow$ amending regulation
b. X:ment of Y:ϕ $\Leftrightarrow$ X:ing Y:ϕ

With such patterns, new paraphrase pairs that would have been missed using only the surface forms are extracted from a monolingual corpus. Obtainable pairs can include those comprising words that are

[1]The term "monolingual corpora" in this study refers to monolingual non-parallel corpora, unless otherwise explicitly noted. As reviewed in Section 2.1.2, monolingual parallel corpora have also been used as a source of paraphrases.

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 630–640,
Denver, Colorado, May 31 – June 5, 2015.

completely different from those of the seed paraphrases, e.g., (2a) and (2b).

(2) a. investment of resources
⇔ investing resources
b. recruitment of engineers
⇔ recruiting engineers

While the generality underlying paraphrases has been exploited either by handcrafted rules (Harris, 1957; Mel'čuk and Polguère, 1987; Jacquemin, 1999; Fujita et al., 2007) or by data-driven techniques (Ganitkevitch et al., 2011; Fujita et al., 2012), we still lack a robust and accurate way of identifying various types of lexical variants. Our method tackles this issue using affix patterns that are also acquired from high-quality seed paraphrases in a fully empirical way. Consequently, our method has the potential to apply to many languages.

2 Previous Work

2.1 Creating Paraphrase Lexicons

Researchers have been intensively studying methods for automatically creating paraphrase lexicons using various types of corpora. There are two major streams: one that uses monolingual corpora and one that uses parallel or comparable corpora.

2.1.1 Monolingual Corpora

A monolingual corpus is the most promising resource when targeting increased coverage, thanks to the availability of Web-scale monolingual data. Techniques that use such corpora mostly extract pairs of expressions by exploiting the **contextual similarity** associated with the Distributional Hypothesis (Harris, 1954). A given expression is represented with its co-occurring expressions such as adjacent word n-grams (Paşca and Dienes, 2005; Bhagat and Ravichandran, 2008; Marton, 2013), nominal elements (Lin and Pantel, 2001; Szpektor et al., 2004; De Saeger et al., 2011), and modifiers and modified words (Hagiwara et al., 2006). The similarity of a pair of expressions is calculated by comparing the distributions of their contexts.

Despite the quantitative advantage, this approach tends to result in low accuracy. This is because contextual information alone often fails to differentiate paraphrases from expressions that have other semantic relations, e.g., antonyms and sibling words.

2.1.2 Parallel and Comparable Corpora

Much effort has gone into compiling monolingual parallel corpora and extracting paraphrases from them by identifying corresponding parts of aligned sentences. Barzilay and McKeown (2001) and Pang et al. (2003) collected multiple human translations of the same source text. Multiple verbalizations of mathematical proofs were also used (Barzilay and Lee, 2002). This triangulating method provides solid anchors that guarantee the semantic equivalence of sentences (or text fragments).

Monolingual comparable corpora are also useful sources of paraphrases. For instance, articles from different newswire services describing the same event can be used in that way (Shinyama et al., 2002; Barzilay and Elhadad, 2003; Dolan et al., 2004; Wubben et al., 2009). Chen and Dolan (2011) created such corpora by collecting multiple descriptions of short movies through crowdsourcing. Web-harvested definition sentences of the same term often contain paraphrases (Hashimoto et al., 2011; Yan et al., 2013).

Bilingual parallel corpora have been recognized as sources of paraphrases since (Bannard and Callison-Burch, 2005). First, a translation table is created using techniques developed for statistical machine translation. Then, pairs of expressions in the same language that share the same translations are extracted. For instance, a pair ("under control", "in check") will be extracted if they are both linked with the German translation "unter controlle." Each paraphrase pair (e_1, e_2) is assigned probabilities, $p(e_2|e_1)$ and $p(e_1|e_2)$, estimated by marginalizing over all the translations F shared by e_1 and e_2, i.e., $p(e_2|e_1) = \sum_{f \in F} p(e_2|f)p(f|e_1)$.

This **bilingual pivoting** approach inspired further techniques such as the use of syntactic information as the basis of constraints (Callison-Burch, 2008; Zhao et al., 2009), learning patterns using synchronous grammar (Ganitkevitch et al., 2011), uncovering missing links by combining multiple translation tables and other lexical resources (Kok and Brockett, 2010), and re-ranking candidate pairs on the basis of contextual similarity (Chan et al., 2011). Ganitkevitch and Callison-Burch (2014) compiled paraphrase lexicons for various languages on this approach.

Parallel/comparable corpora are useful sources of highly accurate paraphrases. However, for most languages, only small paraphrase lexicons can be created due to the limited availability of such corpora.

2.1.3 Combination of Multiple Corpora

Unlike the above methods, which used only a single type of corpus as sources of paraphrases, Fujita et al. (2012) used both bilingual parallel and monolingual corpora as sources. In that method, paraphrase pairs, e.g., (3a), are first acquired from a bilingual parallel corpus using the bilingual pivoting method and several heuristic filters for drastic noise reduction. Second, each paraphrase pair is generalized into a paraphrase pattern[2], e.g., (3b). Finally, new pairs, e.g., (3c), are extracted from a monolingual corpus using the patterns.

(3) a. amendment of regulation
⇔ amending regulation
b. amendment of X ⇔ amending X
c. amendment of documents
⇔ amending documents

Using that method, they were able to expand the seed lexicon by a large multiple (15 to 40 times), and the new paraphrase pairs were of reasonably good quality. However, they introduced variables only for identical word forms shared by both sides of each pair and left corresponding pairs of lexical variants, e.g., (“amendment”, “amending”) in (3a), untouched.

2.2 Dealing with Lexical Variants

In this study, the term **lexical variants** covers, at least, the following three types of word groups.

Lexical derivations: different words that share the same stem and a large part of their meaning, e.g., {“develop”, “developer”, “development”, . . .}. Words in such a group can have different parts-of-speech.

Morphological variants: different surface forms of the same word, e.g., {“amend”, “amends”, “amending”, . . .}. These are derived based on processes such as inflection and conjugation.

Orthographic variants: different spellings of the same inflectional/conjugation form of the same word, e.g., {“color”, “colour”} and {“authorize”, “authorise”}.

Several syntactic and semantic theories, such as transformational grammar (Harris, 1957) and Meaning-Text Theory (Mel’čuk and Polguère, 1987), propose a representation of paraphrases that involve alternations of lexical variants. Jacquemin (1999) and Fujita et al. (2007) addressed this type of paraphrase using manually described syntactic transformation patterns in combination with dictionaries of lexical variants.

Catvar (Habash and Dorr, 2003) is a comprehensive lexical derivation database for English. WordNet (Fellbaum, 1998) also contains information of that kind and is currently available for various languages. Despite its high accuracy, manual creation of rich lexical resources requires a large human effort. Gaussier (1999) and Fujita et al. (2007) extracted groups of lexical derivations from a list of headwords of dictionaries through mining affix patterns. This approach significantly reduces human effort, maintaining reasonable accuracy, but the coverage is still limited because of the reliance on manually compiled dictionaries.

3 Proposed Method

This study is the first attempt to exploit various types of lexical variants for acquiring paraphrases in a completely empirical way.

Given a seed paraphrase lexicon (S_{Seed}) our method (henceforth ***LEXVAR***) expands it in two steps (see also Figure 1).

Step 1. Learning paraphrase patterns: From S_{Seed}, we learn a set of paraphrase patterns, generalizing various types of lexical variants in addition to identical word forms.

Step 2. Harvesting new paraphrase pairs: Using the learned paraphrase patterns, we harvest a set of new paraphrase pairs (S_{LV}) from monolingual corpora.

LEXVAR subsumes Fujita et al. (2012)’s method explained in Section 2.1.3 (henceforth ***IDENT***), and its output S_{LV} always subsumes *IDENT*’s output (S_{ID}). As *LEXVAR* and *IDENT* have the effect of expanding pre-existing paraphrase lexicons, they can be used as a complement to the other methods for acquiring paraphrases, provided they produce a

[2]If a constituency parser is available for the language of interest, one can learn syntax-based patterns during the bilingual pivoting process (Ganitkevitch et al., 2011).

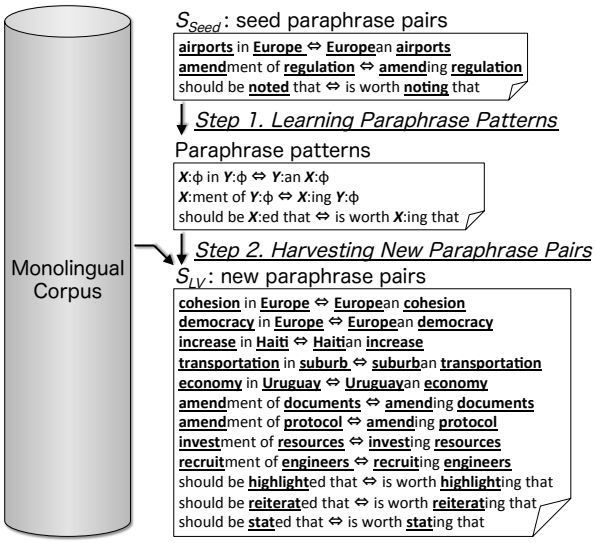

Figure 1: Overview of our proposed method.

sufficient number of high-quality pairs to make lexical generalization possible.

3.0 Step 0. Acquiring Seed Paraphrase Pairs

Our method requires as input a seed paraphrase lexicon (S_{Seed}) that has high quality and preferably exhibits various lexical correspondences that our method will exploit. For this purpose, paraphrases acquired from bilingual or monolingual parallel corpora are preferable (see Section 2.1.2).

In this study, we take the bilingual pivoting method as an example for the sake of reproducibility. However, the method also outputs a large number of non-paraphrases. To obtain further clean seeds, we apply several filters as described in (Fujita et al., 2012) and discard pairs that have low paraphrase probability, i.e., $p(e_2|e_1) < 0.01$, following the convention in (Du et al., 2010; Max, 2010; Denkowski and Lavie, 2010; Fujita et al., 2012).

Previous work (Chan et al., 2011; Fujita et al., 2012; Ganitkevitch et al., 2013) has proved that the information obtained from monolingual data can be used for assessing bilingually originated paraphrases. Thus, pairs that have low contextual similarity are also filtered out. Among various recipes for computing contextual similarity, we use a simple one: cosine measure of two context vectors comprising adjacent word 1–4 grams of all of the phrase appearances in given monolingual data. For a fair comparison with previous work, we eliminate only pairs that have no shared context, i.e., $Sim(e_1, e_2) = 0$.

3.1 Step 1. Learning Paraphrase Patterns

Given a set of seed paraphrases (S_{Seed}) we first induce a set of paraphrase patterns. From a seed paraphrase (4a), for instance, while *IDENT* learns (4b), *LEXVAR* generates (4c) by exploiting the generality exhibited by corresponding pairs of lexical variants, i.e., ("amendment", "amending").

(4) a. amendment of regulation
⇔ amending regulation
b. amendment of X ⇔ amending X
c. X:ment of Y:ϕ ⇔ X:ing Y:ϕ

The central issue at this stage is to robustly and accurately identify various types of lexical variants. We examine a data-driven approach, targeting for increased coverage, but manually created resources such as dictionaries can also be used.

3.1.1 Collecting Affix Patterns

As exemplified by ("X:ment", "X:ing") in (4c), we represent pairs of lexical variants with **affix patterns**. While Gaussier (1999) considered only suffix patterns, we also deal with prefix patterns such as those exhibited by ("reliable", "unreliable") and ("exist", "coexist") observed in the following paraphrase pairs.

(5) a. is not reliable ⇔ is unreliable
b. exist together with ⇔ coexist with

However, we currently do not consider prefix/suffix combinations, such as ("directly", "indirect") and ("believed", "unbelievable"), and other types of affixes than prefixes and suffixes.

Reliable affix patterns are collected from S_{Seed} (cf., headwords of manually compiled dictionaries (Gaussier, 1999; Fujita et al., 2007)). First, candidates of affix patterns are extracted from S_{Seed} on the following assumption.

> A pair of words will share a definite semantic relation if the words appear on opposite sides of a paraphrase pair and have the same stem.

We do not rely on any language resources to identify the stems of words. Instead, we regard word pairs that share at least one character as candidate

Word_1	Word_2	Affix_1	Affix_2	Stem
aimed	aims	X:ed	X:s	aim
aimed	achieve	X:imed	X:chieve	a
achieving	aims	X:chieving	X:ims	a
achieving	achieve	X:ing	X:e	achiev

Table 1: Candidate pairs of lexical variants and corresponding affix patterns extracted from (6).

Affix_1	Affix_2	# of unique stems length $\geq$5	# of unique stems length $<$5	Result
X:chieve	X:imed	0	1	Eliminated
X:chieving	X:ims	0	1	Eliminated
X:ed	X:s	69	22	Retained
X:ing	X:e	330	70	Retained

Table 2: Filtering affix patterns (# of unique stems taken from our experimental result of Europarl setting).

pairs of lexical variants and extract the longest common prefix/suffix as their corresponding affix patterns. From a paraphrase pair (6), for instance, we separately extract four pairs of words and their corresponding affix patterns, as shown in Table 1.

(6) is aimed at achieving $\Leftrightarrow$ aims to achieve

Our candidate affix patterns are then filtered using the following criterion (Gaussier, 1999).

> An affix pattern is retained iff it is associated with at least n unique stems that are at least k characters in length.

This criterion relies on two parameters, n and k. The parameter n assesses whether a pattern is sufficiently productive. The other (k) is more linguistically motivated: a genuine pattern is more likely to be used for long stems, as affixation is a general operation for producing lexical derivations in many languages. In particular, we set $k = 5$ and $n = 2$, as proposed in (Gaussier, 1999). Table 2 presents examples of filtering affix patterns eliminated and retained with this setting.

3.1.2 Generating Paraphrase Patterns

Using the affix patterns acquired in the previous step, paraphrase patterns are generated from the seed paraphrase pairs in S_{Seed}. In this step, we exhaustively consider all the combinations of word forms and lexical variants that match one of the affix patterns. From the paraphrase pair (6), the following pattern is generated.

(7) is X:ed at Y:ing $\Leftrightarrow$ X:s to Y:e

Thanks to the above filtering mechanism, spurious patterns, such as (8), are not generated.

(8) is X:imed at Y:chieving
$\Leftrightarrow$ Y:ims to X:chieve

3.2 Step 2. Harvesting New Paraphrase Pairs

Given a set of paraphrase patterns, e.g., (4c) and (7), new paraphrase pairs are harvested from monolingual corpora. In this process, each paraphrase pattern is used as a template such that the expressions that match both sides of the patterns are collected.

Unlike *IDENT*'s patterns, e.g., (4b), *LEXVAR* also collects corresponding pairs of lexical variants designated by each pattern. However, affix pattern alone cannot guarantee the semantic relation between a corresponding pair of words that each paraphrase pattern implicitly requires. For instance, the pattern (9b) is learned from (9a), where a definite relation is assumed between the two elements of ("X:ϕ", "X:an").

(9) a. countries of Europe
$\Leftrightarrow$ European nations
b. countries of X:ϕ $\Leftrightarrow$ X:an nations

Word pairs inappropriate for this pattern, e.g., ("uncle", "unclean") and ("beg", "began"), would be extracted alongside appropriate ones, e.g., ("Haiti", "Haitian") and ("suburb", "suburban"). Nonetheless, we suppose that the other surface parts of each paraphrase pair, e.g., "countries of" and "nations" in (9b), can effectively constrain instances, guaranteeing the existence of each entire phrase of the pair.

Pattern matching alone can generate pairs that are not suitable as paraphrases in any context. Thus, we assess the reliability of each pair by calculating contextual similarity between two phrases in the same manner as cleaning S_{Seed}: a pair of phrases is eliminated, if the phrases are used in completely dissimilar contexts.

3.3 Limitation

While *LEXVAR* exploits a kind of generality of paraphrases exhibited by pairs of lexical variants, it does not exploit paraphrase pairs comprising completely different surface forms such as those pairs in (10).

(10) a. look like $\Leftrightarrow$ resemble
b. burst into tears $\Leftrightarrow$ cry

To create further large paraphrase lexicons, we need to acquire these idiosyncratic paraphrases by improving existing methods and/or exploring yet another approach.

Another limitation of *LEXVAR* is that it considers only prefixes and suffixes of words as clues of lexical correspondences. We will need extensions to deal with a wider range of lexical correspondences. For instance, depending on the targeted language, other types of affixes, such as infixes and circumfixes, should be taken into account. Gaussier (1999) pointed out that some lexical derivations involve character-level alternations, e.g., "c" and "ç." Fujita et al. (2007) demonstrated that lexical derivations in an ideographic language, i.e., Japanese, can be captured by considering both ideographs and their phonetic transcriptions.

Last but not least, as *LEXVAR* regards only corpus as source, it does not acquire paraphrases that do not appear in a given corpus.

4 Expanding Paraphrase Lexicons

To what extent can our *LEXVAR* method expand a given paraphrase lexicon? We examined this, taking English as a target language and the bilingual pivoting method as the means of acquiring S_{Seed}.

4.1 Seed Paraphrase Pairs

We conducted experiments on the following two corpora configurations.

Europarl setting: The English–French version of the Europarl Parallel Corpus[3] comprising 2.0 M sentence pairs (55.7 M words in English and 61.9 M words in French) was used as a bilingual corpus. Its English side and the 2011–2013 editions of News Crawl corpora[4] comprising 52.0 M sentences (1.20 B words) were used as a monolingual corpus.

NTCIR setting: The Japanese–English Patent Translation data[5] comprising 3.2 M sentence pairs (107 M words in English and 116 M morphemes in Japanese) was used as a bilingual parallel corpus, while its English side and the 39.9 M sentences (1.36 B words) from the 2006–2007 chapters of NTCIR unaligned patent documents were used as a monolingual corpus.

For learning curve experiments, several sizes of bilingual sub-corpora were created by sub-sampling sentence pairs for both settings.

The other language resources involved in this experiment are as follows.

Phrase table learner: SyMGIZA++[6] was used for IBM2 alignment, then grow-diag-final phrase extraction and phrase table pruning were performed using toolkits in Moses[7].

Tokenizer: The tokenizer distributed with Moses was used for both English and French texts. For Japanese data, MeCab[8] was used.

Stoplists: To perform several types of filtering proposed by Fujita et al. (2012), we used the stoplists available on the Web[9]: 571 English and 463 French words. For Japanese, we manually listed 160 morphemes.

4.2 Paraphrase Patterns

Paraphrase patterns were learned from the set of seed paraphrase pairs. Figure 2 shows the numbers of the acquired paraphrase patterns and the percentages of paraphrase pairs in the seed lexicon, S_{Seed}, covered by the patterns.

As illustrated by example (4), *LEXVAR* learns more general paraphrase patterns than *IDENT*. Applied to another seed paraphrase pair (11a), *IDENT* will generate another pattern (11b), but *LEXVAR* will not: the corresponding (4c) is already learned.

(11) a. development of tourism
$\Leftrightarrow$ developing tourism
b. development of $X \Leftrightarrow$ developing X

On the other hand, *LEXVAR* also learns patterns from seed paraphrase pairs that *IDENT* ignores, e.g., (6) and (9a). Consequently, a wider range of seed paraphrases were involved in learning patterns and more patterns were acquired.

4.3 New Paraphrase Pairs

Finally, new paraphrases were acquired from the monolingual data. At this time, only single words

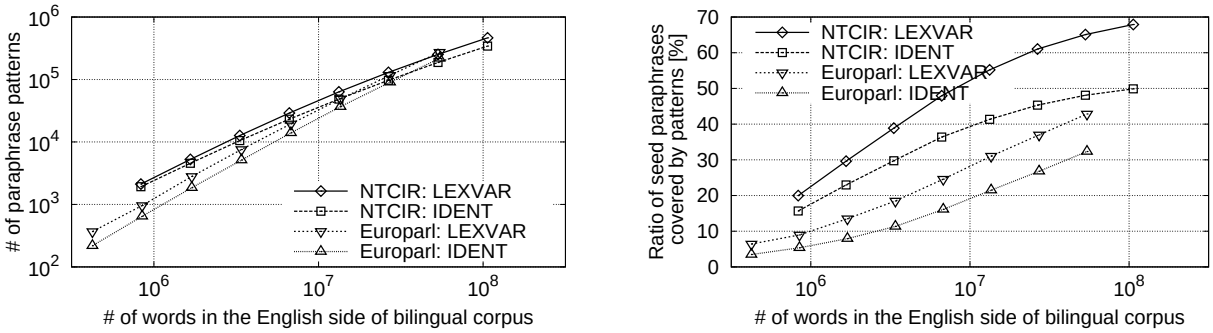

Figure 2: Statistics for the acquired paraphrase patterns: number and coverage against S_{Seed}.

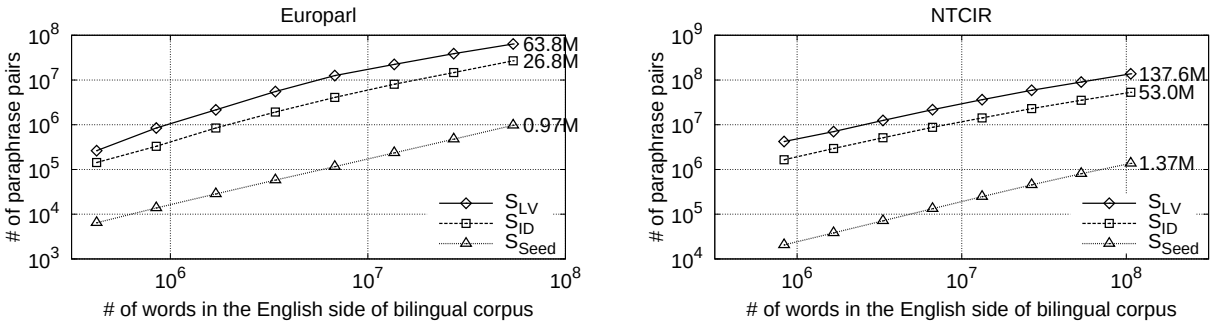

Figure 3: Number of acquired paraphrase pairs (left: Europarl, right: NTCIR).

were regarded as potential slot-fillers for the patterns. Recall that S_{LV} and S_{ID} are the sets of paraphrases generated by *LEXVAR* and *IDENT*, respectively, and $S_{LV} \supseteq S_{ID}$. Pairs that appeared in S_{Seed} and those used in completely dissimilar contexts were excluded from both S_{ID} and S_{LV}.

Figure 3 demonstrates that, irrespective of the size of the bilingual corpus, *LEXVAR* yielded far more (relative) coverage of paraphrase pairs S_{LV} than not only S_{Seed} but also S_{ID}. When the full bilingual corpora were used, S_{LV} contained 63.8 M and 137.6 M paraphrase pairs in the two respective settings, while S_{ID} contained only 26.8 M and 53.0 M pairs. The seed set S_{Seed} can be pooled with S_{LV}; thus, *LEXVAR* expanded S_{Seed} by approximately 67 and 101 times in the two respective settings. Figure 4 illustrates the ratio of the expanded parts of the paraphrase lexicons S_{LV} and S_{ID} against the seed set S_{Seed}. The ratio of S_{LV} against S_{Seed} ranged over 41–109 and 100–205 in the two respective settings. This figure also emphasizes the visible advantage of S_{LV} over S_{ID}: 84%–208% and 139%–159% more coverage.

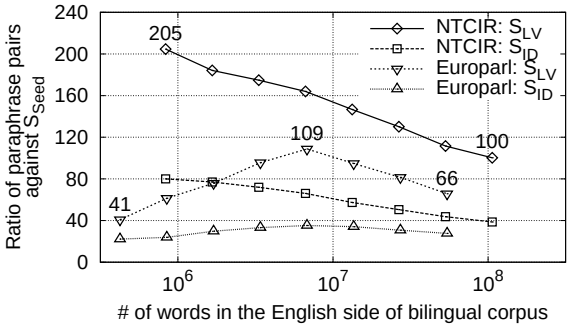

Figure 4: Ratio of S_{LV} and S_{ID} to S_{Seed}.

We expected that the more the bilingual data there are, the lower the leverage ratio is, because when a larger bilingual corpus is used, more seed paraphrases can be acquired, and the relative size of the monolingual data compared to the bilingual is lower. While the leverage ratio in the NTCIR setting follows this, the ratio in the Europarl setting does not: it peaks at approximately the middle of the scale. We found that from a very small bilingual corpus, we do not necessarily obtain seed paraphrases that exhibit

the generality exploited by *LEXVAR* and *IDENT*. In this case, the leverage ratio cannot be extremely high despite the large difference in the corpora sizes.

LEXVAR also largely contributed to discovering paraphrases for phrases that were not paraphrased using only S_{Seed} and S_{ID}. The ratio of the numbers of unique left-hand side phrases in S_{LV} to those in S_{Seed} ranged over 65–147 and 92–415 in the two respective settings, gaining 76%–210% and 145%–175% more coverage than S_{ID}.

5 Quality Assessment

The quality of the created paraphrase lexicons was manually evaluated through a paraphrase substitution test: we generated pairs of paraphrase sentences using the paraphrase lexicons and asked human evaluators to assess their quality.

5.1 Criteria and Procedure

Generating paraphrased sentences by substituting words and phrases involves two different tasks: generating new sentences and ensuring that the meaning is preserved. It is therefore straightforward to separately evaluate the **grammaticality** and **meaning equivalence** of each paraphrased sentence (Callison-Burch, 2008).

Grammaticality: whether the paraphrased sentence is grammatical

Meaning equivalence: whether the meaning of the original sentence is properly preserved by the paraphrased sentence

We adopted the detailed criteria and procedure described in (Fujita, 2013), as they resulted in a reasonably high inter-evaluator agreement ratio. The evaluation protocol is characterized by the following three features introduced for reducing human labor and making results consistent.

Unit-wise: Several paraphrase examples for the same source are packaged into an **example unit** and provided at the same time.

Two-phased: Evaluators are first asked to assess only the grammaticality of each paraphrased sentence without seeing the original sentence. Then, by comparing each pair of original and paraphrased sentences, they assess to what extent the paraphrased sentence retains the meaning of its counterpart.

Classification-based: Evaluators are asked to classify each example into one of the predetermined categories, guided by the decision trees respectively designed for evaluating grammaticality and meaning equivalence.

5.2 Data

We used news sentences as in (Callison-Burch, 2008; Fujita et al., 2012): the English sentences from WMT 2011–2013 "newstest" data (9,000 unique sentences). To reduce the human labor for the evaluation, they were restricted to those with moderate length: 10–30 words, which we expected to provide sufficient but succinct context of the substituted phrases. 5,850 sentences were retained.

By substituting phrases in the above sentences using the paraphrase lexicons S_{Seed} and S_{LV} in the Europarl setting, 88,555 example units comprising 1,013,511 paraphrases were generated. For each example unit, 3-best paraphrases were then selected by a 5-gram language model trained on the monolingual data in the Europarl setting with modified Kneser–Ney smoothing using KenLM[10]. Finally, from 31,149 units that contained at least three paraphrases, we randomly sampled 200 example units for 200 unique left-hand side phrases.

5.3 Results

We collected evaluations from three native English speakers. Table 3 summarizes the inter-evaluator agreement ratio, Cohen's κ (Cohen, 1960). The values for a coarse-grained binary decision[11] were "substantial" for grammaticality and "moderate" for meaning equivalence (Landis and Koch, 1977).

The quality of the examined paraphrase lexicons is measured by the precision of the evaluated examples: an example was regarded as correct if and only if a majority of evaluators (two or three in our case) assigned a label corresponding to the positive class in the binary decision. Table 4 summarizes the results. Despite the low chance of being the 3-best candidates, thanks to various filters,

[10] https://kheafield.com/code/kenlm/

[11] We regarded "Perfect" and "Awkward" for grammaticality, and "Equivalent" and either of three categories of slight differences "Missing Info.," "Additional Info.," and "Ignorable Change" for meaning equivalence as positive. This is consistent with (Callison-Burch, 2008).

Criterion	Fine-grained	Coarse-grained
Grammar	0.51 - 0.56	0.64 - 0.79
Meaning	0.27 - 0.35	0.48 - 0.53

Table 3: Cohen's κ of pairwise agreement.

Lexicon	n	Grammar	Meaning	Both
S_{Seed}	66	0.85	0.91	0.76
S_{ID} ($\subseteq S_{LV}$)	339	0.84	0.78	0.66
S_{LV}	534	0.74	0.78	0.59
Total	600	0.75	0.79	0.61

Table 4: Precision of paraphrase substitution.

paraphrases drawn from S_{Seed} were of substantially high quality. Compared to S_{Seed}, paraphrases sampled from S_{LV} have relatively low precision in both grammaticality and meaning equivalence. However, these scores are reasonably high, considering that no use is made of rich language-specific resources[12].

However, more grammatical errors occurred than with S_{Seed} and S_{ID}. A manual error analysis revealed that the majority of these errors were caused by the differences of syntactic categories between phrases, e.g., (12).

(12) The safety issue was *considered sufficiently* ($\Rightarrow$ *sufficient consideration*) serious for all affected parties to be informed.

Differences of grammatical number and determiners were the other major error sources.

(13) Federal Security Service now spread a big network of fake sites and there are tons of *potential buyers* ($\Rightarrow$ *a potential buyer*) of military weapons.

These types of pairs originally existed in S_{Seed} but were amplified by *LEXVAR*. Ganitkevitch and Callison-Burch (2014) stated that morphological variants of the same word might be desirable depending on the downstream task. For instance, they could be useful for paraphrase recognition tasks including question answering and multi-document summarization. As they are morphological variants rather than genuine paraphrases, substituting them in a given context often degrades grammaticality.

[12] Although we cannot make a direct comparison owing to the differences of data and human evaluators, for reference, Callison-Burch (2008) achieved 0.68, 0.61, and 0.55 precision for grammaticality, meaning equivalence, and both, respectively, by introducing parser-oriented syntactic constraints in bilingual pivoting.

6 Conclusion

We proposed a method for expanding given paraphrase lexicons by first inducing paraphrase patterns and then searching monolingual corpora with these patterns for new paraphrase pairs. To the best of our knowledge, this is the first attempt to exploit various types of lexical variants for acquiring paraphrases in a completely empirical way. Our method requires minimal language-dependent resources, i.e., stoplists and tokenizers, other than raw corpora. We demonstrated the quantitative impact of our method and confirmed the potential quality of the expanded paraphrase lexicon.

Our future work is four-fold. (i) Paraphrase lexicons created by different methods and sources have different properties. Designing an overall model to harmonize such heterogeneous lexicons is an important issue. (ii) We aim to investigate an extensive collection of corpora: there are far more corpora than those we used in this experiment. We are also interested in expanding paraphrase lexicons created by a method other than bilingual pivoting; for instance, those extracted from a Web-harvested monolingual comparable corpus (Hashimoto et al., 2011; Yan et al., 2013). (iii) We will apply our method to various languages for demonstrating its applicability, extending it for a wider range of lexical variants depending on the targeted language. (iv) Paraphrases are the fundamental linguistic phenomena that affect a wide range of NLP tasks. We are therefore interested in determining to what extent our paraphrase lexicons can improve the performance of application tasks such as machine translation, text summarization, and text simplification.

Abstract

We introduce a distantly supervised event extraction approach that extracts complex event templates from microblogs. We show that this near real-time data source is more challenging than news because it contains information that is both approximate (e.g., with values that are close but different from the gold truth) and ambiguous (due to the brevity of the texts), impacting both the evaluation and extraction methods. For the former, we propose a novel, "soft", F1 metric that incorporates similarity between extracted fillers and the gold truth, giving partial credit to different but similar values. With respect to extraction methodology, we propose two extensions to the distant supervision paradigm: to address approximate information, we allow positive training examples to be generated from information that is similar but not identical to gold values; to address ambiguity, we aggregate contexts across tweets discussing the same event. We evaluate our contributions on the complex domain of earthquakes, with events with up to 20 arguments. Our results indicate that, despite their simplicity, our contributions yield a statistically-significant improvement of 33% (relative) over a strong distantly-supervised system. The dataset containing the knowledge base, relevant tweets and manual annotations is publicly available.

1 Introduction

Twitter is an excellent source of near real-time data on recent events, motivating the need for information extraction (IE) systems that operate on tweets rather than traditional news articles. However, using this data comes with its own challenges: tweets tend to use colloquial speech, noisy syntax and discourse, and, more importantly, the information reported is often inaccurate (e.g., reporting a different but similar magnitude for an earthquake) and ambiguous (e.g., reporting multiple potential earthquake locations, with insufficient context to guess which is the correct one).[1] The top rows in Table 1 show examples of these problems for an actual event in our dataset on earthquakes. This comes in contrast with "traditional" IE work on newswire documents, where information is considerably more accurate than microblog material, and none of the above observations hold (Grishman and Sundheim, 1996; Doddington et al., 2004).

As an example of the benefits of event extraction from a near real-time social-media resource, the last row in Table 1 lists a motivating example, where our system extracts the correct depth of an earthquake from the text tweeted by the U.S. Geological Survey, which is novel information that is missing in our manually-curated knowledge base.

In this work we take a classic event extraction (EE) task, where events are defined by templates containing a predefined set of arguments, and implement it using data from Twitter. We avoid the prohibitive cost of manual annotation through distant supervision (DS): we automatically generate train-

[1] We focus on microblogs here because they commonly contain inaccurate and/or ambiguous information. However, we believe that our contributions extend beyond microblogs because these innacuracies, especially inaccurate information, may appear in news article as well.

Table 1: Challenges and opportunities for event extraction from Twitter. The first row shows a tweet with approximate information (in bold); the correct magnitude is 7.3 (cf. Table 2). The second row shows a first tweet with ambiguous information, which leads our baseline model to extract the incorrect country (in bold; correct country is *Peru*). The following two tweets help disambiguate the context. The last row shows a tweet containing information (in bold) that is missing in the knowledge base.

ing data by aligning a knowledge base of known event instances with tweets (Mintz et al., 2009; Hoffmann et al., 2011), which is then used to train a supervised extraction model (sequence tagger in our case). In seminal work on event extraction, (Benson et al., 2011) applied DS to both detect tweets about local events and then extracted values about two arguments (artist and venue). In our work, we work on automatically selected tweets, and scale the task to complex events with a large number of arguments. We focus on the domain of earthquakes, where each event has up to 20 arguments. Table 2 summarizes this task.

The contributions of this work are the following:

1. To our knowledge, this is one of the first works that analyzes the problem of distantly supervised extraction of complex events with many arguments from microblogs.

2. Our analysis shows (Section 3) that the biggest barrier is that information on Twitter can be *inaccurate* (containing approximately correct event argument values) and *ambiguous* (with insufficient context for accurate extraction). The top two blocks in Table 1 show an example of each. These challenges impact both evaluation and system development.

3. The analysis also highlights the need to adapt evaluation metrics to approximately correct information, which may appear both in text and in the knowledge base itself. For example, for a particular earthquake, the USGS reports a depth of 22 km., while NOAA reports 25 km[2]. We propose a new evaluation metric that gives partial credit to extracted argument values based on their similarity to existing values in the knowledge base.

4. We introduce two simple strategies that address the above barriers for system development: *approximate matching*, which addresses inaccurate values by allowing the distant supervision process to map values from the knowledge base to text even when they do not match exactly; and *feature aggregation*, which responds to small, ambiguous contexts by aggregating information across multiple tweets for the same event. For example, the first strategy considers the 7.1 magnitude in the first tweet in Table 1 as a training example because it is close to the value in the knowledge base (7.3). The second strategy classifies all instances of *Peru* jointly using a single set of features, extracted from all available tweets for the corresponding earthquake. For example, this feature set contains three values for the feature `previous-word` (*:*, *rocks*, and *in*). Each approach yields 19% relative improvement, 33% in combination.

5. We release a public dataset containing a knowledge base of earthquake instances and corresponding tweets for each earthquake[3].

2 Experimental framework

In this section we detail the creation of the knowledge base of earthquake events, the collection process for potentially-relevant tweets, and, lastly, our distant supervision framework, which serves as a platform for our contributions (Sections 5 and 6).

2.1 Knowledge base and tweet dataset creation

The **knowledge base (KB)** was created from the list of globally significant earthquakes during the 21st century, as reported by Wikipedia.[4] We se-

Table 2: Event arguments and types in the earthquake domain (first and second column), summary statistics for the knowledge base, i.e., the gold truth (third column), and values for one example earthquake (4th column). (*) indicates multi-valued arguments (all other are single-valued). The two rightmost columns give statistics for the number of mentions in the tweets per argument, as obtained through manual annotation (MA) or distant supervision (DS) (cf. Section 2.4). The argument types are the following: *D* date, *T* time, *L* location, *N* numeric, and *B* boolean.

lected earthquakes from the beginning of 2009, with the last reported earthquake happening on July 7th, 2013, and constructed the KB from the above Wikipedia list page and the individual infoboxes. Where necessary, argument values were normalized.[5] See Table 2 for a summary and an example.

We used the Topsy API[6] to search for **tweets** that are potentially relevant for each earthquake. We formed a query using the word "earthquake" plus the location, encoded as a disjunction of city, region, and country arguments. We retrieved tweets from the day before the date and time of the earthquake, up to seven days after. This procedure might also retrieve tweets about aftershocks, which we consider to be different events. We applied an aggressive method to discard aftershock tweets: we only kept tweets up to the first tweet that mentions a time expression more than a minute different from that of the main earthquake (after adjusting for time zone). For example, this heuristic removes all tweets starting with *"A 4.9 earthquake occurred in Ryukyu Islands, Japan on 2010-2-27 T10:33:21 at epicenter."* because the main earthquake occurred on February 26th at 8:31PM UTC. It is important to note that identifying event-relevant tweets is not the focus of this work (hence the simple heuristics used for tweet extraction). We focus instead on the *extraction* of information from such tweets. In a complete system, our approach would follow a component that detects event tweets automatically (Benson et al., 2011). The final dataset contains 108 earthquakes and 7,841 tweets, 72 tweets per earthquake on average, a maximum of 654 and a minimum of 2. 19 earthquakes had less than 10 tweets.

2.2 Manual annotation of tweets

In order to analyze the challenges faced by our EE system based on distant supervision, we also manually annotated all tweets.[7] The manual annotation included any mention of an event argument in the tweets. This included information already in the KB, but also information that is missing, caused by: variations of dates and times, similar but not identical latitude/longitude values, different reported numbers for dead/injured/missing etc. The first tweet in Table 1 is an example of this situation: even though the reported magnitude is different from the value in the KB (cf. example in Table 2), it was annotated during this process. In total, we annotated 17,672 mentions (at an average of two event arguments per tweet). Table 2 shows the breakdown per argument (the MA column), compared to the automatic annotations generated through distant supervision (the DS column). Note that some of the arguments have a very different coverage in the tweets compared with the KB. For example, latitude and longitude are rarely present in tweets, but affected countries are commonly mentioned. The quality of the manual annotation was assessed on a 5% sample of the dataset, which was annotated by an additional expert. The agreement was very high: 90% ITA and 85% Fleiss Kappa. Disagreements were generally

2013, at 2PM CET.

[5]Time and date expressions were converted to TimeML. Numerical values in English were converted to numbers, latitude and longitudes were converted to decimal format.

[6]http://api.topsy.com/doc/

[7]These manual annotations are used solely for post-hoc analysis, *not* to train our system.

due to missed argument mentions. Note that the cost of annotation was around 75 hours, confirming the cost-saving properties of distant supervision.

2.3 Dataset and experiment organization

We sorted the list of earthquakes in the KB chronologically, and chose the earliest 75% of the earthquakes as the training dataset, and the most recent (25%) for testing. The training set contained 81 earthquakes and their corresponding 6078 tweets, while the testing set contained 27 earthquakes and 1763 tweets. All development experiments were performed using 5-fold cross-validation over the training partition, where the folds were organized randomly by earthquake. Each fold contained tweets for around 15 earthquakes, but the number of tweets varied widely, with one fold having 585 tweets and another 2229.

The evaluation compares the argument values induced by our system with those in the gold KB, and computes precision, recall and F1 using the official scorer from the Knowledge Base Population (KBP) Slot Filling (SF) shared task (Surdeanu, 2013). We also incorporated the notion of equivalence classes proposed in the SF task. For instance, if the system predicted *Guerrero State* for the argument `region`, when the KB contains just *Guerrero*, we consider this result correct because the two strings are equivalent in this context. Our equivalence classes also include countries, regions, and cities with hashtags, unnormalized temporal expressions, etc. Where applicable, we checked statistical significance of performance differences using the bootstrap resampling technique proposed in (Berg-Kirkpatrick et al., 2012), in which we draw many simulated test sets by sampling with replacement from the set of earthquakes in the test partition.

2.4 Distant supervision for event extraction

For the initial extraction experiment, we followed a traditional distant supervision approach (Mintz et al., 2009), which has four steps: the KB of past events is aligned to the text; a supervised system is trained on the resulting annotated text; the system is run on test data; and the output slot values are inferred from the annotations produced by the system. We thus started by aligning the information in the KB to the training tweets using strict matching[8]. Table 2 compares the number of mentions automatically generated through DS against the number of manually annotated mentions. As expected, the strict matching criterion yields fewer mentions than the manual annotation.

As an example of this process, given the Honduras earthquake in Table 2, this procedure will annotate two argument mentions in the first tweet from Table 1, `country` and `affected-country`, as follows:

> Earthquake in <country>Honduras</country>. So strong it was felt in <affected-country>Guatemala</affected-country> as well. 7.1 offshore atlantic.

Note that the magnitude in the tweet is different from the one reported in the KB and it will thus be left unmarked (we revisit this issue in Section 5).

Using this automatically-generated data, we trained a sequential tagger based on Conditional Random Fields (CRF)[9]. Based on the output of the CRF, we inferred the arguments values using noisy-or (Surdeanu et al., 2012), which selects the value with the largest probability for each single-valued argument by aggregating the individual mention probabilities produced by the CRF.[10] In the case of multi-valued arguments (`affected-country` and `affected-region`) we choose all values that had been annotated by the sequential tagger.

3 Initial results and analysis

The left block in Table 3 reports the results on development (5-fold cross-validation) of the initial event

[8] We identified two types of arguments: those that have binary (yes/no) values (`tsunami` and `landslides`) and those having other values. For the first type, we search the tweets corresponding to the target earthquake for a small number of strings (e.g., *tsunami* and *tsunamis*), and annotate all matches (e.g., <*tsunami*> *tsunami* </*tsunami*>). For non-binary valued arguments, we searched the tweets for exact occurrences of the corresponding values, and annotated all matching strings. When the same value appears in more than one argument for the same earthquake (e.g., *7* as both magnitude and number of dead people), we choose the most common label (e.g., magnitude cf. Table 2).

[9] We used the linear CRF in Stanford's CoreNLP package, with the default features (word form, PoS, lemma, NERC) for the `macro` configuration: `http://nlp.stanford.edu/software/corenlp.shtml`.

[10] For multi-token mentions (e.g. *New Zealand*) we use the average of the token probabilities.

	Strict Evaluation

extraction system based on a distantly-supervised CRF (DS-CRF), which notably attains higher precision than recall. These results are fair, e.g., they are comparable to those of (Benson et al., 2011), even though their events had much fewer argument types than ours (two vs. twenty). More importantly, we use this system's output to analyze where the approach could be improved. For the sake of comparison, we trained the same CRF with the manually annotated tweets, cf. Section 2 (MA-CRF). The MA-CRF results in Table 3 indicate that the main loss when doing distant supervision is in recall, but the overall F1 is close. This is remarkable, as the much more expensive MA-CRF (75 hours of human annotation) is taken to be an upperbound for DS-CRF.

Manual inspection showed that that DS-CRF returns fewer argument values than MA-CRF (328 vs. 469), from "easier" (more common) arguments which have a higher chance of appearing both in the text and the KB. Importantly, MA-CRF has lower precision than its distant supervision counterpart because it is trained on manual annotations, which included many mentions not in the KB. The consequence of this strategy is that MA-CRF tends to produce spurious mentions (i.e., mentions not in the KB) at evaluation time, which lowers precision.

In addition, we analyzed the annotations created through distant supervision[11], which produced 13,562 argument mentions in the training tweets (cf. Table 2, which also includes a breakdown by argument). This data contains incorrectly annotated strings (false positives) and also misses relevant argument values (false negatives). A comparison of these DS annotations against the manual annotations on all training tweets (17,672 mentions) yielded that 97.4% were correct, but that 27.4% of the gold manual annotations were missed. This is an important result: it demonstrates that, unlike in the problem of relation extraction (RE) where the major issue is the large percentage (higher than 30%) of false positives in automatically-created annotations (Riedel et al., 2010), here the fundamental roadblock is missing annotations (i.e., false negatives). We explain this difference by the fact that for this event extraction domain, it is trivial to identify domain-relevant tweets, which reduces the number of false positives for event arguments. We believe this generalizes to many other EE domains, e.g., airplane crashes (Reschke et al., 2014) or terrorist attacks, where the event context can be summarized accurately with a small number of keywords (e.g., flight number and date for the airplane crashes domain).

We also did a post-hoc analysis of the quality of the arguments induced by DS-CRF. One of the most significant outcomes of the analysis is that a large portion of numeric values (31.3%) were partially correct, in that the returned values were very similar to those in the KB (see for instance the 7.1 vs. 7.3 example in Section 1). This strongly suggests that the evaluation metric should be more lenient, and give credit to argument values that are similar to the gold ones.

4 Lenient evaluation

The previous analysis suggests that traditional evaluation measures unnecessarily penalize arguments containing values that do not match the gold truth exactly. Rather than giving no credit when predicted values are different from gold ones, we devised a simple extension to the KBP evaluation measures that take into account the similarity between the values of system and gold arguments, where the similarity depends on the type of each slot (cf. Table 2). For numeric values, we use the following formula, where x is the predicted value, and g the gold value:

$$sim(x, g) = max\left(1 - \frac{|x - g|}{g}, 0\right) \quad (1)$$

[11] Note that these are the argument mention annotations used to train DS-CRF, not the arguments inferred by the DS-CRF system.

For example, given a gold value of 7.3, a system value of 7.2 would have a similarity of 0.98, and a system value of 14.6 or larger would have a similarity 0. If both values are equal, similarity is 1.

For the other slot types, the similarity function is discrete, with values set to 1 (proposed slot is correct) or 0 (incorrect) as follows. We consider a proposed *temporal* argument as correct if it is within a span of 5 minutes of the corresponding gold temporal value. *Durations* are judged as correct if they are within 10 seconds of the gold values. We considered proposed *dates* as correct if they differ by at most one day from the gold date.[12]

For *location* arguments, we use GeoNames[13] to obtain the coordinates of the locations produced by the system that do not match the information in the KB. Based on the average size of countries, regions, and cities, we consider these additional locations as correct if they are at the following distance (or closer) from the gold locations: 500 kms for countries, 50 kms for regions, and 10 kms for cities.

The original KBP scorer increases the value of True Positives (TP) by 1 every time a predicted argument matches its gold value. In the proposed lenient scorer, TP is increased by the similarity between the predicted and gold values. The precision and recall will be thus calculated as follows (*SYS* for number of predicted argument values, *GOLD* for number of gold argument values):

$$prec = \frac{\sum sim(x, g)}{SYS} \quad (2)$$

$$rec = \frac{\sum sim(x, g)}{GOLD} \quad (3)$$

The right block in Table 3 lists the results under this lenient evaluation for the experiment initially reported in the left block in the same table. As expected, these results are higher than the ones using the strict measure, but maintain the relative order of the systems in each of the evaluation measures. The difference in precision between DS-CRF and MA-CRF decreases, indicating that the new measure assigns partial credit to the larger amount of argument values extracted by MA-CRF. The difference in recall values remains large. We address this in the next section.

[12]These thresholds might change in other domains, but adjusting these values is trivial.

5 Approximate distant supervision

The previous section demonstrated that many tweets contain argument values which are similar but not identical to the data in the knowledge base. These values would not be annotated during alignment by traditional distant supervision, which expects an exact match between knowledge base values and tweet texts. This means that DS-CRF will be trained with less data than what is available (e.g., without the 7.1 magnitude example in the tweet in Section 2.4). Here we demonstrate that a simple extension to distant supervision that annotates values close to the values in the knowledge base, results in improved performance.

The proposed alignment algorithm scans the training tweets, and labels named and numeric entities as positive argument examples (with the corresponding label from the KB), if they are deemed similar to the gold values according to the similarity formulas introduced in the previous section. This

We include the results of the CRF trained on manual annotations (MA-CRF) as a performance ceiling for this task.

is a trivial process for discrete similarities, but requires some care for continuous similarity functions, which are triggered for numeric arguments. In this situation, numeric entities are considered as positive examples only if their similarity function returns a value over a certain threshold with a known argument in the KB. If a numeric mention has more than one matching argument in the KB, the algorithm chooses the argument label with the highest similarity value; if all have the same similarity, the algorithm chooses the most frequent label in training.

We tuned the threshold hyper parameter for numeric values over the training dataset using 5-fold cross validation, which yielded 0.95 as the optimal value. Table 4 shows the results for the test partition using this threshold, and Figure 1 shows the corresponding P/R curves. Both results are generated using the proposed lenient evaluation. The results in the table show that, despite its simplicity, the proposed alignment algorithm yields considerable, statistically-significant improvements. The P/R curves show that the improvement holds for all recall points[14].

6 Feature aggregation

The second block in Table 1 illustrates a common scenario on Twitter, where a short, ambiguous tweet derails the extraction. We address this problem of insufficient local context with a method inspired by work in relation extraction, where relation instances between identical entities are classified jointly using the conjunction of features from all instances (Mintz et al., 2009). We adapt this idea to our sequence tagging EE model as follows:

1: We focus on location, date and temporal entities (both earthquake time and duration) which are argument candidates that are often ambiguous, i.e., they may be classified as more than one argument type. For example, a location entity may be labeled as `country`, `region`, `country-affected`, etc. We exclude numeric entities due to potential feature collisions between different argument types: we observed that, in training, several earthquakes had different numeric arguments with the same value. For example, the magnitude and depth of the 2012 Zohan earthquake were 5.6. Applying feature aggregation to examples of these arguments would lead to collisions between features from different classes.[15]

2: For each token that appears in one of these named entities, we identify all its instances across the relevant tweets, and share features across all these token instances. For example, for the tweets in the second block in Table 1, our approach identifies *Peru* as an argument mention candidate. All three instances of *Peru* are then classified using the same shared features, e.g., using three values for the fea-

[14]The curves for the strict evaluation are similar, and were omitted for brevity.

[15]Initial experiments confirmed this hypothesis: feature aggregation did not improve results for numeric arguments in development. In future work, we will explore multi-instance multi-label algorithms to handle this situation (Surdeanu et al., 2012).

ture `previous-word` (*:*, *rocks*, and *in*). This process is repeated for each earthquake individually, because tokens may be labeled differently in different earthquakes. This approach produced 37% more features than the DS-CRF baseline.[16]

The positive effect of feature aggregation is confirmed by the formal evaluation on the test dataset. Table 5 shows a statistically significant improvement in overall F1, for the lenient evaluation. The P/R curves (Fig. 2) indicate that DS$^{\text{aggr}}$-CRF's improvement comes from both better recall and better precision that the DS-CRF baseline.

Table 5 and Fig. 2 also show that the combination of approximate matching and aggregation outperforms the individual models, demonstrating that feature aggregation is complementary to approximate matching. The combined model attains a relative improvement of 33% over the DS-CRF baseline, reaching approximately 88% of the ceiling performance for this task (MA-CRF row, the CRF trained on manual annotations).

7 Related work

There has been considerable recent interest in IE from Twitter. However, in general, these works use supervised learning frameworks (Popescu et al., 2011; Ritter et al., 2012), and/or they use either a coarse representation of events, which reduces to topic modeling or classification of entire tweets (Popescu et al., 2011; Becker et al., 2011; Ritter et al., 2012), or a simplified representation of events with few arguments (Sakaki et al., 2010; Popescu et al., 2011; Benson et al., 2011; Ritter et al., 2012). In contrast, our work uses a complex event representation with 20 arguments, and does not require any manual annotation of tweets. Our work is closest, but complementary to the work of (Benson et al., 2011), which also uses distant supervision for event extraction: We provide solutions for two problems they do not address (inaccurate and ambiguous information) and we focus on more complex events (20 arguments vs. two).

This paper is also complementary to systems which detect event-relevant tweets (Sakaki et al., 2010; Petrović et al., 2010). In future work, we plan to replace our simple method of extracting relevant tweets by one of these approaches, producing a system that monitors microblogs in realtime to automatically construct event-specific knowledge bases.

Our work uses the framework of distant supervision, which has also received considerable attention recently. Nevertheless, most of these works focus on the extraction of binary relations from well-formed documents (Mintz et al., 2009; Riedel et al., 2010; Hoffmann et al., 2011; Surdeanu et al., 2012). We use the much noisier Twitter as the underlying text, and extract complex events instead of binary relations. We note, however, that the idea of feature aggregation is inspired by these works (Mintz et al., 2009; Riedel et al., 2010), but, to our knowledge, we are the first to apply it to event extraction and sequence tagging. In the DS space, our work is closest to (Reschke et al., 2014), which use it to extract complex events (airplane crashes) from newswire text. Because they focus on newswire, they do not need to address the potential for inaccurate or ambiguous information, which is the main focus of our work.

MA-CRF	68.76	27.61	39.40

Table 6: Test: Replica of the experiments in Table 5 using a threshold of 0.95 for the lenient evaluation measure. All other settings are identical to the experiments in Table 5. † indicates statistically significant improvement over DS-CRF ($p < 0.05$).

8 Discussion: An alternate evaluation measure

Designing relevant measures for lenient evaluations, such as the one discussed here, is an open research issue. For example, the method proposed in Section 4 gives partial credit to all reported (positive) numeric values in the interval $[0, 2g]$, where g is the correct value for the corresponding slot (see the equation in Section 4). But other, stricter, measures

[16] We also tried skip-chain CRFs (Getoor and Taskar, 2007), but found that our simpler approach converges considerably faster and produces slightly better results. We do not show those results for brevity.

are certainly possible.[17] For example, one stricter variant of our proposed measure would assign partial credit only for predicted values that have a similarity of 0.95 or higher with the gold truth (inline with our approximate DS training process). For example, for the same gold numeric value g, the measure assigns partial credit only for predicted values in the interval $[0.95g, 1.05g]$.

We repeated the experiments in Table 5 using this alternate evaluation measure. The result are summarized in Table 6. The results reported in Table 5 do not alter the findings of the paper. In fact, under this stricter evaluation measure, our results are stronger: DS^{comb}-CRF, which combines both our ideas, approaches with nearly 1 F1 point MA-CRF, which trains on manually annotated data.

9 Conclusions

To our knowledge, this is one of the first works that analyzes the problem of distantly supervised complex event extraction on microblogs. This near real-time data source is challenging, with inaccurate information and short, ambiguous texts, as shown by our empirical analysis of the dataset. We proposed two simple techniques to address these problems: (a) a novel distant supervision paradigm, which implements an alignment algorithm that allows text snippets that are similar but not identical to argument values in the knowledge base to be annotated (thus producing better training data); and (b) a feature aggregation strategy that provides richer information across tweets to cope with ambiguity. Our results on earthquake-related tweets show that each improvement yields 19% significant improvement when applied on top of a strong system based on sequence tagging (CRFs). We show that these contributions are complementary: a model that combines both performs better than each of the above individual models, with an improvement of 33% over the baseline. All in all, our approach attains approximately 88% of the ceiling performance for this task, which is obtained by a system trained on manually-annotated tweets, validating the hypothesis that distant supervision is useful for a complex event extraction task.

In addition, we devised a lenient evaluation measure which incorporates the similarity between the extracted argument values and the gold truth, rather than considering as correct only the extractions that exactly match the gold values. We show that this evaluation models the event extraction task better, and, furthermore, is more realistic, especially in view of imperfect knowledge bases.

Lastly, we release a dataset containing an event knowledge base constructed from Wikipedia information on earthquakes, which contains 108 earthquakes, 20 different argument types, and 1,116 argument values. The dataset also includes a collection of relevant tweets about these earthquakes, totaling 7,841 tweets. The dataset is publicly available.[18]

Unsupervised Dependency Parsing: Let's Use Supervised Parsers

Phong Le and **Willem Zuidema**
Institute for Logic, Language, and Computation
University of Amsterdam, the Netherlands
{p.le,zuidema}@uva.nl

Abstract

We present a self-training approach to unsupervised dependency parsing that reuses existing supervised and unsupervised parsing algorithms. Our approach, called 'iterated reranking' (IR), starts with dependency trees generated by an unsupervised parser, and iteratively improves these trees using the richer probability models used in supervised parsing that are in turn trained on these trees. Our system achieves 1.8% accuracy higher than the state-of-the-part parser of Spitkovsky et al. (2013) on the WSJ corpus.

1 Introduction

Unsupervised dependency parsing and its supervised counterpart have many characteristics in common: they take as input raw sentences, produce dependency structures as output, and often use the same evaluation metric (DDA, or UAS, the percentage of tokens for which the system predicts the correct head). Unsurprisingly, there has been much more research on supervised parsing – producing a wealth of models, datasets and training techniques – than on unsupervised parsing, which is more difficult, much less accurate and generally uses very simple probability models. Surprisingly, however, there have been no reported attempts to reuse supervised approaches to tackle the unsupervised parsing problem (an idea briefly mentioned in Spitkovsky et al. (2010b)).

There are, nevertheless, two aspects of supervised parsers that we would like to exploit in an unsupervised setting. First, we can increase the model expressiveness in order to capture more linguistic regularities. Many recent supervised parsers use third-order (or higher order) features (Koo and Collins, 2010; Martins et al., 2013; Le and Zuidema, 2014) to reach state-of-the-art (SOTA) performance. In contrast, existing models for unsupervised parsing limit themselves to using simple features (e.g., conditioning on heads and valency variables) in order to reduce the computational cost, to identify consistent patterns in data (Naseem, 2014, page 23), and to avoid overfitting (Blunsom and Cohn, 2010). Although this makes learning easier and more efficient, the disadvantage is that many useful linguistic regularities are missed: an upper bound on the performance of such simple models – estimated by using annotated data – is 76.3% on the WSJ corpus (Spitkovsky et al., 2013), compared to over 93% actual performance of the SOTA supervised parsers.

Second, we would like to make use of information available from lexical semantics, as in Bansal et al. (2014), Le and Zuidema (2014), and Chen and Manning (2014). Lexical semantics is a source for handling rare words and syntactic ambiguities. For instance, if a parser can identify that "he" is a dependent of "walks" in the sentence "He walks", then, even if "she" and "runs" do not appear in the training data, the parser may still be able to recognize that "she" should be a dependent of "runs" in the sentence "she runs". Similarly, a parser can make use of the fact that "sauce" and "John" have very different meanings to decide that they have different heads in the two phrases "ate spaghetti with sauce" and "ate spaghetti with John".

However, applying existing supervised parsing

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 651–661,
Denver, Colorado, May 31 – June 5, 2015.

techniques to the task of unsupervised parsing is, unfortunately, not trivial. The reason is that those parsers are optimally designed for being trained on manually annotated data. If we use existing unsupervised training methods (like EM), learning could be easily misled by a large amount of ambiguity naturally embedded in unannotated training data. Moreover, the computational cost could rapidly increase if the training algorithm is not designed properly. To overcome these difficulties we propose a framework, iterated reranking (IR), where existing supervised parsers are trained without the need of manually annotated data, starting with dependency trees provided by an existing unsupervised parser as initialiser. Using this framework, we can employ the work of Le and Zuidema (2014) to build a new system that outperforms the SOTA unsupervised parser of Spitkovsky et al. (2013) on the WSJ corpus.

The contribution of this paper is twofold. First, we show the benefit of using lexical semantics for the unsupervised parsing task. Second, our work is a bridge connecting the two research areas unsupervised parsing and its supervised counterpart. Before going to the next section, in order to avoid confusion introduced by names, it is worth noting that we use *un-trained* existing supervised parsers which will be trained on *automatically annotated* treebanks.

2 Related Work

2.1 Unsupervised Dependency Parsing

The first breakthrough was set by Klein and Manning (2004) with their dependency model with valence (DMV), the first model to outperform the right-branching baseline on the DDA metric: 43.2% vs 33.6% on sentences up to length 10 in the WSJ corpus. Nine years later, Spitkovsky et al. (2013) achieved much higher DDAs: 72.0% on sentences up to length 10, and 64.4% on all sentences in section 23. During this period, many approaches have been proposed to attempt the challenge.

Naseem and Barzilay (2011), Tu and Honavar (2012), Spitkovsky et al. (2012), Spitkovsky et al. (2013), and Marecek and Straka (2013) employ extensions of the DMV but with different learning strategies. Naseem and Barzilay (2011) use semantic cues, which are event annotations from an out-of-domain annotated corpus, in their model during training. Relying on the fact that natural language grammars must be unambiguous in the sense that a sentence should have very few correct parses, Tu and Honavar (2012) incorporate unambiguity regularisation to posterior probabilities. Spitkovsky et al. (2012) bootstrap the learning by slicing up all input sentences at punctuation. Spitkovsky et al. (2013) propose a complete deterministic learning framework for breaking out of local optima using count transforms and model recombination. Marecek and Straka (2013) make use of a large raw text corpus (e.g., Wikipedia) to estimate stop probabilities, using the reducibility principle.

Differing from those works, Bisk and Hockenmaier (2012) rely on Combinatory Categorial Grammars with a small number of hand-crafted general linguistic principles; whereas Blunsom and Cohn (2010) use Tree Substitution Grammars with a hierarchical non-parametric Pitman-Yor process prior biasing the learning to a small grammar.

2.2 Reranking

Our work relies on reranking which is a technique widely used in (semi-)supervised parsing. Reranking requires two components: a k-best parser and a reranker. Given a sentence, the parser generates a list of k best candidates, the reranker then rescores those candidates and picks the one that has the highest score. Reranking was first successfully applied to supervised constituent parsing (Collins, 2000; Charniak and Johnson, 2005). It was then employed in the supervised dependency parsing approaches of Sangati et al. (2009), Hayashi et al. (2013), and Le and Zuidema (2014).

Closest to our work is the work series on semi-supervised constituent parsing of McClosky and colleagues, e.g. McClosky et al. (2006), using self-training. They use a k-best generative parser and a discriminative reranker to parse unannotated sentences, then add resulting parses to the training treebank and re-train the reranker. Different from their work, our work is for unsupervised dependency parsing, without manually annotated data, and uses iterated reranking instead of single reranking. In addition, both two components, k-best parser and reranker, are re-trained after each iteration.

3 The IR Framework

Existing training methods for the unsupervised dependency task, such as Blunsom and Cohn (2010), Gillenwater et al. (2011), and Tu and Honavar (2012), are hypothesis-oriented search with the EM algorithm or its variants: training is to move from a point which represents a model hypothesis to another point. This approach is feasible for optimising models using simple features since existing dynamic programming algorithms can compute expectations, which are sums over all possible parses, or to find the best parse in the whole parse space with low complexities. However, the complexity increases rapidly if rich, complex features are used. One way to reduce the computational cost is to use approximation methods like sampling as in Blunsom and Cohn (2010).

3.1 Treebank-oriented Greedy Search

Believing that the difficulty of using EM is from the fact that treebanks are 'hidden', leading to the need of computing sum (or max) overall possible treebanks, we propose a greedy local search scheme based on another training philosophy: treebank-oriented search. The key idea is to explicitly search for concrete treebanks which are used to train parsing models. This scheme thus allows supervised parsers to be trained in an unsupervised parsing setting since there is a (automatically annotated) treebank at any time.

Given $\mathcal{S}$ a set of raw sentences, the search space consists of all possible treebanks $\mathcal{D} = \{d(s)|s \in \mathcal{S}\}$ where $d(s)$ is a dependency tree of sentence s. The target of search is the optimal treebank $\mathcal{D}^*$ that is as good as human annotations. Greedy search with this philosophy is as follows: starting at an initial point $\mathcal{D}_1$, we pick up a point $\mathcal{D}_2$ among its neighbours $\mathbf{N}(\mathcal{D}_1)$ such that

$$\mathcal{D}_2 = \arg\max_{\mathcal{D} \in \mathbf{N}(\mathcal{D}_1)} f_{\mathcal{D}_1}(\mathcal{D}) \tag{1}$$

where $f_{\mathcal{D}_1}(\mathcal{D})$ is an objective function measuring the goodness of $\mathcal{D}$ (which may or may not be conditioned on $\mathcal{D}_1$). We then continue this search until some stop criterion is satisfied. The crucial factor here is to define $\mathbf{N}(\mathcal{D}_i)$ and $f_{\mathcal{D}_i}(\mathcal{D})$. Below are two special cases of this scheme.

Semi-supervised parsing using reranking (McClosky et al., 2006). This reranking is indeed one-step greedy local search. In this scenario, $\mathbf{N}(\mathcal{D}_1)$ is the Cartesian product of k-best lists generated by a k-best parser, and $f_{\mathcal{D}_i}(\mathcal{D})$ is a reranker.

Unsupervised parsing with hard-EM (Spitkovsky et al., 2010b) In hard-EM, the target is to maximise the following objective function with respect to a parameter set Θ

$$L(\mathcal{S}|\Theta) = \sum_{s \in \mathcal{S}} \max_{d \in Dep(s)} \log P_\Theta(d) \tag{2}$$

where $Dep(s)$ is the set of all possible dependency structures of s. The two EM steps are thus

- Step 1: $\mathcal{D}_{i+1} = \arg\max_{\mathcal{D}} P_{\Theta_i}(\mathcal{D})$
- Step 2: $\Theta_{i+1} = \arg\max_{\Theta} P_\Theta(\mathcal{D}_{i+1})$

In this case, $\mathbf{N}(\mathcal{D}_i)$ is the whole treebank space and $f_{\mathcal{D}_i}(\mathcal{D}) = P_{\Theta_i}(\mathcal{D}) = P_{\arg\max_\Theta P_\Theta(\mathcal{D}_i)}(\mathcal{D})$.

3.2 Iterated Reranking

We instantiate the greedy search scheme by iterated reranking which requires two components: a k-best parser P, and a reranker R. Firstly, $\mathcal{D}_1$ is used to train these two components, resulting in P_1 and R_1. The parser P_1 then generates a set of lists of k candidates ${}_k\mathcal{D}_1$ (whose Cartesian product results in $\mathbf{N}(\mathcal{D}_1)$) for the set of training sentences $\mathcal{S}$. The best candidates, according to reranker R_1, are collected to form $\mathcal{D}_2$ for the next iteration. This process is halted when a pre-defined stop criterion is met.[1]

It is certain that we can, as in the work of Spitkovsky et al. (2010b) and many bootstrapping approaches, employ only parser P. Reranking, however, brings us two benefits. First, it allows us to employ very expressive models like the ∞-order generative model proposed by Le and Zuidema (2014). Second, it embodies a similar idea to co-training (Blum and Mitchell, 1998): P and R play roles as two views of the data.

[1] It is worth noting that, although $\mathbf{N}(\mathcal{D}_i)$ has the size $O(k^n)$ where n is the number of sentences, reranking only needs to process $O(k \times n)$ parses if these sentences are assumed to be independent.

3.3 Multi-phase Iterated Reranking

Training in machine learning often uses *starting big* which is to use up all training data at the same time. However, Elman (1993) suggests that in some cases, learning should start by training simple models on small data and then gradually increase the model complexity and add more difficult data. This is called *starting small*.

In unsupervised dependency parsing, starting small is intuitive. For instance, given a set of long sentences, learning the fact that the head of a sentence is its main verb is difficult because a long sentence always contains many syntactic categories. It would be much easier if we start with only length-one sentences, e.g "Look!", since there is only one choice which is usually a verb. This training scheme was successfully applied by Spitkovsky et al. (2010a) under the name: Baby Step.

We adopt starting small to construct the multi-phase iterated reranking (MPIR) framework. In phase 0, a parser M with a simple model is trained on a set of short sentences $\mathcal{S}^{(0)}$ as in traditional approaches. This parser is used to parse a larger set of sentences $\mathcal{S}^{(1)} \supseteq \mathcal{S}^{(0)}$, resulting in $\mathcal{D}_1^{(1)}$. $\mathcal{D}_1^{(1)}$ is then used as the starting point for the iterated reranking in phase 1. We continue this process until phase N finishes, with $\mathcal{S}^{(i)} \supseteq \mathcal{S}^{(i-1)}$ $(i = 1..N)$. In general, we use the resulting reranker in the previous phase to generate the starting point for the iterated reranking in the current phase.

4 Le and Zuidema (2014)'s Reranker

Le and Zuidema (2014)'s reranker is an exception among supervised parsers because it employs an extremely *expressive* model whose features are ∞-order[2]. To overcome the problem of sparsity, they introduced the inside-outside recursive neural network (IORNN) architecture that can estimate tree-generating models including those proposed by Eisner (1996) and Collins (2003a).

4.1 The ∞-order Generative Model

Le and Zuidema (2014)'s reranker employs the generative model proposed by Eisner (1996). Intuitively, this model is top-down: starting with ROOT, we generate its left dependents and its right dependents. We then generate dependents for each ROOT's dependent. The generative process recursively continues until there is no dependent to generate. Formally, this model is described by the following formula

$$P(d(H)) = \prod_{l=1}^{L} P\left(H_l^L | \mathcal{C}(H_l^L)\right) P\left(d(H_l^L)\right) \times \prod_{r=1}^{R} P\left(H_r^R | \mathcal{C}(H_r^R)\right) P\left(d(H_r^R)\right) \quad (3)$$

where H is the current head, $d(N)$ is the fragment of the dependency parse rooted at N, and $\mathcal{C}(N)$ is the context to generate N. H^L, H^R are respectively H's left dependents and right dependents, plus EOC (End-Of-Children), a special token to inform that there are no more dependents to generate. Thus, $P(d(ROOT))$ is the probability of generating the entire dependency structure d.

Le and Zuidema's ∞-order generative model is defined as Eisner's model in which the context $\mathcal{C}^{\infty}(D)$ to generate D contains *all* of D's generated siblings, its ancestors and their siblings. Because of very large fragments that contexts are allowed to hold, traditional count-based methods are impractical (even if we use smart smoothing techniques). They thus introduced the IORNN architecture to estimate the model.

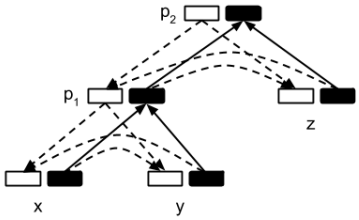

Figure 1: Inside-Outside Recursive Neural Network (IORNN). Black/white rectangles correspond to inner/outer representations.

4.2 Estimation with the IORNN

An IORNN (Figure 1) is a recursive neural network whose topology is a tree. What make this network different from traditional RNNs (Socher et al., 2010) is that each tree node u caries two vectors: $\mathbf{i}_u$ - the inner representation, represents the content of the

[2]In fact, the order is finite but unbound.

phrase covered by the node, and $\mathbf{o}_u$ - the outer representation, represents the context around that phrase. In addition, information in an IORNN is allowed to flow not only bottom-up as in RNNs, but also top-down. That makes IORNNs a natural tool for estimating top-down tree-generating models.

Applying the IORNN architecture to dependency parsing is straightforward, along the generative story of the ∞-order generative model. First of all, the "inside" part of this IORNN is simpler than what is depicted in Figure 1: the inner representation of a phrase is assumed to be the inner representation of its head. This approximation is plausible since the meaning of a phrase is often dominated by the meaning of its head. The inner representation at each node, in turn, is a function of a vector representation for the word (in our case, the word vectors are initially borrowed from Collobert et al. (2011)), the POS-tag and capitalisation feature.

Without loss of generality and ignoring directions for simplicity, they assume that the model is generating dependent u for node h conditioning on context $\mathcal{C}^\infty(u)$ which contains all of u's ancestors (including h) and theirs siblings, and all of previously generated u's sisters. Now there are two types of contexts: *full* contexts of heads (e.g., h) whose dependents are being generated, and contexts to generate nodes (e.g., $\mathcal{C}^\infty(u)$). Contexts of the first type are clearly represented by outer representations. Contexts of the other type are represented by *partial outer representations*, denoted by $\bar{\mathbf{o}}_u$. Because the context to generate a node can be constructed recursively by combining the full context of its head and its previously generated sisters, they can compute $\bar{\mathbf{o}}_u$ as a function of $\mathbf{o}_h$ and the inner representations of its previously generated sisters. On the top of $\bar{\mathbf{o}}_u$, they put a softmax layer to estimate the probability $P(x|\mathcal{C}^\infty(u))$.

Training this IORNN is to minimise the cross entropy over all dependents. This objective function is indeed the negative log likelihood $P(\mathcal{D})$ of training treebank $\mathcal{D}$.

4.3 The Reranker

Le and Zuidema's (generative) reranker is given by

$$d^* = \arg\max_{d \in {}_kDep(s)} P(d)$$

where P (Equation 3) is computed by the ∞-order generative model which is estimated by an IORNN; and ${}_kDep(s)$ is a k-best list.

5 Complete System

Our system is based on the multi-phase IR. In general, any third-party parser for unsupervised dependency parsing can be used in phase 0, and any third-party parser that can generate k-best lists can be used in the other phases. In our experiments, for phase 0, we choose the parser using an extension of the DMV model with stop-probability estimates computed on a large corpus proposed by Marecek and Straka (2013). This system has a moderate performance[3] on the WSJ corpus: 57.1% vs the SOTA 64.4% DDA of Spitkovsky et al. (2013). For the other phases, we use the MSTParser[4] (with the second-order feature mode) (McDonald and Pereira, 2006).

Our system uses Le and Zuidema (2014)'s reranker (Section 4.3). It is worth noting that, in this case, each phase with iterated reranking could be seen as an approximation of hard-EM (see Equation 2) where the first step is replaced by

$$\mathcal{D}_{i+1} = \arg\max_{\mathcal{D} \in \mathbf{N}(\mathcal{D}_i)} P_{\Theta_i}(\mathcal{D}) \quad (4)$$

In other words, instead of searching over the treebank space, the search is limited in a neighbour set $\mathbf{N}(\mathcal{D}_i)$ generated by k-best parser P_i.

5.1 Tuning Parser P

Parser P_i trained on $\mathcal{D}_i$ defines neighbour set $\mathbf{N}(\mathcal{D}_i)$ which is the Cartesian product of the k-best lists in ${}_k\mathcal{D}_i$. The position and shape of $\mathbf{N}(\mathcal{D}_i)$ is thus determined by two factors: how well P_i can fit $\mathcal{D}_i$, and k. Intuitively, the lower the fitness is, the more $\mathbf{N}(\mathcal{D}_i)$ goes far away from $\mathcal{D}_i$; and the larger k is, the larger

[3] Marecek and Straka (2013) did not report any experimental result on the WSJ corpus. We use their source code at `http://ufal.mff.cuni.cz/udp` with the setting presented in Section 6.1. Because the parser does not provide the option to parse unseen sentences, we merge the training sentences (up to length 15) to all the test sentences to evaluate its performance. Note that this result is close to the DDA (55.4%) that the authors reported on CoNLL 2007 English dataset, which is a portion of the WSJ corpus.

[4] `http://sourceforge.net/projects/mstparser/`

$\mathbf{N}(\mathcal{D}_i)$ is. Moreover, the diversity of $\mathbf{N}(\mathcal{D}_i)$ is inversely proportional to the fitness. When the fitness decreases, patterns existing in the training treebank become less certain to the parser, patterns that do not exist in the training treebank thus have more chances to appear in k-best candidates. This leads to high diversity of $\mathbf{N}(\mathcal{D}_i)$. We blindly set $k = 10$ in all of our experiments.

With the MSTParser, there are two hyperparameters: $\texttt{iters}_{\text{MST}}$, the number of epochs, and $\texttt{training-k}_{\text{MST}}$, the k-best parse set size to create constraints during training. $\texttt{training-k}_{\text{MST}}$ is always 1 because constraints from k-best parses with almost incorrect training parses are useless.

Because $\texttt{iters}_{\text{MST}}$ controls the fitness of the parser to training treebank $\mathcal{D}_i$, it, as pointed out above, determines the distance from $\mathbf{N}(\mathcal{D}_i)$ to $\mathcal{D}_i$ and the diversity of the former. Therefore, if we want to encourage the local search to explore more distant areas, we should set $\texttt{iters}_{\text{MST}}$ low. In our experiments, we test two strategies: (i) MaxEnc, $\texttt{iters}_{\text{MST}}$ = 1, maximal encouragement, and (ii) MinEnc, $\texttt{iters}_{\text{MST}}$ = 10, minimal encouragement.

5.2 Tuning Reranker R

Tuning the reranker R is to set values for $\texttt{dim}_{\text{IORNN}}$, the dimensions of inner and outer representations, and $\texttt{iters}_{\text{IORNN}}$, the number of epochs to train the IORNN. Because the ∞-order model is very expressive and feed-forward neural networks are universal approximators (Cybenko, 1989), the reranker is capable of perfectly remembering all training parses. In order to avoid this, we set $\texttt{dim}_{\text{IORNN}}$ = 50, and set $\texttt{iters}_{\text{IORNN}}$ = 5 for *very* early stopping.

5.3 Tuning multi-phase IR

Because Marecek and Straka (2013)'s parser does not distinguish training data from test data, we postulate $\mathcal{S}_0 = \mathcal{S}_1$. Our system has N phases such that $\mathcal{S}_0, \mathcal{S}_1$ contain all sentences up to length $l_1 = 15$, $\mathcal{S}_i$ $(i = 2..N)$ contains all sentences up to length $l_i = l_{i-1} + 1$, and $\mathcal{S}_N$ contains all sentences up to length 25. Phase 1 halts after 100 iterations whereas all the following phases run with one iteration. Note that we force the local search in phase 1 to run intensively because we hypothesise that most of the important patterns for dependency parsing can be found within short sentences.

6 Experiments

6.1 Setting

We use the Penn Treebank WSJ corpus: sections 02-21 for training, and section 23 for testing. We then apply the standard pre-processing[5] for unsupervised dependency parsing task (Klein and Manning, 2004): we strip off all empty sub-trees, punctuation, and terminals (tagged # and $) not pronounced where they appear; we then convert the remaining trees to dependencies using Collins's head rules (Collins, 2003b). Both word forms and gold POS tags are used. The directed dependency accuracy (DDA) metric is used for evaluation.

The vocabulary is taken as a list of words occurring more than two times in the training data. All other words are labelled 'UNKNOWN' and every digit is replaced by '0'. We initialise the IORNN with the 50-dim word embeddings from Collobert et al. (2011) [6] , and train it with the learning rate 0.1,

6.2 Results

We compare our system against recent systems (Table 1 and Section 2.1). Our system with the two encouragement levels, MinEnc and MaxEnc, achieves the highest reported DDAs on section 23: 1.8% and 1.2% higher than Spitkovsky et al. (2013) on all sentences and up to length 10, respectively. Our improvements over the system's initialiser (Marecek and Straka, 2013) are 9.1% and 4.4%.

6.3 Analysis

In this section, we analyse our system along two aspects. First, we examine three factors which determine the performance of the whole system: encouragement level, lexical semantics, and starting point. We then search for what IR (with the MaxEnc option) contributes to the overall performance by comparing the quality of the treebank resulted in the end of phase 1 against the quality of the treebank given by its initialier, i.e. Marecek and Straka (2013).

The effect of encouragement level

Figure 2 shows the differences in DDA between using MaxEnc and MinEnc in each phase: we com-

System	DDA (@10)
Bisk and Hockenmaier (2012)	53.3 (71.5)
Blunsom and Cohn (2010)	55.7 (67.7)
Tu and Honavar (2012)	57.0 (71.4)
Marecek and Straka (2013)[3]	57.1 (68.8)
Naseem and Barzilay (2011)	59.4 (70.2)
Spitkovsky et al. (2012)	61.2 (71.4)
Spitkovsky et al. (2013)	64.4 (72.0)
Our system (MinEnc)	**66.2** (72.7)
Our system (MaxEnc)	65.8 (**73.2**)

Table 1: Performance on section 23 of the WSJ corpus (all sentences and up to length 10) for recent systems and our system. MinEnc and MaxEnc denote $\texttt{iters}_{\text{MST}} = 10$ and $\texttt{iters}_{\text{MST}} = 1$ respectively.

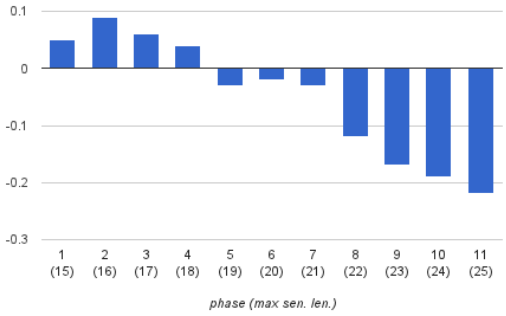

Figure 2: $DDA_{MaxEnc} - DDA_{MinEnc}$ of all phases on the their training sets (e.g., phase 3 with $\mathcal{S}^{(3)}$ containing all training sentences up to length 17).

pute $DDA_{MaxEnc} - DDA_{MinEnc}$ of each phase on its training set (e.g., phase 3 with $\mathcal{S}^{(3)}$ containing all training sentences up to length 17). MinEnc outperforms MaxEnc within phases 1, 2, 3, and 4. However, from phase 5, the latter surpasses the former. It suggests that exploring areas far away from the current point with long sentences is risky. The reason is that long sentences contain more ambiguities than short ones; thus rich diversity, high difference from the current point, but small size (i.e., small k) could easily lead the learning to a wrong path.

The performance of the system with the two encouragement levels on section 23 (Table 1) also suggests the same. MaxEnc strategy helps the system achieve the highest accuracy on short sentences (up to length 10). However, it is less helpful than MinEnc when performing on long sentences.

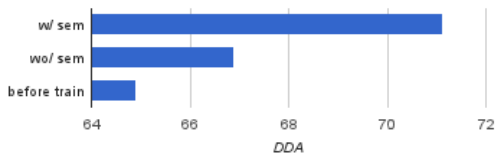

Figure 3: DDA of phase 1 (MaxEnc), with and without the word embeddings (denoted by w/ sem and wo/ sem, respectively), on training sentences up to length 15 (i.e. $\mathcal{S}^{(1)}$).

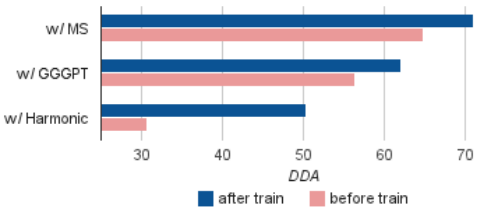

Figure 4: DDA of phase 1 (MaxEnc) before and after training with three different starting points provided by three parsers used in phase 0: MS (Marecek and Straka, 2013), GGGPT (Gillenwater et al., 2011), and Harmonic (Klein and Manning, 2004).

The role of lexical semantics

We examine the role of the lexical semantics, which is given by the word embeddings. Figure 3 shows DDAs on training sentences up to length 15 (i.e. $\mathcal{S}^{(1)}$) of phase 1 (MaxEnc) with and without the word-embeddings. With the word-embeddings, phase 1 achieves 71.11%. When the word-embeddings are not given, i.e. the IORNN uses randomly generated word vectors, the accuracy drops 4.2%. It shows that lexical semantics plays a decisive role in the performance of the system.

However, it is worth noting that, even without that knowledge (i.e., with the ∞-order generative model alone), the DDA of phase 1 is 2% higher than before being trained (66.89% vs 64.9%). It suggests that phase 1 is capable of discovering some useful dependency patterns that are invisible to the parser in phase 0. This, we conjecture, is thanks to high-order features captured by the IORNN.

The importance of the starting point

Starting point is claimed to be important in local search. We examine this by using three different parsers in phase 0: (i) MS (Marecek and Straka,

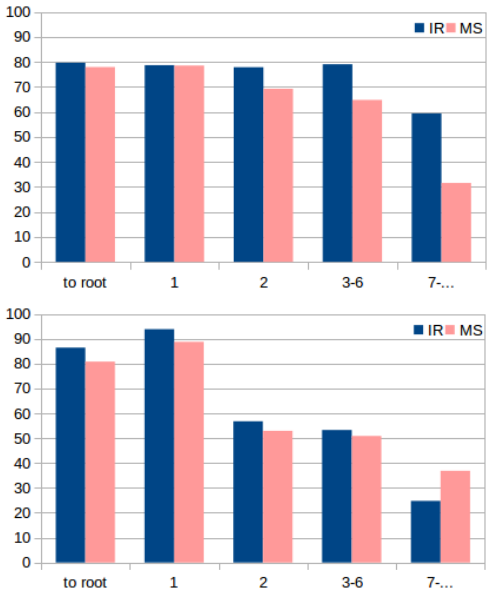

Figure 5: Precision (top) and recall (bottom) over binned HEAD distance of iterated reranking (IR) and its initializer (MS) on the training sentences in phase 1 ($\leq$ 15 words).

2013), the parser used in the previous experiments, (ii) GGGPT (Gillenwater et al., 2011)[7] employing an extension of the DMV model and posterior regularization framework for training, and (iii) Harmonic, the harmonic initializer proposed by Klein and Manning (2004).

Figure 4 shows DDAs of phase 1 (MaxEnc) on training sentences up to length 15 with three starting-points given by those parsers. Starting point is clearly very important to the performance of the iterated reranking: the better the starting point is, the higher performance phase 1 has. However, a remarkable point here is that the iterated reranking of phase 1 always finds out more useful patterns for parsing whatever the starting point is in this experiment. It is certainly due to the high order features and lexical semantics, which are not exploited in those parsers.

The contribution of Iterated Reranking

We compare the quality of the treebank resulted in the end of phase 1 against the quality of the treebank given by the initialier Marecek and Straka (2013). Figure 5 shows precision (top) and recall (bottom) over binned HEAD distance. IR helps to improve the precision on all distance bins, especially on the bins corresponding to long distances ($\geq$ 3). The recall is also improved, except on the bin corresponding to $\geq$ 7 (but the F1-score on this bin is increased). We attribute this improvement to the ∞-order model which uses very large fragments as contexts thus be able to capture long dependencies.

Figure 6 shows the correct-head accuracies over POS-tags. IR helps to improve the accuracies over almost all POS-tags, particularly nouns (e.g. NN, NNP, NNS), verbs (e.g. VBD, VBZ, VBN, VBG) and adjectives (e.g. JJ, JJR). However, as being affected by the initializer, IR performs poorly on conjunction (CC) and modal auxiliary (MD). For instance, in the treebank given by the initializer, almost all modal auxilaries are dependents of their verbs instead of the other way around.

7 Discussion

Our system is different from the other systems shown in Table 1 as it uses an extremely expressive model, the ∞-order generative model, in which conditioning contexts are very large fragments. Only the work of Blunsom and Cohn (2010), whose resulting grammar rules can contain large tree fragments, shares this property. The difference is that their work needs a pre-defined prior, namely hierarchical non-parametric Pitman-Yor process prior, to avoid large, rare fragments and for smoothing. The IORNN of our system, in contrast, does that automatically. It learns by itself how to deal with distant conditioning nodes, which are often less informative than close conditioning nodes on computing $P(x|\mathcal{C}^{\infty}(u))$. In addition, smoothing is given free: recursive neural nets are able to map 'similar' fragments onto close points (Socher et al., 2010) thus an unseen fragment tends to be mapped onto a point close to points corresponding to 'similar' seen fragments.

Another difference is that our system exploits lexical semantics via word embeddings, which were learnt unsupervisedly. By initialising the IORNN with these embeddings, the use of this knowledge turns out easy and transparent. Spitkovsky et al. (2013) also exploit lexical semantics but in a limited way, using a context-based polysemous unsuper-

[7] code.google.com/p/pr-toolkit

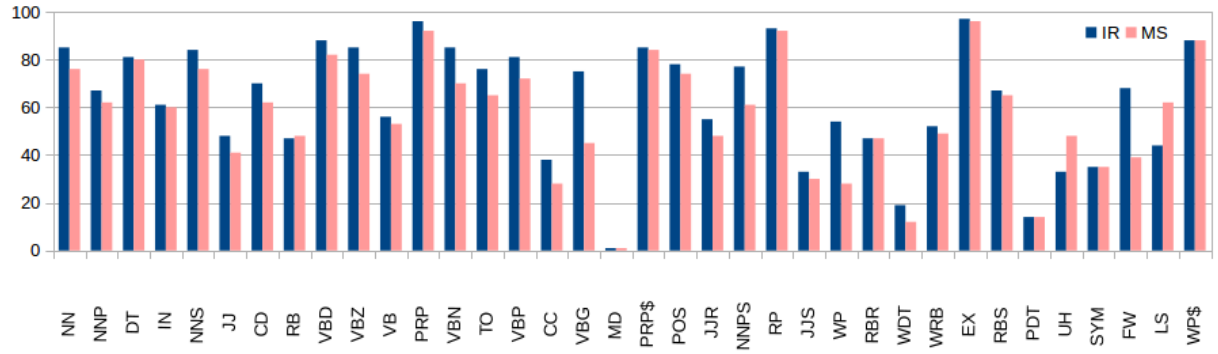

Figure 6: Correct-head accuracies over POS-tags (sorted in the descending order by frequency) of iterated reranking (IR) and its initializer (MS) on the training sentences in phase 1 ($\leq$ 15 words).

vised clustering method to tag words. Although their approach can distinguish polysemes (e.g., 'cool' in 'to cool the selling panic' and in 'it is cool'), it is not able to make use of word meaning similarities (e.g., the meaning of 'dog' is closer to 'animal' than to 'table'). Naseem and Barzilay (2011)'s system uses semantic cues from an out-of-domain annotated corpus, thus is not fully unsupervised.

We have showed that IR with a generative reranker is an approximation of hard-EM (see Equation 4). Our system is thus related to the works of Spitkovsky et al. (2013) and Tu and Honavar (2012). However, what we have proposed is more than that: IR is a general framework that we can have more than one option for choosing k-best parser and reranker. For instance, we can make use of a generative k-best parser and a discriminative reranker that are used for supervised parsing. Our future work is to explore this.

The experimental results reveal that starting point is very important to the iterated reranking with the ∞-order generative model. On the one hand, that is a disadvantage compared to the other systems, which use uninformed or harmonic initialisers. But on the other hand, that is an innovation as our approach is capable of making use of existing systems. The results shown in Figure 4 suggest that if phase 0 uses a better parser which uses less expressive model and/or less external knowledge than our model, such as the one proposed by Spitkovsky et al. (2013), we can expect even a higher performance. The other systems, except Blunsom and Cohn (2010), however, might not benefit from using good existing parsers as initializers because their models are not significantly more expressive than others [8].

8 Conclusion

We have proposed a new framework, iterated reranking (IR), which trains supervised parsers without the need of manually annotated data by using a unsupervised parser as an initialiser. Our system, employing Marecek and Straka (2013)'s unsupervised parser as the initialiser, the k-best MSTParser, and Le and Zuidema (2014)'s reranker, achieved 1.8% DDA higher than the SOTA parser of Spitkovsky et al. (2013) on the WSJ corpus. Moreover, we also showed that unsupervised parsing benefits from lexical semantics through using word-embeddings.

Our future work is to exploit other existing supervised parsers that fit our framework. Besides, taking into account the fast development of the word embedding research (Mikolov et al., 2013; Pennington et al., 2014), we will try different word embeddings.

Acknowledgments

We thank Remko Scha and three anonymous reviewers for helpful comments. Le thanks Miloš Stanojević for helpful discussion.

[8] In an experiment, we used the Marecek and Straka (2013)'s parser as an initializer for the Gillenwater et al. (2011)'s parser. As we expected, the latter was not able to make use of this.

A Linear-Time Transition System for Crossing Interval Trees

Emily Pitler **Ryan McDonald**
Google, Inc.
{epitler,ryanmcd}@google.com

Abstract

We define a restricted class of non-projective trees that 1) covers many natural language sentences; and 2) can be parsed exactly with a generalization of the popular arc-eager system for projective trees (Nivre, 2003). Crucially, this generalization only adds constant overhead in run-time and space keeping the parser's total run-time linear in the worst case. In empirical experiments, our proposed transition-based parser is more accurate on average than both the arc-eager system or the swap-based system, an unconstrained non-projective transition system with a worst-case quadratic runtime (Nivre, 2009).

1 Introduction

Linear-time transition-based parsers that use either greedy inference or beam search are widely used today due to their speed and accuracy (Nivre, 2008; Zhang and Clark, 2008; Zhang and Nivre, 2011). Of the many proposed transition systems (Nivre, 2008), the arc-eager transition system of Nivre (2003) is one of the most popular for a variety of reasons. The arc-eager system has a well-defined output space: it can produce *all* projective trees and *only* projective trees. For an input sentence with n words, the arc-eager system always performs $2n$ operations and each operation takes constant time. Another attractive property of the arc-eager system is the close connection between the parameterization of the parsing problem and the final predicted output structure. In the arc-eager model, each operation has a clear interpretation in terms of constraints on the final output tree (Goldberg and Nivre, 2012), which allows for more robust learning procedures (Goldberg and Nivre, 2012).

The arc-eager system, however, cannot produce trees with crossing arcs. Alternative systems can produce crossing dependencies, but at the cost of taking $O(n^2)$ transitions in the worst case (Nivre, 2008; Nivre, 2009; Choi and McCallum, 2013), requiring more transitions than arc-eager to produce projective trees (Nivre, 2008; Gómez-Rodríguez and Nivre, 2010), or producing trees in an unknown output class[1] (Attardi, 2006).

Graph-based non-projective parsing algorithms, on the other hand, have been able to preserve many of the attractive properties of their corresponding projective parsing algorithms by restricting search to classes of *mildly non-projective trees* (Kuhlmann and Nivre, 2006). Mildly non-projective classes of trees are *characterizable* subsets of directed trees. Classes of particular interest are those that both have high empirical coverage and that can be parsed efficiently. With appropriate definitions of feature functions and output spaces, exact higher-order graph-based non-projective parsers can match the asymptotic time and space of higher-order projective parsers (Pitler, 2014).

In this paper, we propose a class of mildly non-projective trees (§3) and a transition system (§4) that is sound and complete with respect to this class (§5) while preserving desirable properties of arc-eager: it runs in $O(n)$ time in the worst case (§6), and each operation can be interpreted as a prediction about

[1] A characterization independent of the transition system is unknown.

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 662–671,
Denver, Colorado, May 31 – June 5, 2015.

the final tree structure. At the same time, it can produce trees with crossing dependencies. Across ten languages, on average 96.7% of sentences have dependency trees in the proposed class (Table 1), compared with 79.4% for projective trees. The implemented mildly non-projective transition-based parser is more accurate than a fully projective parser (arc-eager, (Nivre, 2003)) and a fully non-projective parser (swap-based, (Nivre, 2009)) (§7.1).

2 Preliminaries

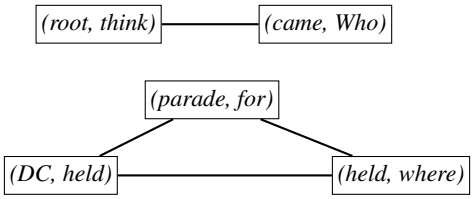
Given an input sentence $w_1 w_2 \dots w_n$, a dependency tree for that sentence is a set of vertices $V = \{0, 1, \dots, n\}$ and arcs $A \subset V \times V$. Each vertex i corresponds to a word in the sentence and vertex 0 corresponds to an artificial *root* word, which is standard in the literature. An arc $(i, j) \in A$ represents a dependency between a modifier w_j and a head w_i. Critically, the arc set A is constrained to form a valid *dependency tree*: its root is at the leftmost vertex 0; each vertex i has exactly one incoming arc (except 0, which has no incoming arcs); and there are no cycles. A common extension is to add labels of syntactic relations to each arc. For ease of exposition, we will focus on the unlabeled variant during the discussion but use a labeled variant during experiments.

A dependency tree is *projective* if and only if the nodes in the yield of each subtree form a contiguous interval with respect to the words and their order in the sentence. For instance, the tree in Figure 1a is *non-projective* since the subtrees rooted at *came* and *parade* do not cover a contiguous set of words. Equivalently, a dependency tree is non-projective if and only if the tree cannot be drawn in the plane above the sentence without crossing arcs. As we will see, these *crossing arcs* are a useful measure when defining sub-classes of non-projectivity. We will often reason about the set of vertices *incident* to a particular arc. The incident vertices of an arc are its endpoints: for an arc (u, v), u and v are the two vertices incident to it.

3 k-Crossing Interval Trees

We begin by defining a class of trees based on restrictions on crossing dependencies. The class definition is independent of any transition system; it is easy to check whether a particular tree is within the

(a) A dependency tree with two disjoint sets (blue and dashed/red and dotted) of crossing arcs (bold).



(b) The auxiliary graph for the sentence above. There are two connected components of crossed arcs, one of which corresponds to the crossing interval *[root, came]* and the other *[DC, for]*.

Figure 1: A sentence with two crossing intervals.

class or not. We compare the coverage of this class on various natural language datasets with the coverage of the class of projective trees.

Definition 1. *Let A be a set of unlabeled arcs. The* Interval *of A,* Interval(A)*, is the interval from the leftmost vertex in A to the rightmost vertex in A, i.e., Interval(A) $= [min(V_A), max(V_A)]$, where $V_A = \{v : \exists u[(u, v) \in A \vee (v, u) \in A]\}$.*

Definition 2. *For any dependency tree T, the below procedure partitions the crossed arcs in T into disjoint sets A_1, A_2, ..., A_l such that Interval(A_1), Interval(A_2), ..., Interval(A_l) are all vertex-disjoint. These intervals are the **crossing intervals** of the tree T.*

Procedure: Construct an auxiliary graph with a vertex for each crossed arc in the original tree. Two such vertices are connected by an arc if the intervals defined by the arcs they correspond to have a non-empty intersection. Figure 1b shows the auxiliary graph for the sentence in Figure 1a. The connected components of this graph form a partition of the graph's vertices, and so also partition the crossed arcs in the original sentence. The intervals defined by these groups cannot overlap, since then the crossed arcs that span the overlapping portion would have been connected by an arc in the auxiliary graph and hence been part of the same connected component. □

Definition 3. *A tree is a* k-Crossing Interval *tree if for each crossing interval, there exists at most k ver-*

Language	2-Crossing Interval	1-Endpoint-Crossing	Projective
Basque	93.5	94.7	74.8
Czech	97.4	98.9	77.9
Dutch	91.4	95.8	63.6
English	99.2	99.3	93.4
German	94.7	96.4	72.3
Greek	99.1	99.7	84.4
Hungarian	95.3	96.3	74.7
Portuguese	99.0	99.6	83.3
Slovene	98.2	99.5	79.6
Turkish	99.1	99.3	89.9
Average	96.7	98.0	79.4

Table 1: Proportion of trees (excluding punctuation) in each tree class for the CoNLL shared tasks training sets: Dutch, German, Portuguese, and Slovene are from Buchholz and Marsi (2006); Basque, Czech, English, Greek, Hungarian, and Turkish data are from Nivre et al. (2007).

tices such that a) all crossed arcs within the interval are incident to at least one of these vertices and b) any vertex in the interval that has a child on the far side of its parent is one of these k vertices.

Figure 1a shows a 2-Crossing Interval tree. For the first crossing interval, *think* and *came* satisfy the conditions; for the second, *parade* and *held* do. The coverage of 2-Crossing Interval trees is shown in Table 1. Across datasets from ten languages with a non-negligible proportion of crossing dependencies, on average 96.7% of dependency trees are 2-Crossing Interval, within 1.3% of the larger 1-Endpoint-Crossing class (Pitler et al., 2013) and substantially larger than the 79.4% coverage of projective trees. Coverage increases as k increases; for 3-Crossing Interval trees, the average coverage reaches 98.6%. Punctuation tokens are excluded when computing coverage to better reflect language specific properties rather than treebank artifacts; for example, the Turkish CoNLL data attaches punctuation tokens to the artificial root, causing a 15% absolute drop in coverage for projective trees when punctuation tokens are included (89.9% vs. 74.7%).

3.1 Connections to Other Tree Classes

$k = 0$ or $k = 1$ gives exactly the class of projective trees (even a single crossing implies two vertex-disjoint crossed edges). 2-Crossing Interval trees are a subset of the linguistically motivated 1-Endpoint-Crossing trees (Pitler et al., 2013) (each crossed edge is incident to one of the two vertices for the interval, so all edges that cross it are incident to the *other* vertex for the interval); all of the examples from the linguistics literature provided in Pitler (2013, p.132-136) for 1-Endpoint-Crossing trees are 2-Crossing Interval trees as well. 2-Crossing Interval trees are *not* necessarily *well-nested* and can have unbounded *block degree* (Kuhlmann, 2013). Figure 2 shows an example of a 2-Crossing Interval tree (all crossed edges are incident to either a or b; no children are on the far side of their parent) in which the subtrees rooted at a and b are ill-nested and each has a block degree of $n + 1$.

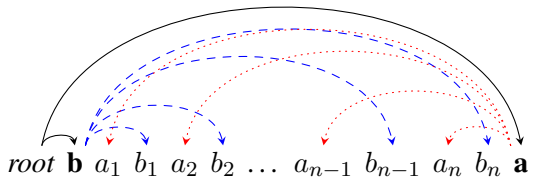


Figure 2: A 2-Crossing Interval tree that is not well-nested and has unbounded block degree.

4 Two-Registers Transition System

A transition system for dependency parsing comprises: 1) an initial configuration for an input sentence; 2) a set of final configurations after which the parsing derivation terminates; and 3) a set of deterministic *transitions* for transitioning from one configuration to another (Nivre, 2008).

Our transition system builds on one of the most commonly used transition systems for parsing projective trees, the arc-eager system (Nivre, 2003). An arc-eager configuration, c, is a tuple, (σ, β, A), where 1) σ is a *stack* consisting of a subset of processed tokens; 2) β is a *buffer* consisting of unprocessed tokens; and 3) A is the set of dependency arcs already added to the tree.

We define a new transition system called *two-registers*. Configurations are updated to include two *registers* $R1$ and $R2$, i.e., $c = (\sigma, \beta, R1, R2, A)$. A register contains one vertex or is empty: $R1, R2 \in V \cup \{null\}$. Table 2 defines both the arc-eager and two-registers transition systems. The two-registers system includes the arc-eager transitions (top half of Table 2) and three new transitions that make use of the registers (bottom half of Table 2):

- **Store**: Moves the token at the front of the buffer into the first available register, optionally

Arc-Eager
- Initial configuration: $(\{0\}, \{1, \ldots, n\}, \{\})$
- Terminal configurations $(\sigma, \{\}, A)$

Two-Registers
- Initial configuration: $(\{\}, \{0, \ldots, n\}, null, null, \{\})$
- Terminal configurations: $(\sigma, \{\}, null, null, A)$

	Transition	σ	β	$R1$	$R2$	A
Arc-Eager	Left-Arc	$\sigma_{m..2}$	$\beta_{1..n}$	$R1$	$R2$	$A \cup \{(\beta_1, \sigma_1)\}$
	Right-Arc	$\sigma_{m..1}\|\beta_1$	$\beta_{2..n}$	$R1$	$R2$	$A \cup \{(\sigma_1, \beta_1)\}$
	Shift	$\sigma_{m..1}\|\beta_1$	$\beta_{2..n}$	$R1$	$R2$	A
	Reduce	$\sigma_{m..2}$	$\beta_{1..n}$	$R1$	$R2$	A
+ Two-Registers	Store(arc)	$\sigma_{m..1}$	$\beta_{2..n}$	$R1'$	$R2'$	$A \cup B$
		Where:	arc $\in$ {left, right, no-arc}			
			$B := \{(\beta_1, R1)\}$ if arc=left, $\{(R1, \beta_1)\}$ if arc=right, and $\emptyset$ otherwise.			
			$R1' := (R1 = null)\ ?\ \beta_1\ :\ R1$; $R2' := (R1 = null)\ ?\ R2\ :\ \beta_1$.			
	Clear	$\sigma_{m..2}\|\psi$	$\gamma\|\beta_{1..n}$	*null*	*null*	A
		Where:	$\gamma := (\sigma_1 = \beta_1 - 1)\ ?\ \sigma_1\ :\ (R2 = \beta_1 - 1)\ ?\ R2\ :\ null$			
			$\psi := \{\sigma_1\} \cup NotCovered(R1) \cup NotCovered(R2) - \{\gamma\}$ in left-to-right order,			
			where *NotCovered*$(x) := x$ if no edges in A cover x and $\emptyset$ otherwise.			
	Register-Stack(k, dir)	$\sigma_{m..2}\|\psi$	$\beta_{1..n}$	$R1$	$R2$	$A \cup B$
		Where:	$k \in \{1, 2\}$ and $dir \in$ {to-register, to-stack}			
			$B := (dir =$ to-register$)\ ?\ \{(\sigma_1, Rk)\}\ :\ \{(Rk, \sigma_1)\}$			
			$\psi := (dir =$ to-stack $\wedge\ \sigma_1 < Rk)\ ?\ null\ :\ \sigma_1$			

Table 2: Transitions and the resulting state after each is applied to the configuration $(\sigma_{m..2}|\sigma_1, \beta_1|\beta_{2..n}, R1, R2, A)$.

Register-Stack(2, to-stack)	[that we Hans]	[]	helped	paint	$\cup$ {(*paint, house*)}
Register-Stack(1, to-stack)	[that we]	[]	helped	paint	$\cup$ {(*helped, Hans*)}
Register-Stack(1, to-stack)	[that]	[]	helped	paint	$\cup$ {(*helped, we*)}
Register-Stack(1, to-register)	[that]	[]	helped	paint	$\cup$ {(*that, helped*)}
Clear	[that]	[paint]	*null*	*null*	

Table 3: An excerpt from a gold standard derivation of the sentence in Figure 3. The two words *paint* and *house* are added to the registers and then crossed arcs are added between them and the top of the stack.

Transition	Precondition	Type
Left-Arc, Right-Arc	$R1 \notin (\sigma_1, \beta_1) \wedge R2 \notin (\sigma_1, \beta_1)$	(2)
Store($\cdot$)	$(R1 = null \vee R2 =$ *null*$) \wedge (\beta_1 > last)$	(1)
Clear	$(R1 \neq null) \wedge (R2 \neq null \vee \beta_1 = null) \wedge (\sigma_2 < R1) \wedge (\sigma_1 \notin (R1, R2))$	(1)
Register-Stack(k, $\cdot$)	$(\sigma_1 > last) \vee (k = 1 \wedge \neg IsCovered(R1))$	(1)
	$\sigma_2 < R_{right}$	(2)
Register-Stack(k, to-register)	$(R_{close}, \sigma_1) \notin A$	(3)
Register-Stack(k, to-stack)	$(\sigma_1, R_{far}) \notin A$	(3)

Table 4: Preconditions that ensure the 2-Crossing Interval property for trees output by the two-registers transition system, applied to a configuration $(\sigma_{m..1}, \beta_{1..n}, R1, R2, A)$. If $\sigma_1 < R1$, $R_{close} := R1$ and $R_{far} := R2$; otherwise, $R_{close} := R2$ and $R_{far} := R1$. $R_{right} := (R2 = null)\ ?\ R1\ :\ R2$. Preconditions of type (1) ensure each pair of registers defines a disjoint crossing interval; type (2) that only edges incident to registers are crossed; and type (3) that only registers can have children on the far side of their parent.

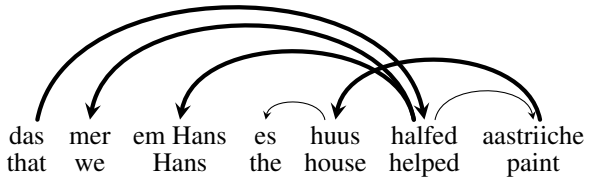

Figure 3: A clause with crossing edges (Shieber, 1985).

adding an arc between this token and the token in the first register.

- **Clear**: Removes tokens from the registers, reducing them completely if they are covered by an edge in A or otherwise placing them back on the stack in order. If either $R2$ or the top of the stack is the token immediately to the left of the front of the buffer, that token is placed back on the buffer instead.
- **Register-Stack**: Adds an arc between the top of the stack and one of the registers.

A derivation excerpt for the clause in Figure 3 is shown in Table 3. The two tokens incident to all crossed arcs *helped* and *paint* are stored in the registers. The crossed arcs are then added through Register-Stack transitions, working outward from the registers through the previous words in the sentence: *(paint, house)*, then *(helped, Hans)*, etc. After all the crossed arcs incident to these two tokens have been added, the registers are cleared.

Preconditions related to rootedness, single-headedness, and acyclicity follow the arc-eager system straightforwardly: each transition that adds an arc (h, m) checks that m is not the root, m does not already have a head, and that h is not a descendant of m. Preconditions used to guarantee that trees output by the system are within the desired class are listed in Table 4. In particular, they ensure that all crossed arcs are incident to registers, and that each pair of registers entails an interval corresponding to a self-contained set of crossed edges. To avoid traversing A while checking preconditions, two helper constants are used: *IsCovered(Rk)*[2] and *last*[3].

[2] $IsCovered(R1)$ is true if there exists an arc in A with endpoints on either side of $R1$. Rather than enumerating arcs, this boolean can be updated in constant time by setting it to true only after a Register-Stack(2, dir) transition with $\sigma_1 < R1$; likewise R2 can only be covered with a Register-Stack(1, dir) transition with $\sigma_1 > R2$.

[3] *last* is used to indicate the rightmost partially processed unreduced vertex after the last pair of registers were cleared (set to the rightmost in γ, ψ after each Clear transition).

Lemma 1. *In the two-registers system, all crossed arcs are added through register-stack operations.*

Proof. Suppose for the sake of contradiction that a right arc (s, b) added when $\sigma_1 = s$ and $\beta_1 = b$ is crossed in the final output tree (the argument for left-arcs is identical). Let (l, r) with $l < r$ be an arc that crosses (s, b). One of $\{l, r\}$ must be within the open interval (s, b) and one of $\{l, r\} \notin [s, b]$. When the arc (s, b) is added, no tokens in the open interval (s, b) remain. They cannot be in the stack or buffer since the stack and buffer always remain in order; they cannot be in registers by the precondition $R1 \notin (\sigma_1, \beta_1) \wedge R2 \notin (\sigma_1, \beta_1)$ for Right-Arc transitions. Thus, (l, r) must already have been added. It cannot be that $l \in (s, b)$ and $r > b$, since the rest of the buffer has never been accessible to tokens left of b. The ordering must then be $l < s < r < b$. Figure 4 shows that for each way (l, r) could have been added (Right-Arc, 4a; Store(right), 4b; Register-Stack(k, to-stack), 4c; Register-Stack(k, to-register), 4d), it is impossible to keep s unreduced without violating one of the preconditions.

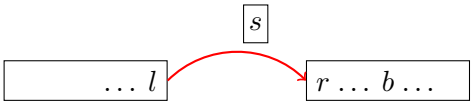
The only other type of arc-adding operation is Store. Similar logic holds: arcs added through Left-Arc and Right-Arc transitions cannot cross these arcs, since they would violate the preconditions $R1 \notin (\sigma_1, \beta_1) \wedge R2 \notin (\sigma_1, \beta_1)$; later arcs involving other registers would imply Clear operations that violate $\sigma_2 < R1 \wedge \sigma_1 \notin (R1, R2)$. □

5 Parsing 2-Crossing Interval Trees with the Two-Registers Transition System

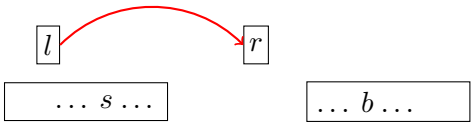
In this section we show the correspondence between the two-registers transition system and 2-Crossing Interval trees: each forest output by the transition system is a 2-Crossing Interval tree (*soundness*) and every 2-Crossing Interval tree can be produced by the two-registers system (*completeness*).

5.1 Soundness: Two-Registers System → 2-Crossing Interval trees

Proof. Every crossed arc is incident to a token that was in a register (Lemma 1). There cannot be any overlap between register arcs where the corresponding tokens were not in the registers simultaneously: the Clear transition updates the book-keeping constant $last$ to be the rightmost vertex associated with

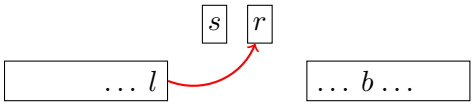


(a) Right-Arc: s would have been in a register, and the Right-Arc would have violated $R1 \notin (\sigma_1, \beta_1) \wedge R2 \notin (\sigma_1, \beta_1)$.



(b) Store(right): s would be on the stack when the registers were cleared, so Clear would have violated $\sigma_2 < R1 \wedge \sigma_1 \notin (R1, R2)$.

(c) Register-Stack(k, to-stack): If s was on the stack, then if $s > R2$, Register-Stack(k, t-stack) would have violated $\sigma_2 < R2$; if $s < R2$, then $s \in (R1, R2)$, and Clear would have violated $\sigma_2 < R1 \wedge \sigma_1 \notin (R1, R2)$. If s instead was in $R2$ (not shown), then it would get covered by (l, r) and reduced by Clear.



(d) Register-Stack(k, to-register): s must have been in $R2$. s would get covered by (l, r) and reduced by Clear.

Figure 4: If a stack-buffer arc (s, b) is added in the two-registers system, there cannot have been an earlier arc (l, r) with $l < s < r < b$, since it would then be impossible to keep s unreduced without violating the preconditions.

the registers being cleared, and subsequent actions cannot introduce crossed arcs to the $last$ token or to its left (by the $\beta_1 > last$ and $\sigma_1 > last$ preconditions on storing and register-stack arcs, respectively). Thus, each set of tokens that were in registers simultaneously defines a crossing interval. Condition (a) of Definition 3 is satisfied, since all crossed arcs are incident to registers and at most two vertices are in registers at the same time.

Assume that a vertex h, $h \notin \{R1, R2\}$, has a child m on the far side of its parent g (i.e., either $h < g < m$ or $m < g < h$). The edge (h, m) is guaranteed to be crossed and so was added through a register-stack arc (Lemma 1). The ordering $h < g < m$ is not possible, since if (g, h) had been added through a left-arc, then h would have been reduced, and if (g, h) and (h, m) were both added through register-stack arcs, then one of them would have violated the $(R_{close}, \sigma_1) \notin A$ or the $(\sigma_1, R_{far}) \notin A$ precondition. Similar reasoning can rule out $m < g < h$. Thus Condition (b) of Definition 3 is also satisfied. □

5.2 Completeness: 2-Crossing Interval trees → Two-Registers System

Proof. The portions of a 2-Crossing Interval tree in-between the crossing intervals can be constructed using the transitions from arc-eager. For a particular crossing interval $[l, r]$ and a particular choice of two vertices a and b incident to all all crossed arcs in the interval ($l \leq a < b \leq r$), a and b divide the interval into: $L = [l, a)$, a, $M = (a, b)$, b, $R = (b, r]$. All arcs incident to neither a nor b must lie entirely within L, M, or R.[4]

The parser begins by adding all arcs with both endpoints in L, using the standard arc-eager Shift/Reduce/Left-Arc/Right-Arc. It then shifts until a is at the front of the buffer and stores a. It then repeats the same process to add the arcs lying entirely in M until b reaches the front of the buffer, adding the parent of a with a Register-Stack(1, to-register) transition if the parent is in M and the arc is uncrossed. b is then stored, adding the arc between a and b if necessary. Throughout this process, the precondition $R1 \notin (\sigma_1, \beta_1) \wedge R2 \notin (\sigma_1, \beta_1)$ for left and right arcs is satisfied.

Next, the parser will repeatedly take Register-Stack transitions, interspersed with Reduce transitions, to add all the arcs with one endpoint in $\{a, b\}$ and the other in L or M, working right-to-left from b (i.e., from the top of the stack downwards). No shifts are done at this stage, so the $\sigma_2 < R2$ precondition on Register-Stack arcs is always satisfied. The $\sigma_1 > last$ precondition is also always satisfied since all vertices in the crossing interval will be to the right of the previous crossing interval boundary point. After all these arcs are done, if there are any uncrossed arcs incident to a to the left that go outside of the crossing interval, they are added now with a Register-Stack transition.[5]

[4] E.g., if there were an arc not incident to a or b with one endpoint left of a and one endpoint right of a, then this arc must be crossed or lie outside of the crossing interval.

[5] Only possible in the case $l = a$, in which case $\neg$IsCovered(a) and the transition is allowed.

Finally, the arcs with at least one endpoint in R are added, using Register-Stack arcs for those with the other endpoint in $\{a, b\}$ and Left-Arc/Right-Arc for those with both endpoints in R. Before any vertex incident to a or b is shifted onto the stack, all tokens on the stack to the right of b are reduced.

After all these arcs are added, the crossing interval is complete. The boundary points of the interval that can still participate in uncrossed arcs with the exterior are left on the stack and buffer after the clear operation, so the rest of the tree is still parsable. □

6 Worst-case Runtime

The two-registers system runs in $O(n)$ time: it completes after at most $O(n)$ transitions and each transition takes constant time.

The total number of arc-adding actions (Left-Arc, Right-Arc, Register-Stack, or a Store that includes an arc) is bounded by n, as there are at most n arcs in the final output. The net result of {Store, Store, Clear} triples of transitions decreases the number of tokens on the buffer by at least one, so these triples, plus the number of Shifts and Right-Arcs, are bounded by n. Finally, each token can be removed completely at most once, so the number of Left-Arcs and Reduces is bounded by n. Every transition fell into one of these categories, so the total number of transitions is bounded by $5n = O(n)$.

Each operation can be performed in constant time, as all operations involve moving vertices and/or adding arcs, and at most three vertices are ever moved (Clear) and at most one arc is ever added. Most preconditions can be trivially checked in constant time, such as checking whether a vertex already has a parent or not. The non-trivial precondition to check is acyclicity, and this can also be checked by adding some book-keeping variables that can be updated in constant time (full proof omitted due to space constraints). For example, in the derivation in Table 3, prior to the Register-Stack(2, to-stack) transition, $R1 \rightarrow^A R2$ (*helped* $\rightarrow^A$ *paint*). After the arc $(R2, \sigma_1)$ (*paint*, *house*) is added, $R2 \rightarrow^A \sigma_1$ and by transitivity, $R1 \rightarrow^A \sigma_1$. The top of the stack is then reduced, and since σ_2 does not have a parent to its right, it is not a descendant of σ_1, and so after *Hans* becomes the new σ_1, the system makes the update that $R1$, $R2 \twoheadrightarrow^A \sigma_1$.

7 Experiments

The experiments compare the two-registers transition system for mildly non-projective trees proposed here with two other transition systems: the arc-eager system for projective trees (Nivre, 2003) and the swap-based system for all non-projective trees (Nivre, 2009). We choose the swap-based system as our non-projective baseline as it currently represents the state-of-the-art in transition-based parsing (Bohnet et al., 2013), with higher empirical performance than the Attardi system or pseudo-projective parsing (Kuhlmann and Nivre, 2010).

The arc-eager system is a reimplementation of Zhang and Nivre (2011), using their rich feature set and beam search. The features for the two other transition systems are based on the same set, but with slight modifications to account for the different relevant domains of locality. In particular, for the swap transition system, we updated the features to account for the fact that this transition system is based on the arc-standard model and so the most relevant positions are the top two tokens on the stack. For the two-register system, we added features over properties of the tokens stored in each of the registers. All experiments use beam search with a beam of size 32 and are trained with ten iterations of averaged structured perceptron training. Training set trees that are outside of the reachable class (projective for arc-eager, 2-Crossing Intervals for two-registers) are transformed by lifting arcs (Nivre and Nilsson, 2005) until the tree is within the class. The test sets are left unchanged. We use the standard technique of parameterizing arc creating actions with dependency labels to produce labeled dependency trees.

Experiments use the ten datasets in Table 1 from the CoNLL 2006 and 2007 shared tasks (Buchholz and Marsi, 2006; Nivre et al., 2007). We report numbers using both gold and automatically predicted part-of-speech tags and morphological attribute-values as features. For the latter, the part of speech tagger is a first-order CRF model and the morphological tagger uses a greedy SVM per-attribute classifier. Evaluation uses CoNLL-X scoring conventions (Buchholz and Marsi, 2006) and we report both labeled and unlabeled attachment scores.

7.1 Results

Table 5 shows the results using gold tags as features, which is the most common set-up in the literature. The two-registers transition system has on average 0.8% absolute higher unlabeled attachment accuracy than arc-eager across the ten datasets investigated. Its UAS is higher than arc-eager for eight out of the ten languages and is up to 2.5% (Dutch) or 3.0% (Turkish) absolute higher, while never more than 0.4% worse (Portuguese). The two-registers transition system is also more accurate than the alternate non-projective swap system on seven out of the ten languages, with more than 1% absolute improvements in UAS for Basque, Dutch, and German. The two-registers transition-system is still on average more accurate than either the arc-eager or swap systems using predicted tags as features (Table 6).

Table 7: UAS from Table 5 for tokens in which the incoming arc in the gold tree is crossed or uncrossed (recall of both crossed and uncrossed arcs).

Finally, we analyzed the performance of each of these parsers on both crossed *and uncrossed* arcs. Even on languages with many non-projective sentences, the majority of arcs are not crossed. Table 7 partitions all scoring tokens into those whose incoming arc in the gold tree is crossed and those whose incoming arc is not crossed, and presents the UAS scores from Table 5 for each of these groups. On the crossed arcs, the swap system does the best, followed by the two-registers system, with the arc-eager system about 20% absolute less accurate. On the uncrossed arcs, the arc-eager and two-registers systems are tied, with the swap system less accurate.

8 Discussion and Related Work

There has been a significant amount of recent work on non-projective dependency parsing. In the transition-based parsing paradigm, the pseudo-projective parser of Nivre and Nilsson (2005) was an early attempt and modeled the problem by transforming non-projective trees into projective trees via transformations encoded in arc labels. While improving parsing accuracies for many languages, this method was both approximate and inefficient as the increase in the cardinality of the label set affected run time.

Attardi (2006) directly augmented the transition system to permit limited non-projectivity by allowing transitions between words not directly at the top of the stack or buffer. While this transition system had significant coverage, it is unclear how to precisely characterize the set of dependency trees that it

covers. Nivre (2009) introduced a transition system that covered all non-projective trees via a new *swap* transition that locally re-ordered words in the sentence. The downside of the swap transition is that it made worst-case run time quadratic. Also, as shown in Table 7, the attachment scores of *uncrossed* arcs decreases compared with arc-eager.

Two other transition systems that can be seen as generalizations of arc-eager are the 2-Planar transition system (Gómez-Rodríguez and Nivre, 2010; Gómez-Rodríguez and Nivre, 2013), which adds a second stack, and the transition system of Choi (Choi and McCallum, 2013), which adds a deque. The arc-eager, 2-registers, 2-planar, and the Choi transition systems can be seen as along a continuum for trading off various properties. In terms of coverage, projective trees (arc-eager) $\subset$ 2-Crossing Interval trees (this paper) $\subset$ 2-planar trees $\subset$ all directed trees (Choi). The Choi system uses a quadratic number of transitions in the worst case, while arc-eager, 2-registers, and 2-planar all use at most $O(n)$ transitions. Checking for cycles does not need to be done at all in the arc-eager system, can be with a few constant operations in the 2-registers system, and can be done in amortized constant time for the other systems (Gómez-Rodríguez and Nivre, 2013).

In the graph-based parsing literature, there has also been a plethora of work on non-projective parsing (McDonald et al., 2005; Martins et al., 2009; Koo et al., 2010). Recent work by Pitler and colleagues is the most relevant to the work described here (Pitler et al., 2012, 2013, 2014). Like this work, Pitler et al. define a restricted class of non-projective trees and then a graph-based parsing algorithm that parses exactly that set.

The register mechanism in two-registers transition parsing bears a resemblance to registers in Augmented Transition Networks (ATNs) (Woods, 1970). In ATNs, global registers are introduced to account for a wide range of natural language phenomena. This includes long-distance dependencies, which is a common source of non-projective trees. While transition-based parsing and ATNs use quite different control and data structures, this observation does raise an interesting question about the relationship between these two parsing paradigms.

There are many additional points of interest to explore based on this study. A first step would be to generalize the two-registers transition system to a k-registers system that can parse exactly k-Crossing Interval trees. This will necessarily lead to an asymptotic increase in run-time as k approaches n. With larger values of k, the system would need additional transitions to add arcs between the registers (extending the Store transition to consider all subsets of arcs with the existing registers would become exponential in k). If k were to increase all the way to n, such a system would probably look very similar to list-based systems that consider all pairs of arcs (Covington, 2001; Nivre, 2008).

Another direction would be to define dynamic oracles around the two-registers transition system (Goldberg and Nivre, 2012; Goldberg and Nivre, 2013). The additional transitions here have interpretations in terms of which trees are still reachable (Register-Stack($\cdot$) adds an arc; Store and Clear indicate that particular vertices should be incident to crossed arcs or are finished with crossed arcs, respectively). The two-registers system is not quite arc-decomposable (Goldberg and Nivre, 2013): if the wrong vertex is stored in a register then a later pair of crossed arcs might both be individually reachable but not jointly reachable. However, there may be a "crossing-sensitive" variant of arc-decomposability that takes into account the vertices crossed arcs are incident to that would apply here.

9 Conclusion

In this paper we presented k-Crossing Interval trees, a class of mildly non-projective trees with high empirical coverage. For the case of $k = 2$, we also presented a transition system that is sound and complete with respect to this class that is a generalization of the arc-eager transition system and maintains many of its desirable properties, most notably a linear worst-case run-time. Empirically, this transition system outperforms its projective counterpart as well as a quadratic swap-based transition system with larger coverage.

Unsupervised Multi-Domain Adaptation with Feature Embeddings

Abstract

Representation learning is the dominant technique for unsupervised domain adaptation, but existing approaches have two major weaknesses. First, they often require the specification of "pivot features" that generalize across domains, which are selected by task-specific heuristics. We show that a novel but simple *feature embedding* approach provides better performance, by exploiting the feature template structure common in NLP problems. Second, unsupervised domain adaptation is typically treated as a task of moving from a single source to a single target domain. In reality, test data may be diverse, relating to the training data in some ways but not others. We propose an alternative formulation, in which each instance has a vector of *domain attributes*, can be used to learn distill the domain-invariant properties of each feature.[1]

1 Introduction

Domain adaptation is crucial if natural language processing is to be successfully employed in high-impact application areas such as social media, patient medical records, and historical texts. Unsupervised domain adaptation is particularly appealing, since it requires no labeled data in the target domain. Some of the most successful approaches to unsupervised domain adaptation are based on representation learning: transforming sparse high-dimensional surface features into dense vector representations, which are often more robust to domain shift (Blitzer et al., 2006; Glorot et al., 2011). However, these methods are computationally expensive to train, and often require special task-specific heuristics to select good "pivot features."

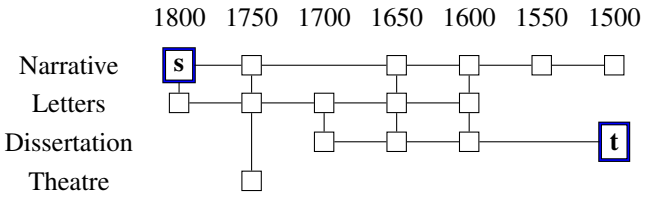

Figure 1: Domain graph for the Tycho Brahe corpus (Galves and Faria, 2010). **Suppose we want to adapt from 19th Century narratives to 16th Century dissertations: can unlabeled data from other domains help?**

A second, more subtle challenge for unsupervised domain adaptation is that it is normally framed as adapting from a single source domain to a single target domain. For example, we may be given part-of-speech labeled text from 19th Century narratives, and we hope to adapt the tagger to work on academic dissertations from the 16th Century. This ignores text from the intervening centuries, as well as text that is related by genre, such as 16th Century narratives and 19th Century dissertations (see Figure 1). We address a new challenge of *unsupervised multi-domain adaptation*, where the goal is to leverage this additional unlabeled data to improve performance in the target domain.[2]

[1] Source code and a demo are available at https://github.com/yiyang-gt/feat2vec

[2] Multiple domains have been considered in **supervised** domain adaptation (e.g., Mansour et al., 2009), but these approaches are not directly applicable when there is no labeled data outside the source domain.

(a) Learning a dense transformation $\mathbf{W}$ by reconstructing pivot features.

(b) Directly learning of feature embeddings by maximizing Skip-Gram objective.

Figure 2: Representation learning techniques in structured feature spaces

We present FEMA (**F**eature **EM**beddings for domain **A**daptation), a novel representation learning approach for domain adaptation in structured feature spaces. Like prior work in representation learning, FEMA learns dense features that are more robust to domain shift. However, rather than performing representation learning by reconstructing pivot features, FEMA uses techniques from neural language models to obtain low-dimensional embeddings directly. FEMA outperforms prior work on adapting POS tagging from the Penn Treebank to web text, and it easily generalizes to unsupervised multi-domain adaptation, further improving performance by learning generalizable models across multiple domains.

2 Learning feature embeddings

Feature co-occurrence statistics are the primary source of information driving many unsupervised methods for domain adaptation; they enable the induction of representations that are more similar across the source and target domain, reducing the error introduced by domain shift (Ben-David et al., 2010). For example, both Structural Correspondence Learning (SCL; Blitzer et al., 2006) and Denoising Autoencoders (Chen et al., 2012) learn to reconstruct a subset of "pivot features", as shown in Figure 2(a). The reconstruction function — which is learned from unlabeled data in both domains — is then employed to project each instance into a dense representation, which will hopefully be better suited to cross-domain generalization. The pivot features are chosen to be both predictive of the label and general across domains. Meeting these two criteria requires task-specific heuristics; for example, different pivot selection techniques are employed in SCL for syntactic tagging (Blitzer et al., 2006) and sentiment analysis (Blitzer et al., 2007). Furthermore, the pivot features correspond to a small subspace of the feature co-occurrence matrix. In Denoising Autoencoders, each pivot feature corresponds to a dense feature in the transformed representation, but large dense feature vectors impose substantial computational costs at learning time. In SCL, each pivot feature introduces a new classification problem, which makes computation of the cross-domain representation expensive. In either case, we face a tradeoff between the amount of feature co-occurrence information that we can use, and the computational complexity for representation learning and downstream training.

This tradeoff can be avoided by inducing low dimensional feature embeddings directly. We exploit the tendency of many NLP tasks to divide features into *templates*, with exactly one active feature per template (Smith, 2011); this is shown in the center of Figure 2. Rather than treating each instance as an undifferentiated bag-of-features, we use this template structure to induce *feature embeddings*, which are dense representations of individual features. Each embedding is selected to help predict the features that fill out the other templates: for example, an embedding for the current word feature is selected to help predict the previous word feature and successor word feature, and vice versa; see Figure 2(b). The embeddings for each active feature are then concatenated together across templates, giving a dense representation for the entire instance.

Our approach is motivated by word embeddings,

in which dense representations are learned for individual words based on their neighbors (Turian et al., 2010; Xiao and Guo, 2013), but rather than learning a single embedding for each word, we learn embeddings for each *feature*. This means that the embedding of, say, 'toughness' will differ depending on whether it appears in the current-word template or the previous-word template (see Table 6). This provides additional flexibility for the downstream learning algorithm, and the increase in the dimensionality of the overall dense representation can be offset by learning shorter embeddings for each feature. In Section 4, we show that feature embeddings convincingly outperform word embeddings on two part-of-speech tagging tasks.

Our feature embeddings are based on the skip-gram model, trained with negative sampling (Mikolov et al., 2013a), which is a simple yet efficient method for learning word embeddings. Rather than predicting adjacent words, the training objective in our case is to find feature embeddings that are useful for predicting other active features in the instance. For the instance $n \in \{1 \dots N\}$ and feature template $t \in \{1 \dots T\}$, we denote $f_n(t)$ as the index of the active feature; for example, in the instance shown in Figure 2, $f_n(t) =$ 'new' when t indicates the previous-word template. The skip-gram approach induces distinct "input" and "output" embeddings for each feature, written $\mathbf{u}_{f_n(t)}$ and $\mathbf{v}_{f_n(t)}$, respectively. The role of these embeddings can be seen in the negative sampling objective,

$$\ell_n = \frac{1}{T} \sum_{t=1}^{T} \sum_{t' \neq t}^{T} \Big[\log \sigma(\mathbf{u}_{f_n(t)}^\top \mathbf{v}_{f_n(t')}) + k \mathbb{E}_{i \sim P_{t'}^{(n)}} \log \sigma(-\mathbf{u}_{f_n(t)}^\top \mathbf{v}_i) \Big], \quad (1)$$

where t and t' are feature templates, k is the number of negative samples, $P_{t'}^{(n)}$ is a *noise distribution* for template t', and σ is the sigmoid function. This objective is derived from noise-contrastive estimation (Gutmann and Hyvärinen, 2012), and is chosen to maximize the unnormalized log-likelihood of the observed feature co-occurrence pairs, while minimizing the unnormalized log-likelihood of "negative" samples, drawn from the noise distribution.

Feature embeddings can be applied to domain adaptation by learning embeddings of all features on the union of the source and target data sets; we consider the extension to multiple domains in the next section. The dense feature vector for each instance is obtained by concatenating the feature embeddings for each template. Finally, since it has been shown that nonlinearity is important for generating robust representations (Bengio et al., 2013), we follow Chen et al. (2012) and apply the hyperbolic tangent function to the embeddings. The augmented representation $\mathbf{x}_n^{(\text{aug})}$ of instance n is the concatenation of the original feature vector and the feature embeddings,

$$\mathbf{x}_n^{(\text{aug})} = \mathbf{x}_n \oplus \tanh[\mathbf{u}_{f_n(1)} \oplus \cdots \oplus \mathbf{u}_{f_n(T)}],$$

where $\oplus$ is vector concatenation.

3 Feature embeddings across domains

We now describe how to extend the feature embedding idea beyond a single source and target domain, to unsupervised multi-attribute domain adaptation (Joshi et al., 2013). In this setting, each instance is associated with M metadata domain attributes, which could encode temporal epoch, genre, or other aspects of the domain. The challenge of domain adaptation is that the meaning of features can shift across each metadata dimension: for example, the meaning of 'plant' may depend on genre (agriculture versus industry), while the meaning of 'like' may depend on epoch. To account for this, the feature embeddings should smoothly shift over domain graphs, such as the one shown in Figure 1; this would allow us to isolate the domain general aspects of each feature. Related settings have been considered only for supervised domain adaptation, where some labeled data is available in each domain (Joshi et al., 2013), but not in the unsupervised case.

More formally, we assume each instance n is augmented with a vector of M binary domain attributes, $\boldsymbol{z}_n \in \{0, 1\}^M$. These attributes may overlap, so that we could have an attribute for the epoch 1800-1849, and another for the epoch 1800-1899. We define $z_{n,0} = 1$ as a shared attribute, which is active for all instances. We capture domain shift by estimating embeddings $\mathbf{h}_i^{(m)}$ for each feature i crossed with each domain attribute m. We then compute the embedding for each instance by summing across the relevant domain attributes, as shown

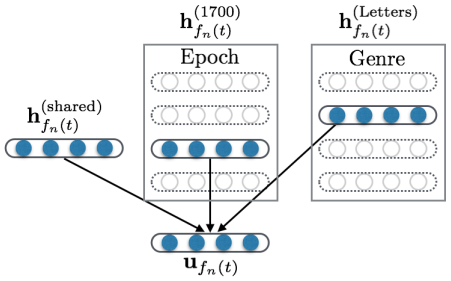

Figure 3: Aggregating multiple embeddings.

in Figure 3. The local "input" feature embedding $\mathbf{u}_{f_n(t)}$ is then defined as the summation, $\mathbf{u}_{f_n(t)} = \sum_{m=0}^{M} z_{n,m}\mathbf{h}^{(m)}_{f_n(t)}$.

The role of the global embedding $\mathbf{h}^{(0)}_i$ is to capture domain-neutral information about the feature i, while the other embeddings capture attribute-specific information. The global feature embeddings should therefore be more robust to domain shift, which is "explained away" by the attribute-specific embeddings. We therefore use only these embeddings when constructing the augmented representation, $\boldsymbol{x}^{(\text{aug})}_n$. To ensure that the global embeddings capture all of the domain-general information about each feature, we place an L2 regularizer on the attribute-specific embeddings. Note that we do not learn attribute-specific "output" embeddings $\mathbf{v}$; these are shared across all instances, regardless of domain.

The attribute-based embeddings yield a new training objective for instance n,

$$\ell_n = \frac{1}{T}\sum_{t=1}^{T}\sum_{t'\neq t}^{T}\Bigg[\log\sigma([\sum_{m=0}^{M} z_{n,m}\mathbf{h}^{(m)}_{f_n(t)}]^\top \mathbf{v}_{f_n(t')}) + k\mathbb{E}_{i\sim P^{(n)}_{t'}}\log\sigma(-[\sum_{m=0}^{M} z_{n,m}\mathbf{h}^{(m)}_{f_n(t)}]^\top \mathbf{v}_i)\Bigg]. \quad (2)$$

For brevity, we omit the regularizer from Equation 2. For feature $f_n(t)$, the (unregularized) gradients of $\mathbf{h}^{(m)}_{f_n(t)}$ and $\mathbf{v}_{f_n(t')}$ *w.r.t* $\ell_{n,t}$ are

$$\frac{\partial \ell_{n,t}}{\mathbf{h}^{(m)}_{f_n(t)}} = \frac{1}{T}\sum_{t'\neq t}^{T} z_{n,m}\Big[(1-\sigma(\mathbf{u}^\top_{f_n(t)}\mathbf{v}_{f_n(t')}))\mathbf{v}_{f_n(t')} - k\mathbb{E}_{i\sim P^{(n)}_{t'}}\sigma(\mathbf{u}^\top_{f_n(t)}\mathbf{v}_i)\mathbf{v}_i\Big] \quad (3)$$

$$\frac{\partial \ell_{n,t}}{\mathbf{v}_{f_n(t')}} = \frac{1}{T}\sum_{t'\neq t}^{T}(1-\sigma(\mathbf{u}^\top_{f_n(t)}\mathbf{v}_{f_n(t')}))\mathbf{u}_{f_n(t)}. \quad (4)$$

For each feature i drawn from the noise distribution $P^{(n)}_{t'}$, the gradient of $\mathbf{v}_i$ *w.r.t* $\ell_{n,t}$ is

$$\frac{\partial \ell_{n,t}}{\mathbf{v}_i} = -\frac{1}{T}\sigma(\mathbf{u}^\top_{f_n(t)}\mathbf{v}_i)\mathbf{u}_{f_n(t)}. \quad (5)$$

4 Experiments

We evaluate FEMA on part-of-speech (POS) tagging, in two settings: (1) adaptation of English POS tagging from news text to web text, as in the SANCL shared task (Petrov and McDonald, 2012); (2) adaptation of Portuguese POS tagging across a graph of related domains over several centuries and genres, from the Tycho Brahe corpus (Galves and Faria, 2010). These evaluations are complementary: English POS tagging gives us the opportunity to evaluate feature embeddings in a well-studied and high-impact application; Portuguese POS tagging enables evaluation of multi-attribute domain adaptation, and demonstrates the capability of our approach in a morphologically-rich language, with a correspondingly large number of part-of-speech tags (383). As more historical labeled data becomes available for English and other languages, we will be able to evaluate feature embeddings and related techniques there.

4.1 Implementation details

While POS tagging is classically treated as a structured prediction problem, we follow Schnabel and Schütze (2014) by taking a classification-based approach. Feature embeddings can easily be used in feature-rich sequence labeling algorithms such as conditional random fields or structured perceptron, but our pilot experiments suggest that with sufficiently rich features, classification-based methods can be extremely competitive on these datasets, at a fraction of the computational cost. Specifically, we apply a support vector machine (SVM) classifier,

Component	Feature template
Lexical (5)	$w_{i-2} = X, w_{i-1} = Y, \ldots$
Affixes (8)	X is prefix of w_i, $\lvert X\rvert \leq 4$ X is suffix of w_i, $\lvert X\rvert \leq 4$
Orthography (3)	w_i contains number, uppercase character, or hyphen

Table 1: Basic feature templates for token w_i.

adding dense features from FEMA (and the alternative representation learning techniques) to a set of basic features.

4.1.1 Basic features

We apply sixteen feature templates, motivated by by Ratnaparkhi (1996). Table 1 provides a summary of the templates; there are four templates each for the prefix and suffix features. Feature embeddings are learned for all lexical and affix features, yielding a total of thirteen embeddings per instance. We do not learn embeddings for the binary orthographic features. Santos and Zadrozny (2014) demonstrate the utility of embeddings for affix features.

4.1.2 Competitive systems

We consider three competitive unsupervised domain adaptation methods. Structural Correspondence Learning (Blitzer et al., 2006, SCL) creates a binary classification problem for each pivot feature, and uses the weights of the resulting classifiers to project the instances into a dense representation. Marginalized Denoising Autoencoders (Chen et al., 2012, mDA) learn robust representation across domains by reconstructing pivot features from artificially corrupted input instances. We use structured dropout noise, which has achieved state-of-art results on domain adaptation for part-of-speech tagging (Yang and Eisenstein, 2014). We also directly compare with WORD2VEC[3] word embeddings, and with a "no-adaptation" baseline in which only surface features are used.

4.1.3 Parameter tuning

All the hyperparameters are tuned on development data. Following Blitzer et al. (2006), we consider pivot features that appear more than 50 times in all the domains for SCL and mDA. In SCL, the parameter K selects the number of singular vectors of the projection matrix to consider; we try values between 10 and 100, and also employ feature normalization and rescaling. For embedding-based methods, we choose embedding sizes and numbers of negative samples from $\{25, 50, 100, 150, 200\}$ and $\{5, 10, 15, 20\}$ respectively. The noise distribution $P_t^{(n)}$ is simply the unigram probability of each feature in the template t. Mikolov et al. (2013b) argue for exponentiating the unigram distribution, but we find it makes little difference here. The window size of word embeddings is set as 5. As noted above, the attribute-specific embeddings are regularized, to encourage use of the shared embedding $\mathbf{h}^{(0)}$. The regularization penalty is selected by grid search over $\{0.001, 0.01, 0.1, 1.0, 10.0\}$. In general, we find that the hyperparameters that yield good word embeddings tend to yield good feature embeddings too.

4.2 Evaluation 1: Web text

Recent work in domain adaptation for natural language processing has focused on the data from the shared task on Syntactic Analysis of Non-Canonical Language (SANCL; Petrov and McDonald, 2012), which contains several web-related corpora (newsgroups, reviews, weblogs, answers, emails) as well as the WSJ portion of OntoNotes corpus (Hovy et al., 2006). Following Schnabel and Schütze (2014), we use sections 02-21 of WSJ for training and section 22 for development, and use 100,000 unlabeled WSJ sentences from 1988 for learning representations. On the web text side, each of the five target domains has an unlabeled training set of 100,000 sentences (except the ANSWERS domain, which has 27,274 unlabeled sentences), along with development and test sets of about 1000 labeled sentences each. In the spirit of truly unsupervised domain adaptation, we do not use any target domain data for parameter tuning.

Settings For FEMA, we consider only the single-embedding setting, learning a single feature embedding jointly across all domains. We select 6918 pivot features for SCL, according to the method described above; the final dense representation is produced by performing a truncated singular value decomposition on the projection matrix that arises from the

weights of the pivot feature predictors. The mDA method does not include any such matrix factorization step, and therefore generates a number of dense features equal to the number of pivot features. Memory constraints force us to choose fewer pivots, which we achieve by raising the threshold to 200, yielding 2754 pivot features.

Additional systems Aside from SCL and mDA, we compare against published results of FLORS (Schnabel and Schütze, 2014), which uses distributional features for domain adaptation. We also republish the baseline results of Schnabel and Schütze (2014) using the Stanford POS Tagger, a maximum entropy Markov model (MEMM) tagger.

Results As shown in Table 2 and 3, FEMA outperforms competitive systems on all target domains except REVIEW, where FLORS performs slightly better. FLORS uses more basic features than FEMA; these features could in principle be combined with feature embeddings for better performance. Compared with the other representation learning approaches, FEMA is roughly 1% better on average, corresponding to an error reduction of 10%. Its training time is approximately 70 minutes on a 24-core machine, using an implementation based on gensim.[4] This is slightly faster than SCL, although slower than mDA with structured dropout noise.

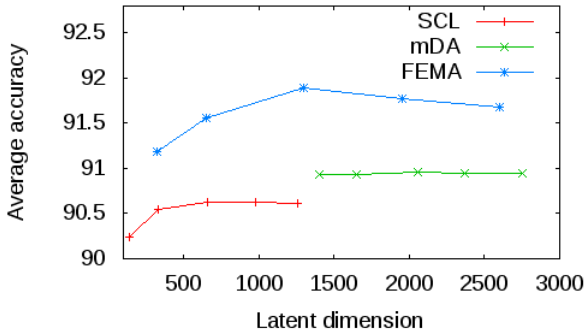

Figure 4: Accuracy results with different latent dimensions on SANCL dev sets.

Figure 4 shows the average accuracy on the SANCL development set, versus the latent dimensions of different methods. The latent dimension of SCL is modulated by the number of singular vectors; we consider sizes 10, 25, 50, 75, and 100. In mDA, we consider pivot feature frequency thresholds 500, 400, 300, 250, and 200. For FEMA, we consider embedding sizes 25, 50, 100, 150, and 200. The resulting latent dimensionality multiplies these sizes by the number of non-binary templates

Table 4: Accuracy results for adaptation in the Tycho Brahe corpus of historical Portuguese.

13. FEMA dominates the other approaches across the complete range of latent dimensionalities. The best parameters for SCL are dimensionality $K = 50$ and rescale factor $\alpha = 5$. For both FEMA and WORD2VEC, the best embedding size is 100 and the best number of negative samples is 5.

4.3 Evaluation 2: Historical Portuguese

Next, we consider the problem of *multi-attribute domain adaptation*, using the Tycho Brahe corpus of historical Portuguese text (Galves and Faria, 2010), which contains syntactic annotations of Portuguese texts in four genres over several centuries (Figure 1). We focus on temporal adaptation: training on the most modern data in the corpus, and testing on increasingly distant historical text.

Settings For FEMA, we consider domain attributes for 50-year temporal epochs and genres; we also create an additional attribute merging all instances that are in neither the source nor target domain. In SCL and mDA, 1823 pivot features pass the threshold. Optimizing on a source-domain development set, we find that the best parameters for SCL are dimensionality $K = 25$ and rescale factor $\alpha = 5$. The best embedding size and negative sample number are 50 and 15 for both FEMA and WORD2VEC.

Results As shown in Table 4, FEMA outperforms competitive systems on all tasks. The column "single embedding" reports results with a single feature embedding per feature, ignoring domain attributes; the column "attribute embeddings" shows that learning feature embeddings for domain attributes further improves performance, by 0.3-0.4% on average.

5 Similarity in the embedding space

The utility of word and feature embeddings for POS tagging task can be evaluated through word similarity in the embedding space, and its relationship to type-level part-of-speech labels. To measure the label consistency between each word and its top Q closest words in the vocabulary we compute,

$$\text{Consistency} = \frac{\sum_{i=1}^{|V|} \sum_{j=1}^{Q} \beta(w_i, c_{ij})}{|V| \times Q} \quad (6)$$

where $|V|$ is the number of words in the vocabulary, w_i is the i-th word in the vocabulary, c_{ij} is the j-th closest word to w_i in the embedding space (using cosine similarity), $\beta(w_i, c_{ij})$ is an indicator function that is equal to 1 if w_i and c_{ij} have the same most common part-of-speech in labeled data.

We compare feature embeddings of different templates against WORD2VEC embeddings. All embeddings are trained on the SANCL data, which is

Embedding	$Q = 5$	$Q = 10$	$Q = 50$	$Q = 100$
WORD2VEC	47.64	46.17	41.96	40.09
FEMA-current	68.54	66.93	62.36	59.94
FEMA-prev	55.34	54.18	50.41	48.39
FEMA-next	57.13	55.78	52.04	49.97
FEMA-all	70.63	69.60	65.95	63.91

Table 5: Label consistency of the Q-most similar words in each embedding. FEMA-all is the concatenation of the current, previous, and next-word FEMA embeddings.

also used to obtain the most common tag for each word. Table 5 shows that the FEMA embeddings are more consistent with the type-level POS tags than WORD2VEC embeddings. This is not surprising, since they are based on feature templates that are specifically designed for capturing syntactic regularities. In simultaneously published work, Ling et al. (2015) present "position-specific" word embeddings, which are an alternative method to induce more syntactically-oriented word embeddings.

Table 6 shows the most similar words for three query keywords, in each of four different embeddings. The next-word and previous-word embeddings are most related to syntax, because they help to predict each other and the current-word feature; the current-word embedding brings in aspects of orthography, because it must help to predict the affix features. In morphologically rich languages such as Portuguese, this can help to compute good embeddings for rare inflected words. This advantage holds even in English: the word 'toughness' appears only once in the SANCL data, but the FEMA-current embedding is able to capture its morphological similarity to words such as 'tightness' and 'thickness'. In WORD2VEC, the lists of most similar words tend to combine syntax and topic information, and fail to capture syntactic regularities such as the relationship between 'and' and 'or'.

'new'	
FEMA-current	nephew, news, newlywed, newer, newspaper
FEMA-prev	current, local, existing, international, entire
FEMA-next	real, big, basic, local, personal

6 Related Work

Representation learning Representational differences between source and target domains can be a major source of errors in the target domain (Ben-David et al., 2010). To solve this problem, cross-domain representations were first induced via auxiliary prediction problems (Ando and Zhang, 2005), such as the prediction of *pivot features* (Blitzer et al., 2006). In these approaches, as well as in later work on denoising autoencoders (Chen et al., 2012), the key mechanism is to learn a function to predict a subset of features for each instance, based on other features of the instance. Since no labeled data is required to learn the representation, target-domain instances can be incorporated, revealing connections between features that appear only in the target domain and features that appear in the source domain training data. The design of auxiliary prediction problems and the selection of pivot features both involve heuristic decisions, which may vary depending on the task. FEMA avoids the selection of pivot features by directly learning a low-dimensional representation, through which features in each template predict the other templates.

An alternative is to link unsupervised learning in the source and target domains with the label distribution in the source domain, through the framework of posterior regularization (Ganchev et al., 2010). This idea is applied to domain adaptation by Huang and Yates (2012), and to cross-lingual

learning by Ganchev and Das (2013). This approach requires a forward-backward computation for representation learning, while FEMA representations can be learned without dynamic programming, through negative sampling.

Word embeddings Word embeddings can be viewed as special case of representation learning, where the goal is to learn representations for each word, and then to supply these representations in place of lexical features. Early work focused on discrete clusters (Brown et al., 1990), while more recent approaches induce dense vector representations; Turian et al. (2010) compare Brown clusters with neural word embeddings from Collobert and Weston (2008) and Mnih and Hinton (2009). Word embeddings can also be computed via neural language models (Mikolov et al., 2013b), or from canonical correlation analysis (Dhillon et al., 2011). Xiao and Guo (2013) induce word embeddings across multiple domains, and concatenate these representations into a single feature vector for labeled instances in each domain, following EasyAdapt (Daumé III, 2007). However, they do not apply this idea to unsupervised domain adaptation, and do not work in the structured feature setting that we consider here. Bamman et al. (2014) learn geographically-specific word embeddings, in an approach that is similar to our multi-domain feature embeddings, but they do not consider the application to domain adaptation. We can also view the distributed representations in FLORS as a sort of word embedding, computed directly from rescaled bigram counts (Schnabel and Schütze, 2014).

Feature embeddings are based on a different philosophy than word embeddings. While many NLP features are lexical in nature, the role of a word towards linguistic structure prediction may differ across feature templates. Applying a single word representation across all templates is therefore suboptimal. Another difference is that feature embeddings can apply to units other than words, such as character strings and shape features. The tradeoff is that feature embeddings must be recomputed for each set of feature templates, unlike word embeddings, which can simply be downloaded and plugged into any NLP problem. However, computing feature embeddings is easy in practice, since it requires only a light modification to existing well-optimized implementations for computing word embeddings.

Multi-domain adaptation The question of adaptation across multiple domains has mainly been addressed in the context of supervised multi-domain learning, with labeled data available in all domains (Daumé III, 2007). Finkel and Manning (2009) propagate classification parameters across a tree of domains, so that classifiers for sibling domains are more similar; Daumé III (2009) shows how to induce such trees using a nonparametric Bayesian model. Dredze et al. (2010) combine classifier weights using confidence-weighted learning, which represents the covariance of the weight vectors. Joshi et al. (2013) formulate the problem of multi-attribute multi-domain learning, where all attributes are potential distinctions between domains; Wang et al. (2013) present an approach for automatically partitioning instances into domains according to such metadata features. Our formulation is related to multi-domain learning, particularly in the multi-attribute setting. However, rather than partitioning all instances into domains, the domain attribute formulation allows information to be shared across instances which share metadata attributes. We are unaware of prior research on unsupervised multi-domain adaptation.

7 Conclusion

Feature embeddings can be used for domain adaptation in any problem involving feature templates. They offer strong performance, avoid practical drawbacks of alternative representation learning approaches, and are easy to learn using existing word embedding methods. By combining feature embeddings with metadata domain attributes, we can perform domain adaptation across a network of interrelated domains, distilling the domain-invariant essence of each feature to obtain more robust representations.

Abstract

Words are polysemous. However, most approaches to representation learning for lexical semantics assign a single vector to every surface word type. Meanwhile, lexical ontologies such as WordNet provide a source of complementary knowledge to distributional information, including a word sense inventory. In this paper we propose two novel and general approaches for generating sense-specific word embeddings that are grounded in an ontology. The first applies graph smoothing as a post-processing step to tease the vectors of different senses apart, and is applicable to any vector space model. The second adapts predictive maximum likelihood models that learn word embeddings with latent variables representing senses grounded in an specified ontology. Empirical results on lexical semantic tasks show that our approaches effectively captures information from both the ontology and distributional statistics. Moreover, in most cases our sense-specific models outperform other models we compare against.

1 Introduction

Vector space models (VSMs) of word meaning play a central role in computational semantics. These represent meanings of words as contextual feature vectors in a high-dimensional space (Deerwester et al., 1990) or some embedding thereof (Collobert and Weston, 2008) and are learned from unannotated corpora. Word vectors in these continuous space representations can be used for meaningful semantic operations such as computing word similarity (Turney, 2006), performing analogical reasoning (Turney, 2013) and discovering lexical relationships (Mikolov et al., 2013b). They have also proved useful in downstream NLP applications such as information retrieval (Manning et al., 2008) and question answering (Tellex et al., 2003), among others.

However, VSMs remain flawed because they assign a single vector to every word, thus ignoring the possibility that words may have more than one meaning. For example, the word "bank" can either denote a financial institution or the shore of a river. The ability to model multiple meanings is an important component of any NLP system, given how common polysemy is in language. The lack of sense annotated corpora large enough to robustly train VSMs, and the absence of fast, high quality word sense disambiguation (WSD) systems makes handling polysemy difficult.

Meanwhile, lexical ontologies, such as WordNet (Miller, 1995) specifically catalog sense inventories and provide typologies that link these senses to one another. These hand-curated ontologies provide a complementary source of information to distributional statistics. Recent research tries to leverage this information to train better VSMs (Yu and Dredze, 2014; Faruqui et al., 2014), but does not tackle the problem of polysemy. Parallely, work on polysemy for VSMs revolves primarily around techniques that cluster contexts to distinguish between different word senses (Reisinger and Mooney, 2010; Huang et al., 2012), but does not integrate ontologies in any way.

In this paper we present two novel approaches to integrating ontological and distributional sources of information. Our focus is on allowing already existing, proven techniques to be adapted to produce ontologically grounded word sense embeddings. Our first technique is applicable to any sense-agnostic

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 683–693,
Denver, Colorado, May 31 – June 5, 2015.

VSM as a post-processing step that performs graph propagation on the structure of the ontology. The second is applicable to the wide range of current techniques that learn word embeddings from predictive models that maximize the likelihood of a corpus (Collobert and Weston, 2008; Mnih and Teh, 2012; Mikolov et al., 2013a). Our technique adds a latent variable representing the word sense to each token in the corpus, and uses EM to find parameters. Using a structured regularizer based on the ontological graph, we learn grounded sense-specific vectors.

There are several reasons to prefer ontologies as distant sources of supervision for learning sense-aware VSMs over previously proposed unsupervised context clustering techniques. Clustering approaches must often parametrize the number of clusters (senses), which is neither known a priori nor constant across words (Kilgarriff, 1997). Also the resulting vectors remain abstract and uninterpretable. With ontologies, interpretable sense vectors can be used in downstream applications such as WSD, or for better human error analysis. Moreover, clustering techniques operate on distributional similarity only whereas ontologies support other kinds of relationships between senses. Finally, the existence of cross-lingual ontologies would permit learning multi-lingual vectors, without compounded errors from word alignment and context clustering.

We evaluate our methods on 3 lexical semantic tasks across 7 datasets and show that our sense-specific VSMs effectively integrate knowledge from the ontology with distributional statistics. Empirically, this results in consistently and significantly better performance over baselines in most cases. In the more marginal cases, analysis reveals that our performance is a result of the deficient structure of the ontology. We discuss and compare the two different approaches from the perspectives of performance, generalizability, flexibility and computational efficiency. Finally, we qualitatively analyze the vectors and show that they indeed capture sense-specific semantics.

2 Unified Symbolic and Distributional Semantics

In this section, we present our two techniques for inferring sense-specific vectors grounded in an ontology. We begin with notation. Let $W = \{w_1, ..., w_n\}$ be a set of word types, and $W_s = \{s_{ij} \mid \forall w_i \in W\ ,\ 1 \leq j \leq k_i\}$ a set of senses, with k_i the number of senses of w_i. Moreover, let $\Omega = (T_\Omega, E_\Omega)$ be an ontology represented by an undirected graph. The vertices $T_\Omega = \{t_{ij} | \ \forall\ s_{ij} \in W_s\}$ correspond to the word senses in the set W_s, while the edges $E_\Omega = \{e^r_{ij-i'j'}\}$ connect some subset of word sense pairs $(s_{ij}, s_{i'j'})$ by semantic relation r[1].

2.1 Retrofitting Vectors to an Ontology

Our first technique assumes that we already have a vector space embedding of a vocabulary $\hat{U} = \{\hat{u}_i | \ \forall\ w_i \in W\}$. We wish to infer vectors $V = \{v_{ij} | \ \forall\ s_{ij} \in W_s\}$ for word senses that are maximally consistent with both $\hat{U}$ and Ω, by some notion of consistency. We formalize this notion as MAP inference in a Markov network (MN).

The MN we propose contains variables for every vector in $\hat{U}$ and V. These variables are connected to one another by dependencies as follows. Variables for vectors v_{ij} and $v_{i'j'}$ are connected iff there exists an edge $e^r_{ij-i'j'} \in E_\Omega$ connecting their respective word senses in the ontology. Furthermore, vectors $\hat{u}_i$ for the word types w_i are each connected to all the vectors v_{ij} of the different senses s_{ij} of w_i. If w_i is not contained in the ontology, we assume it has a single unconnected sense and set it's only sense vector v_{i1} to it's empirical estimate $\hat{u}_i$.

The structure of this MN is illustrated in Figure 1, where the neighborhood of the ambiguous word "bank" is presented as a factor graph.

We set each pairwise clique potential to be of the form $\exp(a\|u - v\|^2)$ between neighboring nodes. Here u and v are the vectors corresponding to these nodes, and a is a weight controlling the strength of the relation between them. We use the Euclidean norm instead of a distance based on cosine similarity because it is more convenient from an optimization perspective.

Our inference problem is to find the MAP estimate of the vectors V, given $\hat{U}$, which may be stated

[1]For example there might be a "synonym" edge between the word senses "cat(1)" and "feline(1)".

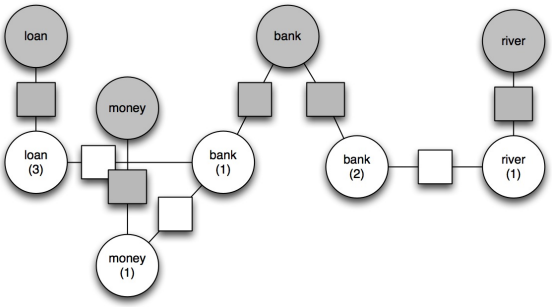

Figure 1: A factor graph depicting the retrofitting model in the neighborhood of the word "bank". Observed variables corresponding to word types are shaded in grey, while latent variables for word senses are in white.

as follows:

$$C(V) = \arg\min_{V} \sum_{i-ij} \alpha \|\hat{u}_i - v_{ij}\|^2 + \sum_{ij-i'j'} \beta_r \|v_{ij} - v_{i'j'}\|^2 \quad (1)$$

Here α is the sense-agnostic weight and β_r are relation-specific weights for different semantic relations. This objective encourages vectors of neighboring nodes in the MN to pull closer together, leveraging the tension between sense-agnostic neighbors (the first summation term) and ontological neighbors (the second summation term). This allows the different neighborhoods of each sense-specific vector to tease it apart from its sense-agnostic vector.

Taking the partial derivative of the objective in equation 1 with respect to vector v_{ij} and setting to zero gives the following solution:

$$v_{ij} = \frac{\alpha\hat{u}_i + \sum_{i'j' \in \mathcal{N}_{ij}} \beta_r v_{i'j'}}{\alpha + \sum_{i'j' \in \mathcal{N}_{ij}} \beta_r} \quad (2)$$

where $\mathcal{N}_{ij}$ denotes the set of neighbors of ij. Thus, the MAP sense-specific vector is an α-weighted combination of its sense-agnostic vector and the β_r-weighted sense-specific vectors in its ontological neighborhood.

We use coordinate descent to iteratively update the variables V using equation 2. The optimization problem in equation 1 is convex, and we normally converge to a numerically satisfactory stationary point within 10 to 15 iterations. This procedure is summarized in Algorithm 1. The generality of this algorithm allows it to be applicable to any VSM as a computationally attractive post-processing step.

Algorithm 1 Outputs a sense-specific VSM, given a sense-agnostic VSM and ontology

```
function RETROFIT(Û, Ω)
    V^(0) ← {v_ij^(0) = û_i | ∀ s_ij ∈ W_s}
    while ||v_ij^(t) − v_ij^(t−1)|| ≥ ε ∀i, j do
        for t_ij ∈ T_Ω do
            v_ij^(t+1) ← update using equation 2
        end for
    end while
    return V^(t)
end function
```

An implementation of this technique is available at `https://github.com/sjauhar/SenseRetrofit`.

2.2 Adapting Predictive Models with Latent Variables and Structured Regularizers

Many successful techniques for semantic representation learning are formulated as models where the desired embeddings are parameters that are learnt to maximize the likelihood of a corpus (Collobert and Weston, 2008; Mnih and Teh, 2012; Mikolov et al., 2013a). In our second approach we extend an existing probability model by adding latent variables representing the senses, and we use a structured prior based on the topology of the ontology to ground the sense embeddings. Formally, we assume a corpus $D = \{(w_1, c_1), \ldots, (w_N, c_N)\}$ of pairs of target and context words, and the ontology Ω, and we wish to infer sense-specific vectors $V = \{v_{ij} | \forall\ s_{ij} \in W_s\}$.

Consider a model with parameters θ ($V \in \theta$) that factorizes the probability over the corpus as $\prod_{(w_i,c_i)\in D} p(w_i, c_i; \theta)$. We propose to extend such a model to learn ontologically grounded sense vectors by presenting a general class of objectives of the following form:

$$C(\theta) = \arg\max_{\theta} \sum_{(w_i,c_i)\in D} \log(\sum_{s_{ij}} p(w_i, c_i, s_{ij}; \theta)) + \log p_\Omega(\theta) \quad (3)$$

This objective introduces latent variables s_{ij} for senses and adds a structured regularizer $p_\Omega(\theta)$

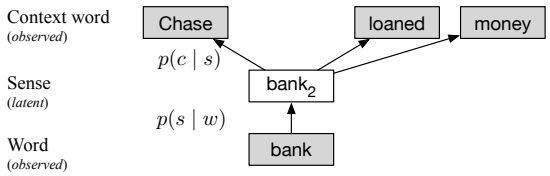

Figure 2: The generative process associated with the skip-gram model, modified to account for latent senses. Here, the context of the ambiguous word "bank" is generated from the selection of a specific latent sense.

that grounds the vectors V in an ontology. This form permits flexibility in the definition of both $p(w_i, c_i, s_{ij}; \theta)$ and $p_\Omega(\theta)$ allowing for a general yet powerful framework for adapting MLE models.

In what follows we show that the popular skip-gram model (Mikolov et al., 2013a) can be adapted to generate ontologically grounded sense vectors. The classic skip-gram model uses a set of parameters $\theta = (U, V)$, with $U = \{u_i \mid \forall c_i \in W\}$ and $V = \{v_i \mid \forall w_i \in W\}$ being sets of vectors for context and target words respectively. The generative story of the skip-gram model involves generating the context word c_i conditioned on an observed word w_i. The conditional probability is defined to be $p(c_i \mid w_i; \theta) = \frac{\exp(u_i \cdot v_i)}{\sum_{c_{i'} \in W} \exp(u_{i'} \cdot v_i)}$.

We modify the generative story of the skip-gram model to account for latent sense variables by first selecting a latent word sense s_{ij} conditional on the observed word w_i, then generating the context word c_i from the sense distinguished word s_{ij}. This process is illustrated in Figure 2. The factorization $p(c_i \mid w_i; \theta) = \sum_{s_{ij}} p(c_i \mid s_{ij}; \theta) \times p(s_{ij} \mid w_i; \theta)$ follows from the chain rule since senses are word-specific. To parameterize this distribution, we define a new set of model parameters $\theta = (U, V, \Pi)$, where U remains identical to the original skip-gram, $V = \{v_{ij} \mid \forall s_{ij} \in W_s\}$ are a set of vectors for word senses, and Π are the context-independent sense proportions $\pi_{ij} = p(s_{ij} \mid w_i)$. We use a Dirichlet prior over the multinomial distributions π_i for every w_i, with a shared concentration parameter λ.

We define the ontological prior on vectors as $p_\Omega(\theta) \propto \exp(-\gamma \sum_{ij-i'j'} \beta_r \|v_{ij} - v_{i'j'}\|^2)$, where γ controls the strength of the prior. We note the similarity to the retrofitting objective in equation 1, except with $\alpha = 0$. This leads to the following realization of the objective in equation 3:

$$C(\theta) = \arg\max_\theta \sum_{(w_i, c_i) \in D} \log \Big(\sum_{s_{ij}} p(c_i \mid s_{ij}; \theta) \times p(s_{ij} \mid w_i; \theta) \Big) - \gamma \sum_{ij-i'j'} \beta_r \|v_{ij} - v_{i'j'}\|^2 \quad (4)$$

This objective can be optimized using EM, for the latent variables, and with lazy updates (Carpenter, 2008) every k words to account for the prior regularizer. However, since we are primarily interested in learning good vector representations, and we want to learn efficiently from large datasets, we make the following simplifications. First, we perform "hard" EM, selecting the most likely sense at each position rather than using the full posterior over senses. Also, given that the structured regularizer $p_\Omega(\theta)$ is essentially the retrofitting objective in equation 1, we run retrofitting periodically every k words (with $\alpha = 0$ in equation 2) instead of lazy updates.[2]

The following decision rule is used in the "hard" E-step:

$$s_{ij} = \arg\max_{s_{ij}} p(c_i \mid s_{ij}; \theta^{(t)}) \pi_{ij}^{(t)} \quad (5)$$

In the M-step we use Variational Bayes to update Π with:

$$\pi_{ij}^{(t+1)} \propto \frac{\exp\left(\psi\left(\tilde{c}(w_i, s_{ij}) + \lambda \pi_{ij}^{(0)}\right)\right)}{\exp\left(\psi\left(\tilde{c}(w_i) + \lambda\right)\right)} \quad (6)$$

where $\tilde{c}(\cdot)$ is the online expected count and $\psi(\cdot)$ is the digamma function. This approach is motivated by Johnson (2007) who found that naive EM leads to poor results, while Variational Bayes is consistently better and promotes faster convergence of the likelihood function. To update the parameters U and V, we use negative sampling (Mikolov et al., 2013a) which is an efficient approximation to the original skip-gram objective. Negative sampling attempts to distinguish between true word pairs in the data, relative to noise. Stochastic gradient descent on the following equation is used to update the model pa-

[2] We find this gives slightly better performance.

rameters U and V:

$$\mathcal{L} = \log \sigma(u_i \cdot v_{ij}) + \sum_{\substack{j' \\ j' \neq j}} \log \sigma(-u_i \cdot v_{ij'}) + \sum_{m} \mathbb{E}_{c_{i'} \sim P_n(c)} \left[\log \sigma(-u_{i'} \cdot v_{ij}) \right] \quad (7)$$

Here $\sigma(\cdot)$ is the sigmoid function, $P_n(c)$ is a noise distribution computed over unigrams and m is the negative sampling parameter. This is almost exactly the same as negative sampling proposed for the original skip-gram model. The only change is that we additionally take a negative gradient step with respect to all the senses that were not selected in the hard E-step. We summarize the training procedure for the adapted skip-gram model in Algorithm 2.

Algorithm 2 Outputs a sense-specific VSM, given a corpus and an ontology

3 Evaluation

In this section we detail experimental results on 3 lexical semantics tasks across 8 different datasets. We begin by detailing the training and setup for our experiments.

3.1 Resources, Data and Training

We use WordNet (Miller, 1995) as the sense repository and ontology in all our experiments. WordNet is a large, hand-annotated ontology of English composed of 117,000 clusters of senses, or "synsets" that are related to one another through semantic relations such as hypernymy and hyponymy. Each synset additionally comprises a list of sense specific lemmas which we use to form the nodes in our graph. There are 206,949 such sense specific lemmas, which we connect with synonym, hypernym and hyponym[3] relations for a total of 488,432 edges.

To show the applicability of our techniques to different VSMs we experiment with two different kinds of base vectors.

Global Context Vectors (GC) (Huang et al., 2012): These word vectors were trained using a neural network which not only uses local context but also defines global features at the document level to further enhance the VSM. We distinguish three variants: the original single-sense vectors (SINGLE), a multi-prototype variant (MULTI), – both are available as pre-trained vectors for download[4] – and a sense-based version obtained by running retrofitting on the original vectors (RETRO).

Skip-gram Vectors (SG) (Mikolov et al., 2013a): We use the word vector tool `Word2Vec`[5] to train skip-gram vectors. We define 6 variants: a single-sense version (SINGLE), two multi-sense variants that were trained by first sense disambiguating the entire corpus using WSD tools, – one unsupervised (Pedersen and Kolhatkar, 2009) (WSD) and the other supervised (Zhong and Ng, 2010) (IMS) – a retrofitted version obtained from the single-sense vectors (RETRO), an EM implementation of the skip-gram model with the structured regularizer as described in section 2.2 (EM+RETRO), and the same EM technique but ignoring the ontology (EM). All models were trained on publicly available WMT-2011[6] English monolingual data. This corpus of 355 million words, although adequate in size, is smaller than typically used billion word corpora. We use this corpus because the WSD baseline involves preprocessing the corpus with sense disambiguation, which is slow enough that running it on corpora orders of magnitude larger was infeasible.

Retrofitted variants of vectors (RETRO) are trained using the procedure described in algorithm 1. We set the convergence criteria to $\epsilon = 0.01$ with a maximum number of iterations of 10. The weights

[3] We treat edges as undirected, so hypernymy and hyponymy are collapsed and unified in our representation schema.

[4] `http://nlp.stanford.edu/~socherr/ACL2012_wordVectorsTextFile.zip`

[5] `https://code.google.com/p/word2vec/`

[6] `http://www.statmt.org/wmt11/`

in the update equation 2 are set heuristically: the sense agnostic weight α is 1.0, and relations-specific weights β_r are 1.0 for synonyms and 0.5 for hypernyms and hyponyms. EM+RETRO vectors are the exception where we use a weight of $\alpha = 0.0$ instead, as required by the derivation in section 2.2.

For skip-gram vectors (SG) we use the following standard settings, and do not tune any of the values. We filter all words with frequency < 5, and pre-normalize the corpus to replace all numeric tokens with a placeholder. We set the dimensionality of the vectors to 80, and the window size to 10 (5 context words to either side of a target). The learning rate is set to an initial value of 0.025 and diminished linearly throughout training. The negative sampling parameter is set to 5. Additionally for the EM variants (section 2.2) we set the Dirichlet concentration parameter λ to 1000. We use 5 abstract senses for the EM vectors, and initialize the priors uniformly. For EM+RETRO, WordNet dictates the number of senses; also when available WordNet lemma counts are used to initialize the priors. Finally, we set the retrofitting period k to 50 million words.

3.2 Experimental Results

We evaluate our models on 3 kinds of lexical semantic tasks: similarity scoring, synonym selection, and similarity scoring in context.

Similarity Scoring: This task involves using a semantic model to assign a score to pairs of words. We use the following 4 standard datasets in this evaluation: WS-353 (Finkelstein et al., 2002), RG-65 (Rubenstein and Goodenough, 1965), MC-30 (Miller and Charles, 1991) and MEN-3k (Bruni et al., 2014). Each dataset consists of pairs of words along with an averaged similarity score obtained from several human annotators. For example an item in the WS-353 dataset is "book, paper → 7.46". We use standard cosine similarity to assign a score to word pairs in single-sense VSMs, and the following average similarity score to multi-sense variants, as proposed by Reisinger and Mooney (2010):

$$avgSim(w_i, w_{i'}) = \frac{1}{k_i k_j} \sum_{j,j'} cos(v_{ij}, v_{i'j'}) \quad (8)$$

The output of systems is evaluated against the gold standard using Spearman's rank correlation coefficient.

Synonym Selection: In this task, VSMs are used to select the semantically closest word to a target from a list of candidates. We use the following 3 standard datasets in this evaluation: ESL-50 (Turney, 2001), RD-300 (Jarmasz and Szpakowicz, 2004) and TOEFL-80 (Landauer and Dumais, 1997). These datasets consist of a list of target words that appear with several candidate lexical items. An example from the TOEFL dataset is "rug → sofa, ottoman, carpet, hallway", with "carpet" being the most synonym-like candidate to the target. We begin by scoring all pairs composed of the target and one of the candidates. We use cosine similarity for single-sense VSMs, and max similarity for multi-sense models[7]:

$$maxSim(w_i, w_{i'}) = \max_{j,j'} cos(v_{ij}, v_{i'j'}) \quad (9)$$

These scores are then sorted in descending order, with the top-ranking score yielding the semantically closest candidate to the target. Systems are evaluated on the basis of their accuracy at discriminating the top-ranked candidate.

The results for similarity scoring and synonym selection are presented in table 1. On both tasks and on all datasets, with the partial exception of WS-353 and MEN-3k, our vectors (RETRO & EM+RETRO) consistently yield better results than other VSMs. Notably, both our techniques perform better than preprocessing a corpus with WSD information in unsupervised or supervised fashion (SG-WSD & SG-IMS). Simple EM without an ontological prior to ground the vectors (SG-EM) also performs poorly.

We investigated the observed drop in performance on WS-353 and found that this dataset consists of two parts: a set of *similar* word pairs (e.g. "tiger" and "cat") and another set of *related* word pairs (e.g. "weather" and "forecast"). The synonym, hypernym and hyponym relations we use tend to encourage *similarity* to the detriment of *relatedness*.

We ran an auxiliary experiment to show this. SG-EM+RETRO training also learns vectors for context words – which can be thought of as a proxy for relatedness. Using this VSM we scored a word pair by the average similarity of all the sense vectors of

[7] Here we are specifically looking for synonyms, so the max makes more sense than taking an average.

		Word Similarity (ρ)				Synonym Selection (%)		
		WS-353	RG-65	MC-30	MEN-3k	ESL-50	RD-300	TOEFL-80
GC	SINGLE	**0.623**	0.629	0.657	0.314	47.73	45.07	60.87
	MULTI	0.535	0.510	0.309	0.359	27.27	47.89	52.17
	RETRO	0.543	**0.661**	**0.714**	**0.528**	**63.64**	**66.20**	**71.01**
SG	SINGLE	**0.639**	0.546	0.627	**0.646**	52.08	55.66	66.67
	EM	0.194	0.278	0.167	0.228	27.08	33.96	40.00
	WSD	0.481	0.298	0.396	0.175	16.67	49.06	42.67
	IMS	0.549	0.579	0.606	0.591	41.67	53.77	66.67
	RETRO	0.552	0.673	0.705	0.560	56.25	65.09	**73.33**
	EM+RETRO	0.321	**0.734**	**0.758**	0.428	**62.22**	**66.67**	68.63

Table 1: Similarity scoring and synonym selection in English across several datasets involving different VSMs. Higher scores are better; best scores within each category are in bold. In most cases our models consistently and significantly outperform the other VSMs.

one word to the context vector of the other word, averaged over both words. With this scoring function the correlation ρ jumped from 0.321 to 0.493. While still not as good as some of the other VSMs, it should be noted that this scoring function negatively influences the *similar* word pairs in the dataset.

The MEN-3k dataset is crowd-sourced and contains much diversity, with word pairs evidencing similarity as well as relatedness. However, we aren't sure why the performance for GC-RETRO improves greatly over GC-SINGLE for this dataset, while that of SG-RETRO and SG-RETRO+EM drops in relation to SG-SINGLE.

Similarity Scoring in Context: As outlined by Reisinger and Mooney (2010), multi-sense VSMs can be used to consider context when computing similarity between words. We use the SCWS dataset (Huang et al., 2012) in these experiments. This dataset is similar to the similarity scoring datasets, except that they additionally are presented in context. For example an item involving the words "bank" and "money", gives the words in their respective contexts, "along the east **bank** of the Des Moines River" and "the basis of all **money** laundering" with a low averaged similarity score of 2.5 (on a scale of 1.0 to 10.0). Following Reisinger and Mooney (2010) we use the following function to assign a score to word pairs in their respective contexts, given a multi-sense VSM:

$$avgSimC(w_i, c_i, w_{i'}, c_{i'}) = \sum_{j,j'} p(s_{ij}|c_i, w_i)p(s_{i'j'}|c_{i'}, w_{i'})cos(v_{ij}, v_{i'j'}) \quad (10)$$

Vectors	SCWS (ρ)
SG-WSD	0.343
SG-IMS	0.528
SG-RETRO	0.417
GC-RETRO	0.420
SG-EM	0.613
SG-EM+RETRO	0.587
GC-MULTI	**0.657**

Table 2: Contextual word similarity in English. Higher scores are better.

As with similarity scoring, the output of systems is evaluated against gold standard using Spearman's rank correlation coefficient.

The results are presented in table 2. Preprocessing a corpus with WSD information in an unsupervised fashion (SG-WSD) yields poor results. In comparison, the retrofitted vectors (SG-RETRO & GC-RETRO) already perform better, even though they do not have access to context vectors, and thus do not take contextual information into account. Supervised sense vectors (SG-IMS) are also competent, scoring better than both retrofitting techniques. Our EM vectors (SG-EM & SG-EM+RETRO) yield even better results and are able to capitalize on contextual information, however they still fall short of the pretrained GC-MULTI vectors. We were surprised that SG-EM+RETRO actually performed worse than SG-EM, given how poorly SG-EM performed in the other evaluations. However, an analysis again revealed that this was due to the kind of similarity encouraged by WordNet rather than an inability of the model to learn useful vectors. The SCWS dataset, in addition to containing related

Method	CPU Time
RETRO	~20 secs
EM+RETRO	~4 hours
IMS	~3 days
WSD	~1 year

Table 3: Training time associated with different methods of generating sense-specific VSMs.

words – which we showed, hurt our performance on WS-353 – also contains word pairs with different POS tags. WordNet synonymy, hypernymy and hyponymy relations are exclusively defined between lemmas of the same POS tag, which adversely affects performance further.

3.3 Discussion

While both our approaches are capable of integrating ontological information into VSMs, an important question is which one should be preferred? From an empirical point of view, the EM+RETRO framework yields better performance than RETRO across most of our semantic evaluations. Additionally EM+RETRO is more powerful, allowing to adapt more expressive models that can jointly learn other useful parameters – such as context vectors in the case of skip-gram. However, RETRO is far more generalizable, allowing it to be used for *any* VSM, not just predictive MLE models, and is also empirically competitive. Another consideration is computational efficiency, which is summarized in table 3.

Not only is RETRO much faster, but it scales linearly with respect to the vocabulary size, unlike EM+RETRO, WSD, and IMS which are dependent on the input training corpus. Nevertheless, both our techniques are empirically superior as well as computationally more efficient than both unsupervised and supervised word-sense disambiguation paradigms.

Both our approaches are sensitive to the structure of the ontology. Therefore, an important consideration is the relations we use and the weights we associate with them. In our experiments we selected the simplest set of relations and assigned weights heuristically, showing that our methods can effectively integrate ontological information into VSMs. A more exhaustive selection procedure with weight tuning on held-out data would almost certainly lead to better performance on our evaluation suite.

3.4 Qualitative Analysis

We qualitatively attempt to address the question of whether the vectors are truly sense specific. In table 4 we present the three most similar words of an ambiguous lexical item in a standard VSM (SG-SINGLE) in comparison with the three most similar words of different lemma senses of the same lexical item in grounded sense VSMs (SG-RETRO & SG-EM+RETRO).

Word or Sense	Top 3 Most Similar
hanging	hung dangled hangs
hanging (suspending)	shoring support suspension
hanging (decoration)	tapestry braid smock
climber	climbers skier Loretan
climber (sportsman)	lifter swinger sharpshooter
climber (vine)	woodbine brier kiwi

Table 4: The top 3 most similar words for two polysemous types. Single sense VSMs capture the most frequent sense. Our techniques effectively separates out the different senses of words, and are grounded in WordNet.

The sense-agnostic VSMs tend to capture only the most frequent sense of a lexical item. On the other hand, the disambiguated vectors capture sense specificity of even less frequent senses successfully. This is probably due to the nature of WordNet where the nearest neighbors of the words in question are in fact these rare words. A careful tuning of weights will likely optimize the trade-off between ontologically rare neighbors and distributionally common words.

In our analyses, we noticed that lemma senses that had many neighbors (i.e. synonyms, hypernyms and hyponyms), tended to have more clearly sense specific vectors. This is expected, since it is these neighborhoods that disambiguate and help to distinguish the vectors from their single sense embeddings.

4 Related Work

Since Reisinger and Mooney (2010) first proposed a simple context clustering technique to generate multi-prototype VSMs, a number of related efforts have worked on adaptations and improvements relying on the same clustering principle. Huang et al. (2012) train their vectors with a neural network and additionally take global context into account. Neelakantan et al. (2014) extend the popular skip-gram model (Mikolov et al., 2013a) in a non-parametric

fashion to allow for different number of senses for words. Guo et al. (2014) exploit bilingual alignments to perform better context clustering during training. Tian et al. (2014) propose a probabilistic extension to skip-gram that treats the different prototypes as latent variables. This is similar to our second EM training framework, and turns out to be a special case of our general model. In all these papers, however, the multiple senses remain abstract and are not grounded in an ontology.

Conceptually, our work is also similar to Yu and Dredze (2014) and Faruqui et al. (2014), who treat lexicons such as the paraphrase database (PPDB) (Ganitkevitch et al., 2013) or WordNet (Miller, 1995) as an auxiliary thesaurus to improve VSMs. However, they do not model senses in any way. Pilehvar et al. (2013) do model senses from an ontology by performing random-walks on the Wordnet graph, however their approach does not take distributional information from VSMs into account.

Thus, to the best of our knowledge, our work presents the first attempt at producing sense grounded VSMs that are symbolically tied to lexical ontologies. From a modelling point of view, it is also the first to outline a unified, principled and extensible framework that effectively combines the symbolic and distributional paradigms of semantics.

Both our models leverage the graph structure of ontologies to effectively ground the senses of a VSM. This ties into previous research (Das and Smith, 2011; Das and Petrov, 2011) that propagates information through a factor graph to perform tasks such as frame-semantic parsing and POS-tagging across languages. More generally, this approach can be viewed from the perspective of semi-supervised learning, with an optimization over a graph loss function defined on smoothness properties (Corduneanu and Jaakkola, 2002; Zhu et al., 2003; Subramanya and Bilmes, 2009).

Related to the problem of polysemy is the issue of different shades of meaning a word assumes based on context. The space of research on this topic can be divided into three broad categories: models for computing contextual lexical semantics based on composition (Mitchell and Lapata, 2008; Erk and Padó, 2008; Thater et al., 2011), models that use fuzzy exemplar-based contexts without composing them (Erk and Padó, 2010; Reddy et al., 2011), and models that propose latent variable techniques (Dinu and Lapata, 2010; Séaghdha and Korhonen, 2011; Van de Cruys et al., 2011). Our work, which tackles the stronger form of lexical ambiguity in polysemy falls into the latter two of three categories.

5 Conclusion and Future Work

We have presented two general and flexible approaches to producing sense-specific VSMs grounded in an ontology. The first technique is applicable to any VSM as an efficient post-processing step while the second provides a framework to integrate ontological information with existing MLE-based predictive models. We presented an evaluation of 3 semantic tasks on 7 datasets. Our results show that our proposed methods are effectively able to capture the different senses in an ontology. In most cases this results in significant improvements over baselines. We have also discussed the trade-offs between the two techniques from several different perspectives. Finally, we have presented a qualitative analysis investigating the nature of the sense-specific vectors, and shown that they capture the semantics of different senses.

Our findings suggest several avenues for future research. We propose to use sense-specific vectors as features in downstream applications such a Word Sense Disambiguation. Our current approach assumes a fixed ontology, but we hope to explore a more bi-directional relationship between ontology and VSM in future work. In particularly we envisage simultaneously incrementing ontologies with structure learning in addition to improving VSMs. We also hope to extend our research to the multi-lingual domain. We are particularly excited by the idea of using multi-lingual WordNets to learn sense specific semantic vectors that generalize across languages.

Acknowledgments

The authors would like to thank Manaal Faruqui, Jesse Dodge and Noah Smith for their insight and feedback. Thanks also go to the anonymous reviewers for their valuable comments and suggestions to improve the quality of the paper. Subsentential Sentiment on a Shoestring: A Crosslingual Analysis of Compositional Classification

Michael Haas and **Yannick Versley**
Institute for Computational Linguistics
University of Heidelberg
{haas,versley}@cl.uni-heidelberg.de

Abstract

Sentiment analysis has undergone a shift from *document-level* analysis, where labels expresses the sentiment of a whole document or whole sentence, to subsentential approaches, which assess the contribution of individual phrases, in particular including the *composition* of sentiment terms and phrases such as negators and intensifiers.

Starting from a small sentiment treebank modeled after the Stanford Sentiment Treebank of Socher et al. (2013), we investigate suitable methods to perform compositional sentiment classification for German in a data-scarce setting, harnessing cross-lingual methods as well as existing general-domain lexical resources.

1 Introduction

In sentiment classification, we find a general tendency from document-level classification towards more fine-grained approaches that yield a more detailed appraisal of the judgement performed in the text - in particular, using composition over syntactic structure to get a more detailed approach over phrases.

For English movie reviews, work using the Stanford Sentiment Treebank (SSTb) has shown that such subsentential sentiment information can yield approaches with both very high accuracy (Socher et al., 2013; Dong et al., 2014; Hall et al., 2014) and precise information about the role of each phrase – information which can subsequently used for extracting or summarizing the sentiment expressed in the text.

The effort for creating a sentiment treebank such as the SSTb, however, seems prohibitive if we wanted to create such a resource for each pair of relevant domain and language: Compared to document-level annotations for sentiment, which are easy to come by (e.g., star ratings), annotating individual syntactic phrases requires considerable effort.

The main focus of this paper is the question if and how it is possible to reach sensible performance for compositional sentiment classification when we only have limited resources to spend on an in-language, in-domain sentiment treebank. For this goal, we use a new resource, the *Heidelberg Sentiment Treebank* (HeiST), which is a German-language counterpart to the Stanford Sentiment Treebank in the sense that it makes explicit the composition of sentiment expression over syntactic phrases. Our experiments on HeiST provide a direct comparison of different techniques for harnessing cross-lingual, cross-domain, or cross-task information, and are the first of this kind to specifically target *compositional* sentiment analysis.

Figure 1 (next page) shows a schematic overview of the experiments: beyond supervised baseline experiments using SVM classification and a supervised RNTN model (section 3), we evaluated cross-lingual projection (section 4), lexicon-based approaches (section 5), as well as semi-supervised approaches based on word clusters (section 6).

2 Related Work

The starting point for our research is the idea that the sentiment of larger stretches of text can be calculated through composition over smaller stretches of text, which was investigated in a learning framework by both Yessenalina and Cardie (2011) and Socher et al. (2011, 2012), both learning in a compositional

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 694–704,
Denver, Colorado, May 31 – June 5, 2015.

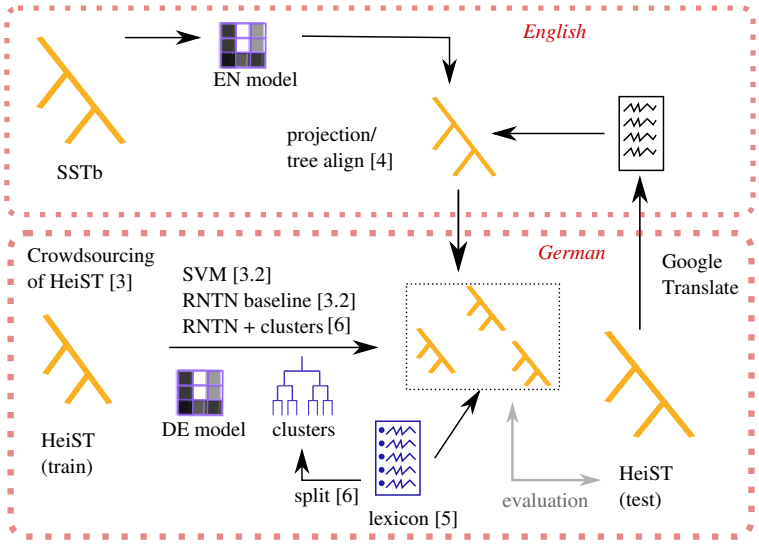

Figure 1: Plan to the experiments described in this paper

fashion from datasets that only have document-level sentiment annotation.

On the same dataset as Socher et al., Wang and Manning (2012) later demonstrated that unigram and bigram features in an SVM-based classification framework can reach a greater accuracy than the earlier recursive neural network approach of Socher et al. (2011, 2012), which calls into question the assumption that sentiment composition can be learned purely from sentence-level annotations.

Compositionality through Tensors In subsequent work, Socher et al. (2013) introduce the Stanford Sentiment Treebank, which contains detailed annotations of sentiment values for individual syntactic phrases in a binarized tree, and an approach based on recursive neural tensor networks (RNTN) which yields significant improvements over the earlier approaches using token-level features.

The RNTN represents the contribution of individual nodes as vectors of reals and achieves its precision by using a tensor $V^{[1:d]} \in \mathbb{R}^{2d \times 2d \times d}$ as well as a matrix $W \in \mathbb{R}^{2d \times d}$ to capture second-order dependencies between the two children of a node in the tree (with vectors a, b), yielding first a vector h by

$$h_i = \begin{bmatrix} a \\ b \end{bmatrix}^T V^{[i]} \begin{bmatrix} a \\ b \end{bmatrix} + W_i \begin{bmatrix} a \\ b \end{bmatrix}$$

then using a monotonic nonlinear function on h (here: *tanh*) to yield the vector for this node. The sentiment label of a node is then gained by multiplying these *hidden vectors* by a matrix W_s, yielding a five-dimensional vector with the classification. Using hidden vectors for each node and capturing second-order interaction between the two child vectors a and b, the RNTN model achieves descriptive power greater than that of TreeCRFs (Nakagawa et al., 2010), and similar to latent-variable models that have been very successful in syntactic parsing (Petrov et al., 2006).

In later work, Zhu et al. (2014) show that the RNTN's lexicalized modeling of negators and their behaviour leads to increased descriptive power of the model, which results in an improved treatment of negation. Dong et al. (2014) introduce an approach that chooses between multiple composition tensors (AdaMC-RNTN), which yields further gains with respect to RNTN performance.

In contrast to the lexicalized and high-dimensional RNTN model, there are several lines of work that attempt to work in a more data-scarce setting.

Lexicon-based approaches The classical approach for performing sentiment classification in a setting where training data is sparse can be seen in the SO-CAL approach of Taboada et al. (2011): Using a manually curated dictionary with sentiment values for multiple parts of speech, and a set of heuristics that predict how intensifiers, nega-

tors/shifters as well as nonveridical moods affect the sentiment of a phrase, they show that it is possible to reach good results across different domains.

Choi and Cardie (2009) show that it is possible to adapt an existing general-domain sentiment lexicon to a specific domain using an approach that optimizes a joint objective of classification loss, sparsity of the changes made to the lexicon, and ambiguity of lexicon entries. Their approach yields appreciable gains over the general-domain lexicon, both with CRF-based machine learning classification and with a simpler "vote & flip" algorithm that is based on majority voting and negators.

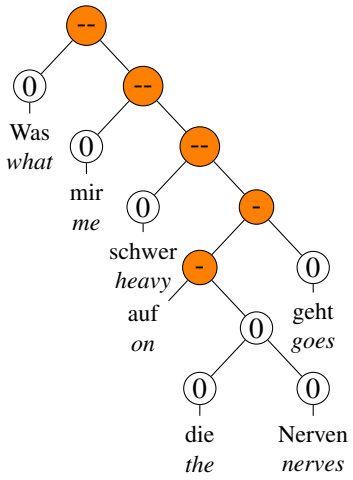
Crosslingual Sentiment Analysis involves the usage of a dataset in one language to perform sentiment analysis in another language; in their work, Banea et al. (2013) show that translating text in the target language to the source language and applying a well-tuned sentiment classification system works better than either translating the training corpus or the lexicon used by the system.

In research by other groups, Wan (2009) advocates a bootstrapping approach that combines source-side and target-side features in one classifier; Duh et al. (2011) note that crosslingual sentiment analysis techniques always incur a loss due to the shift in language from the source language texts to the target language even though the general domain is the same. Popat et al. (2013) argue that full machine translation is not useful for resource-scarce languages, and propose to use cross-lingual clustering both to improve the generalization capability within a single language as well as for crosslingual projection, which works better than machine translation with the English-Hindi language pair.

It should be noted that most of the work presented in the last two paragraph works with document-level sentiment, or (in the case of Choi and Cardie) with shallower annotations, and offers additional challenges in the case of sentiment composition.

3 Low-Budget Treebanking for Sentiment

For both supervised training and for evaluation, we created a German dataset that is close in domain to the Stanford Sentiment treebank (Socher et al., 2013), covering opinionated sentences from movie reviews with phrase-level sentiment annotations.



"*What really gets on my nerves . . .*"

Figure 2: A multiword expression in HeiST

The original Stanford Sentiment Treebank is based on the dataset of Pang and Lee (2005), which includes 10,662 sentences from excerpts of movie reviews published on `rottentomatoes.com`. It should be noted that these excerpts are much more likely to express an opinion than general text or even the main body of a movie review since they contain precisely a summary of the opinion.

In order to match both domain and role of these sentences most precisely, we collected creative-commons-licensed reviews from a German movie review site, `filmrezensionen.de`, and used only the summary part of these documents, yielding 1184 sentences, for which we crowdsourced annotation for each individual phrase in the binary tree (see Figure 2 for an example tree fragment).

For the purpose of getting binary phrase trees, sentences were processed with the Berkeley Parser (Petrov et al., 2006), NP nodes were added inside PPs (Samuelsson and Volk, 2004) and the resulting parse trees binarized using the head table in CoreNLP (Rafferty and Manning, 2008), yielding 14,321 unique phrases.

Annotation was outsourced via the CrowdFlower service, which collects three judgements for each phrase and computes an end result through voting, using unambiguous test items (which we composed from strongly positive or strongly negative adjective-noun combinations) to filter out annotators lacking the requisite understanding of German.

Experiment A: Features, Confidence	Prec	Recl
SentiWS	0.882	0.959
SentiWS+Regression	0.894	0.967
SentiWS+Regression, @50%	0.935	0.985
SentiWS+Regression+POS	0.912	0.960
SentiWS+Regression+POS, @50%	0.978	0.997
Experiment B: Classifier (@50%)	Prec	Recl
Linear SVM	0.975	0.980
Random Forest	0.984	0.992
Gradient Boosting	0.978	0.997

Table 1: Filtering out objective phrases

The HeiST treebank, as well as the code used in these experiments, are available for research purposes.[1]

3.1 Selecting Subjective Phrases

One possible approach to reduce annotation effort would be to annotate only those phrases that a classification model deems to have sentiment content in the first place. As a more extreme example of such an approach, consider the MLSA sentiment dataset for German, where 270 sentences were selected that already contained two words from an existing sentiment lexicon (Clematide et al., 2012), with the goal of getting sentences with interesting interactions between sentiment words. Given the potential benefits (getting more data for the same annotation effort), an approach that filters out non-interesting (confidently objective) phrases would be highly appealing.

For the pre-classification experiment, we used cross-validation on 20 to assess the potential impact of strategies for saving. For the corresponding classifier, we used features from a German general-domain sentiment lexicon, a regression model for document-level sentiment (see section 5.2), as well as part-of-speech tag features in a gradient boosting classifier. As seen in table 1, the sentiment lexicon, especially in conjunction with the regression model and a POS-based filter, would allow to detect uninteresting (objective) phrases with high accuracy. We limit ourselves to the 50% of most confident classifications, and as a measure of caution, the filter is bypassed for any phrase that contains a word in one of several sentiment dictionaries (see section 5). The classifier has a precision of 96.5% for objective phrases while catching about 66.7% of all objective nodes. While this would correspond to substantial savings (about a quarter of all nodes would be assigned the "neutral" label and not annotated), we would also lose a fraction of non-neutral phrase and introduce an unwanted bias (towards lexicon-based resources) into our dataset.

Table 3: Comparison figures on subsets of the Stanford Sentiment Treebank

3.2 Baseline results

We use the existing RNTN implementation of Socher et al. (2013) to train and test supervised learning for sentiment composition, using cross-validation. For parameter tuning, we varied the number of vector dimensions as well as the size of the minibatches used in training, and found that the resulting classifier yields very sensible results compared to a similarly-sized sample from SSTb (see

Tables 2 and 3). We evaluate our results as in Socher et al. (2013): we consider the recall of positive and negative nodes while ignoring both neutral nodes and the difference between positive (+) and strongly positive (++) or between negative (-) and strongly negative (--) nodes, respectively. Socher et al. remove sentences with neutral overall sentiment in training as well as in testing, which seems to worsen the RNTN performance on our dataset (see Table 2), although other methods seem to be less affected by it. For comparability reasons, all other reported figures are based on Socher's non-neutral-sentences-only setting. In comparison results on SSTb (see Table 3), classification experiments from the English data also show poor results for the RNTN classifier at small data sizes, in parallel with anecdotal evidence on recurrent neural networks having trouble with small dataset sizes.[2]

4 Crosslingual Projection for Compositional Sentiment

Our crosslingual approach follows Banea et al. (2013) in assuming that machine translation of the target documents to the source language, then applying a source-language sentiment analysis, and finally projecting the result back to the target side will yield usable sentiment classification. In difference to previous approaches for cross-lingual sentiment analysis, however, our annotation transfer concerns not just analysis results for the complete sentence, but for individual syntactic nodes.

After translating the target-language trees using the Google Translate API, we parsed the sentences using the English model of the Stanford parser, and applied the RNTN model of Socher et al. (2013) trained on the English Stanford Sentiment Treebank, yielding a labeling for each syntactic node with a sentiment value. We then performed word alignment using the PostCAT word aligner (Ganchev et al., 2008) with a model trained on the OPUS version of the EuroParl corpus (Tiedemann, 2012), and alignment of syntactic nodes using the `Lingua::Align` toolbox for tree alignment Tiedemann (2010) with a model trained on the Smultron parallel treebank (Volk et al., 2010).

Table 4: Lexicon-based phrase labeling

Using the word alignment and our `Lingua::Align` model, we are able to map 98.6% of the target-language nodes to a corresponding node on the source (English) side, whereas the remaining nodes are assigned the same sentiment label as the root. As can be seen in table 2, a model that uses simpler features for `Lingua::Align` works less well than the full feature model. Considering that the RNTN on the Stanford Sentiment Treebank reaches 87.6% node accuracy and 85.4% root accuracy, we see that the crosslingual projection step induces a loss in accuracy, but still performs well in comparison to the approaches that use the HeiST training data.

5 Lexicon-based Approaches

Considering that the size of HeiST creates a sparse data problem for the RNTN learner, it is natural to ask whether we can improve the generalization capabilities of the system by either using a less-supervised approach or by generalizing over individual word forms to alleviate the sparse data problem.

5.1 General-domain lexicon

Several general-domain sentiment lexicons exist for German, including those of Klenner et al. (2009), Waltinger (2010a), Remus et al. (2010), and Emerson and Declerck (2014).

Klenner et al. (2009) created their polarity lexicon by semiautomatic extension of an existing one: starting from a set of 2866 adjective seeds, they looked for adjectives that often co-occur in coordinations with known sentiment-bearing adjectives, which were added to the lexicon after a manual filtering step. The current version of Klenner et al.'s PolArt lexicon also contains other parts of speech, and a list of *shifters* and *intensifiers* that interact with subjective terms.

The GermanPolarityClues lexicon of Waltinger (2010a) combines translation from English lexicons with a semi-automatic approach for merging and manually correcting lexicon entries.

The SentiWS lexicon (Remus et al., 2010) contains translations of the English General Inquirer (Stone et al., 1966), which have been translated via Google Translate, as well as a small number of terms that were mined from positive and negative product reviews, expanded using a collocation dictionary.

Finally, the SentiMerge lexicon (Emerson and Declerck, 2014) has been constructed as a Bayesian combination (i.e., averaging with imputation for missing entries) of the three resources above together with the *German SentiSpin* resource of Waltinger (2010b), which contains automatic (dictionary-based) translations of the SentiSpin lexicon of Tamura et al. (2005).

We tested all lexicons using two approaches: In the **vote-only** approach, the sentiment of a phrase is determined by the sum of the scores of the words in that phrase as they are assigned in the sentiment lexicon. In the **vote-and-flip** approach, we consider the average of the sentiment terms, but invert the sentiment value whenever a term from the *shifter* category of Klenner et al.'s lexicon is found within the yield of the node. A similar strategy was used in many papers on sentiment composition, usually with a performance rather close to the best system (see e.g. the CompoMC baseline in Choi and Cardie, 2008, or the Vote-and-Flip baseline in Choi and Cardie, 2009).

5.2 Near-domain lexicon construction

While the *filmrezensionen* web site offers a good number of reviews, the final collection is rather small. To complement our small in-domain dataset we use the most common way of getting text with document-level annotations, namely customer-written reviews from the movies section of `amazon.de` web site.

Perhaps expectedly, customer reviews do not focus exclusively on the film and its performance. Rather, it often occurs that customer reviews include a discussion of the physical (or other) medium that the film came on:[3]

(1) *I am with Lovefilm (now Prime) and tried to stream the series. Terrible! Always [issues with] loading time and loss of the stream. It seems that Amazon hasn't come to terms with the technology yet.*

Other reviews on Amazon match our domain fairly well, as in the following:

(2) *If this is truly a sequel to "Speed", it only shows in the second hour of the film. It's only then that deBont shows why he would be an action [film] specialist. Admittedly, even then we don't get the same tension as in the predecessor, but in any case it's better than the first hour of the film.*

While we found that a small quantity of data (20+20 hand-classified sentences) together with a 300-class LDA representation was sufficient to reach 100% accuracy in separating content-related versus media-related text, we found that filtering out the irrelevant texts made no difference for the mean square error, in sharp contrast to L1/Lasso regularization, which allows to learn a sparse lexicon.

6 Variants of the RNTN Model

While the RNTN model certainly performs well on the full Stanford Sentiment Treebank, it is likely that its performance on HeiST is suffering from sparse data problems, and that both words and particular constructions can be novel and unseen.

In syntactic parsing, Koo et al. (2008) and Candito and Seddah (2010) have shown that using Brown clusters can be beneficial for alleviating sparse data problems in parsing. In a similar vein, Popat et al. (2013) have successfully applied crosslingual clustering to generalizing over potentially unseen words

Table 5: Incorporating additional information

in (document-level) sentiment analysis for English, Hindi and Marathi.

In our experiments, we follow Candito and Seddah (2010) in simply replacing words by clusters: in their experiments, even this simple procedure can yield an improvement, with improved results when the unlabeled data stems from the target domain. Since Brown clusters are mostly syntactic/semantic in nature and do not automatically distinguish positive or negative sentiment, we additionally performed multiple experiments to use clusters while incorporating additional sentiment information:

On one hand, we try to incorporate the judgements on the Amazon near-domain dataset more directly into the clusters by using the repeated bisecting K-Means algorithm as implemented in CLUTO (Zhao and Karypis, 2005), with previous/next word, part-of-speech tag, and the score of the containing review as features. On the other hand, we split the Brown clusters according to the sentiment value that they have in a particular sentiment lexicon (e.g. SentiMerge), yielding three clusters *01101+*, *01101-* and *01101?* instead of the original cluster *01101*.

As a final experiment, we consider replacing *only sentiment words* by a concatenation of their part-of-speech and the sentiment class (turning "*a great film*" into "*a JJ++ film*"), and leaving neutral words intact. As an upper baseline for this approach, we can get words' sentiment polarity directly from training and testing data, which yields the *replace-gold* entry in table 5.

rule type	# in SSTb	# in HeiST
AVG	119468	19228
INV	2158	289
INT	6614	646
MWE	18235	1936

Table 6: Rule types in SSTb and HeiST

7 Results and Error analysis

Looking at the results in tables 2, 4 and 5, we see that simple support vector machine classification is very effective for reproducing the positive/negative sentiment of nodes and complete sentences, followed by crosslingual projection and a simple averaging approach; we also see that handling negation in the *vote-and-flip* approach seems to lower the score, just as the best model with word clusters and splitting (using the *GermanPolarityClues* lexicon) performs better than the word-based RNTN approach, but less well than the lexicon by itself. Even the *replace-gold* upper baseline – replacing sentiment-carrying words by their sentiment label, which raises the performance substantially – gives results below the simpler SVM approach, which is counterintuitive.

7.1 Is it about Compositionality?

One motivation for using sub-sentence structure both in approaches for rule-based composition (as, e.g. in Taboada et al. (2011) and other lexicon-based approaches) as well as in more complex learning approaches such as RNN (Socher et al., 2011) and RNTN (Socher et al., 2013) is the idea that such approaches are able to model the interaction between sentiment-bearing words and sentiment-modifying words. An example for investigations based on this assumption is the work by Zhu et al. (2014), who contrast different lexicon-based approaches for handling negation with an RNTN model of negation and a modification of said model.

Given the results using a lexicon-based approach implementing the *vote-and-flip* heuristic in comparison to the *vote-only* heuristic, we found it worth investigating what specific types of interaction exist in compositional sentiment treebanks, also considering that Zhu et al.'s investigations yielded a more precise picture of the sentiment-shifting action of negators as a highly lexicalized phenomenon.

For our analysis, we grouped the production rules $s_p \rightarrow s_l s_r$ in a sentiment treebank into one of the following categories:

AVG A production is said to be *averaging* if the parent category is within the range of either daughter category. (e.g. *mind-numbingly good* would be the composition of a negative term and a positive term to a positive term, which still fits the averaging heuristic).

INV A production is said to be *inverting* if one daughter category is neutral and the other daughter category is on the other side on the spectrum (e.g. "not great" landing on the negative side)

INT A production is said to be *intensifying* if the parent category is on the same side of the scale as the daughters but more extreme.

MWE A production is said to be a *multi-word* production if the daughter categories are classified as neutral while the parent category is not.[4]

As can be seen in table 6, the number of *inverting* and *intensifying* productions is dwarfed, both for the SST and for HeiST, by the number of *multi-word* rules. While it is likely that these counts are slightly distorted by noise in the annotation (as both datasets are the product of crowdsourcing), this fact is remarkable and merits further investigation.

Types of multiword expressions If we try to group the nodes with a "multiword" production, we can distinguish at least the following categories:

- **aspect descriptions**: In some cases, an adjective is specifically used to describe a (positive or negative) aspect of the movie, such as an *elaborate continuation*, or an *expanded vision*, where individual words have a neutral sentiment label (and conceivable could have been used in a non-aspect-specific way to convey a neutral or negative sentiment, such as an *elaborate perversion*, or an *expanded nightshift*). Similarly, *wenig Handlung* (not much action) has a negative meaning as a construction despite "*wenig*" (few/not much) not having a negative meaning itself.
- **expression strengthening** is a phenomenon that occurs when a term is judged as neutral by annotators by itself, but gains a sentiment value when paired with an intensifier or negator. For example, *intrusive* was labeled as neutral in SSTb, but *simply intrusive* as negative.
- **comparatives** are a very regular construction where too much of something is almost always bad: *too long*, *too insistent*, *too much*, *too many* are all negative in SSTb, just as *zu viel* (too many) and *zu wenig* (not enough) and other counterparts in HeiST are negative.
- **true constructions** such as *plot holes* or *historically significant* in SSTB, or *ruhigen Gewissens* (with a calm conscience) and *Finger weg* (don't touch it) in HeiST are both a problem for approaches relying purely on composition and not regular enough that we would expect to model it as a regular construction.

Some of the neutral-to-positive or neutral-to-negative transitions don't seem well-motivated and may be regarded as artifacts from the crowdsourcing, as *does n't*, *is n't* and *are n't* are negative in SSTb whereas *'s not*, *do n't* and *did n't* get a neutral label. In HeiST, *nicht immer* (not always) as well as *nicht ganz* (not quite) are negative, whereas *auch nicht* (neither) and *nicht so* (not as) or *nicht unbedingt* (not necessarily) are neutral.

The MWE productions seem to overlap with well-known linguistic phenomena – consider Fahrni and Klenner (2008) and their claim that most adjectives have a polarity that is dependent on the target they modify instead of having a '*prior*' polarity that holds independently of the target, or the observation of Su and Markert (2009) that sentiment should be dependent on word senses instead of word forms (which would capture a large number of examples within the *expression strengthening* category). Yet, others may be idiosyncracies introduced by the crowdsourcing process, and powerful learners such as RNTN or the approach of Hall et al. (2014) will gain performance from simply memorizing the idiosyncracies of the data when there is

[4]The MWE category also contains a small number – about 5% of total MWE productions – of positive-to-neutral and negative-to-neutral productions, which we found to be predominantly noise from the crowdsourcing process.

		SVM		CLSA		RNTN		+*replace-gold*	
Type	Total	Corr	Prec	Corr	Prec	Corr	Prec	Corr	Prec
AVG	6341	3408	0.546	3158	0.506	3604	0.577	4309	0.690
MWE	1638	369	0.225	538	0.328	538	0.359	546	0.333
INT	612	370	0.605	362	0.592	413	0.675	470	0.768
ID	392	283	0.722	269	0.686	286	0.730	323	0.824
INV	259	76	0.293	65	0.251	93	0.359	79	0.305

Table 7: Precision of rules with non-neutral parent label (ID: daughters and parent have identical labels)

enough of it – because of the way the Stanford Sentiment Treebank is constructed, phrases always have the same (context-independent) label, while we may get a more accurate (and possibly different) picture from introducing additional means of quality control (which in turn increases the necessary investment for such a sentiment treebank).

7.2 Contrasting SVM and RNTN behaviour

In table 7, we tabulated the classification accuracy for the parent node in different types of productions in HeiST. In this evaluation, we counted a production as correct whenever the parent node has the right sentiment label (in parallel with the *labeled recall* in syntactic evaluation), ignoring for the moment the question whether the production produced by a system falls into the same category. It is easy to see that AVG-type productions are the least error-prone for all classifiers, whereas MWE and INV productions pose a significant challenge for the models. We also see that on these challenging production, the RNTN performs better than the other methods.

8 Summary

We presented a novel dataset for subsentential sentiment classification, which uses the same conventions as the Stanford Sentiment Treebank (SSTb), which is the only German resource of this type besides the smaller (270 sentences) MLSA corpus (Clematide et al., 2012). We performed a systematic exploration into supervised, cross-lingual, and lexicon-based approaches on this dataset and found that, paradoxically, the performance of the state-of-the-art recursive neural tensor network (RNTN) models are severely impeded in this data-sparse situation, unlike latent-variable models for syntax which can deal with such conditions quite well: Lavelli and Corazza (2009), for example, reports that the best results for parsing on the very small TUT treebank (slightly more than 2000 sentences) can be achieved using a PCFG-LA model.

We showed that a wide variety of models – from lexicon-based sentiment prediction over SVM with unigram features to crosslingual classification – performs better than the RNTN, and that methods to improve RNTN performance that work in other settings (syntax) do not offer any easy fix.

In a second step, we took a closer look at the crowdsourced data in order to explain certain counterintuitive results (such as the fact that most sentiment lexicons do not benefit from negation handling, or that the *upper* baseline achievable with the RNTN by getting gold-standard information on positive and negative words is at about the same level as our SVM classifier), and found that SSTb-type resources show marked differences from e.g., the MLSA dataset as they incorporate *multiword* items, but seem to be challenging for the study of compositionality due to noise that is not present in expert-annotated resources.

Cost Optimization for Crowdsourcing Translation

Mingkun Gao, Wei Xu and **Chris Callison-Burch**
Computer and Information Science Department
University of Pennsylvania, Philadelphia, PA, USA
{gmingkun, xwe, ccb}@seas.upenn.edu

Abstract

Crowdsourcing makes it possible to create translations at much lower cost than hiring professional translators. However, it is still expensive to obtain the millions of translations that are needed to train statistical machine translation systems. We propose two mechanisms to reduce the cost of crowdsourcing while maintaining high translation quality. First, we develop a method to reduce redundant translations. We train a linear model to evaluate the translation quality on a sentence-by-sentence basis, and fit a threshold between acceptable and unacceptable translations. Unlike past work, which always paid for a fixed number of translations for each source sentence and then chose the best from them, we can stop earlier and pay less when we receive a translation that is good enough. Second, we introduce a method to reduce the pool of translators by quickly identifying bad translators after they have translated only a few sentences. This also allows us to rank translators, so that we re-hire only good translators to reduce cost.

1 Introduction

Crowdsourcing is a promising new mechanism for collecting large volumes of annotated data at low cost. Many NLP researchers have started creating speech and language data through crowdsourcing (for example, Snow et al. (2008), Callison-Burch and Dredze (2010) and others). One NLP application that has been the focus of crowdsourced data collection is statistical machine translation (SMT) which requires large bilingual sentence-aligned parallel corpora to train translation models. Crowdsourcing's low cost has made it possible to hire people to create sufficient volumes of translation in order to train SMT systems (for example, Ambati and Vogel (2010), Zbib et al. (2012), Post et al. (2012), Zbib et al. (2013)).

However, crowdsourcing is not perfect, and one of its most pressing challenges is how to ensure the quality of the data that is created by it. Unlike in more traditional employment scenarios, where annotators are pre-vetted and their skills are clear, in crowdsourcing very little is known about the annotators. They are not professional translators, and there are no built-in mechanisms for testing their language skills. They complete tasks without any oversight. Thus, translations produced via crowdousrcing may be low quality. Previous work has addressed this problem, showing that non-professional translators hired on Amazon Mechanical Turk (MTurk) can achieve professional-level quality, by soliciting multiple translations of each source sentence and then choosing the best translation (Zaidan and Callison-Burch, 2011).

In this paper we focus on a different aspect of crowdsourcing than Zaidan and Callison-Burch (2011). We attempt to achieve the same high quality while **minimizing the associated costs**. We propose two complementary methods: (1) We reduce the number of translations that we solicit for each source sentence. Instead of soliciting a fixed number of translations for each foreign sentence, we stop soliciting translations after we get an acceptable one. We do so by building models to distinguish between

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 705–713,
Denver, Colorado, May 31 – June 5, 2015.

acceptable translations and unacceptable ones. (2) We reduce the number of workers we hire, and retain only high quality translators by quickly identifying and filtering out workers who produce low quality translations. Our work stands in contrast with Zaidan and Callison-Burch (2011) who always solicited and paid for a fixed number of translations for each source sentence, and who had no model of annotator quality.

In this paper we demonstrate that:

- Our model can predict whether a given translation is acceptable with high accuracy, substantially reducing the number of redundant translations needed for every source segment.
- Translators can be ranked well even when observing only small amounts of data. Compared with a gold standard ranking, we achieve a correlation of 0.94 after seeing the translations of only 20 sentences from each worker. Therefore, bad workers can be filtered out quickly.
- We can achieve a similar BLEU score as Zaidan and Callison-Burch (2011) at half the cost using our cost optimizing methods.

2 Problem Setup

We start with a corpus of source sentences to be translated, and we may solicit one or more translation for every sentence in the corpus. Our targeted task is to assemble a single high quality translation for each source sentence while minimizing the associated cost. This process can be repeated to obtain multiple high quality translations.

We study the data collected by Zaidan and Callison-Burch (2011) through Amazon's Mechanical Turk. They hired Turkers to translate 1792 Urdu sentences from the 2009 NIST Urdu-English Open Machine Translation Evaluation set[1]. A total of 52 Turkers contributed translations. Turkers also filled out a survey about their language skills and their countries of origin. Each Urdu sentence was translated by 4 non-professional translators (the Turkers) and 4 professional translators hired by the LDC. The cost of non-professional translation was \$0.10 per sentence and we estimate the cost of professional translation to be approximately \$0.30 per word (or \$6 per sentence, with 20 words on average).

Following Zaidan and Callison-Burch (2011), we use BLEU (Papineni et al., 2002) to gauge the quality of human translations. We can compute the expected quality of professional translation by comparing each of the professional translators against the other 3. This results in an average BLEU score of 42.38. In comparison, the average Turker translations score only 28.13 without quality control. Zaidan and Callison-Burch trained a MERT (Och, 2003; Zaidan, 2009) model to select one non-professional translation out of the four and pushed the quality of crowdsourcing translation to 38.99, closer to the expected quality of professional translation. They used a small amount of professional translations (10%) as calibration data to estimate the goodness of the non-professional translation. The component costs of their approach are the 4 non-professional translations for each source sentence, and the professional translations for the calibration data.

Although Zaidan and Callison-Burch demonstrated that non-professional translation was significantly cheaper than professionals, we are interested in further reducing the costs. Cost reduction plays an important role if we want to assemble a large enough parallel corpus to train a statistical machine translation system which typically require millions of translated sentences. Here, we introduce several methods for reducing the number of non-professional translations while still maintaining high quality.

3 Estimating Translation Quality

We use a linear regression model[2] to predict a quality score ($score(t) \in \mathbb{R}$) for an input translation t.

$$score(t) = \vec{w} \cdot \vec{f}(t)$$

where $\vec{w}$ is the associated weight vector and $\vec{f}(t)$ is the feature vector of the translation t.

We replicate the feature set used by Zaidan and Callison-Burch (2011) in their MERT model:

- Sentence-level features: 9 features based on

[1] LDC Catalog number LDC2010T23

[2] We used WEKA package: `http://www.cs.waikato.ac.nz/ml/weka/`

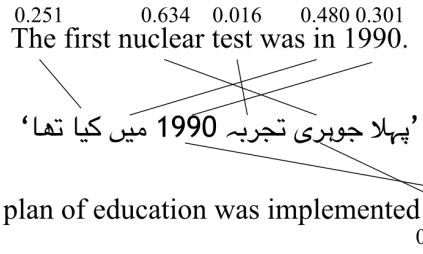

Figure 1: Example bilingual features for two crowdsourced translations of an Urdu sentence. The numbers are alignment probabilities for each aligned word. The bilingual feature is the average of these probabilities, thus 0.240 for the good translation and 0.043 for the bad translation. Some words are not aligned if potential word pairs don't exist in bilingual training corpus.

language model, sentence length and edit distance to other translations.

- Worker-level features: 15 features based on worker's language ability, location and average sentence-level scores.
- Ranking features: 3 features based on the judgments of monolingual English speakers' ranking the translations from best to worst.
- Calibration features: 1 feature based on the average BLEU score of a worker's translations provided is computed against professional references.

We additionally introduce a new bilingual feature based on IBM Model 1. We align words between each candidate translation and its corresponding source sentence. The bilingual feature is the average of its alignment probabilities between words in the source sentence and words in the Turker's translation. In Figure 1, we show how the bilingual feature allows us to distinguish between a valid translation (top) and an invalid/spammy translation (bottom).

4 Reducing the Number of Translations

The first way that we optimize cost is to solicit fewer redundant translations. The strategy is to recognize when we have got a good translation of a source sentence and to immediately stop purchasing additional translations of that sentence. The crux of this method is to decide whether a translation is 'good enough,' in which case we do not gain any benefit from paying for another redundant translation.

Algorithm 1 How good is good enough

Input: δ, the allowable deviation from the expected upper bound on BLEU score (using all redundant translations); α, the upper bound BLEU score; a training set $S = \{\vec{f}^{s}_{i,j}, y^{s}_{i,j})^{j=1..m}_{i=1..n}\}$ and a validation set $V = \{(\vec{f}^{v}_{i,j}, y^{v}_{i,j})^{j=1..m}_{i=1..n}\}$ where $\vec{f}_{i,j}$ is the feature vector for $t_{i,j}$ which is the jth translation of the source sentence s_i and $y_{i,j}$ is the label for $\vec{f}_{i,j}$.
Output: θ, the threshold between acceptable and unacceptable translations; $\vec{w}$, a linear regression model parameter.

initialize $\theta \leftarrow 0$,$\vec{w} \leftarrow \emptyset$
$\vec{w'} \leftarrow$ train a linear regression model on S
$maxbleu \leftarrow$ select best translations for each $s_i \in S$ based on the model parameter $\vec{w'}$ and record the highest model predicted BLEU score
while $\theta \neq maxbleu$ **do**
  for $i \leftarrow 1$ to n **do**
    for $j \leftarrow 1$ to m **do**
      if $\vec{w'} \cdot \vec{f}^{v}_{i,j} > \theta \wedge j < m$ **then** select $t^{v}_{i,j}$ for s_i and **break**
      if $j == m$ **then** select $t^{v}_{i,m}$ for s_i
  $q \leftarrow$ calculate translation quality for V
  if $q > \delta \cdot \alpha$ **then break**
  else $\theta = \theta + stepsize$
$\vec{w} \leftarrow$ train a linear regression model on $S \cup V$
Return: θ and model parameter $\vec{w}$

Our translation reduction method allows us to set an empirical definition of 'good enough'. We define an Oracle upper bound α to be the estimated BLEU score using the full set of non-professional translations. We introduce a parameter δ to set the allowable degradation in translation quality. We train a model to search for a threshold θ between acceptable and unacceptable translations for a specific value of δ. For instance, we may fix δ at 95%, meaning that the resulting BLEU score should not drop below 95% of the α after reducing the number of translations.

For a new translation, our model scores it, and if its score is higher than θ, then we do not solicit another translation. Otherwise, we continue to so-

δ(%)	BLEU Score	# Trans.
90	36.26	1.63
91	36.66	1.69
92	36.93	1.78
93	37.23	1.85
94	37.48	1.93
95	38.05	2.21
96	38.16	2.30
97	38.48	2.47
98	38.67	2.59
99	38.95	2.78
100	39.54	3.18

Table 1: The relationship between δ (the allowable deviation from the expected upper bound on BLEU score), the BLEU score for translations selected by models from partial sets and the average number of translation candidates set for each source sentence (*# Trans*).

licit translations. Algorithm 1 details the process of model training and searching for θ.

4.1 Experiments

We divide data into a training set (10%), a validation set (10%) and a test set (80%). Each source sentence has four translations in total. We use the validation set to search for θ. The Oracle upper bound on BLEU is set to be 40.13 empirically. We then vary the value of δ from 90% to 100%, and sweep values of θ by incrementing it in step sizes of 0.01. We report results based on a five-fold cross validation, rotating the training, validation and test sets.

4.1.1 Baseline and upper bound

The baseline selection method of randomly picking one translation for each source sentence achieves a BLEU score of 29.56. To establish an upper bound on translation quality, we perform an oracle experiment to select best translation for each source segment from full sets of candidates. It reaches a BLEU score of 40.13.

4.1.2 Translation reducing method

Table 1 shows the results for translation reducing method. The δ variable correctly predicts the deviation in BLEU score when compared to using the full set of translations. If we set $\delta < 0.95$ then we lose 2 BLEU points, but we cut the cost of translations in half, since we pay for only two translations of each source segment on average.

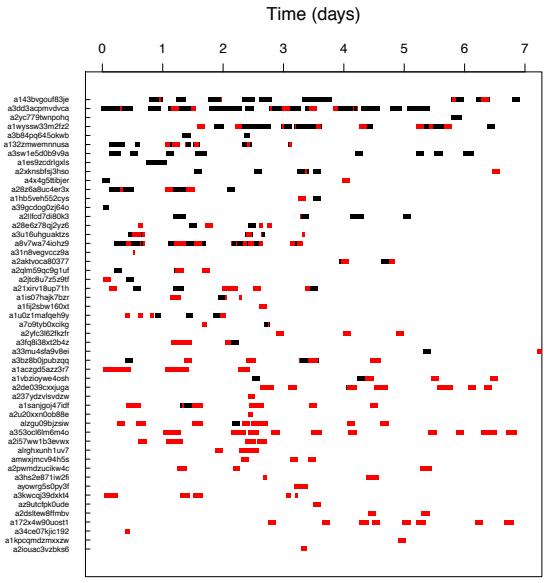

Figure 2: A time-series plot of all of the translations produced by Turkers (identified by their WorkerID serial number). Turkers are sorted with the best translator at the top of the y-axis. Each tick represent a single translation and black means better than average quality.

5 Choosing Better Translators

The second mechanism that we use to optimize cost is to reduce the number of non-professional translators that we hire. Our goal is to quickly identify whether Turkers are good or bad translators, so that we can continue to hire only the good translators and stop hiring the bad translators after they are identified as such. Before presenting our method, we first demonstrate that Turkers produce consistent quality translations over time.

5.1 Turkers' behavior in translating sentences

Do Turkers produce good (or bad) translations consistently or not? Are some Turkers consistent and others not? We used the professional translations as a gold-standard to analyze the individual Turkers, and we found that most Turkers' performance stayed surprisingly consistent over time.

Figure 2 illustrates the consistency of workers' quality by plotting quality of their individual translations on a timeline. The translation quality is com-

puted based on the BLEU against professional translations. Each tick represent a single translation and depicts the BLEU score using two colors. The tick is black if its BLEU score is higher than the median and it is red otherwise. Good translators tend to produce consistently good translations and bad translators rarely produce good translations.

5.2 Evaluating Rankings

We use weighted Pearson correlation (Pozzi et al., 2012) to evaluate our ranking of workers against gold standard ranking. Since workers translated different number of sentences, it is more important to rank the workers who translated more sentences correctly. Taking the importance of workers into consideration, we set a weight to each worker using the number of translations he or she submitted when calculating the correlation. Given two lists of worker scores *x* and *y* and the weight vector *w*, the weighted Pearson correlation ρ can be calculated as:

$$\rho(x, y; w) = \frac{cov(x, y; w)}{\sqrt{cov(x, x; w) cov(y, y; w)}} \quad (1)$$

where cov is weighted covariance:

$$cov(x, y; w) = \frac{\sum_i w_i (x_i - m(x; w))(y_i - m(y; w))}{\sum_i w_i} \quad (2)$$

and m is weighted mean:

$$m(x; w) = \frac{\sum_i w_i x_i}{\sum_i w_i} \quad (3)$$

5.3 Automatically Ranking Translators

We introduce two approaches to rank workers using a small portion of the work that they submitted. The strategy is to filter out bad workers, and to select the best translation from translations provided by the remaining workers. We propose two different ranking methods:

Ranking workers using their first k translations We rank the Turkers using their first few translations by comparing their translations against the professional translations of those sentences. Ranking workers on gold standard data would allow us to discard bad workers. This is similar to the idea of a qualification test in MTurk.

Ranking workers using a model In addition to ranking workers by comparing them against a gold standard, we also attempt to automatically predict their ranks with a model. We use the linear regression model to score each translation and rank workers by their model predicted performance. The model predicted performance of the worker w is:

$$performance(w) = \frac{\sum_{t \in T_w} score(t)}{|T_w|} \quad (4)$$

where T_w is the set of translations completed by the worker w and $score(t)$ is the model predicted score for translation t.

5.4 Experiments

After we rank workers, we keep top-ranked workers and select the best translation only from their translations. For both ranking approaches, we vary the number of good workers that we retain.

We report both rankings' correlation with the gold standard ranking. Since the top worker threshold is varied and since we change the value of k in first k sentence ranking, we have a different test set in different settings. Each test set excludes any items which were used to rank the workers, or which did not have any translations from the top workers according to our rankings.

5.4.1 Gold standard and Baseline

We evaluate ranking quality using the weighted Pearson correlation (ρ) compared with the gold standard ranking of workers. To establish the gold standard ranking, we score each Turker based on the BLEU score comparing all of his or her translations to the corresponding professional references.

We use the ranking by the MERT model developed by Zaidan and Callison-Burch (2011) as baseline. It achieves a correlation of 0.73 against the gold standard ranking.

5.4.2 Ranking workers using their first k translations

Without using any model, we rank workers using their first k translations. We select best translation of each source sentence from the top ranked worker who translated that sentence.

Table 2 shows the results of Pearson correlations for different value of k. As k increases, our rankings

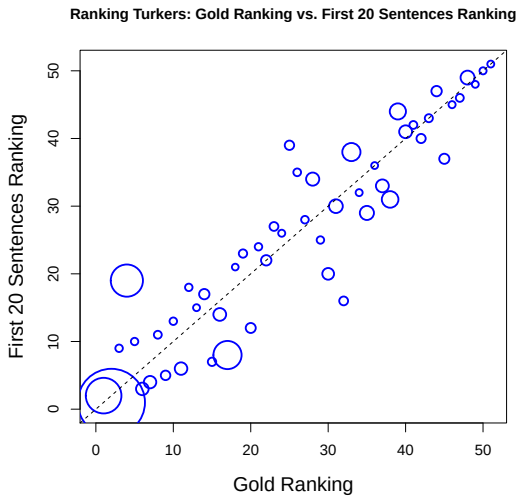

Figure 3: Correlation between gold standard ranking and ranking computed using the first 20 sentences as calibration. Each bubble represents a worker. The radius of each bubble shows the relative volume of translations completed by the worker. The weighted correlation is 0.94.

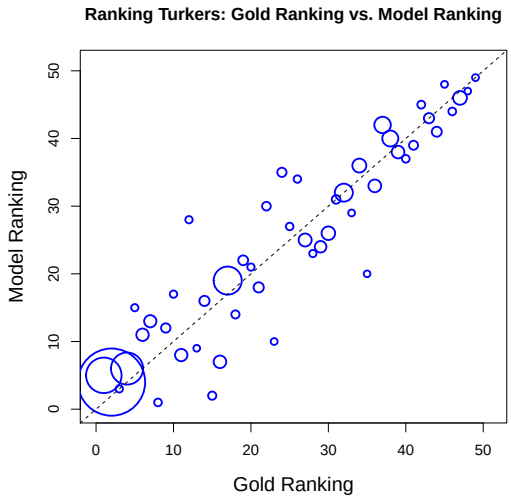

Figure 4: Correlation between gold standard ranking and our model's ranking. The corresponding weighted correlation is 0.95.

fit the gold ranking better. Consequently, we can decide whether to continue to hire a worker in a very short time after analyzing the first k sentences ($k \leq 20$) provided by each worker. Figure 3 shows the correlation of gold ranking and the ranking based on workers' first 20 sentences.

5.4.3 Ranking workers using a model

We train a linear regression model on 10% of the data to rank workers. We use the model to select the best translation in one of two ways:

- Using the model's prediction of workers' rank, and selecting the translation from the best worker.
- Using the model's score for each translation and selecting the highest scoring translation of each source sentence.

Table 3 shows that the model trained on all features achieves a very high correlation with the gold standard ranking (Pearson's $\rho = 0.95$), and a BLEU score of 39.80.

Figure 4 presents a visualization of the gold ranking and model ranking. The workers who produce the largest number of translations (large bubbles in the figure) are ranked extremely well.

5.5 Filtering out bad workers

Ranking translators would allow us to reduce costs by only re-hiring top workers. Table 4 shows what happens when we vary the percentage of top ranked workers we retain. In general, the model does a good job of picking the best translations from the remaining good translators. Compared to actually knowing the gold ranking, the model loses only 0.55 BLEU when we filter out 75% of the workers. In this case we only need to solicit two translations for each source sentence on average.

6 Cost Analysis

We have introduced several ways of significantly lowering the costs associated with crowdsourcing translations when a large amount of data are solicited (on the order of millions of samples):

- We show that after we have collected one translation of a source sentence, we can consult a model that predicts whether its quality is sufficiently high or whether we should pay to have the sentence re-translated. The cost savings for non-professionals here comes from reducing the number of redundant translations. We

Proportion of Calibration Data		ρ
First k sentences	Percentage	
1	0.7%	0.21
2	1.3%	0.38
3	2.0%	0.41
4	2.7%	0.56
5	3.3%	0.70
10	6.6%	0.81
20	13.3%	0.94
30	19.9%	0.96
40	26.6%	0.98
50	33.2%	0.98
60	39.8%	0.98

Table 2: Pearson Correlations for calibration data in different proportion. The percentage column shows what proportion of the whole data set is used for calibration.

Feature Set	ρ	BLEU rank	BLEU score
(S)entence features	0.80	36.66	37.84
(W)orker features	0.78	36.92	36.92
(R)anking features	0.81	36.94	35.69
Calibration features	0.93	38.27	38.27
S+W+R features	0.86	37.39	38.69
S+W+R+Bilingual features	0.88	37.59	39.23
All features	**0.95**	**38.37**	**39.80**
Baseline (MERT)	0.73	-	38.99

Table 3: Correlation (ρ) and translation quality for the various features used by our model. Translation quality is computed by selecting best translations based on model-predicted ranking for workers (rank) and model-predicted scores for translations (score). Here we do not filter out bad workers when selecting the best translation.

can save almost half of the cost associated with non-professional translations to get 95% of the translation quality using the full set of redundant translations.

- We show that we can quickly identify bad translators, either by having them first translate a small number of sentences to be tested against professional translations, or by estimating their performance using a feature-based linear regression model. The cost savings for non-professionals here comes from not hiring bad workers. Similarly, we reduce the non-professional translation cost to the half of the original cost.
- In both cases we need some amount of professionally translated materials to use as a gold standard for calibration. Although the unit cost for each reference is much higher than the unit cost for each non-professional translation, the cost associated with non-professional translations can dominate the total cost since the large amount of data need to be collected. Thus, we focus on reducing cost associated with non-professional translations.

Top (%)	BLEU random	BLEU model	BLEU gold	Δ	# Trans
25	29.85	38.53	39.08	0.55	1.95
50	29.80	38.40	39.00	0.60	2.73
75	29.76	38.37	38.98	0.61	3.48
100	29.83	38.37	38.99	0.62	4.00

Table 4: A comparison of the translation quality when we retain the top translators under different rankings. The rankings shown are random, the model's ranking (using all features from Table 3) and the gold ranking. Δ is the difference between the BLEU scores for the gold ranking and the model ranking. # Trans is the average number of translations needed for each source sentence.

7 Related Work

Sheng et al. (2008) focused on training a machine learning model from noisy labels. We cannot always get high-quality labeled data from crowdsourcing, but we can still ensure that a model trained on the data is accurate by redundantly labeling the data. Sheng et al. (2008) proposed a framework for repeated-labeling that resolves the uncertainty in labeling via majority voting. The experimental results show that a model's accuracy is improved even if labels in its training data are noisy and imperfect. As long as the integrated quality (the probability of the integrated labeling being correct) is higher than 0.5, repeated labeling benefits model training.

Passonneau and Carpenter (2013) created a Bayesian model of annotation. They applied it to the problem of word sense annotation. Passonneau and Carpenter (2013) also proposed an approach to detect and avoid spam workers. They measured the

performance of worker by comparing worker's labels to the current majority labels. Workers with bad performance can be identified and blocked.

Lin et al. (2014) examined the relationship between worker accuracy and budget in the context of using crowdsourcing to train a machine learning classifier. They show that if the goal is to train a classifier on the labels, that the properties of the classifier will determine whether it is better to re-label data (resulting in higher quality labels) or get more single labeled items (of lower quality). They showed that classifiers with weak inductive bias benefit more from relabeling, and that relabeling is more important when worker accuracy is low.

Novotney and Callison-Burch (2010) showed a similar result for training an automatic speech recognition (ASR) system. When creating training data for an ASR system, given a fixed budget, their system's accuracy was higher when it is trained on more low quality transcription data compared to when it was trained on fewer high quality transcriptions.

8 Conclusion

In this paper, we propose two mechanisms to optimize cost: a translation reducing method and a translator reducing method. They have different applicable scenarios for large corpus construction. The translation reducing method works if there exists a specific requirement that the quality must reach a certain threshold. This model is most effective when reasonable amounts of pre-existing professional translations are available for setting the model's threshold. The translator reducing method is very simple and easy to implement. This approach is inspired by the intuition that workers' performance is consistent. The translator reducing method is suitable for crowdsourcing tasks which do not have specific requirements about the quality of the translations, or when only very limited amounts of gold standard data is available.

Abstract

We investigate the problem of predicting the quality of automatic speech recognition (ASR) output under the following rigid constraints: *i)* reference transcriptions are not available, *ii)* confidence information about the system that produced the transcriptions is not accessible, and *iii)* training and test data come from multiple domains. To cope with these constraints (typical of the constantly increasing amount of automatic transcriptions that can be found on the Web), we propose a domain-adaptive approach based on multitask learning. Different algorithms and strategies are evaluated with English data coming from four domains, showing that the proposed approach can cope with the limitations of previously proposed single task learning methods.

1 Introduction

The variety of applications for large vocabulary speech recognition technology (LVCSR) is rapidly growing. For instance, automatic transcriptions are now used, either *as-is* or as rough material to be checked and corrected by humans, for captioning and subtitling DVD movies, Youtube videos, TV programs and recordings in noisy environments such as meetings and teleconferences. To enable further integration in these and other scenarios, the improvement of the core automatic speech recognition (ASR) technology should go hand in hand with the development of evaluation methods adequate to address new needs and constraints. Indeed, the standard evaluation protocol, based on computing the word error rate of transcription hypotheses against reference transcripts,[1] is not always a viable solution.

In terms of *needs*, the aforementioned applications call for efficient and replicable evaluation methods suitable for real-time processing. While the availability of manually-created reference transcripts is a core ingredient for system development, tuning and lab testing, their use for on-field evaluation (*i.e.* during the actual use) is impractical for obvious reasons (*i.e.* the need of a quick response).

In terms of *constraints*, the problem is that ASR technology is often used as a black-box, that is, without any knowledge of how the transcriptions are generated.[2] This calls for techniques capable to estimate ASR output quality under the rigid constraint of having, as a basic source of information, only the spoken utterance (the acoustic signal) and the transcription itself. Indeed, the invaluable information provided by current confidence estimation methods (*e.g.* word posterior probabilities (Evermann and Woodland, 2000; Wessel et al., 2001), consensus decoding (Mangu et al., 2000) and minimum Bayes-risk decoding (Xu et al., 2010)) is not accessible when evaluating the output of an unknown system.

[1]The word error rate (WER) is the minimum edit distance between an hypothesis and the reference transcription. Edit distance is calculated as the number of edits (word insertions, deletions, substitutions) divided by the number of words in the reference.

[2]For instance, as announced by Google, in 2012 about 157 million YouTube videos in 10 languages already featured captions generated by a black-box ASR system (source: http://techcrunch.com/2012/06/15/youtube-launches-auto-captions-in-spanish/).

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 714–724,
Denver, Colorado, May 31 – June 5, 2015.

To cope with these issues, Negri et al. (2014) proposed a reference-free ASR *quality estimation* (QE) method capable to operate both in a glass-box (*i.e.* having access to confidence information) and in a black-box fashion (*i.e.* without any knowledge about the ASR system's inner workings). According to the authors, despite the promising evaluation results, the supervised learning approach adopted has a main limitation: the degradation in performance when models are trained on non-homogeneous data that comes from different domains, speakers, or systems. However, although empirical evidence of this limitation is provided, the robustness of ASR QE systems to the heterogeneity of training and test data is left as an open issue.

Filling this gap, which is the goal of this paper, would be a significant step towards real-time ASR output evaluation, and its seamless integration in a number of application frameworks. Along this direction, we propose and evaluate a supervised domain adaptation technique based on *multitask learning* (Caruana, 1997). Our approach aims to exploit training data coming from different "domains" (in a broad sense, *e.g.* different genres, speakers, topics, styles, etc.) and to obtain ASR QE models that are robust to differences with respect to the test data. Experiments are carried out with English data coming from four domains, and by comparing different algorithms and strategies.

Overall, our contributions can be summarized as follows:

- Multitask learning (MTL) is investigated for the first time in the ASR QE scenario, as a way to cope with the dissimilarity between training and test data coming from multiple domains.

- The QE problem is approached both as a regression (assignment of real-valued quality labels) and as a binary classification task (assignment of 'good'/'bad' labels according to a given, arbitrary WER threshold). The latter task is introduced as a preliminary study.

- Results are thoroughly analyzed, considering both the amount of training data coming from the different domains and the relative distance between their distributions.

2 Related Work

In the ASR field, most prior works that address the reference-free estimation of output quality fall into the confidence estimation (CE) framework. In this framework, the reliability of a transcription is estimated from the system's standpoint, that is, as a function of the process that generated the transcription (Sukkar and Lee, 1996; Evermann and Woodland, 2000; Wessel et al., 2001; Sanchis et al., 2012; Seigel, 2013, *inter alia*). In CE, the information available to the estimator covers all the aspects of the decoding process (*e.g.* word posterior probabilities, n-best lists, hypotheses density, language model scores). Although related to our problem, CE hence builds on a strong assumption (*i.e.* the ASR system is known), which does not hold in many situations.

Quality estimation, instead, operates in the least favorable condition in which, besides the lack of references, the ASR system is regarded as a "black-box". To our knowledge, the study proposed in (Negri et al., 2014) is the most relevant related work along this direction. In their investigation, the authors run a set of experiments aimed to predict the WER of automatically transcribed utterances in different testing conditions (by varying the distance between training and test data), with different state-of-the-art learning algorithms (all for regression), and with different groups of features (the so called "black-box" and "glass-box" feature groups). The major problem emphasized in their analysis is the strong dependency between QE models and the degree of homogeneity of training and test data. From the application perspective, this is a severe limitation since (as in any other supervised learning setting) the similarity of training and test sets is a strong requirement that should be bypassed (possibly with minimal loss in performance). This issue, which has not been addressed yet, is the starting point of our investigation.

Another aspect that so far has been disregarded concerns the type of estimates that a model should return. Indeed, while ASR QE has been explored as a regression task (*i.e.* aiming to return real-valued quality estimates), nothing has been done to approach it as a classification problem (*i.e.* assigning quality estimates chosen from two or more classes). In classification mode, we return explicit good/bad

labels based on a fixed, application-dependent quality criterion defined a priori (a threshold set on training data). Since the way to present the quality estimates can have interesting effects on their practical use, the impact of the aforementioned learning problem on a supervised classification setting is another aspect that deserves investigation and motivates our work.

3 Multitask Learning for Adaptive ASR Quality Estimation

The problem of dealing with different distributions between training and test data is broadly investigated by the machine learning community. In particular, approaches for dealing with domain drift are proposed within the scope of *transfer learning*, whose aim is to explore knowledge from one or more source tasks (henceforth, we use the terms domain and task interchangeably) and apply it to a target task (Pan and Yang, 2010). In this paper we use a transfer learning technique called *multitask learning* (MTL), which explores domain-specific training signals of related tasks to improve model generalization (Caruana, 1997).

MTL is an inductive transfer method that assumes that the tasks are related and share a certain structure that allows knowledge transfer. In early works, for instance, these shared structures are the hidden layers of a neural network (Caruana, 1997).[3] The authors showed that MTL improves over learning each task in isolation (called single task learning, STL henceforth) for different problems. Several approaches to MTL have been proposed and each makes different assumptions about the structure shared among the tasks. In this work we explore three different MTL algorithms that deal with task relatedness in different ways.

Before defining each one of the three approaches, we introduce some basic notation previously used by Chen et al. (2011). In MTL there are $K \in \mathbb{N}$ tasks and each task $k \in [1, K]$ has m_k training instances $\{(\mathbf{x}_1, y_1), \ldots, (\mathbf{x}_{m_k}, y_{m_k})\}$, with $\mathbf{x}_i \in \mathbb{R}^d$ where d is the number of features and $y_i \in \mathbb{R}$ is the output (the response variable or label). For each task, the input features and labels form two different matrices $\mathbf{X}_{(k)} = [\mathbf{x}_{1,(k)}, \ldots, \mathbf{x}_{m_k,(k)}]$ and $\mathbf{Y}_{(k)} = [y_{1,(k)}, \ldots, y_{m_k,(k)}]$, respectively. The weights of the features for all tasks are represented by matrix $\mathbf{W}$, where each column corresponds to a task and each row corresponds to a feature. The function $\mathcal{L}(\mathbf{W}, \mathbf{X}, \mathbf{Y})$ is the loss function defined for each algorithm. We work with two loss functions:

- Least squares (for regression), defined as $(\mathbf{X}_{(k)}^T \mathbf{W}_k - \mathbf{Y}_{(k)})^2$, where k is the task identifier and $\mathbf{W}_k$ is the k-th column of $\mathbf{W}$;
- Logistic Regression (for classification), defined as $\log(1 + \exp(-\mathbf{Y}_{(k)} \mathbf{X}_{(k)}^T \mathbf{W}_k))$.

MTL Lasso. This algorithm extends the idea of the Lasso (Tibshirani, 1996) to the MTL setting. In MTL Lasso the ℓ_1-norm (the sum of the absolute values of the weights vector, given by $\sum_{i=1}^{d} |w_i|$) is applied to all the tasks at once (the $||\mathbf{W}||_1$ component in Eq. 1). The $\lambda \in [0, 1]$ parameter controls the level of regularization applied to the model. In other words, the sparsity of the predicted model is controlled via λ which weights the ℓ_1-norm across all tasks.

$$\min_W \sum_{k=1}^{K} \mathcal{L}(\mathbf{W}_k, \mathbf{X}_{(k)}, \mathbf{Y}_{(k)}) + \lambda ||\mathbf{W}||_1 \qquad (1)$$

MTL L21. This algorithm (Argyriou et al., 2007) learns a low-dimensional representation of the features across tasks, and induces sparsity on the feature weights for all the tasks at the same time. This is achieved through the use of a group regularizer that penalizes the weights matrix $\mathbf{W}$ with the $\ell_{2,1}$-norm (Eq. 2). This norm is defined as $||\mathbf{W}||_{2,1} = \sum_{i=1}^{d} ||\mathbf{W}_i||_2$, where d is the number of features and $\mathbf{W}_i$ is the i-th row of $\mathbf{W}$. It is obtained by first computing the 2-norm of each row in $\mathbf{W}$ (the features) and then computing the 1-norm over the resulting vector. The 2-norm of a vector is given by $||\mathbf{x}||_2 = \sqrt{\sum_i x_i^2}$. The parameter $\lambda \in [0, 1]$ controls the regularization applied to the model. MTL L21 assumes that all tasks share the same feature representation.

[3] Another intuitive example of transferable knowledge is the fact that, for some domains, a fraction of the extracted features can show a correlated behavior.

$$\min_{W} \sum_{k=1}^{K} \mathcal{L}(\mathbf{W}_k, \mathbf{X}_{(k)}, \mathbf{Y}_{(k)}) + \lambda ||\mathbf{W}||_{2,1} \quad (2)$$

Robust MTL. This algorithm does not assume that all the tasks share the same feature representation as the previous two algorithms do (Chen et al., 2011). Moreover, RMTL uses two different structures: one for grouping related tasks to share knowledge; the other for identifying irrelevant tasks and keeping them in a different group that does not share information with the first one. This is to cope with situations in which, since tasks are not related, negative transfer of information across tasks might occur, thus harming the generalization of the model. The algorithm approximates task relatedness via a low-rank structure and identifies outlier tasks using a group-sparse structure (column-sparse, at task level). RMTL minimizes the expression described in 3. It employs a non-negative linear combination of the trace norm (the task relatedness component $\mathbf{L}$) and a column-sparse structure induced by the $\ell_{1,2}$-norm (the outlier task detection component $\mathbf{S}$). If a task is an outlier it will have non-zero entries in $\mathbf{S}$.

$$\min_{W} \sum_{k=1}^{K} \mathcal{L}(\mathbf{W}_k, \mathbf{X}_{(k)}, \mathbf{Y}_{(k)}) + \lambda_l ||\mathbf{L}||_* + \lambda_s ||\mathbf{S}||_{1,2} \quad (3)$$

In Eq. 3 $\mathbf{W}$ is subject to $\mathbf{L} + \mathbf{S}$, where $||.||_*$ is the trace norm, given by the sum of the singular values σ_i of $\mathbf{W}$, and $||\mathbf{S}||_{1,2}$ is the group regularizer that induces sparsity on the tasks. It is obtained by first computing the ℓ_1-norm over the columns of $\mathbf{W}$ and then applying the ℓ_2-norm over the resulting vector. The λ_l and λ_s parameters control the level of regularization of $\mathbf{L}$ and $\mathbf{S}$, respectively.

All the MTL algorithms presented in this section are linear, with different regularization terms. While RMTL is only defined for regression, the other algorithms are defined for both regression and classification.

4 Experimental Setting

Our experiments aim to measure the capability of MTL methods to learn across different domains. To this aim, the algorithms[4] previously described are compared with the STL baseline, both in regression and in binary classification. Given a set of *(signal, transcription, WER)* tuples as training instances, our task is to label new unseen *(signal, transcription)* test pairs with a WER prediction (regression models) or with a good/bad tag (classification models) depending on the quality of the transcription.

In classification, the class boundary is defined a priori, according to an arbitrary threshold τ set on the WER of the instances: those with a $WER \leq \tau$ will be considered as positive examples while the others will be considered as negative examples. Different thresholds can be set to experiment with testing conditions that reflect a variety of application-oriented requirements. We work at one extreme, in which a value of τ close to zero (0.05) emphasizes systems' ability to precisely identify high-quality transcriptions (those with $WER \leq \tau$). Any application that requires precise judgments to isolate high-quality ASR output can potentially benefit of such optimization (*e.g.* data selection for acoustic modeling using a QE-based active learning model). The investigation of other thresholding schemes, however, is certainly an aspect that we want to explore in the future.

The small value of τ selected produces a skewed distribution of classes, with a ratio of good to bad labels across the four domains of about 75% "good" and 25% "bad". To cope with this issue, we use a sample weighting technique while training the classification models (Veropoulos et al., 1999). We assign a weight w to each of the training instances, computed as the inverse of its class frequency in the training set. In other words, w is obtained by dividing the total number of training samples by the number of training samples belonging to the class of the given utterance.

4.1 Data

Our datasets include English audio recordings from four different domains: broadcast news (henceforth News), political speeches (Legal), weather reports (Weather) and talks of single speakers in the context of the TED talks (TED). All datasets (see Table 1 for details) were used in past ASR evaluation campaigns, and are provided with manual reference transcriptions associated to each audio recording.

[4] In our experiments we used the implementations available in the Malsar toolkit (Zhou et al., 2012)

	News	Legal	Weather	TED
Total dur. (min)	150	338	108	340
# running words	26,282	53,846	23,722	41,545
# utterances	737	2,922	1,290	2,245
# speakers	178	95	36	28
Avg. utt. dur. (s)	12.2	6.9	5.0	9.1
WER	17.7	20.4	11.9	22.9

Table 1: Some characteristics of the four domains.

News. We use the HUB4[5] corpus, which contains 104 hours of broadcasts from different television and radio networks. We selected the 1999 test set of the DARPA Hub-4 evaluation, consisting of two recordings acquired in TV studios and containing speech of professional speakers reading news.

Legal. This audio database[6] contains recordings of European Parliament members speaking in plenary sessions, as well as recordings of interpreters (non-native speakers). Speech is hence quite spontaneous, and a relevant level of reverberation is present due to the usage of table-mounted microphones. The data that we used for our experiments are both the English EPPS development (dev06) and evaluation (eval07) sets of the 2007 TC-STAR ASR evaluation campaign (Hamon et al., 2007).

Weather. This dataset is formed by recordings of weather reports broadcasted by the BBC English TV channel, and contains both national and local weather forecasts. There are roughly 50 native speakers and the speech is delivered very quickly. Although the speakers are native and the recordings are performed in a controlled environment, there are some hesitations, grammar errors or lengthy formulations in the recordings which are corrected in the captions (which can thus be considered as loose reference transcripts (Mohr et al., 2013)).

TED. This dataset contains audio recordings of English speakers (28 different talks) and was used within the IWSLT 2013 evaluation campaign (Cettolo et al., 2013). This domain presents large variability of topics (hence a large, unconstrained vocabulary), presence of non-native speakers, and a rather informal speaking style.

Given their diverse nature, the four domains present a big challenge both for ASR and QE systems. From Table 1 it is possible to grasp several differences among them. One aspect that reflects such differences is the WER of the ASR system we used to transcribe the utterances (described in Section 4.2). The lowest WER is for Weather, a domain in which the speech is planned. This is also the domain with the shortest average utterance duration (5 sec.), the lowest number of speakers (36) and the lowest number of running words (23,722). The higher WER achieved on the other domains is due to the more challenging conditions posed by each of them. TED and News include speeches about unconstrained topics, and their average utterance durations tend to be longer than for the other two domains. News is the shortest domain in duration and the smallest in number of utterances (150 min. for 737 utterances), but has the highest number of speakers. This means that there are very few utterances for each speaker, in average, and that both the ASR and the QE system must cope with the differences in speech for all these subjects. Legal presents the second largest number of speakers, both native and non-native, using a specific terminology on a varied number of topics.

4.2 ASR System

The ASR engine used in our experiments makes use of Hidden Markov Models (HMMs) of triphone units and of 4-gram back-off language models (LMs). HMMs are trained on domain-specific sets of audio data. The HUB4 training corpus is released with "verbatim" transcriptions of the audio signals while, for the other three domains (*i.e.* Legal, Weather and TED), training data have only associated captions, which are not always exact transcriptions of the corresponding audio recordings. To extract audio segments with reliable transcriptions we hence applied a lightly supervised training procedure (Lamel et al., 2001). This resulted in 67 hours of recordings for the Weather domain, 144 hours for TED, 164 hours for News and 100 hours for Legal. For LM training, first, a general purpose LM is trained on the Gigaword text corpus (5th ed.) (Parker et al., 2011) then, it is adapted to all domains, using domain specific text data. Each auto-

[5]distributed by the Linguistic Data Consortium and available at https://catalog.ldc.upenn.edu/docs/LDC2000S88/

[6]http://catalog.elra.info/product_info.php?products_id=1032

matic transcription of the data presented in Table 1 is generated with the corresponding word and time boundaries that are aligned with the reference utterances. This allows us to compute the utterance WER and the features for the various prediction models.

4.3 Features

Our models are trained with the same 52 "*black-box*" features proposed by Negri et al. (2014), which can be categorized in three groups: Signal, Hybrid and Textual. The first group aims to capture the difficulty to transcribe the input and is extracted by looking at the signal segment as a whole. Hybrid features provide a more fine-grained way to capture the transcription difficulty, by linking the signal to the output transcription. Textual features aim to capture the plausibility/fluency of a transcription considering its surface word information.

4.4 Evaluation Metrics

Regression. Our regression models are evaluated in terms of mean absolute error (MAE). The MAE, a standard error measure for regression, is the average of the absolute difference between the prediction $\hat{y_i}$ of a model and the gold standard response y_i for all instances in the test set. As it is an error measure, lower values indicate better performance.

Classification. To handle the imbalanced class distribution, and equally reward the correct classification on both classes, our evaluation is carried out in terms of balanced accuracy (BA – the higher the better), which is computed as the average of the accuracies on the two classes (Brodersen et al., 2010). When the distribution of classes is balanced, BA is equal to the accuracy metric.

4.5 Baselines

Regression. We compare the MTL methods against two baselines. The first one, simple but often hard to beat for regression models, is computed by labeling all the test instances with the *Mean* WER value calculated on the training set. The second baseline is an STL algorithm trained on data from the target domain. The algorithm that we used (STL Elastic henceforth) is the elastic net (Zou and Hastie, 2005). Parameter estimation is performed with 5-fold cross-validation.

Classification. In this setting we also consider two baselines. The first one (*Majority*) is computed by labeling all the test instances with the most frequent label in the training set and, by definition, corresponds to a score of 0.5 in terms of balanced accuracy. The second classification baseline is the logistic regression (STL LogReg henceforth), also known as maximum entropy algorithm (Hastie et al., 2009). We perform parameter optimization for LogReg using stratified 5-fold cross-validation in a randomized search process (Bergstra and Bengio, 2012).

For both STL baselines we selected algorithms[7] that induce linear models and use the same loss functions (least squares for regression and logistic regression for classification) of the MTL methods.

5 Results and Discussion

To mitigate the effect of having considerably different amounts of training data in the four domains, and equally weight their contribution to the learning task, all our models (STL and MTL) are trained using the same number of instances from all the domains and, at most, half of the data available for the smallest domain, News (*i.e.* 362 instances). To analyze performance variations with different amounts of data, we create subsets of the 362 instances, for 10 different sizes ranging from 10% to 100% of the instances for each domain.[8] We repeat this process 30 times by randomly shuffling all the data available for each domain. For each of the resulting learning curves, the plots in this section present the confidence intervals[9] (at 95%) for the 30 different train/test splits.

In addition to the STL model trained only on in-domain data, we also experiment with an STL model trained on the concatenation of the training data of all domains. Its results are, on average, statistically comparable to, or worse than, STL in-domain for both regression and classification.

Regression. Among the three MTL regression algorithms, RMTL achieves the best results in all our

[7] We used the implementations available in Scikit-learn (Pedregosa et al., 2011).

[8] That is, for instance, with 10% of training data from four domains, the total amount of instances is 144 (36*4).

[9] The confidence intervals are used to show whether there are statistically significant differences in performance among the models.

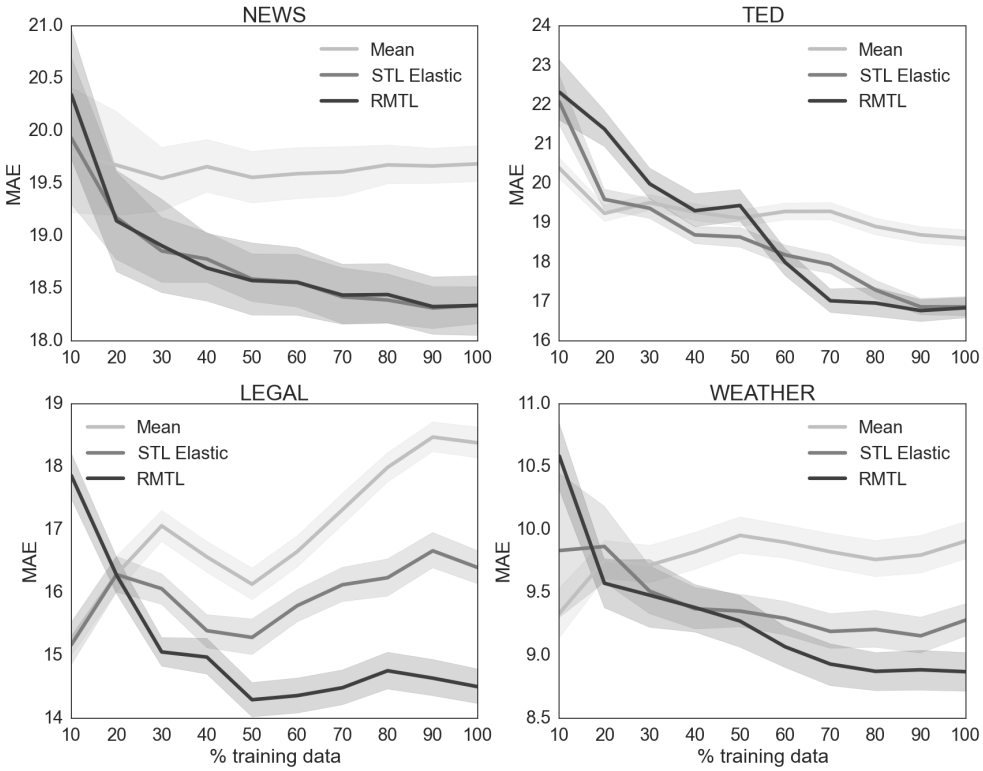

Figure 1: Learning curves for the regression models evaluated on the four domains. The evaluation metric is MAE (↓).

tests. This suggests that its capability to handle domain divergence, thus avoiding negative transfer, is required to increase performance. For the sake of visualization, in the plots in Figure 1 we hence omit the curves of the other MTL methods, keeping only those of RMTL and the two baselines.

As shown in the figure, for the Legal domain, RMTL results are better than those of both the baselines (lower MAE) even with 30% of the data and, except in one case (40% of the data), the improvement over STL (always the stronger baseline) is statistically significant. For Weather and TED, the improvement is less evident: more data are required to outperform the STL baseline (respectively 50% and 60%), the improvements are not always statistically significant and, for TED, the MAE results converge to those of STL with 100% of the data. For the News domain RMTL's performance is always comparable to STL. An interesting behavior can be observed in the Legal domain, in which the Mean baseline degrades as we add training data. This suggests that, even internally to the domain, training and test labels have very different distributions. A smaller degradation is observed for the STL model, which improves over the Mean baseline as it also uses the information captured by the features. The two baselines, however, assume that both training and test data come from similar distributions. Instead, by taking advantage also of the knowledge transferred from the other domains, RMTL allows to cope with the differences between training and test.

Classification. In this setting we compare the MTL algorithms (L21 and Lasso) with the STL (LogReg) and Majority baselines. As shown in Figure 2, the two MTL models (which significantly outperform the Majority baseline in all conditions) always achieve a higher balanced accuracy than single task learning in three domains (TED, Legal and Weather). In the Weather domain, the performance improvement over the STL baseline is always statistically significant when using from 20% to 100% of the training data. For TED and Legal, MTL performance tends to converge to the results of STL when the models are trained on 100% of the data (around 65% BA), with an improvement that remains statis-

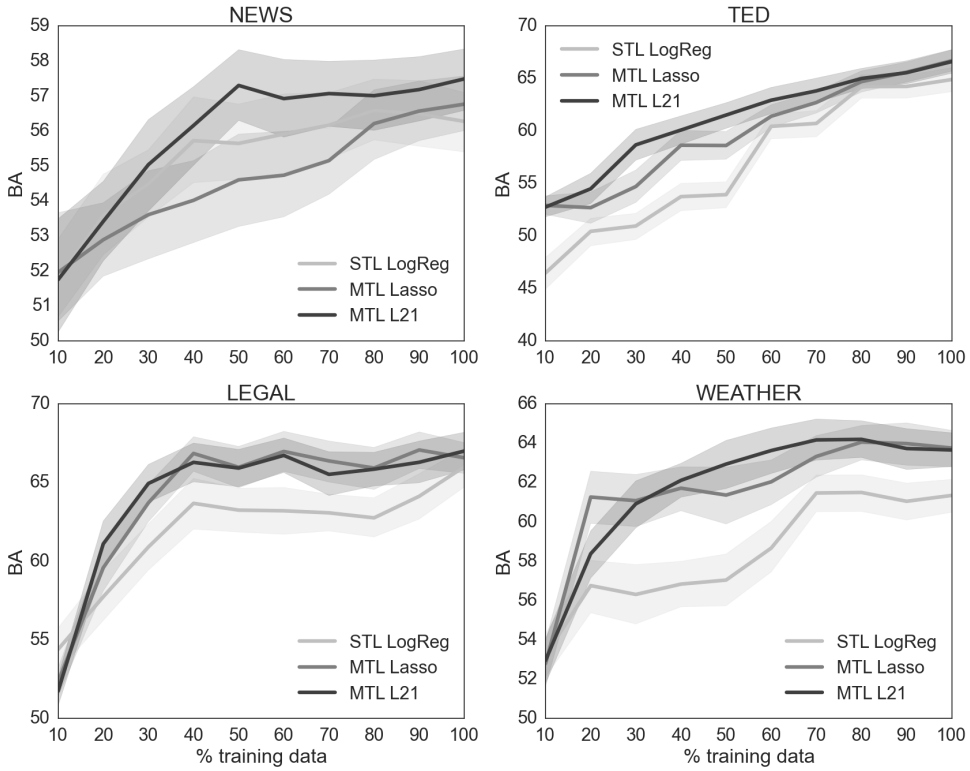

Figure 2: Learning curves for the classification models evaluated on four domains for WER scores with threshold at 0.05. Evaluation is calculated with balanced accuracy (↑).

tically significant only for TED. For the News domain, similar to the regression setting, the improvement of MTL over STL is less evident. Indeed, only L21 outperforms the single task baseline but the difference is not statistically significant.

Our classification results can be explained taking into consideration the distribution of positive and negative instances in each domain. Weather, for which MTL always outperforms STL, has the most balanced distribution (35% good and 65% bad). In the other three domains, instead, the proportion of negative samples is always above 77%. Although in this penalized condition all algorithms are supported by sample weighting, MTL seems to better exploit this technique when the target domain is balanced.

The challenging nature of the data we are using (described in Section 4.1) is corroborated by the moderate performance achieved by STL. Although it is trained with in-domain data, the best STL classification model (for the Legal domain) does not exceed a BA of 66%. In this difficult scenario, the usefulness of MTL is demonstrated by its capability of reaching the best performance of STL with smaller amounts of data in most of the cases (*e.g.* 30% of the data for the Legal domain).

Domains divergence. To further analyze the performance of MTL in regression and classification, following previous works on MTL and domain adaptation in computer vision (Costante et al., 2014; Samanta et al., 2014), we use maximum mean discrepancy (MMD) as a measure of divergence between domains. MMD is an effective way to compare two multivariate distributions p and q by minimizing the difference in Reproducing Kernel Hilbert Space (RKHS) between the means of the projected distributions (Gretton et al., 2012). It is defined as $\sup_{f \in \mathbb{F}} \mathbb{E}_p[f(p)] - \mathbb{E}_q[f(q)]$ where p and q are points sampled i.i.d. from two domains and $f(.)$ is a continuous bounded function on p and q (usually a unit ball function). We measure the pairwise divergences among the domains described in Section 4.1 using the features extracted and a radial basis function kernel. The divergences are presented in Figure 3.

According to the pairwise MMD, the most di-

vergent pair is News-Weather, which is followed by News-Legal. The distance between News and the other domains indicates that, when it is used as target, knowledge transfer from the other domains might be problematic. In fact, looking at the results obtained by classification and regression models for News, we notice that none of the MTL methods achieves significant improvements over the STL baselines. Furthermore, the RMTL regression learning curve (Figure 1) for News shows that RMTL follows the same curve of STL, meaning that it is able to handle the high divergence between News and the other domains and hence, it learns mostly from in-domain data.

In general, the divergence measurements between the domains are relatively high (the values are closer to 1 than to 0). This is not surprising given the intra- and inter-domain variability of speakers and topics, the different conditions in which speech was recorded, and the WER differences across domains. However, the interesting aspect evidenced by the measurements is that MMD allows to successfully approximate such domain differences (and, likely, other more implicit diversity indicators), thus being a useful instrument to measure domain relatedness.

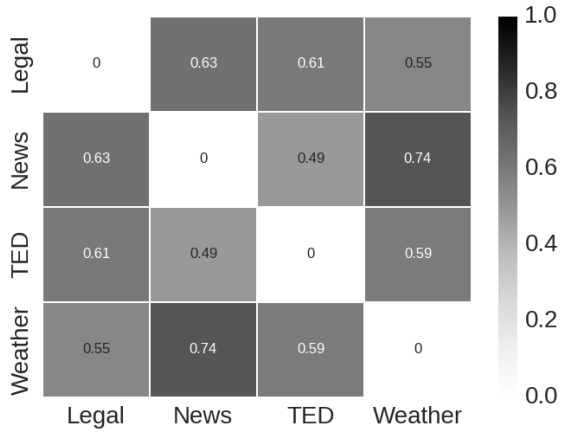

Figure 3: Domains divergence given by MMD (0 means similar and 1 means dissimilar).

6 Conclusion

We presented a supervised approach to ASR quality estimation aimed to cope with large differences between training and test data. To achieve robustness and adaptability to such differences, we exploited the capability of multitask learning, which allows QE models to make the best use of training data coming from multiple domains by transferring knowledge across them. The MTL learning paradigm was applied both in regression mode (WER prediction) and, in a preliminary investigation, for binary classification (assignment of 'good'/'bad' quality labels). In both settings, we experimented with different amounts of English data coming from four very diverse domains (different genres, speakers, topics, and styles).

Our results indicate that MTL, which we used for the first time in ASR QE[10], is able to take advantage of data coming from such heterogeneous domains and to significantly improve over single-task learning baselines both in regression and in classification. Although the extent of the improvement depends on the divergence between the domains (a major issue for any supervised learning task), our results show that in the worst case MTL performance converges to the results of single-task learning. Overall, by suggesting a way to overcome the main limitations of previous approaches, our study opens interesting research avenues towards reference-free, system-agnostic and real-time ASR output evaluation.

Abstract

This paper studies how to incorporate the external word correlation knowledge to improve the coherence of topic modeling. Existing topic models assume words are generated independently and lack the mechanism to utilize the rich similarity relationships among words to learn coherent topics. To solve this problem, we build a Markov Random Field (MRF) regularized Latent Dirichlet Allocation (LDA) model, which defines a MRF on the latent topic layer of LDA to encourage words labeled as similar to share the same topic label. Under our model, the topic assignment of each word is not independent, but rather affected by the topic labels of its correlated words. Similar words have better chance to be put into the same topic due to the regularization of MRF, hence the coherence of topics can be boosted. In addition, our model can accommodate the subtlety that whether two words are similar depends on which topic they appear in, which allows word with multiple senses to be put into different topics properly. We derive a variational inference method to infer the posterior probabilities and learn model parameters and present techniques to deal with the hard-to-compute partition function in MRF. Experiments on two datasets demonstrate the effectiveness of our model.

1 Introduction

Probabilistic topic models (PTM), such as probabilistic latent semantic indexing(PLSI) (Hofmann, 1999) and latent Dirichlet allocation(LDA) (Blei et al., 2003) have shown great success in documents modeling and analysis. Topic models posit document collection exhibits multiple latent semantic topics where each topic is represented as a multinomial distribution over a given vocabulary and each document is a mixture of hidden topics. To generate a document d, PTM first samples a topic proportion vector, then for each word w in d, samples a topic indicator z and generates w from the topic-word multinomial corresponding to topic z.

A key limitation of the existing PTMs is that words are assumed to be uncorrelated and generated independently. The topic assignment for each word is irrelevant to all other words. While this assumption facilitates computational efficiency, it loses the rich correlations between words. In many applications, users have external knowledge regarding word correlation, which can be taken into account to improve the semantic coherence of topic modeling. For example, WordNet (Miller, 1995a) presents a large amount of synonym relationships between words, Wikipedia[1] provides a knowledge graph by linking correlated concepts together and named entity recognizer identifies the categories of entity mentions. All of these external knowledge can be leveraged to learn more coherent topics if we can design a mechanism to encourage similar words, correlated concepts, entities of the same category to be assigned to the same topic.

Many approaches (Andrzejewski et al., 2009; Petterson et al., 2010; Newman et al., 2011) have attempted to solve this problem by enforcing hard and topic-independent rules that similar words should have similar probabilities in all topics, which is

Denver, Colorado, May 31 – June 5, 2015.

questionable in that two words with similar representativeness of one topic are not necessarily of equal importance for another topic. For example, in the *fruit* topic, the words *apple* and *orange* have similar representativeness, while in an *IT company* topic, *apple* has much higher importance than *orange*. As another example, $church$ and $bible$ are similarly relevant to a $religion$ topic, whereas their relevance to an $architecture$ topic are vastly different. Exiting approaches are unable to differentiate the subtleties of word sense across topics and would falsely put irrelevant words into the same topic. For instance, since *orange* and *microsoft* are both labeled as similar to *apple* and are required to have similar probabilities in all topics as *apple* has, in the end, they will be unreasonably allocated to the same topic.

The existing approaches fail to properly use the word correlation knowledge, which is usually a list of word pairs labeled as *similar*. The similarity is computed based on statistics such as co-occurrence which are unable to accommodate the subtlety that whether two words labeled as similar are truly similar depends on which topic they appear in, as explained by the aforementioned examples. Ideally, the knowledge would be word A and B are similar under topic C. However, in reality, we only know two words are similar, but not under which topic. In this paper, we aim to abridge this gap. Gaining insights from (Verbeek and Triggs, 2007; Zhao et al., 2010; Zhu and Xing, 2010), we design a Markov Random Field regularized LDA model (MRF-LDA) which utilizes the external knowledge in a soft and topic-dependent manner to improve the coherence of topic modeling. We define a MRF on the latent topic layer of LDA to encode word correlations. Within a document, if two words are labeled as similar according to the external knowledge, their latent topic nodes will be connected by an undirected edge and a binary potential function is defined to encourage them to share the same topic label. This mechanism gives correlated words a better chance to be put into the same topic, thereby, improves the coherence of the learned topics. Our model provides a mechanism to automatically decide under which topic, two words labeled as similar are truly similar. We encourage words labeled as similar to share the same topic label, but do not specify which topic label they should share, and leave this to be decided by data. In the above mentioned *apple*, *orange*, *microsoft* example, we encourage *apple* and *orange* to share the same topic label A and try to push *apple* and *microsoft* to the same topic B. But A and B are not necessarily the same and they will be inferred according to the fitness of data. Different from the existing approaches which directly use the word similarities to control the topic-word distributions in a hard and topic-independent way, our method imposes constraints on the latent topic layer by which the topic-word multinomials are influenced indirectly and softly and are topic-aware.

The rest of the paper is organized as follows. In Section 2, we introduce related work. In Section 3, we propose the MRF-LDA model and present the variational inference method. Section 4 gives experimental results. Section 5 concludes the paper.

2 Related Work

Different from purely unsupervised topics models that often result in incoherent topics, knowledge based topic models enable us to take prior knowledge into account to produce more meaningful topics. Various approaches have been proposed to exploit the correlations and similarities among words to improve topic modeling instead of purely relying on how often words co-occur in different contexts (Heinrich, 2009). For instance, Andrzejewski et al. (2009) imposes Dirichlet Forest prior over the topic-word multinomials to encode the Must-Links and Cannot-Links between words. Words with Must-Links are encouraged to have similar probabilities within all topics while those with Cannot-Links are disallowed to simultaneously have large probabilities within any topic. Similarly, Petterson et al. (2010) adopted word information as features rather than as explicit constraints and defined a prior over the topic-word multinomials such that similar words share similar topic distributions. Newman et al. (2011) proposed a quadratic regularizer and a convolved Dirichlet regularizer over topic-word multinomials to incorporate the correlation between words. All of these methods directly incorporate the word correlation knowledge into the topic-word distributions in a hard and topic-independent way, which ignore the fact that whether two words are

correlated depends on which topic they appear in.

There are several works utilizing knowledge with more complex structure to improve topic modeling. Boyd-Graber et al. (2007) incorporate the synset structure in WordNet (Miller, 1995b) into LDA for word sense disambiguation, where each topic is a random process defined over the synsets. Hu et al. (2011) proposed interactive topic modeling, which allows users to iteratively refine the discovered topics by adding constraints such as certain set of words must appear together in the same topic. Andrzejewski et al. (2011) proposed a general framework which uses first order logic to encode various domain knowledge regarding documents, topics and side information into LDA. The vast generality and expressivity of this model makes its inference to be very hard. Chen et al. (2013) proposed a topic model to model multi-domain knowledge, where each document is an admixture of latent topics and each topic is a probability distribution over domain knowledge. Jagarlamudi et al. (2012) proposed to guide topic modeling by setting a set of seed words in the beginning that user believes could represent certain topics. While these knowledge are rich in structure, they are hard to acquire in the real world applications. In this paper, we focus on pairwise word correlation knowledge which are widely attainable in many scenarios.

In the domain of computer vision, the idea of using MRF to enforce topical coherence between neighboring patches or superpixels has been exploited by several works. Verbeek and Triggs (2007) proposed Markov field aspect model where each image patch is modeled using PLSA (Hofmann, 1999) and a Potts model is imposed on the hidden topic layer to enforce spatial coherence. Zhao et al. (2010) proposed topic random field model where each superpixel is modeled using a combination of LDA and mixture of Gaussian model and a Potts model is defined on the topic layer to encourage neighboring superpixels to share the same topic. Similarly, Zhu and Xing (2010) proposed a conditional topic random field to incorporate features about words and documents into topic modeling. In their model, the MRF is restricted to be a linear chain, which can only capture the dependencies between neighboring words and is unable to incorporate long range word correlations. Different from these works, the MRF in our model is not restricted to Potts or chain structure. Instead, its structure is decided by the word correlation knowledge and can be arbitrary.

3 Markov Random Field Regularized Latent Dirichlet Allocation

In this section, we present the MRF-LDA model and the variational inference technique.

3.1 MRF-LDA

We propose the MRF-LDA model to incorporate word similarities into topic modeling. As shown in Figure 1, MRF-LDA extends the standard LDA model by imposing a Markov Random Field on the latent topic layer. Similar to LDA, we assume a document possesses a topic proportion vector θ sampled from a Dirichlet distribution. Each topic $\boldsymbol{\beta}_k$ is a multinomial distribution over words. Each word w has a topic label z indicating which topic w belongs to.

In many scenarios, we have access to external knowledge regarding the correlations between words, such as *apple* and *orange* are similar, *church* and *bible* are semantically related. These similarity relationships among words can be leveraged to improve the coherence of learned topics. To do this, we define a Markov Random Field over the latent topic layer. Given a document d containing N words $\{w_i\}_{i=1}^N$, we examine each word pair (w_i, w_j). If they are correlated according to the external knowledge, we create an undirected edge between their topic labels (z_i, z_j). In the end, we obtain an undirected graph G where the nodes are latent topic labels $\{z_i\}_{i=1}^N$ and edges connect topic labels of correlated words. In the example shown in Figure 1, G contains five nodes z_1, z_2, z_3, z_4, z_5 and four edges connecting $(z_1, z_3), (z_2, z_5), (z_3, z_4), (z_3, z_5)$.

Given the undirected graph G, we can turn it into a Markov Random Field by defining unary potentials over nodes and binary potentials over edges. We define the unary potential for z_i as $p(z_i|\boldsymbol{\theta})$, which is a multinomial distribution parameterized by $\boldsymbol{\theta}$. In standard LDA, this is how a topic is sampled from the topic proportion vector. For binary potential, with the goal to encourage similar words to have similar topic assignments, we define the edge potential between (z_i, z_j) as $\exp\{\mathbb{I}(z_i = z_j)\}$, where $\mathbb{I}(\cdot)$ is the indicator function. This potential func-

tion yields a larger value if the two topic labels are the same and a smaller value if the two topic labels are different. Hence, it encourages similar words to be assigned to the same topic. Under the MRF model, the joint probability of all topic assignments $\mathbf{z} = \{z_i\}_{i=1}^N$ can be written as

$$p(\mathbf{z}|\boldsymbol{\theta}, \lambda) = \frac{1}{A(\boldsymbol{\theta},\lambda)} \prod_{i=1}^{N} p(z_i|\boldsymbol{\theta}) \exp\{\lambda \sum_{(m,n)\in\mathcal{P}} \mathbb{I}(z_m = z_n)\} \quad (1)$$

where $\mathcal{P}$ denotes the edges in G and $A(\boldsymbol{\theta}, \lambda)$ is the partition function

$$A(\boldsymbol{\theta}) = \sum_{\mathbf{z}} \prod_{i=1}^{N} p(z_i|\boldsymbol{\theta}) \exp\{\lambda \sum_{(m,n)\in\mathcal{P}} \mathbb{I}(z_m = z_n)\} \quad (2)$$

We introduce $\lambda \geq 0$ as a trade-off parameter between unary potential and binary potential. In standard LDA, topic label z_i only depends on topic proportion vector $\boldsymbol{\theta}$. In MRF-LDA, z_i not only depends on $\boldsymbol{\theta}$, but also depends on the topic labels of similar words. If γ is set to zero, the correlation between words is ignored and MRF-LDA is reduced to LDA. Given the topic labels, the generation of words is the same as LDA. w_i is generated from the topic-words multinomial distribution $\boldsymbol{\beta}_{z_i}$ corresponding to z_i.

In MRF-LDA, the generative process of a document is summarized as follows:

- Draw a topic proportion vector $\boldsymbol{\theta} \sim Dir(\boldsymbol{\alpha})$
- Draw topic labels $\mathbf{z}$ for all words from the joint distribution defined in Eq.(1)
- For each word w_i, drawn $w_i \sim multi(\boldsymbol{\beta}_{z_i})$

Accordingly, the joint distribution of $\boldsymbol{\theta}, \mathbf{z}$ and $\mathbf{w}$ can be written as

$$p(\boldsymbol{\theta}, \mathbf{z}, \mathbf{w}|\boldsymbol{\alpha}, \boldsymbol{\beta}, \lambda) = p(\boldsymbol{\theta}|\boldsymbol{\alpha}) p(\mathbf{z}|\boldsymbol{\theta}, \lambda) \prod_{i=1}^{N} p(w_i|z_i, \boldsymbol{\beta}) \quad (3)$$

3.2 Variational Inference and Parameter Learning

The key inference problem we need to solve in MRF-LDA is to compute the posterior $p(\boldsymbol{\theta}, \mathbf{z}|\mathbf{w})$ of latent variables $\boldsymbol{\theta}, \mathbf{z}$ given observed data $\mathbf{w}$. As in LDA (Blei et al., 2003), exact computation is intractable. What makes things even challenging in MRF-LDA is that, an undirected MRF is coupled with a directed LDA and the hard-to-compute partition function of MRF makes the posterior inference and parameter learning very difficult. To solve this problem, we resort to variational inference (Wainwright and Jordan, 2008), which uses a easy-to-handle variational distribution to approximate the true posterior of latent variables. To deal with the partition function in MRF, we seek lower bound of the variational lower bound to achieve tractability. We introduce a variational distribution

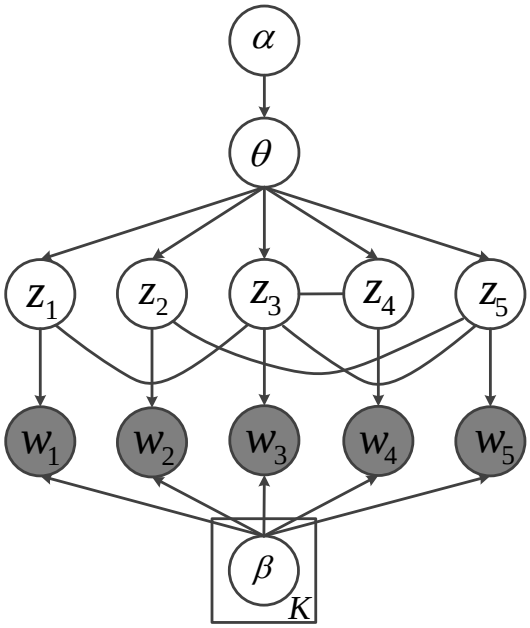

Figure 1: Markov Random Field Regularized Latent Dirichlet Allocation Model

$$q(\boldsymbol{\theta}, \mathbf{z}) = q(\boldsymbol{\theta}|\boldsymbol{\eta}) \prod_{i=1}^{N} q(z_i|\boldsymbol{\phi}_i) \quad (4)$$

where Dirichlet parameter $\boldsymbol{\eta}$ and multinomial parameters $\{\boldsymbol{\phi}_i\}_{i=1}^N$ are free variational parameters. Using Jensen's inequality (Wainwright and Jordan, 2008), we can obtain a variational lower bound

$$\mathcal{L} = \mathbb{E}_q[\log p(\boldsymbol{\theta}|\boldsymbol{\alpha})] + \mathbb{E}_q[\log p(\mathbf{z}|\boldsymbol{\theta}, \lambda)] + \mathbb{E}_q[\log \prod_{i=1}^{N} p(w_i|z_i, \boldsymbol{\beta})] - \mathbb{E}_q[\log q(\boldsymbol{\theta}|\boldsymbol{\eta})] - \mathbb{E}_q[\log \prod_{i=1}^{N} q(z_i|\boldsymbol{\phi}_i)] \quad (5)$$

in which $\mathbb{E}_q[\log p(\mathbf{z}|\boldsymbol{\theta}, \lambda)]$ can be expanded as

$$\begin{aligned}&\mathbb{E}_q[\log p(\mathbf{z}|\boldsymbol{\theta}, \lambda)]\\&= -\mathbb{E}_q[\log A(\boldsymbol{\theta}, \lambda)] + \lambda \sum_{(m,n)\in\mathcal{P}} \sum_{k=1}^{K} \phi_{mk}\phi_{nk}\\&+ \sum_{i=1}^{N}\sum_{k=1}^{K} \phi_{ik}(\Psi(\eta_k) - \Psi(\sum_{j=1}^{K}\eta_j))\end{aligned} \tag{6}$$

The item $\mathbb{E}_q[\log A(\boldsymbol{\theta}, \lambda)]$ involves the hard-to-compute partition function, which has no analytical expressions. We discuss how to deal with it in the sequel. With Taylor expansion, we can obtain an upper bound of $\mathbb{E}_q[\log A(\boldsymbol{\theta}, \lambda)]$

$$\mathbb{E}_q[\log A(\boldsymbol{\theta}, \lambda)] \leq c^{-1}\mathbb{E}_q[A(\boldsymbol{\theta}, \lambda)] - 1 + \log c \tag{7}$$

where $c \geq 0$ is a new variational parameter. $\mathbb{E}_q[A(\boldsymbol{\theta}, \lambda)]$ can be further upper bounded as

$$\begin{aligned}&\mathbb{E}_q[\log A(\boldsymbol{\theta}, \lambda)] \leq \exp\{\sum_{(m,n)\in\mathcal{P}} \lambda\}\\&\sum_{n_1,n_2,\cdots,n_K} \mathbb{E}_q[\prod_{k=1}^{K} \boldsymbol{\theta}^{n_k}]\end{aligned} \tag{8}$$

where n_k denotes the number of words assigned with topic label k and $\sum_{k=1}^{K} n_k = N$. We further bound $\sum_{n_1,n_2,\cdots,n_K} \mathbb{E}_q[\prod_{k=1}^{K} \boldsymbol{\theta}^{n_k}]$ as follows

$$\begin{aligned}&\sum_{n_1,n_2,\cdots,n_K} \mathbb{E}_q[\prod_{k=1}^{K} \boldsymbol{\theta}^{n_k}]\\&= \sum_{n_1,n_2,\cdots,n_K} \frac{\Gamma(\sum_{k=1}^{K}\eta_k)}{\prod_{k=1}^{K}\Gamma(\eta_k)} \int \prod_{k=1}^{K} \theta^{n_k+\eta_k-1} \mathrm{d}\boldsymbol{\theta}\\&= \sum_{n_1,n_2,\cdots,n_K} \frac{\Gamma(\sum_{k=1}^{K}\eta_k)}{\prod_{k=1}^{K}\Gamma(\eta_k)} \frac{\prod_{k=1}^{K}\Gamma(n_k+\eta_k)}{\Gamma(\sum_{k=1}^{K} n_k+\eta_k)}\\&= \sum_{n_1,n_2,\cdots,n_K} \frac{\prod_{k=1}^{K}(\eta_k)_{n_k}}{(\sum_{k=1}^{K}\eta_k)_N}\\&\leq \sum_{n_1,n_2,\cdots,n_K} \frac{\prod_{k=1}^{K}(n_k)!}{(N)!}\end{aligned} \tag{9}$$

where $(a)_n$ denotes the Pochhammer symbol, which is defined as $(a)_n = a(a+1)\ldots(a+n-1)$ and $\sum_{n_1,n_2,\cdots,n_K} \frac{\prod_{k=1}^{K}(n_k)!}{(N)!}$ is a constant. Setting $c = c/\sum_{n_1,n_2,\cdots,n_K} \frac{\prod_{k=1}^{K}(n_k)!}{(N)!}$, we get

$$\mathbb{E}_q[\log A(\boldsymbol{\theta}, \lambda)] \leq c^{-1}\exp\{\sum_{(i,j)\in\mathcal{P}} \lambda\} - 1 + \log c \tag{10}$$

Given this upper bound, we can obtain a lower bound of the variational lower bound defined in Eq.(5). Variational parameters and model parameters can be learned by maximizing the lower bound using iterative EM algorithm. In E-step, we fix the model parameters and compute the variational parameters by setting the derivatives of the lower bound w.r.t the variational parameters to zero

$$\eta_k = \alpha_k + \sum_{i=1}^{N} \phi_{ik}, c = \exp\{\sum_{(m,n)\in\mathcal{P}} \lambda\} \tag{11}$$

$$\begin{aligned}&\phi_{ik} \propto \exp\{\Psi(\eta_k) - \Psi(\sum_{j=1}^{K}\eta_j) + \lambda \sum_{j\in\mathcal{N}(i)} \phi_{jk}\\&+ \sum_{v=1}^{V} w_{iv}\log\beta_{kv}\}\end{aligned} \tag{12}$$

In Eq.(12), $\mathcal{N}(i)$ denotes the words that are labeled to be similar to i. As can be seen from this equation, the probability ϕ_{ik} that word i is assigned to topic k depends on the probability ϕ_{jk} of i's correlated words j. This explains how our model can incorporate word correlations in topic assignments. In M-step, we fix the variational parameters and update the model parameters by maximizing the lower bound defined on the set of documents $\{\mathbf{w}_d\}_{d=1}^{D}$

$$\beta_{kv} \propto \sum_{d=1}^{D}\sum_{i=1}^{N_d} \phi_{d,i,k} w_{d,i,v} \tag{13}$$

$$\lambda = \frac{1}{|P|}\log \frac{\sum_{d=1}^{D}\sum_{(m,n)\in P_d}\sum_{k=1}^{K} \phi_{d,m,k}\phi_{d,n,k}}{|P|\sum_{d=1}^{D}\frac{1}{c_d}} \tag{14}$$

4 Experiment

In this section, we corroborate the effectiveness of our model by comparing it with three baseline methods on two datasets.

dataset	20-Newsgroups	NIPS
# documents	18846	1500
# words	40343	12419

Table 1: Dataset Statistics

4.1 Experiment Setup

- **Dataset**: We use two datasets in the experiments: 20-Newsgroups[2] and NIPS[3]. Their statistics are summarized in Table 1.

- **External Knowledge**: We extract word correlation knowledge from Web Eigenwords[4], where each word has a real-valued vector capturing the semantic meaning of this word based on distributional similarity. Two words are regarded as correlated if their representation vectors are similar enough. It is worth mentioning that, other sources of external word correlation knowledge, such as Word2Vec (Mikolov et al., 2013) and Glove (Pennington et al., 2014), can be readily incorporated into MRF-LDA.

- **Baselines**: We compare our model with three baseline methods: LDA (Blei et al., 2003), DF-LDA (Andrzejewski et al., 2009) and Quad-LDA (Newman et al., 2011). LDA is the most widely used topic model, but it is unable to incorporate external knowledge. DF-LDA and Quad-LDA are two models designed to incorporate word correlation to improve topic modeling. DF-LDA puts a Dirichlet Forest prior over the topic-word multinomials to encode the Must-Links and Cannot-Links between words. Quad-LDA regularizes the topic-word distributions with a structured prior to incorporate word relation.

- **Parameter Settings:** For all methods, we learn 100 topics. LDA parameters are set to their default settings in (Andrzejewski et al., 2009). For DF-LDA, we set its parameters as $\alpha = 1$, $\beta = 0.01$ and $\eta = 100$. The Must/Cannot links between words are generated based on the cosine similarity of words' vector representations in Web Eigenwords. Word pairs with similarity higher than 0.99 are set as Must-Links, and pairs with similarity lower than 0.1 are put into Cannot-Link set. For Quad-LDA, β is set as 0.01; α is defined as $\frac{0.05 \cdot N}{D \cdot T}$, where N is the total occurrences of all words in all documents, D is the number of documents and T is topic number. For MRF-LDA, word pairs with similarity higher than 0.99 are labeled as correlated.

4.2 Results

We compare our model with the baseline methods both qualitatively and quantitatively.

4.2.1 Qualitative Evaluation

Table 2 shows some exemplar topics learned by the four methods on the 20-Newsgroups dataset. Each topic is visualized by the top ten words. Words that are noisy and lack representativeness are highlighted with bold font. Topic 1 is about crime and guns. Topic 2 is about sex. Topic 3 is about sports and topic 4 is about health insurance. As can be seen from the table, our method MRF-LDA can learn more coherent topics with fewer noisy and meaningless words than the baseline methods. LDA lacks the mechanism to incorporate word correlation knowledge and generates the words independently. The similarity relationships among words cannot be utilized to imporve the coherence of topic modeling. Consequently, noise words such as *will*, *year*, *used* which cannot effectively represent a topic, show up due to their high frequency. DF-LDA and Quad-LDA proposed to use word correlations to enhance the coherence of learned topics. However, they improperly enforce words labeled as similar to have similar probabilities in all topics, which violates the fact that whether two words are similar depend on which topic they appear in. As a consequence, the topics extracted by these two methods are unsatisfactory. For example, topic 2 learned by DF-LDA mixed up a *sex* topic and a *reading* topic. Less relevant words such as *columbia*, *year*, *write* show up in the health insurance topic (topic 4) learned by Quad-LDA. Our method MRF-LDA incorporates the word correlation knowledge by imposing a MRF over the latent topic layer to encourage correlated words to share the same topic label, hence similar words have better chance to be put into the same topic. Conse-

quently, the learned topics are of high coherence. As shown in Table 2, the topics learned by our method are largely better than those learned by the baseline methods. The topics are of high coherence and contain fewer noise and irrelevant words.

Our method provides a mechanism to automatically decide under which topic, two words labeled as similar are truly similar. The decision is made flexibly by data according to their fitness to the model, rather than by a hard rule adopted by DF-LDA and Quad-LDA. For instance, according to the external knowledge, the word *child* is correlated with *gun* and with *men* simultaneously. Under a *crime* topic, *child* and *gun* are truly correlated because they co-occur a lot in youth crime news, whereas, *child* and *men* are less correlated in this topic. Under a *sex* topic, *child* and *men* are truly correlated whereas *child* and *gun* are not. Our method can differentiate this subtlety and successfully put *child* and *gun* into the *crime* topic and put *child* and *men* into the *sex* topic. This is because our method encourages *child* and *gun* to be put into the same topic A and encourages *child* and *men* to be put into the same topic B, but does not require A and B to be the same. A and B are freely decided by data.

Table 3 shows some topics learned on NIPS dataset. The four topics correspond to vision, neural network, speech recognition and electronic circuits respectively. From this table, we observe that the topics learned by our method are better in coherence than those learned from the baseline methods, which again demonstrates the effectiveness of our model.

4.2.2 Quantitative Evaluation

We also evaluate our method in a quantitative manner. Similar to (Xie and Xing, 2013), we use the coherence measure (CM) to assess how coherent the learned topics are. For each topic, we pick up the top 10 candidate words and ask human annotators to judge whether they are relevant to the topic. First, annotators needs to judge whether a topic is interpretable or not. If not, the ten candidate words in this

topic are automatically labeled as irrelevant. Otherwise, annotators are asked to identify words that are relevant to this topic. Coherence measure (CM) is defined as the ratio between the number of relevant words and total number of candidate words. In our experiments, four graduate students participated the labeling. For each dataset and each method, 10% of topics were randomly chosen for labeling.

Table 4 and 5 summarize the coherence measure of topics learned on 20-Newsgroups dataset and NIPS dataset respectively. As shown in the table, our method significantly outperforms the baseline methods with a large margin. On the 20-Newsgroups dataset, our method achieves an average coherence measure of 60.8%, which is two times better than LDA. On the NIPS dataset, our method is also much better than the baselines. In summary, we conclude that MRF-LDA produces much better results on both datasets compared to baselines, which demonstrates the effectiveness of our model in exploiting word correlation knowledge to improve the quality of topic modeling. To assess the consistency of the labelings made by different annotators, we computed the intraclass correlation coefficient (ICC). The ICCs on 20-Newsgroups and NIPS dataset are 0.925 and 0.725 respectively, which indicate good agreement between different annotators.

5 Conclusion

In this paper, we propose a MRF-LDA model, aiming to incorporate word correlation knowledge to improve topic modeling. Our model defines a MRF over the latent topic layer of LDA, to encourage correlated words to be put into the same topic. Our model provides the flexibility to enable a word to be similar to different words under different topics, which is more plausible and allows a word to show up in multiple topics properly. We evaluate our model on two datasets and corroborate its effectiveness both qualitatively and quantitatively.

The Unreasonable Effectiveness of Word Representations for Twitter Named Entity Recognition

Colin Cherry and **Hongyu Guo**
National Research Council Canada
first.last@nrc-cnrc.gc.ca

Abstract

Named entity recognition (NER) systems trained on newswire perform very badly when tested on Twitter. Signals that were reliable in copy-edited text disappear almost entirely in Twitter's informal chatter, requiring the construction of specialized models. Using well-understood techniques, we set out to improve Twitter NER performance when given a small set of annotated training tweets. To leverage unlabeled tweets, we build Brown clusters and word vectors, enabling generalizations across distributionally similar words. To leverage annotated newswire data, we employ an importance weighting scheme. Taken all together, we establish a new state-of-the-art on two common test sets. Though it is well-known that word representations are useful for NER, supporting experiments have thus far focused on newswire data. We emphasize the effectiveness of representations on Twitter NER, and demonstrate that their inclusion can improve performance by up to 20 F1.

1 Introduction

Named entity recognition (NER) is the task of finding rigid designators as they appear in free text and classifying them into coarse categories such as *person* or *location* (Nadeau and Sekine, 2007). NER enables many other information extraction tasks such as relation extraction (Bunescu and Mooney, 2005) and entity linking (Ratinov et al., 2011).

There is considerable excitement at the prospect of porting information extraction technology to social media platforms such as Twitter. Social media reacts to world events faster than traditional news sources, and its sub-communities pay close attention to topics that other sources might ignore. An early example of the potential inherent in social information extraction is the Twitter Calendar (Ritter et al., 2012), which detects upcoming events (concerts, elections, video game releases, etc.) based on the anticipatory chatter of Twitter users. Unfortunately, processing social media text presents a unique set of challenges, especially for technologies designed for newswire: Twitter posts are short, the language is informal, capitalization is inconsistent at best, and spelling variations and abbreviations run rampant.

Armed with an affordable training set of 1,000 annotated tweets, we establish a strong baseline for Twitter NER using well-understood techniques. We build two unsupervised word representations in order to leverage a large collection of unannotated tweets, while a data-weighting technique allows us to benefit from annotated newswire data. Taken together, these two simple ideas establish a new state-of-the-art for both our test sets. We rigorously test the impact of both continuous and cluster-based word representations on Twitter NER, emphasizing the dramatic improvement that they bring. We also bring the experimental methodology of the domain adaptation community to Twitter NER, testing in-domain, out-of-domain and combined training scenarios, and revealing that it is not trivial to benefit from out-of-domain training data. Finally, an error analysis helps us begin to understand which social media challenges are being addressed by our adaptations, and which problems persist.

2 Background

Our work builds on a long line of research in discriminative tagging (Collins, 2002), and its application to named entity recognition (McCallum and Li, 2003). Our baseline tagger draws inspiration from Sarawagi and Cohen (2004), who introduce the no-

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 735–745,
Denver, Colorado, May 31 – June 5, 2015.

tion of semi-Markov tagging for NER, and from de Bruijn et al. (2011), who apply a similar tagger to clinical information extraction.

A number of previous studies have closely examined the use of word representations in NER, where one leverages unlabeled data to build features that help the tagger generalize across similar words. Miller et al. (2004) introduce this idea and provide the framework to build representation features from word clusters, while Lin and Wu (2009) extend this technique with phrases and sheer masses of unlabeled data. Turian et al. (2010) introduce continuous vectors as alternative word representations, and provide several experiments comparing these with clusters. Recently, Passos et al. (2014) have shown how continuous representations can be tailored to NER with a combination of context- and gazetteer-aware objectives. All of these studies employ representations only in newswire scenarios. Ratinov and Roth (2009) investigate cluster representations in a Web NER task, but the performance of their baseline indicates that it is not nearly so drastic a domain shift as our Twitter task.

2.1 Adapting to Social Media

There has been much recent activity in adapting NLP tools for social media. Ritter et al. (2011) collect training data and adapt tools for a number of tasks, including part-of-speech (POS) tagging, shallow parsing and NER. Owoputi et al. (2013) extends a line of research on building robust POS taggers for Twitter, and share our focus on the utility of word representations in this domain.

Liu et al. (2011) carry out the first study to specifically examine NER on Twitter. They use a nearest-neighbour word classifier stacked with a CRF, along with a boot-strapping scheme for semi-supervised learning. Interestingly, they find no utility in using cluster-based word representations, perhaps because their model directly accounts for a type's global context with bag-of-word features. Ritter et al. (2011) also examine Twitter NER, developing a semi-supervised technique that uses labeled LDA to project information from Freebase gazetteers onto unlabeled tweets. Plank et al. (2014) suggest a distant-supervision scheme, creating artificial training data by projecting reliable NER tags from web pages onto the tweets that link to those pages.

Fromreide et al. (2014) and Plank et al. (2014) point out that NER performance can be overestimated when a system is tested on data extracted from the same pool as its training data. Temporal effects and annotation biases can result in gains that disappear when shifting to another test set. We follow their lead by testing on data that was annotated independently from our training data.

3 Methods

Our named entity recognizer is a discriminative, semi-Markov tagger, trained online using large-margin updates. It differs from word-based CRF systems in three ways: its inference algorithm, its tag structure, and its learning algorithm. This tagger allows us to develop new systems quickly, but it is important to emphasize that the adaptation strategies described later in this section can just as easily be applied to word-based CRFs.

Semi-Markov Inference

Sarawagi and Cohen (2004) describe a straightforward extension to the Viterbi algorithm that enables the tagging of contiguous phrases instead of words. Because each phrasal entity is tagged as a unit, we can recover entity boundaries without distinguishing between *Begin* and *Inside* tags, leaving the tagger to track only entity classes and *Outside* tags. This in turn allows us to run our tagger without Markov features. Since most entities are surrounded by *Outside* tags, conditioning on previous tag assignments has only limited utility. Finally, our phrasal tags enable useful features that consider entire entities, such as phrase-identity indicators.

Phrasal and Word-level Tags

In word-based models, it is beneficial to not only identify words that *Begin* entities, but also those that are in the middle (*Inside*) or at the end of entities (*Last*), as well as entities that consist of exactly one *Unique* word (Ratinov and Roth, 2009). Since we tag entire phrases at once, we can easily assign each word in the phrase to one of these four entity-relative positions. Therefore, even though our tagger tracks only entity class, its word-level features are annotated as if we maintained a full *BILUO* tag set.

Passive-Aggressive Learning

We train our model with a structured version of the Passive-Aggressive (PA) algorithm (Crammer et al., 2006). The benefits of using PA in place of a CRF are that we require only Viterbi inference, and memory requirements are minimized, as we update the model one training sentence at a time.

PA is an online, large-margin learning algorithm that attempts to separate correct sequences from incorrect ones by a margin of 1. For each update to the weight vector w, we select a training sentence x and its gold-standard tag sequence y. We use dynamic programming to search for a response $\hat{y}$ that maximizes the structured hinge loss:[1]

$$\hat{y} = \arg\max_{y' \neq y} = \left[1 + w^{\mathrm{T}}\big(\Phi(x, y') - \Phi(x, y)\big)\right] \quad (1)$$

where $\Phi()$ maps an (x, y) pair to a feature vector. If the loss is greater than 0, we update our model:

$$w = w + \tau\big(\Phi(x, y) - \Phi(x, \hat{y})\big) \quad (2)$$

where τ is an adaptive learning rate that scales the update to the smallest step size that achieves 0 loss:

$$\tau = \min\left(C, \frac{1 + w^{\mathrm{T}}\big(\Phi(x, \hat{y}) - \Phi(x, y)\big)}{||\Phi(x, y) - \Phi(x, \hat{y})||}\right) \quad (3)$$

C is a hyper-parameter that truncates large steps to prevent over-fitting. It is related to the C-parameter of an SVM (Martins et al., 2010). To further guard against over-fitting, we use the average of all vectors w seen during training when tagging new text (Collins, 2002).

Features

The feature function $\Phi(x, y)$ must decompose into the semi-Markov dynamic program:

$$\Phi(x, y) = \sum_{(s,t,y_j) \in D(x,y)} \phi(s, t, y_j, x) \quad (4)$$

where D is a derivation decomposing (x, y) into J entity-tag assignments (s, t, y_j), each asserting that the phrase $x_s \dots x_{t-1}$ is assigned the tag y_j. Tagged spans are non-overlapping, and to eliminate spurious ambiguity, constrained so that *Outside* can tag only single-word spans ($t = s + 1$).

[1] This can be done by running a 2-best tagger. If the 1-best answer is not correct ($y' \neq y$), then it maximizes the loss, otherwise, the 2-best answer maximizes the loss.

Phrase:
$[y_j]$, $[y_j, x_s \dots x_{t-1}]$,
$[y_j, lc(x_s \dots x_{t-1})]$, $[y_j, ss(x_s \dots x_{t-1})]$
Word, for each i s.t. $s \leq i < t$:
$\{[y_j, x_{i+k}, k]\}_{k=-2}^{2}$, $\{[y_j, er_{s,t}(i), x_{i+k}, k]\}_{k=-2}^{2}$,
$\{[y_j, lc(x_{i+k}), k]\}_{k=-2}^{2}$,
$\{[y_j, er_{s,t}(i), lc(x_{i+k}), k]\}_{k=-2}^{2}$,
$\{[y_j, ss(x_{i+k}), k]\}_{k=-2}^{2}$,
$\{[y_j, er_{s,t}(i), ss(x_{i+k}), k]\}_{k=-2}^{2}$,
$\{[y_j, pf(n, x_i)]\}_{n=1}^{3}$, $\{[y_j, er_{s,t}(i), pf(n, x_i)]\}_{n=1}^{3}$,
$\{[y_j, sf(n, x_i)]\}_{n=1}^{3}$, $\{[y_j, er_{s,t}(i), sf(n, x_i)]\}_{n=1}^{3}$,

Table 1: Baseline features $\phi(s, t, y_j, x)$. $[str]$ stands for an indicator feature with the name *str*; $lc()$ maps a string onto its lowercased form; $ss()$ maps a string onto its word shape ("Apple Inc." becomes "Aa Aa."); $pf(n, x_i)$ and $sf(n, x_i)$ are n-character prefixes and suffixes of x_i; and $er_{s,t}(i)$ maps an absolute sentence position i ($s \leq i < t$) to a relative entity position drawn from $\{B, I, L, U\}$.

Our baseline feature set, shown in Table 1, closely mimics the set proposed by Ratnaparkhi (1996), covering word identity, prefixes, suffixes and surrounding words. It has been augmented with phrase-identity indicators and hierarchical word-level tags. These conjoin the entity class y_j with the word's entity-relative position, backing off to y_j alone. Most features look only at a single word x_i, which improves efficiency by allowing the tagger to re-use word-level scores across many phrasal tags.

There are some standard NER features that we chose not to include. We follow Lin and Wu (2009) in omitting POS tags and gazetteers in order to reduce our dependence on linguistic resources. We expect similar information to be provided by unsupervised word representations, and we test this assumption in Section 5.2. We omit context aggregation, which accounts for the repetition of entities (Ratinov and Roth, 2009), because Twitter's short message length reduces the utility of document-level features.

3.1 Word Representations

Our primary tool for domain adaptation will be unsupervised word representations, which convey information about a word's distributional profile.

Brown clusters, for each i s.t. $s \leq i < t$:
$\{[y_j, \textit{brn}(n, x_i), n]\}_{n \in \{2,4,8,12\}}$,
$\{[y_j, \textit{er}_{s,t}(i), \textit{brn}(n, x_i), n]\}_{n \in \{2,4,8,12\}}$
Word vectors, for each i s.t. $s \leq i < t$:
$\{[y_j, n] = \textit{w2v}(n, x_i)\}_{n=1}^{300}$,
$\{[y_j, \textit{er}_{s,t}(i), n] = \textit{w2v}(n, x_i)\}_{n=1}^{300}$

Table 2: Word representation features in $\phi(s, t, y_j, x)$. $\textit{brn}(n, x_i)$ maps a word x_i to the first n bits of its Brown cluster bit sequence. $\textit{w2v}(n, x_i)$ maps x_i to the n^{th} component of its word vector, and $[\textit{str}] = v$ stands for a real-valued feature with name *str* and value v.

Brown Clusters

The Brown clustering algorithm assigns types to a deterministic, hierarchical clustering, which has been trained to optimize the likelihood of a first-order, class-based language model (Brown et al., 1992). The clusters capture both syntactic and semantic regularities, and have been shown to perform well as unsupervised part-of-speech taggers (Blunsom and Cohn, 2011).

The clusters are organized into a binary tree structure; therefore, each cluster can be represented as a bit string that encodes the branching decisions required to reach its leaf from the root. By truncating the bit string at different prefix lengths, one can access different granularities of clusters. Cluster membership can then be used to create indicators similar to the baseline's word identity features. This results in two feature templates, shown in Table 2.[2]

This technique has been previously applied to both newswire NER (Miller et al., 2004; Turian et al., 2010; Passos et al., 2014) and Twitter NER (Ritter et al., 2011; Plank et al., 2014). But previous work on Twitter NER has not directly tested the impact of Brown clusters; instead, they generally appear as part of an adapted baseline.

Word Vectors

An alternative word representation maps each word type deterministically to a low-dimensional continuous vector space. This technique was originally used as the bottom layer for continuous-space language models (Bengio et al., 2003), where the type-to-vector mapping can be learned with back-propagation. However, Mikolov et al. (2013) have shown that useful vector representations can be learned more efficiently by eschewing the language-modeling objective. Their skip-gram model, which we adopt here, optimizes for each token, the likelihood of the tokens in a window surrounding it. This training process creates a linear classifier that predicts words conditioned on the central token's vector representation. The classifier and the word vectors are learned simultaneously, but once training is complete, the classifier is usually discarded, leaving only the vectors.

These continuous representations project words into a low-dimensional space. Words that tend to have similar contexts, and therefore similar syntactic and semantic properties, will tend to be near one another in this space. We incorporate these representations into our NER system as real-valued features of each word x_i, as shown in Table 2.

3.2 Data Weighting

Our next tool for domain adaptation is a small pool of in-domain, annotated data. The easiest way to make use of this data is to append it to our large pool of out-of-domain training data, which is what has been done in previous work on Twitter NER (Ritter et al., 2011; Plank et al., 2014). However, we have the strong intuition that greater weight should be placed on the in-domain data.

Assume that for each training pair (x, y) we also have an importance weight η. In our case, all out-of-domain pairs will share one value for η, and all in-domain pairs will share another, higher η. We modify our PA learner to calculate τ using a version of Equation 3 that replaces C with ηC. Unlike scaling τ directly, scaling C has the desirable property of having even high-η examples stop updating at precisely 0 loss, just as if we had duplicated that training example η times (Karampatziakis and Langford, 2010). If we view C as a regularization term, then this modification can also be interpreted as implementing example-specific regularization. Importance weights can also be incorporated into CRFs by modifying their training objective; however, this is not a standard feature of most CRF packages.

[2] We also experimented with templates over clusters and vectors for surrounding words, to no benefit.

Data	Lines	Types	Tokens	# PER	# LOC	# ORG

Unlabeled Tweets	98M	57M	1,995M	–	–	–

Table 3: Details of our NER-annotated corpora. A *line* is a tweet in Twitter and a sentence in newswire.

4 Experimental Design

Vital statistics for all of our data sets are shown in Table 3. For in-domain NER data, we use three collections of annotated tweets: Fin10 was originally crowd-sourced by Finin et al. (2010), and was manually corrected by Fromreide et al. (2014), while Rit11 (Ritter et al., 2011) and Fro14 (Fromreide et al., 2014) were built by expert annotators. We divide Fin10 temporally into a training set and a development set, and we consider Rit11 and Fro14 to be our test sets. This reflects a plausible training scenario, with train and dev drawn from the same pool, but with distinct tests drawn from later in time. These three data sets were collected and unified by Plank et al. (2014), who normalized the tags into three entity classes: *person* (PER), *location* (LOC) and *organization* (ORG). The source text has also been normalized; notably, all numbers are normalized to NUMBER, and all URLs and Twitter @user names have been normalized to URL and @USER respectively. In the gold-standard, we choose to reverse a tagging normalization performed by Plank et al. (2014), who had post-processed the data so that all @user names are tagged as PER. These tags are trivial to replicate, and we found that they inflate scores quite dramatically. Therefore, all @user names are untagged in both the gold standard and our system outputs.

We use the CoNLL 2003 newswire training set as a source of out-of-domain NER annotations (Tjong Kim Sang and De Meulder, 2003). The source text has been normalized to match the Twitter NER data, and we have removed the MISC tag from the gold-standard, leaving PER, LOC and ORG.

Finally, we also use a large corpus of unannotated tweets, collected from between May 2011 and April 2012. It has been tokenized by the CMU Twokenizer,[3] but is otherwise unnormalized.

4.1 Hyper-parameter Configuration

Our NER system is trained for 10 epochs with its regularization parameter C set to 0.01.

We train our word vectors with an in-house implementation of word2vec (Mikolov et al., 2013), with vector size set to 300, a hierarchical soft-max objective, down-sampling frequent words at a rate of 0.001, a window-size of 10 tokens, and a minimum frequency count of 10. When run on our unannotated tweets, this produces vector representations for 2.5M types. We generate a random vector, with each component sampled from the standard normal, to use as the representation for any word that did not occur in our unlabeled data, including begin- and end-of-sentence markers. We do not scale the vectors before using them as NER features.

We train Brown clusters on the same data using the implementation by Liang (2005), with 1,000 clusters and a minimum frequency of 10, resulting in cluster assignments for the same 2.5M types.

5 Results

We evaluate our various NER taggers using the CoNLL 2003 metrics: phrase-level precision, recall, and balanced F-measure (F1).

We begin by testing our system on the CoNLL newswire task, both to confirm that our implementation is reasonable, and to help situate the Twitter results that appear later. We train on the unmodified CoNLL training corpus, and report F1 on the CoNLL development and test sets. We compare our baseline to the baseline from Ratinov and Roth (2009) (RR09), and we compare our representation-enhanced system (+*Reps*) to their "All External

[3] http://www.ark.cs.cmu.edu/TweetNLP/

Table 5: Impact of our components on Twitter NER performance, as measured by F1, under 3 data scenarios.

Knowledge" system. Both use Brown clusters, but RR09 uses Wikipedia gazetteers where we use word vectors. Results are shown in Table 4.

We achieve broadly comparable scores in both settings. Our external knowledge features are not as useful as theirs, which may be due to our lack of Wikipedia gazetteers, or due to a domain mismatch in our unannotated training data. Their clusters are trained on the 1996 Reuters corpus, a superset of the CoNLL data, matching it in both era and domain. Conversely, our clusters and vectors are both trained on tweets from 2011, so it is somewhat surprising that they help to the extent that they do.

5.1 Performance on Twitter

Our primary results are shown in Table 5, where we compare our word representation and data weighting techniques under three scenarios: training on out-of-domain data only (*CoNLL*), on in-domain data only (*Fin10*), and on both. Our data weighting technique (+*Weights*, see Section 3.2) only applies when we use both training sets. We used Fin10Dev to determine our importance weights, selecting $\eta = 0.01$ for CoNLL and $\eta = 1$ for Fin10. For these experiments, we test Brown clusters (+*Brown*), word vectors (+*Vector*), and both together (+*Reps*).

System	Prec	Rec	F1
CoNLL	43.0	49.8	46.2
Fin10	75.3	50.2	60.2
CoNLL+Fin10	66.0	58.0	61.8
+Weights	73.8	55.4	63.3

Table 6: Precision, recall and F1 on the *Fro14* test set with the *Base+All Reps* feature set.

Our Twitter NER results are much lower than the newswire results from Table 4, with our best Twitter system scoring more than 25 F1 below our best CoNLL system. But the picture would look much worse without word representations, which boost performance in every training scenario. Our best representation-free system lags nearly 20 F1 behind our best system that uses representations.

Looking across scenarios, we note that *CoNLL+Reps* outperforms *CoNLL+Fin10* on 2 out of 3 tests. This is interesting, as it shows that, given the hypothetical choice between collecting 100 million unannotated tweets for word representations, and collecting one thousand annotated tweets for NER training, we are better served by the unannotated data. Of course, it is even better to use both; their combined benefit in *CoNLL+Fin10+Reps* is more than additive.

Across all data scenarios and test sets, Brown clusters help less than word vectors. This contradicts the observations from Turian et al. (2010), who generally found Brown clusters to perform best. This may be because of our domain adaptation scenario, or it could be due to our use of word2vec, which did not exist at the time of the Turian study. The combination of Brown clusters and word vectors is consistently better than using either alone. The two representations track different sorts of information: our use of a large window leads word2vec to build topic-focused vectors (Turney, 2012), while Brown clustering is naturally more local, creating very syntactic, part-of-speech-like clusters. It is easy to see how both types of information can be useful to NER.

Ritter et al. (2011) report that including out-of-

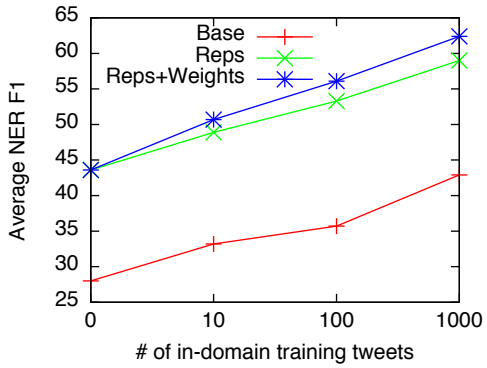

Figure 1: F1 averaged over all 3 test sets as we add Fin10 training data to CoNLL.

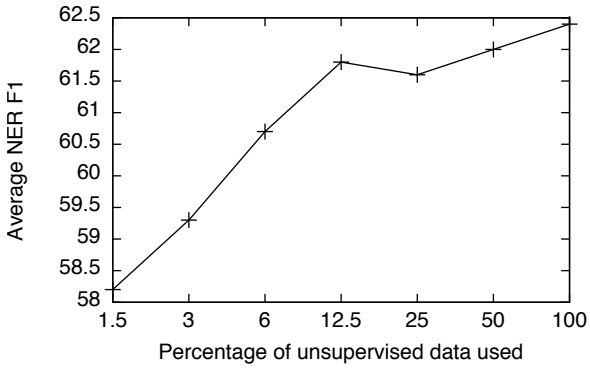

Figure 2: F1 averaged over all 3 test sets as we increase the percentage of tweets used to build representations.

Test Set	PER	LOC	ORG
Fin10Dev	71.3	72.4	48.8
Rit11	70.8	61.9	36.9
Fro14	69.4	70.2	42.6

Table 7: F1 for our *All Data+Reps+Weights* system, organized by entity class.

domain data hurts NER performance. Focusing on the lines *Fin10+Reps* and *CoNLL+Fin10+Reps*, we see the same problem. In the presence of word representations, unweighted CoNLL data hurts performance when added to a *Fin10* system. Fortunately, the inclusion of importance weights (+*Weights*) reverses this trend, giving us our best result on each test. We saw no consistent improvement from importance weights on the representation-free system.

To better understand the benefits of importance weights, Table 6 reports detailed scores for the Fro14 test set under the *Base+Reps* feature set, as we vary training scenarios. Results on the other test sets are similar. The *Fin10* system achieves high precision but low recall, while the *CoNLL+Fin10* does the opposite. This is because the CoNLL data is much more entity-dense than the Twitter data, which biases systems trained on CoNLL to return too many entities. By down-weighting the CoNLL data, we reduce this bias and gain 6.8 points of precision at the cost of only 2.6 points of recall.

Figure 1 gives learning curves as we add *Fin10* data to *CoNLL* across several feature sets. There is a steady improvement for all systems as the in-domain data grows, and importance weighting increases the impact of in-domain data even at very low quantities. Though the curves shows no sign of flattening out, note that the x-axis is log-scaled.

We have access to roughly 100 million tweets for unsupervised representation learning. Figure 2 provides a learning curve for our *Reps+Weights* system as we increase the percentage of unlabeled tweets used to train both Brown clusters and word vectors from 1.5% to 100% of that data, doubling the amount with each step. With only 1.5 million tweets, average performance is already very good, and we can see that the benefits of scale are starting to level off after we clear 12.5 million.

Table 7 reports our best system's performance by entity class. For all three test sets, ORG is the most difficult. ORG is perhaps the broadest entity class, but we suspect it is also the most likely to be annotated inconsistently, as it is rife with subtle distinctions: bands (ORG) versus musicians (PER); companies (ORG) versus their products (O); and teams (ORG) versus their home cities (LOC). During an inspection of 25 incorrect ORG predictions by our best system, drawn from a test on *Fin10Dev*, we found 10 cases where the gold standard was questionable. Two of these incorrectly placed "the" inside a chunk, ("[the Mariners]" is wrong; "the [Mariners]" is right), while the remaining 8 involved company-product distinctions, which are tricky even for human annotators. The NER task is not always as intuitive as we would like, and *organizations* tend to highlight these difficulties.

5.2 Comparison with Linguistic Resources

Thus far, we have restricted ourselves to a setting without access to linguistic resources, but for some

	Base +X	Reps +X
∅	42.9	62.4
[P]OS Tags	47.1	63.0
[G]azetteers	52.8	63.2
[P]+[G]	55.6	63.5

Table 8: Adding linguistic resources to our baseline and representation-enabled systems, as measured by F1 averaged over 3 test sets. All systems are trained on CoNLL+Fin10, and all but Base+∅ use data weighting.

System	Rit11	Fro14
PHMS14 Baseline	77.4	82.1
PHMS14 Dict ≺ Web	78.5	83.9
All Data+Reps+Weights	82.3	86.4
All Data+Ling+Reps+Weights	82.6	86.9

Table 9: Comparison with the state-of-the-art, reporting test F1. Both the gold-standard and the system outputs have `@user` names deterministically tagged as PER.

languages, such as English, rich resources exist and can be very useful. We now examine how word representations compare and interact with gazetteers and POS taggers.

For gazetteers, we use those included with the Illinois NER system (Ratinov and Roth, 2009), generating features that indicate when a word appears as part of a phrase found in a gazetteer. For POS tags, we use the CMU Twitter Tagger (Owoputi et al., 2013), and generate POS tag indicators for the current word and for tags within a 2-word window. For some of our corpora, notably CoNLL and Rit11, the corpus tokenization did not match the POS tagger's tokenization. We resolve mismatches by allowing the POS tagger to further tokenize the input sentence to better match its assumptions. After POS tagging, we merge any split tokens back to the original tokenization, picking a representative tag from among merged tags according to a priority list (verb $>$ noun $>$ adjective, etc.). The POS tags may have performed better if we had used the tagger's native tokenization throughout.[4]

Results of our comparison are shown in Table 8. Comparing *Base+∅* and *Base+[P]+[G]*, we see that linguistic resources boost the baseline's performance considerably. Turning to *Reps+[P]+[G]*, we see that adding word representations to linguistic resources provides another substantial boost of 7.9 F1. Conversely, adding linguistic resources to a system that already has representations increases F1 by only 1.1 points, indicating that not much new information is being added. The per-feature analysis indicates that much of this boost comes from the gazetteers.

[4]Inconsistent tokenization also hinders the word representations, which were constructed from a corpus tokenized by the CMU Twokenizer.

5.3 Comparison with the State-of-the-Art

In Table 9, we compare our best system, including linguistic resources, to the state-of-the-art results reported by Plank et al. (2014).[5] In order to create a fair comparison, we post-process both our system output and the gold-standard to tag all @user names as PER, just as they do.

Like our system, their baseline includes CoNLL and Twitter data, and uses Brown clusters trained on a comparable number of unlabeled tweets. Their strongest system uses distant supervision over linked web-pages to create artificial training data. But we are able to outperform it with our vector representations and importance weights. Note that this comparison is not perfect, as they train on a much larger pool of crowd-sourced, NER-annotated tweets, consisting of 170k tokens compared to our 17k. The size of their training data is balanced by the fact that its annotations were automatically correctly using MACE (Hovy et al., 2013), where ours were corrected manually, making it unclear which group has the advantage. Nonetheless, our results establish a new state-of-the-art for both test sets, and they do so using only 1k annotated tweets.

6 Analysis

We inspected 100 tweets from the Rit11 test set, focusing on the output from our primary system, *Base+Reps+Weights*, and our baseline, *Base*, both trained on the *CoNLL+Fin10* data. We noted cases where the primary system improved upon the baseline, and cases where it failed to achieve the gold-standard, and placed the phenomena we observed into bins. In general, the baseline was observed

[5]We omit the Fin10 test set from this comparison, as Plank et al. (2014) test on the entirety of Fin10, while we have divided it into training and development sets.

(c,d): examples where our final system (top) falls short of the gold-standard (bottom)

to rely heavily on local context and capitalization, while the primary system has a much stronger global prior on a given type's entity assignment.

Reps+Weights improved the baseline in 54 out of 100 tweets. There were 31 cases where the primary system corrected a baseline error caused by a misleading capitalization cue. Some of these, such as Figure 3(a) are patched by world knowledge provided by word representations, but many simply reflect a reduced reliance on capitalization. We were surprised to find only 11 cases where Twitter's informal language led to an error, often due to a vaguely name-shaped colloquialism, such as in 3(b). 6 of these 11 cases were fixed by the primary system.

Reps+Weights fell short of the gold-standard in 62 of 100 tweets. We observed 39 recall errors that were difficult to divide into smaller bins. These entities were often missed despite clear capitalization cues, as in Figure 3(c). This particular example is actually a symptom of inconsistent annotation: CoNLL and Rit11 consistently annotate *God* as a person, while our Fin10 training data leaves *God* untagged. The next largest class of errors consists of 11 problems caused by uniform casing (all caps or all lowercase). We also have 5 remaining errors due to informal language, which are interesting, as they highlight gaps in our representations. These include cases where the system generates false entities for variants of rare words (*Tidying* → *Tidyin*), or unusual lengthenings (*Yayaayayay*, as opposed to the well-attested *Yayayayay*). We also saw cases where entities were missed due to creative punctuation (*Go V-I-K-I-N-G-S!*). Finally, we found 4 cases where the system actually over-relies on its word representations, such as in 3(d), where the global PER interpretation of *corbin* overrides a fairly strong LOC signal provided by the local context word *in*.

7 Discussion

We have shown that the combination of Brown clusters, word vectors, and a simple data weighting scheme is sufficient to establish a new state-of-the-art on two Twitter NER test sets, using only 1,000 annotated tweets. We have designed our experiments to emphasize the dramatic impact of word representations in this domain, and to clarify the effects of in- and out-of-domain training sets.

Word representations learned on a large, unlabeled Twitter corpus have addressed a surprising number of issues with inconsistent capitalization and informal language. However, our continuing problems with uncased tweets and unusual colloquialisms demonstrate that there are still many human-readable words that remain a mystery to our system. In response to these observations, we would like to investigate more flexible representations, perhaps similar to those of Botha and Blunsom (2014), who use a linear combination of morpheme vectors to create representations that can generalize across words with similar forms.

Acknowledgments

Thanks to the anonymous reviewers for their helpful comments, to Alan Ritter for providing us with our corpus of unlabeled tweets, and to Barbara Plank for providing us with our three labeled corpora.

Abstract

Topic models provide insights into document collections, and their supervised extensions also capture associated document-level metadata such as sentiment. However, inferring such models from data is often slow and cannot scale to big data. We build upon the "anchor" method for learning topic models to capture the relationship between metadata and latent topics by extending the vector-space representation of word-cooccurrence to include metadata-specific dimensions. These additional dimensions reveal new anchor words that reflect specific combinations of metadata and topic. We show that these new latent representations predict sentiment as accurately as supervised topic models, and we find these representations more quickly without sacrificing interpretability.

Topic models were introduced in an unsupervised setting (Blei et al., 2003), aiding in the discovery of topical structure in text: large corpora can be distilled into human-interpretable themes that facilitate quick understanding. In addition to illuminating document collections for humans, topic models have increasingly been used for automatic downstream applications such as sentiment analysis (Titov and McDonald, 2008; Paul and Girju, 2010; Nguyen et al., 2013).

Unfortunately, the structure discovered by unsupervised topic models does not necessarily constitute the best set of features for tasks such as sentiment analysis. Consider a topic model trained on Amazon product reviews. A topic model might discover a topic about vampire romance. However, we often want to go deeper, discovering facets of a topic that reflect topic-specific sentiment, e.g., "buffy" and "spike" for positive sentiment vs. "twilight" and "cullen" for negative sentiment. Techniques for discovering such associations, called supervised topic models (Section 2), both produce interpretable topics and predict metadata values. While unsupervised topic models now have scalable inference strategies (Hoffman et al., 2013; Zhai et al., 2012), supervised topic model inference has not received as much attention and often scales poorly.

The anchor algorithm is a fast, scalable unsupervised approach for finding "anchor words"—precise words with unique co-occurrence patterns that can define the topics of a collection of documents. We augment the anchor algorithm to find supervised sentiment-specific anchor words (Section 3). Our algorithm is faster and just as effective as traditional schemes for supervised topic modeling (Section 4).

1 Anchors: Speedy Unsupervised Models

The anchor algorithm (Arora et al., 2013) begins with a $V \times V$ matrix $\bar{Q}$ of word co-occurrences, where V is the size of the vocabulary. Each word type defines a vector $\bar{Q}_{i,\cdot}$ of length V so that $\bar{Q}_{i,j}$ encodes the conditional probability of seeing word j given that word i has already been seen. Spectral methods (Anandkumar et al., 2012) and the anchor algorithm are fast alternatives to traditional topic model inference schemes because they can discover topics via these summary statistics (quadratic in the number of *types*) rather than examining the whole dataset (proportional to the much larger number of *tokens*).

The anchor algorithm takes its name from the idea

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 746–755,
Denver, Colorado, May 31 – June 5, 2015.

of anchor words—words which unambiguously identify a particular topic. For instance, "wicket" might be an anchor word for the cricket topic. Thus, for any anchor word a, $\bar{Q}_{a,\cdot}$ will look like a topic distribution. $\bar{Q}_{\text{wicket},\cdot}$ will have high probability for "bowl", "century", "pitch", and "bat"; these words are related to cricket, but they cannot be anchor words because they are also related to other topics.

Because these other non-anchor words could be topically ambiguous, their co-occurrence must be explained through some combination of anchor words; thus for non-anchor word i,

$$\bar{Q}_{i,\cdot} = \sum_{g_k \in \mathcal{G}} C_{i,k} \bar{Q}_{g_k,\cdot}, \quad (1)$$

where $\mathcal{G} = \{g_1, g_2, \ldots, g_K\}$ is the set of K anchor words. The coefficients $C_{i,k}$ of this linear combination correspond to the probability of seeing a topic *given a word*, from which we can recover the probability of a word *given a topic* (represented in a matrix A) using Bayes' rule. In our experiments, we follow Arora et al. (2013) to first estimate $\bar{Q}$ based on the training data and then recover the C matrix

$$C^*_{i,\cdot} = argmin_{C_{i,\cdot}} D_{KL}(\bar{Q}_{i,\cdot} \,||\, \sum_{g_k \in \mathcal{G}} C_{i,k} \bar{Q}_{g_k,\cdot}),$$

where $D_{KL}(x, y)$ denotes the Kullback-Leibler divergence between x and y.

In addition to discovering topics from a given set of anchor words as described above, Arora et al. (2013) also provide a geometric interpretation of a process for finding the needed anchor words. If we view the rows of $\bar{Q}$ as points in a high-dimensional space, the convex hull of those points provides the anchor words.[1]

Equation 1 linearly combines anchor words' co-occurrence vectors $\bar{Q}_{g_k,\cdot}$ to create the representation of other words. The convex hull corresponds to the perimeter of the space of all possible co-occurrence vectors that can be formed from the set of basis anchor vectors. However, the convex hull only encodes an unsupervised view of the data. To capture topics informed by metadata such as sentiment, we need to explicitly represent the combination of words and metadata.

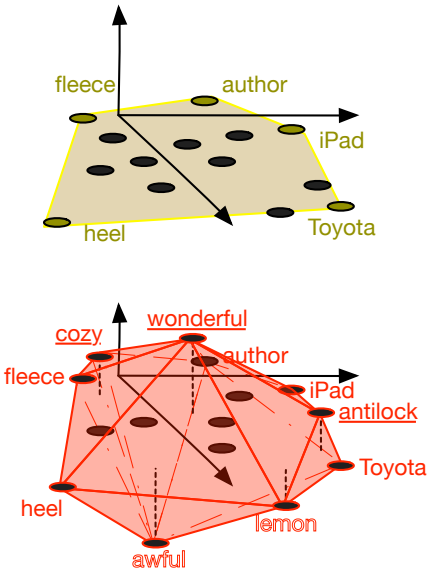

Figure 1: Graphical intuition behind supervised anchor words. Anchor words (in gold) form the convex hull of word co-occurrence probabilities in unsupervised topic modeling (top). Adding an additional dimension to capture metadata, such as sentiment, changes the convex hull: positive words appear above the original 2D plane (underlined) and negative words appear below (in outline).

One problem inherited by the anchor method from parametric topic models is the determination of the number of anchor words (and thus topics) to use. Because word co-occurrence statistics live in an extremely high-dimensional space, the number of anchor words needed to cover all of the data will be quite high. Thus, Arora et al. (2013) require a user to specify the number of anchor words *a priori* (just as for parametric topic models). They use a form of the Gram-Schmidt process to find the best words that enclose the maximum volume of points.

[1] As discussed by Arora et al. (2013), this is a slight simplification, since the most extreme points will be words that only appear infrequently. Thus, there is some nuance to choosing the anchor words. For instance, a key step for effective topic modeling is choosing a minimum number of documents a word must appear in before it can be considered an anchor word. (c.f. Figure 3).

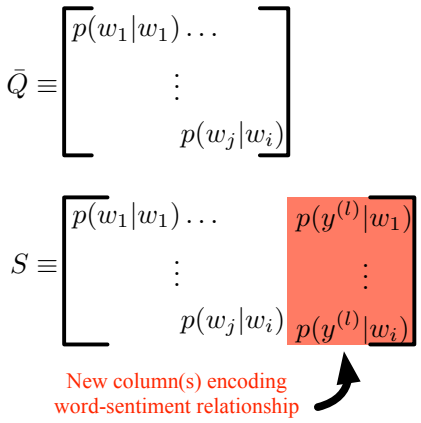

Figure 2: We form a new column to capture the relationship between words *and* each sentiment level: per entry is the conditional probability of observing a sentiment level $y^{(l)}$ given an observation of the word w_i. Adding all of these columns to $\bar{Q}$ to form an augmented matrix S.

2 Supervised Topics: Effective but Slow

Topic models discover a set of topics A. Each topic is a distribution over the V word types in the corpus. $A_{i,t}$ is the probability of seeing word i in topic t. Supervised topic models relate those topics with predictions of document metadata such as sentiment by discovering a vector of regression parameters $\vec{\mu}$ that connects topics to per-document observations y_d (Blei and McAuliffe, 2007). Blei and McAuliffe (2007) treat this as a regression: seeing one word with topic k in document d means that prediction of y_d should be adjusted by μ_k. Given a document's distribution over topics $\bar{z}_d$, the response y_d is normally distributed with mean $\vec{\mu}^\top \bar{z}_d$.[2]

Typically, the topics are discovered through a process of probabilistic inference, either variational EM (Wang et al., 2009) or Gibbs sampling (Boyd-Graber and Resnik, 2010). However, these methods scale poorly to large datasets. Variational inference requires dozens of expensive passes over the entire dataset, and Gibbs sampling requires multiple Markov chains (Nguyen et al., 2014b).

[2]We are eliding some details in the interest of a more compact presentation. The topics used by a document, $\bar{z}_d$, are based on per-token inference of topic assignments; this detail is not relevant to our contribution, and in Section 4.2 we use existing techniques to discover documents' topics.

3 Supervised Anchor Words

Because the anchor algorithm scales so well compared to traditional probabilistic inference, we now unify the supervised topic models of Section 2 with the anchor algorithm discussed in Section 1. We do so by augmenting the matrix $\bar{Q}$ with an additional dimension for each metadata attribute, such as sentiment. We provide the geometric intuition in Figure 1.

Picture the anchor words projected down to two dimensions (Lee and Mimno, 2014): each word is a point, and the anchor words are the vertices of a polygon encompassing every point. Every non-anchor word can be approximated by a convex combination of the anchor words (Figure 1, top).

Now add an additional dimension as a column to $\bar{Q}$ (Figure 2). This column encodes the metadata specific to a word. For example, we have encoded sentiment metadata in a new dimension (Figure 1, bottom). Neutral sentiment words will stay in the plane inhabited by the other words, positive sentiment words will move up, and negative sentiment words will move down. For simplicity, we only show a single additional dimension, but in general we can add as many dimensions as needed to encode the metadata.

In this new space some of the original anchor words may still be anchor words ("author"). Other words that were near the convex hull boundary in the unaugmented representation may become anchor words in the augmented representation because they capture both topic and sentiment ("anti-lock" vs. "lemon"). Finally, extreme sentiment words might become anchor words in the new higher-dimensional space because they are so important for explaining extreme sentiment values ("wonderful" vs. "awful").

3.1 Words to Sentiment

Having explained how a word is connected to sentiment, we now elaborates on how to model that connection using the conditional probability of sentiment given a particular word. Assume that sentiment is discretized into a finite set of L sentiment levels $\{y^{(1)}, y^{(2)}, \ldots, y^{(L)}\}$ and that each document is assigned to one of these levels. We define a matrix S of size $V \times (V + L)$. The first V columns are the same as $\bar{Q}$ and the L additional columns capture the relationship of a word to each discrete sentiment

level.

For each additional column l, $S_{i,(V+l)} \equiv p(y = y^{(l)} \mid w = i)$ is the conditional probability of observing a sentiment level $y^{(l)}$ given an observation of word i. We compute the conditional probability of a sentiment level $y^{(l)}$ given word i

$$S_{i,(V+l)} \equiv \frac{\sum_d (\mathbb{1}\left[i \in d\right] \cdot \mathbb{1}\left[y_d = y^{(l)}\right])}{\sum_d \mathbb{1}\left[i \in d\right]}, \quad (2)$$

where the numerator is the number of documents that contain word type i and have sentiment level $y^{(l)}$ and the denominator is the number of documents containing word i.

Given this augmented matrix, we again want to find the set of anchor words $\mathcal{G}$ and coefficients $C_{i,k}$ that best capture the relationship between words and sentiment (c.f. Equation 1)

$$S_{i,\cdot} = \sum_{g_k \in \mathcal{G}} C_{i,k} S_{g_k,\cdot}. \quad (3)$$

Because we retain the property that non-anchor words are explained through a linear combination of the anchor words, our method retains the same theoretical guarantees of sampling complexity and robustness as the original anchor algorithm.

To facilitate direct comparisons, we keep the number of anchor words fixed in our experiments. Even so, the introduction of metadata forces the anchor method to select the words that best capture this metadata-augmented view of the data. Consequently, some of the original anchor words will remain, and some will be replaced by sentiment-specific anchor words.

4 Quantitative Comparison of Supervised Topic Models

In this section, we evaluate the effectiveness of our new method on a binary sentiment classification problem. Because the supervised anchor algorithm (**SUP ANCHOR**) finds anchor words (and thus different topics) which capture the sentiment metadata, we evaluate the degree to which its latent representation improves upon the original unsupervised anchor algorithm (Arora et al., 2013, **ANCHOR**) for classification in terms of both accuracy and speed.

4.1 Sentiment Datasets

We use three common sentiment datasets for evaluation: AMAZON product reviews (Jindal and Liu, 2008), YELP restaurant reviews (Jo and Oh, 2011), and TRIPADVISOR hotel reviews (Wang et al., 2010). For each dataset, we preprocess by tokenizing and removing all non-alphanumeric words and stopwords. As very short reviews are often inscrutable and lack cues to connect to the sentiment, we only consider documents with at least thirty words. We also reduce the vocabulary size by keeping only words that appear in a sufficient number of documents: 50 for AMAZON and YELP datasets, and 150 for TRIPADVISOR (Table 1).

4.2 Documents to Labels

Our goal is to perform binary classification of sentiment. Due to a positive skew of the datasets, the median for all datasets is four out of five. All 5-star reviews are assigned to y^+ and the rest of the reviews are assigned to y^-. Table 1 summarizes the composition of each dataset and the percentage of documents with high positive sentiment.[3]

We compare the effectiveness of different representations in predicting high-sentiment documents: unsupervised topic models (**LDA**), traditional supervised topic models (**SLDA**), the unmodified anchor algorithm (**ANCHOR**), our supervised anchor algorithm (**SUP ANCHOR**), and a traditional TF-IDF (Salton, 1968, **TF-IDF**) representation of the words.

The anchor algorithm only provides the topic distribution over words; it does not provide the per-document assignment of topics needed to represent the document in a low-dimensional space necessary for producing a prediction y_d. Fortunately, this requires a very quick—because the topics are fixed—pass over the documents using a traditional topic model inference algorithm. We use the variational inference implementation for **LDA** of Blei et al. (2003)[4] to obtain $\bar{z}_d$, the topic distribution for document d.[5]

[3] Multiclass labeling for each sentiment label also works well, but binary classification simplifies the analysis and presentation.

[4] `http://www.cs.princeton.edu/~blei/lda-c/`

[5] For other inference schemes, we use native inference to apply pre-trained topics to extract DEV and TEST topic proportions.

Corpus	Train Documents	Test Documents	Tokens	Types	Percentage with Positive Sentiment
AMAZON	13,300	3,314	1,031,659	2,662	52.2%
TRIPADVISOR	115,384	28,828	12,752,444	4,867	41.5%
YELP	13,955	3,482	1,142,555	2,585	27.7%

Table 1: Statistics for the datasets employed in the experiments.

Classifiers Given a low-dimensional representation of a test document, we predict the document's sentiment y_d. We have already inferred the topic distribution $\bar{z}_d$ for each document, and we use $log(\bar{z}_d)$ as the features for a classifier. Feature vectors from training data are used to train the classifiers, and feature vectors from the development or test set are used to evaluate the classifiers.

We run three standard machine learning classifiers: decision trees (Quinlan, 1986), logistic regression (Friedman et al., 1998), and a discriminative classifier. For decision trees (hence TREE) and logistic regression (hence LOGISTIC), we use SKLEARN.[6] For the discriminative classifier, we use a linear classifier with hinge loss (hence HINGE) in Vowpal Wabbit.[7] Because HINGE outputs a regression value in $[0, 1]$, we use a threshold 0.5 to make predictions.

Parameter Tuning Parameter tuning is important in topic models, so we cross-validate: each sentiment dataset is split randomly into five folds. We used four folds to form the TRAIN set and reserved the last fold for the TEST set. All cross-validation results are averaged over the four held out DEV sets; the best cross-validation result provides the parameter settings we use on the TEST set.

For **ANCHOR** and **SUP ANCHOR**, the parameter for the document-level Dirichlet prior α is required for inferring document-topic distributions given learned topics. Despite selecting this parameter using grid search, α does not affect our final results. The same is also true for **SLDA**: its predictive performance does not significantly vary as α varies, given a fixed number of topics K.[8]

Anchor algorithms are sensitive to the value of anchor threshold M (the minimum document frequency for a word to be considered an anchor word). For each number of topics K, we perform a grid search to find the best value of M. Figure 3 shows the performance trends.

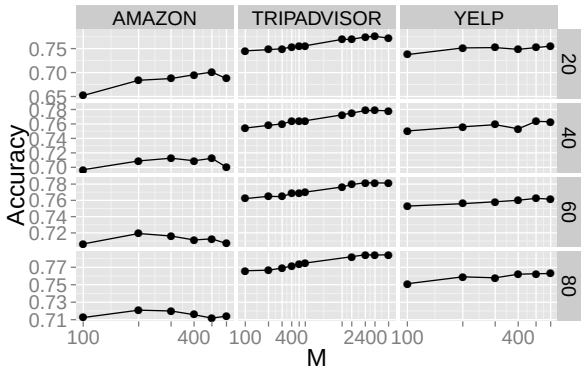

Figure 3: Grid search for selecting the word-document threshold M for **SUP ANCHOR** based on development set accuracy.

For **LDA**, we use the Gibbs sampling implementation in Mallet.[9] For training the model, we run **LDA** with 5,000 iterations; and for inference (on DEV and TEST) of document topic distribution we iterate 100 times, with lag 5 and 50 burn-in iterations. As Mallet accepts $\sum \alpha_i$ as a parameter, we always initialize $\sum \alpha_i = 1$ and only perform a grid search over different values of β, the hyper-parameter for Dirichlet prior over the per-topic topic-word distribution, starting from 0.01 and doubling until reaching 0.5.

4.3 SUP ANCHOR Outperforms ANCHOR

Learning topics that jointly reflect words and metadata improves subsequent prediction. The results for both **SUP ANCHOR** and **ANCHOR** on the TEST set are shown in Figure 4. **SUP ANCHOR** outperforms **ANCHOR** on all datasets. This trend holds consistently for LOGISTIC, TREE, and HINGE methods for sentiment prediction. For example, with twenty topics on the AMAZON dataset, **SUP ANCHOR** gives an

[6] http://scikit-learn.org/stable/

[7] http://hunch.net/~vw/

[8] We use the SLDA implementation by Chong Wang: http://www.cs.cmu.edu/~chongw/slda/ to estimate α.

[9] http://mallet.cs.umass.edu/topics.php

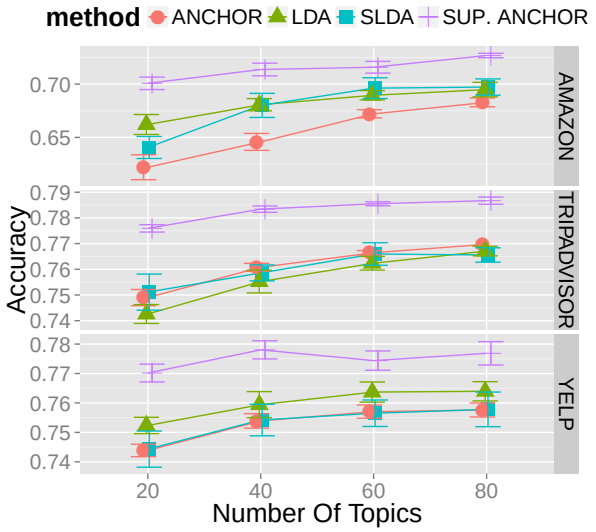

Figure 4: Results on TEST fold, **SUP ANCHOR** outperforms **ANCHOR**, **LDA**, and **SLDA** on all three datasets. We report the results based on LOGISTIC as it produces the best accuracy consistently for **ANCHOR**, **SUP ANCHOR**, and **LDA**.

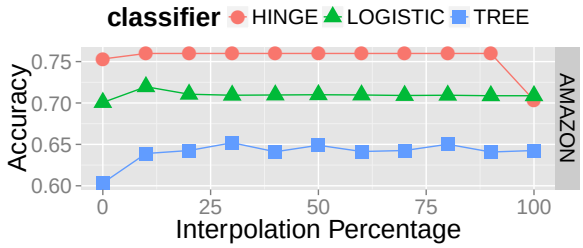

Figure 5: Accuracy on AMAZON with twenty topics. **SUP ANCHOR** produces good representations for sentiment classification that can be improved by interpolating with lexical **TF-IDF** features. The interpolation (x-axis) ranges from zero (all **TF-IDF** features) to one hundred (all **SUP ANCHOR** topic features).

accuracy of 0.71 in comparison to only 0.62 from **ANCHOR**. Similarly, with twenty topics on the YELP dataset, **SUP ANCHOR** has 0.77 accuracy while **ANCHOR** has 0.74. Our **SUP ANCHOR** model is able to incorporate metadata to learn better representations for predicting sentiment. Moreover, in Section 5 we show that **SUP ANCHOR** does not need to sacrifice topic quality to gain predictive power.

4.4 SUP ANCHOR Outperforms SLDA

More surprising is that **SUP ANCHOR** also outperforms **SLDA**. Like **SUP ANCHOR**, **SLDA** jointly learns topics and their relation to metadata such as sentiment. Figure 4 shows that this trend is consistent on all sentiment datasets. On average, **SUP ANCHOR** is 2.2 percent better than **SLDA** on AMAZON, and 2.0 percent better on both YELP and TRIPADVISOR. Furthermore, **SUP ANCHOR** is much faster than **SLDA**.

SLDA performs worse than **SUP ANCHOR** in part because **SUP ANCHOR** is able to jointly find specific lexical terms that improve prediction. Nguyen et al. (2013) show that this improves supervised topic models; forming anchor words around the same strong lexical cues could discover better topics. In contrast, **SLDA** must discover the relationship through the proxy of topics.

4.5 Lexical Features

Ramage et al. (2010) show that interpolating topic and lexical features often provides better classification than either alone. Here, we take the same approach and show how different interpolations of topic and lexical features create better classifiers. We first select an interpolation value λ in $\{0, 0.1, 0.2, \ldots, 1\}$, and we then form a new feature vector by concatenating λ-weighted topic features with $(1 - \lambda)$-weighted lexical features. Figure 5 shows the interplay between topic features and **TF-IDF** features[10] as the weight of topic features increases from zero (all **TF-IDF**) to one hundred (all **SUP ANCHOR** topic features) percent on the AMAZON dataset (other datasets are similar). Combining both feature sets is better than either alone, although the interpolation depends on the classifier.

4.6 Runtime Analysis

Having shown that **SUP ANCHOR** outperforms both **ANCHOR** and **SLDA**, in this section we show that **SUP ANCHOR** also inherits the runtime efficiency from **ANCHOR**. Table 2 summarizes the runtimes on both AMAZON and TRIPADVISOR; these results were obtained using a six-core 2.8GHz Intel Xeon X5660. On the small dataset AMAZON, **SUP ANCHOR** finishes the training within one minute, and for the larger TRIPADVISOR dataset it completes the

[10] As before, we do parameter selection on DEV data and report final TEST results.

Dataset	Measure	SUP ANCHOR	LDA	SLDA
AMAZON	Preprocessing	32	32	32
	Generating $\bar{Q}/S$	29		
	Training	33	886	4,762
	LDAC inference	38 (train), 13 (dev/test)		
	Classification	<5	<5	
TRIPADVISOR	Preprocessing	305	305	305
	Generating $\bar{Q}/S$	262		
	Training	181	8,158	71,967
	LDAC inference	830 (train), 280 (dev/test)		
	Classification	<5	<5	

Table 2: Runtime statistics (in seconds) for the AMAZON and TRIPADVISOR datasets. Blank cells indicate a timing which does not apply to a particular model. **SUP ANCHOR** is significantly faster than conventional methods.

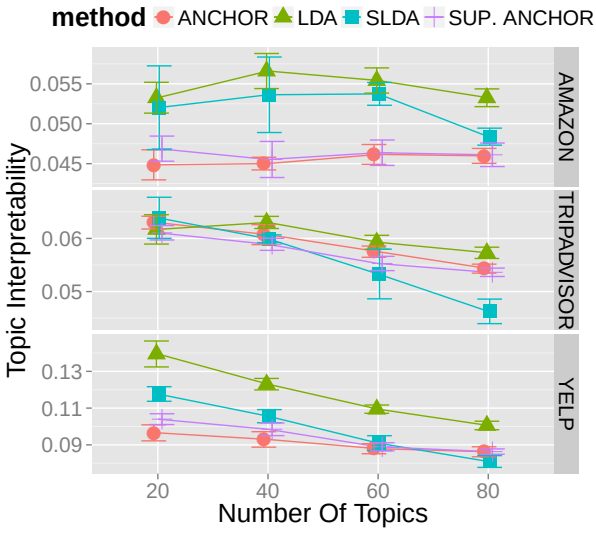

Figure 6: **SUP ANCHOR** and **ANCHOR** produce the same topic quality. **LDA** outperforms all other models and produces the best topics. Performance of **SLDA** degrades significantly as the number of topic increases.

learning in around three minutes. The main bottleneck for **SUP ANCHOR** is learning the document distributions over topics, although even this stage is fast for known topic distributions. This result is far better than the twenty hours required by **SLDA** to train on TRIPADVISOR.

5 Inspecting Anchors and their Topics

One important evaluation for topic models is how easy it is for a human reader to understand the topics. In this section, we evaluate topics produced by each model using topic interpretability (Chang et al., 2009). Topic interpretability measures how human users understand topics presented by a topic modeling algorithm. We use an automated approximation of interpretability that uses a reference corpus as a proxy for which words belong together (Newman et al., 2010). Using half a million documents from Wikipedia, we compute the induced normalized pairwise mutual information (Lau et al., 2014, NPMI) on the top ten words in topics as a proxy for interpretability.

Figure 6 shows the NPMI scores for each model. Unsurprisingly, unsupervised models (**LDA**) produce the best topic quality. In contrast, supervised models must balance metadata (i.e., response variable) prediction against capturing word meaning. Consequently, **SLDA** does slightly worse with respect to topic interpretability.

SUP ANCHOR and **ANCHOR** produce the same topic quality consistently on all datasets. Since **SUP ANCHOR** and **ANCHOR** have nearly identical runtime, **SUP ANCHOR** is better suited for supervised tasks because it improves classification without sacrificing interpretability. It is possible that regularization would improve the interpretability of these topics; Nguyen et al. (2014a) show that adding regularization removes overly frequent words from anchor-discovered topics.

The topics produced by the **ANCHOR** and **SUP ANCHOR** algorithms have many similarities. In Table 3, nearly all of the anchor words discovered by **ANCHOR** are also used by **SUP ANCHOR**. These anchor words tend to describe general food types, such as

Model	Anchor Words and Top Words in Topics	
ANCHOR and **SUP ANCHOR**	**pizza burger sushi ice garlic hot amp chicken pork french sandwich coffee cake steak beer fish**	
ANCHOR	**wine**	wine restaurant dinner menu nice night bar table meal experience
	hour	wait hour people minutes line long table waiting worth order
	late	night late ive people pretty love youre friends restaurant open
SUP ANCHOR	**favorite**	love favorite ive amazing delicious restaurant eat menu fresh awesome
	decent	pretty didnt restaurant ordered decent wasnt nice night bad stars
	line	line wait people long tacos worth order waiting minutes taco

Table 3: Comparing topics generated for the YELP dataset: anchor words shared by both **ANCHOR** and **SUP ANCHOR** are listed. Unique anchor words for each algorithm are listed along with the top ten words for that topic. For clarity, we pruned words which appear in more than 3000 documents as these words appear in every topic. The distinct anchor words reflect positive ("favorite") and negative ("line") sentiment rather than less sentiment-specific qualities of restaurants (e.g., restaurants open "late").

"pizza" or "burger", and characterize the YELP dataset well. The similarity of these shared topics explains why both **ANCHOR** and **SUP ANCHOR** achieve similar topic interpretability scores.

To explain the predictive power of **SUP ANCHOR** we must examine the anchor words and topics unique to both algorithms. The anchor words which are unique to **ANCHOR** include a general topic about wine, and two somewhat coherent topics related to time. By adding supervision to the model we get three new anchor words which identify sentiment ranging from extremely positive reviews mentioning a favorite restaurant to extremely negative reviews complaining about long waits.

This general trend is seen across each of the datasets. For example, **ANCHOR** and **SUP ANCHOR** both discover shared topics describing consumer goods, but **SUP ANCHOR** replaces two topics discussing headphones with topics describing "frustrating" products and "great" products. Similarly, in the TRIPADVISOR data, both **ANCHOR** and **SUP ANCHOR** share topics about specific destinations, but only **SUP ANCHOR** discovers a topic describing "disgusting" hotel rooms.

6 Related Work

Improving the scalability of statistical learning has taken many forms: creating online approximations of large batch algorithms (Hoffman et al., 2013; Zhai et al., 2014) or improving the efficiency of sampling (Yao et al., 2009; Hu and Boyd-Graber, 2012; Li et al., 2014).

These insights have also improved supervised topic models. For example, Zhu et al. (2013) train the max-margin supervised topic models **MEDLDA** (Zhu et al., 2009) by reformulating the model such that the hinge loss is included inside a collapsed Gibbs sampler, rather than being applied externally on the sampler using costly SVMs. Using insights from Smola and Narayanamurthy (2010), the samplers run in parallel to train the model. While these advancements improve the scalability of max-margin supervised topic models, the improvement is limited by the fact that the sampling algorithm grows with the number of tokens.

In contrast, this paper explores a different vein of research that focuses on using efficient representations of summary statistics to estimate statistical models. While this has seen great success in unsupervised models (Cohen and Collins, 2014), it has increasingly also been applied to supervised models. Wang and Zhu (2014) show how to use tensor decomposition to estimate the parameters of **SLDA** instead of sampling to find maximum likelihood estimates. In contrast, anchor-based methods rely on non-negative matrix factorization.

We found that a discriminative classifier did not always perform best on the downstream classification task. Zhu et al. (2009) make a comprehensive comparison between **MEDLDA**, **SLDA**, and SVM+LDA, and they show that SVM+LDA performs worse than **MEDLDA** and **SLDA** on binary classification. It could be that better feature preprocessing could improve our performance.

Bag-of-words representations are not ideal for sentiment tasks. Rubin et al. (2012) introduce Dependency LDA which associates individual word tokens with different labels; their model also outperforms linear SVMs on a very large multi-labeled corpus. Latent variable models that consider grammatical structure (Sayeed et al., 2012; Socher et al., 2011; Iyyer et al., 2014) could also be improved through efficient inference (Cohen and Collins, 2014).

7 Discussion

Supervised anchor word topic modeling provides a general framework for learning better topic representations by taking advantage of both word-cooccurrence and metadata. Our straightforward extension (Equation 2) places each word in a vector space that not only captures co-occurrence with other terms but also the interaction of the word and its sentiment, in contrast to algorithms that only consider raw words.

While our experiments focus on binary classification, the same extension is also applicable to multi-class classification.

Moreover, supervised anchor word topic modeling is fast: it inherits the polynomial-time efficiency from the original unsupervised anchor word algorithm. It is also effective: it is better at providing features for classification than unsupervised topic models and also better than supervised topic models with conventional inference.

Our supervised anchor word algorithm offers the ability to quickly analyze datasets without the overhead of Gibbs sampling or variational inference, allowing users to more quickly understand big data and to make decisions. Combining bag-of-words analysis with metadata through efficient, low-latency topic analysis allows users to have deep insights more quickly.

Abstract

Recently, there has been increasing interest in learning semantic parsers with indirect supervision, but existing work focuses almost exclusively on question answering. Separately, there have been active pursuits in leveraging databases for distant supervision in information extraction, yet such methods are often limited to binary relations and none can handle nested events. In this paper, we generalize distant supervision to complex knowledge extraction, by proposing the first approach to learn a semantic parser for extracting nested event structures without annotated examples, using only a database of such complex events and unannotated text. The key idea is to model the annotations as latent variables, and incorporate a prior that favors semantic parses containing known events. Experiments on the GENIA event extraction dataset show that our approach can learn from and extract complex biological pathway events. Moreover, when supplied with just five example words per event type, it becomes competitive even among supervised systems, outperforming 19 out of 24 teams that participated in the original shared task.

1 Introduction

The goal of semantic parsing is to map text into a complete and detailed meaning representation (Mooney, 2007). Supervised approaches for learning a semantic parser require annotated examples, which are expensive and time-consuming to acquire (Zelle and Mooney, 1993; Zettlemoyer and Collins, 2005; Zettlemoyer and Collins, 2007). As a result, there has been rising interest in learning semantic parsers from indirect supervision. Examples include unsupervised approaches that leverage distributional similarity by recursive clustering (Poon and Domingos, 2009; Poon and Domingos, 2010; Titov and Klementiev, 2011), semi-supervised approaches that learn from dialog context (Artzi and Zettlemoyer, 2011), grounded approaches that learn from annotated question-answer pairs (Clarke et al., 2010; Liang et al., 2011) or virtual worlds (Chen and Mooney, 2011; Artzi and Zettlemoyer, 2013).

Such progress is exciting, but most applications focus on question answering, where the semantic parser is used to convert natural-language questions into formal queries. In contrast, complex knowledge extraction represents a relatively untapped ap-

Information Extraction:
(NEG-REG,BCL,RFLAT)
(NEG-REG,IL-10,RFLAT)

Complex Event:
(POS-REG,BCL,(NEG-REG,IL-10,RFLAT))

GENIA Event Annotation:

ID	TYPE	CAUSE	THEME	TRIGGER
T1	PROTEIN	-	-	BCL
T2	PROTEIN	-	-	RFLAT
T3	PROTEIN	-	-	IL-10
E1	POS-REG	T1	E2	stimulates
E2	NEG-REG	T3	T2	inhibition

Figure 1: Given sentence "BCL stimulates inhibition of RFLAT by IL-10", information extraction focuses on classifying simple relations among entities (top), whereas ideally we want to extract the complex event that captures important contextual information (middle), as exemplified by the GENIA event annotation (bottom).

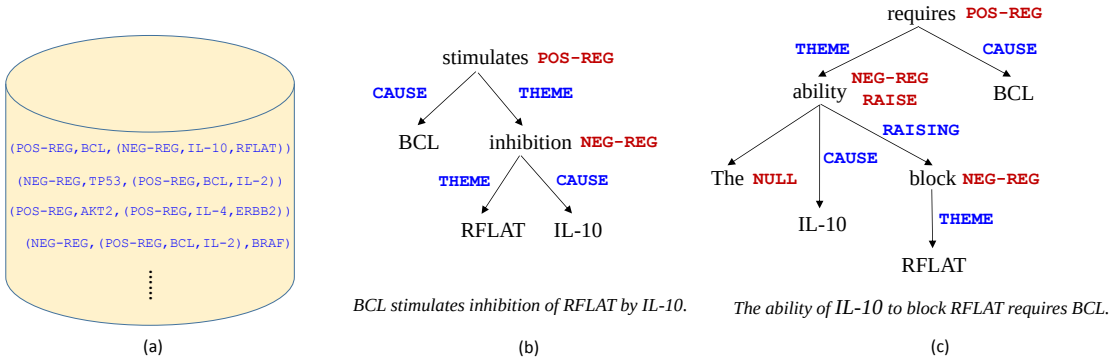

Figure 2: Grounded semantic parsing for complex knowledge extraction: (a) input database of complex events, without textual annotation; (b) event extraction as semantic parsing; (c) a complex sentence that requires RAISING.

plication area for semantic parsing, with great potential. Text with valuable information has been undergoing rapid growth across scientific and business disciplines alike. A prominent example is PubMed (www.ncbi.nlm.nih.gov/pubmed), which contains over 24 million biomedical research articles and grows by over one million each year. Research on information extraction abounds, but it tends to focus on classifying simple relations among entities, so is incapable of extracting the prevalent complex knowledge with nested event structures. Figure 1 illustrates this problem with an example sentence "BCL stimulates inhibition of RFLAT by IL-10". Traditional information extraction would be content with extracting two binary relation instances (NEG-REG,BCL,RFLAT) and (NEG-REG,IL-10,RFLAT), where NEG-REG represents a negative regulation (i.e., inhibition). However, the sentence also discloses important contextual information, i.e., BCL regulates RFLAT by stimulating the inhibitive effect of IL-10, and likewise the inhibition of RFLAT by IL-10 is controlled by BCL. Such context-specific knowledge is crucial in translational medicine: imagine a targeted therapy that tries to suppress RFLAT by inducing either BCL or IL-10, without taking into account their interdependency. As Figure 1 shows, this knowledge can be represented by events with nested structures (e.g., the THEME argument of E1 is an event E2), as exemplified by the GENIA event extraction dataset (Kim et al., 2009).

Complex knowledge extraction can be naturally framed as a semantic parsing problem, with the event structure represented by a semantic parse; see Figure 2. However, annotating example sentences is expensive and time-consuming. GENIA is the only corpus of its kind by far; its annotation took years and its scope is limited to the narrow domain of transcription in human blood cells. In contrast, databases are usually available. For example, due to the central importance of biological pathways in understanding diseases and developing drug targets, there exist many pathway databases (Schaefer et al., 2009; Kanehisa, 2002; Cerami et al., 2011). Limited by manual curation, they are incomplete and not up-to-date, thereby the need for automated extraction. But compared to question answering, knowledge extraction can derive more leverage from such databases via distant supervision (Craven and Kumlien, 1999; Mintz et al., 2009). The key insight is that databases can be used to automatically annotate sentences with a relation if the arguments of a known instance co-occur in the sentence. This learning paradigm, however, has never been applied to extracting nested events.

In this paper, we propose the first approach to learn a semantic parser from a database of complex events and unannotated text, by generalizing distant supervision to complex knowledge extraction. The key idea is to recover the latent annotations via EM, guided by a structured prior that favors semantic parses containing known events in the database, in the form of virtual evidence (Pearl, 1988; Subramanya and Bilmes, 2007). Experiments on the GENIA dataset demonstrate the promise of this direction. Our GUSPEE (*GroUnded Semantic Parsing for Event Extraction*) system can successfully learn from and extract complex events, without requiring

textual annotations (Figure 2). Moreover, after incorporating prototype-driven learning using just five example words for each event type, GUSPEE becomes competitive even among supervised systems, outperforming 19 out of 24 teams that participated in the GENIA event extraction shared task. With significant information loss (skipping event triggers and, most importantly, the nested event structures), it is possible to reduce GENIA events to binary relations so that existing distant-supervision methods are applicable. Yet even in such an evaluation tailored for existing methods, our system still outperformed them by a wide margin.

2 Related Work

Existing approaches for GENIA event extraction are supervised methods that either used a carefully engineered classification pipeline (Bjorne et al., 2009; Quirk et al., 2011) or applied joint inference (Riedel et al., 2009; Poon and Vanderwende, 2010; Riedel and McCallum, 2011). Poon and Vanderwende (2010) used a dependency-based formulation that resembled our semantic parsing one, but learned from supervised data. Classification approaches first need to classify words into event triggers, where distant supervision is not directly applicable.

In distant supervision (Craven and Kumlien, 1999; Mintz et al., 2009), if two entities are known to have a binary relation in the database, their co-occurrence in a sentence justifies labeling the instance with the relation. This assumption is often incorrect, and Riedel et al. (2010) introduced latent variables to model the uncertainty; the model was later improved by Hoffmann et al. (2011). GUSPEE generalizes this idea to structured prediction where the latent annotations are not simple classification decisions, but nested events. Krishnamurthy and Mitchell (2012) and Reddy et al. (2014) took an important step toward this direction, by learning a semantic parser based on combinatorial categorial grammar (CCG) from Freebase and web sentences. However, Krishnamurthy and Mitchell (2012) still learned from binary relations, using only simple sentences (of length ten or less). Reddy et al. (2014) learned from n-ary relations as well, yet their formulation only allows relations between entities, not relations between relations. Thus their approach cannot represent nested events, let alone extracting them. And like Krishnamurthy and Mitchell (2012), Reddy et al. (2014) focused on simple text and excluded sentences where entities were not dependency neighbors (i.e., not directly connected in the ungrounded graph), as well as sentences with unknown entities. While such restrictions do not impede parsing simple questions in their evaluation, their approach is not directly applicable to complex knowledge extraction. Reschke et al. (2014) also generalized distant supervision to n-ary relations for extracting template-based events, but similar to Reddy et al. (2014), they did not consider nested events.

Distant supervision can be viewed as a special case of the more general paradigm of *grounded learning* from a database. Clarke et al. (2010) and Liang et al. (2011) used the database to determine if a candidate semantic parse would yield the annotated answer, whereas distant supervision uses the database to determine if a relation instance is contained therein. Our GUSPEE system is inspired by grounded unsupervised semantic parsing (GUSP) (Poon, 2013) and shares a similar semantic representation. GUSP, like most grounded learning approaches, applied to question answering and did not leverage distant supervision. GUSPEE can thus be viewed as an extension of GUSP to leverage distant supervision for complex knowledge extraction.

Grounding in GUSPEE is materialized by virtual evidence favoring semantic structures that conform with the database. The idea of virtual evidence was first introduced by Pearl (1988) and later applied in several applications such as Subramanya and Bilmes (2007). Unlike in prior work, the virtual evidence in GUSPEE involves non-local factors (comparing a semantic parse with complex events in the database) and presents a major challenge to efficient learning.

Existing semantic parsers often adopt highly expressive formalisms such as CCG (Steedman, 2000). Such formalisms are extremely powerful, but also difficult to learn. We instead adopted a dependency-based formalism (Poon and Domingos, 2009; Liang et al., 2011; Poon, 2013). Moreover, following Poon and Domingos (2009), Krishnamurthy and Mitchell (2012), Poon (2013), we started with syntactic dependency parses, and focused on annotating nodes and edges with semantic states.

3 Grounded Semantic Parsing for Event Extraction

We use the GENIA event extraction task (Kim et al., 2009) as a representative example of complex knowledge extraction. The goal is to identify biological events from text, including the trigger words and arguments (Figure 1, bottom). There are nine event types, including simple ones such as `Expression` and `Transcription` that can only have one `THEME` argument, `Binding` that can have more than one `THEME` argument, and regulations that can have both `THEME` and `CAUSE` arguments. Protein annotations are given as input.

We formulate this task as semantic parsing and present our GUSPEE system (Figure 2). The core of GUSPEE is a tree HMM (Section 3.1), which extracts events from a sentence by annotating its syntactic dependency tree with event and argument states. In training, GUSPEE takes as input unannotated text and a database of complex events, and learns the tree HMM using EM, guided by grounded learning from the database via virtual evidence.

3.1 Problem Formulation

Let t be a syntactic dependency tree for a sentence, with nodes n_i and dependency edges $d_{i,j}$ (n_j is a child of n_i). A semantic parse of t is an assignment z that maps each node to an event state and each dependency to an argument state. The semantic state of a protein word is fixed to that protein annotation. Basic event states are the nine event types and `NULL` (signifying a non-event, e.g., "The" in Figure 2 (c)). Basic argument states are `THEME`, `CAUSE`, and `NULL`. Additional states will be introduced later in Section 3.2 and 3.4.

GUSPEE models z, t by a tree HMM:

$$P_\theta(z,t) = \prod_m P_{\texttt{EMIT}}(t_m|z_m,\theta) \cdot P_{\texttt{TRANS}}(z_m|z_{\pi(m)},\theta)$$

where θ are the emission and transition parameters, m ranges over the nodes and dependency edges, $\pi(n_j) = d_{i,j}$ and $\pi(d_{i,j}) = n_i$. Note that this formulation implicitly assumes a fixed underlying directed tree, while the words and dependencies may vary.

Semantic parsing finds the most probable semantic assignment given the dependency tree:

$$z^* = \arg\max_z \log P_\theta(z|t) = \arg\max_z \log P_\theta(z,t)$$

In training, GUSPEE takes as input a set of complex events (database K) and syntactic dependency trees (unannotated text T), and maximizes the likelihood of T augmented by virtual evidence $\phi_K(z)$.

$$\begin{aligned}\theta^* &= \arg\max_\theta \quad \log P_\theta(T|K) \\ &= \arg\max_\theta \quad \sum_{t\in T} \log \sum_z P_\theta(z,t) \cdot \phi_K(z)\end{aligned}$$

Virtual evidence is analogous to a Bayesian prior, but applies to variable states rather than model parameters (Subramanya and Bilmes, 2007).

3.2 Handling Syntax-Semantics Mismatch

For simple sentences such as the one in Figure 2(b), the complex event can be represented by a semantic parse using only basic states. In general, however, syntax and semantics often diverge. For example, in Figure 2(c), "requires" triggers the top `POS-NEG` event that has a `THEME` argument triggered by "block", but "ability" stands in between the two; likewise for "block" and "IL-10". Additionally, mismatch could stem from errors in the syntactic parse. In such cases, the correct semantic parse can no longer be represented by basic states alone. Following GUSP (Poon, 2013), we introduced a new argument state `RAISING` which, if assigned to a dependency, would require that the parent and child be assigned the same basic event state. We also introduce a corresponding `RAISE` version for each non-null event state, to signify that the word derives its basic state from `RAISING` of a child. `RAISING` is related to but not identical with type raising in CCG and other grammars. For simplicity, we did not use other complex states explored in Poon (2013).

3.3 Virtual Evidence for Grounded Learning

Grounded learning in GUSPEE is attained by incorporating the virtual evidence $\phi_K(z)$, which favors the z's containing known events in K and penalizes those containing unknown events. Intuitively, this can be accomplished by identifying events in z and comparing them with events in K. But this is not robust as individual events and mentions may be fragmental and incomplete. Insisting on matching an event in full would miss partial matches that still convey valuable supervision. Proteins are given as

input and can be mapped to event arguments a priori. Matching sub-events with only one protein argument would be too noisy without direct supervision on triggers. We thus consider matching minimum sub-events with two protein arguments.

Specifically, we preprocessed complex events in K to identify minimum logical forms containing two protein arguments from each complex event, where arguments not directly leading to either protein are skipped. For example, the complex event in Figure 1 would generate three sub-events: `(NEG-REG,IL-10,RFLAT)`, `(POS-REG,BCL,(NEG-REG,-,RFLAT))`, `(POS-REG,BCL,(NEG-REG,IL-10,-))`, where – signifies underspecification. We denote the set of such sub-events as $S(K)$.

Likewise, given a semantic parse z, for every protein pair in z, we would convert the minimum semantic parse subtree spanning the two proteins into the canonical logical form and compare it with elements in $S(K)$. If the minimum subtree contains `NULL`, either in an event or argument state, it signifies a non-event and would be ignored. Otherwise, the canonical form is derived by collapsing `RAISING` states. For example, in both Figure 2 (b) and (c), the minimum subtree spanning the proteins `IL-10` and `RFLAT` is converted into the same logical form of `(NEG-REG,IL-10,RFLAT)`. We denote the set of such logical forms as $E(z)$.

Formally, the virtual evidence in GUSPEE are:

$$\phi_K(z) = \exp \sum_{e \in E(z)} \sigma(e, K)$$

where

$$\sigma(e, K) = \begin{cases} \kappa & : e \in S(K) \\ -\kappa & : e \notin S(K) \end{cases}$$

In distant supervision, where z is simply a binary relation, it is trivial to evaluate $\phi_K(z)$. (In fact, the original distant supervision algorithm is exactly equivalent to this form, with $\kappa = \infty$.) In GUSPEE, however, z is a semantic parse and evaluating $E(z)$ and $\sigma(e, K)$ involves a global factor that does not decompose into local dependencies as the tree HMM $P_\theta(z, t)$. The naive way to compute the augmented likelihood (Section 3.1) is thus intractable.

3.4 Efficient Learning with Virtual Evidence

To render learning tractable, the key idea is to augment the local event and argument states so that they contain sufficient information for evaluating $\phi_K(z)$. Specifically, the semantic state $z(n_i)$ needs to represent not only the semantic assignment to n_i (e.g., a `NEG-REG` event trigger), but also the set of (possibly incomplete) sub-events in the subtree under n_i. We accomplished this by representing the semantic paths from n_i to proteins in the subtree. For example, in Figure 2 (b), the augmented state of "inhibition" would be (`NEG-REG`→`THEME`→`RFLAT`, `NEG-REG`→`CAUSE`→`IL-10`). To facilitate canonicalization and sub-event comparison, a path containing `NULL` will be skipped, and `RAISING` will be collapsed. E.g., in Figure 2(c), the augmented state of "ability" would become (`NEG-REG`→`THEME`→`RFLAT`, `NEG-REG`→`CAUSE`→`IL-10`).

With these augmented states, $\phi_K(z)$ decomposes into local factors. The proteins under n_i are known a priori, as well as the children containing them. Semantic paths from n_i to proteins can thus be computed by imposing consistency constraints for each child. Namely, for child n_j that contains protein p, the semantic path from n_i to p should result from combining $z(n_i)$, $z(d_{i,j})$, and the semantic path from n_j to p. The minimum sub-events spanning two proteins under n_i, if any, can be derived from the semantic paths in the augmented state. Note that if both proteins come from the same child n_j, the pair needs not be considered at n_i, as their minimum spanning sub-event, if any, would be under n_j and already be factored in there.

The number of augmented states is $O(s^p)$, and the number of sub-event evaluations is $O(s \cdot p^2)$, where s is the number of distinct semantic paths, and p is the number of proteins in the subtree. Below, we show how s, p can be constrained to reasonable ranges to make computation efficient.

First, consider s. The number of semantic paths is theoretically unbounded since a path can be arbitrarily long. However, semantic paths contained in a database event are bounded in length and can be precomputed from the database (the maximum in GENIA is four). Longer paths can be represented by a special dummy path signifying that they

would not match any database events. Likewise, certain sub-paths would not occur in database events. E.g., in GENIA, simple events cannot take events as arguments, so paths containing sub-paths such as `Expression` → `Transcription` are also illegitimate and can be represented same as the above. We also notice that for regulation events with other regulation events as arguments, the semantics can be compressed into a single regulation event, e.g., `POS-REG`→`NEG-REG` is semantically equivalent with `NEG-REG`, as the collective effect of a positive regulation on top of a negative one is negative. Therefore, when evaulating the semantic path from n_i to a protein during dynamic programming, we would collapse consecutive regulation events in the child path, if any. This further reduces the length of semantic paths to at most three (regulation - regulation - simple event - protein).

Next, we notice that p is bounded to begin with, but it could be quite large. When a sentence contains many proteins (i.e., large p), it often stems from conjunction of proteins, as in "TP53 regulates many downstream targets such as ABCB1, AFP, APC, ATF3, BAX". All proteins in the conjunct play a similar role in their respective events, such as `THEME` in the above example among "ABCB1, AFP, APC, ATF3, BAX", and so share the same semantic paths. Therefore, prior to learning, we preprocessed the sentences to condense each conjunct into a single *effective* protein node. We identified conjunction by Stanford dependencies (`conj_*`). In GENIA, this reduces the maximum number of effective protein nodes to two for the vast majority of sentences (over 90%). Both representation and evaluation are now reasonably efficient. To further speed up learning, in our experiments we only trained on sentences with at most two effective protein nodes, as this already performed quite well. Training on GENIA took 1.5 hours and semantic parsing of a sentence took less than a second (with one i7 core at 2.4 GHz).

Unlike `RAISING`, the augmented states introduced in this section are specific to GENIA events. However, the rules to canonicalize states are general and can potentially be adapted to other domains. An alternative strategy to combat state explosion is by embedding the discrete states in a low-dimensional vector space (Socher et al., 2013), which is a direction for future research.

3.5 Features

The GUSPEE model uses log-linear models for the emission and transition probabilities and trains using feature-rich EM (Berg-Kirkpatrick et al., 2010). The features are:

Word emission $\mathbb{I}[\text{lemma} = l, z_m = n]$;

Dependency emission $\mathbb{I}[\text{dependency} = d, z_m = e]$ where $e \notin \{\texttt{NULL}, \texttt{RAISE}\}$;

Transition $\mathbb{I}[z_m = a, z_{\pi(m)} = b]$ where $a, b \notin \{\texttt{NULL}, \texttt{RAISE}\}$.

To modulate the model complexity, GUSPEE imposes a standard L_2 prior on the weights, and includes the following features with fixed weights:

- $W_{\texttt{NULL}}$: apply to `NULL` states;
- $W_{\texttt{RAISE}-P}$: apply to protein `RAISING`;
- $W_{\texttt{RAISE}-E}$: apply to event `RAISING`.

The advantage of a feature-rich representation is flexibility in feature engineering. Here, we excluded `NULL` and `RAISE` in dependency emission and transition features, and regulated them separately to enable parameter tying for better generalization.

4 Experiments

4.1 Evaluation on GENIA Event Extraction

In principle, we can learn GUSPEE from any pathway database. However, evaluation is challenging as these databases do not contain textual annotations. Prior work on distant supervision resorted to sampling and annotating new extractions. This is effective for comparing among distant-supervision systems, but it cannot be used to compare them with supervised learning. Moreover, as annotation is conducted by the authors or crowdsourcing, consistency and quality are hard to control.

We thus adopted a novel approach to evaluation by simulating a grounded learning scenario using the GENIA event extraction dataset (Kim et al., 2009). Specifically, we generated a set of complex events from the annotations of training sentences as the database. The annotations were discarded afterwards and GUSPEE learned from the database and unannotated text alone. The learned model was then applied to semantic parsing of test sentences and evaluated on event precision, recall, and F1. This

Table 2: GENIA event extraction results of state-of-the-art supervised system MSR11 (Quirk et al., 2011).

evaluation methodology enables us to assess the true accuracy and compare head-to-head with supervised methods.

GENIA contains 800 abstracts for training and 150 for development. It also has a test set, but its annotation is not made public. Therefore, we used the training set for grounded learning and development, and reserved the development set for testing. The majority events are Regulation (including Positive_regulation, Negative_regulation). See Kim et al. (2009) for details. We processed all sentences using SPLAT (Quirk et al., 2012), to conduct tokenization, part-of-speech tagging, and constituency parsing. We then postprocessed the parses to obtain Stanford dependencies (de Marneffe et al., 2006). During development on the training data, we found the following parameters (Section 3) to perform quite well and used them in all subsequent experiments: $\kappa = 20$, $W_{\texttt{NULL}} = 4$, $W_{\texttt{RAISE}-P} = 2$, $W_{\texttt{RAISE}-E} = -6$, L_2 prior $= 0.1$. Interestingly, we found that encouraging protein RAISING is beneficial, which probably stems from the fact that proteins are often separated from event triggers by noun modifiers, such as "the BCL gene", "IL-10 protein".

Table 1 shows GUSPEE's results on GENIA event extraction. Note that this event-based evaluation is rather stringent, as it considers an event incorrect if one of its argument events is not completely correct, thus an incorrect event will render all its upstream events incorrect. See Kim et al. (2009) for details. For comparison, Table 2 shows the results of MSR11, a state-of-the-art supervised system. MSR11 also provides a upper bound for the supervised version of GUSPEE, as the latter is much less engineered.

Not surprisingly, grounded learning with GUSPEE still lags behind supervised learning. MSR11 used a rich set of features, including POS tags, linear and dependency n-grams, etc. Also, it is expected that indirect supervision do not provide as effective signals as direct supervision. However, the comparison reveals a particularly interesting contrast. Event types such as Expression, Catabolism, Phosphorylation, and Localization are relatively easy, yet GUSPEE performed rather poorly on them. Simple events do not admit multiple arguments, so they appear less often in the virtual evidence, and grounded learning has difficulty learning these event types, especially their triggers. In light of this, it's actually remarkable that GUSPEE still learned a substantial portion of them.

4.2 Prototype-Driven Learning

While full-blown annotations are undoubtedly expensive and time-consuming to generate, it is rather easy for a domain expert to provide a few trigger words per event type, such as "expression", "expressed" for Expression. This motivates us to explore prototype-driven learning (Haghighi and Klein, 2006) in combination with grounded learning. Specifically, we simulated expert selection by picking the top five most frequent trigger words for each event type from training data. We then augmented grounded learning in GUSPEE by incorporating word emission features for each prototype word and the corresponding event state, e.g., $\mathbb{I}[\text{lemma} = \text{express}, z_m = \texttt{Expression}]$. The weights are fixed to a large number (five in our case). Table 3 shows the results with prototypes, which improved substantially. Not surprisingly, simple

Table 3: GENIA event extraction results of GUSPEE with five prototype words per event type

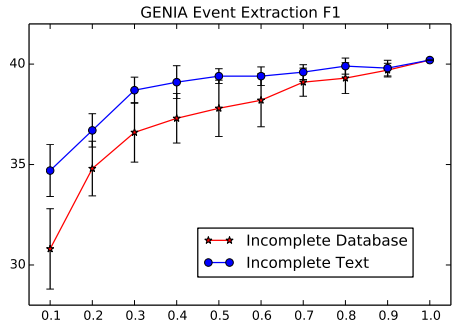

Figure 3: GENIA Event F1 of GUSPEE with prototypes, using incomplete database or text.

events such as Catabolism benefited the most from prototypes, as they have fewer variations in triggers. While the F1 score 40.2 still lags behind the supervised state of the art, it would have been competitive compared to the 24 teams participating in the original shared task, outperforming 19 of them (the top 5th system scored an F1 of 40.5, see www.nactem.ac.uk/tsujii/GENIA/SharedTask/results/results-master.html, Task 1).

4.3 Database-Text Mismatch

In our simulation of grounded learning, every event in the database is mentioned in some text and vice versa. In practice, however, there is usually a mismatch between database and text: the unannotated text generally contains more facts than are already populated in the database; conversely, a database fact may not be explicitly mentioned in the text.

The GENIA dataset offers an excellent opportunity to study the robustness of grounded learning in light of such mismatch. Specifically, we simulated a grounded learning scenario with an incomplete database by populating events from the annotations of a random fraction of training text, and then learning GUSPEE with this database and all training text. Likewise, we simulated a scenario with incomplete text using the training event database in full, but only a fraction of unannotated text.

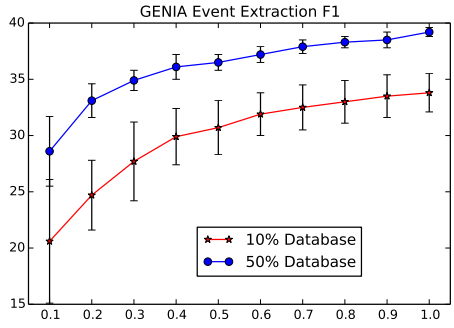

Figure 4: GENIA Event F1 of GUSPEE with prototypes, using a fraction of database and increasing amount of unannotated text.

Figure 3 shows the results of GUSPEE with prototypes as the fraction varies between 0.1 and 1, by averaging five random runs. In both scenarios, the F1 score degrades smoothly as the fraction gets smaller. Precision stays roughly the same while recall gradually degrades (curves not shown). This shows that GUSPEE is reasonably robust. Not surprisingly, the degradation is steeper with incomplete database than with incomplete text.

To further investigate the effect of unannotated text, we also randomly sampled a fraction of database events for grounded supervision, and evaluated GUSPEE with increasing amounts of unannotated text. Figure 4 shows the results by averaging nine random runs. The F1 increases steadily with additional unannotated text, mainly due to rising recall (curves not shown). This suggests that GUSPEE could potentially benefit from more unannotated text and is reasonably robust even when some text is not relevant to the available events. As expected, more grounded supervision (50% vs. 10% database) led to substantially better F1 and lower variation.

4.4 Error Analysis

Upon manual inspection, we found that syntactic errors considerably affect performance. Poon (2013)

introduced complex states such as `Sinking` and `Implicit` to combat syntax-semantics mismatch, which could also be incorporated into GUSPEE. Improving syntactic parsing, either separately by adapting to the biomedical domain, or jointly along with semantic parsing, is another important future direction. GUSPEE achieved better precision than recall, especially when learning with prototypes, and might benefit from augmenting prototypes by distributional similarity (Haghighi and Klein, 2006).

4.5 Comparison with Existing Distant Supervision Approaches

Existing distant supervision approaches are not directly applicable to extracting nested events. However, we can convert the extraction task into classifying minimum sub-events between proteins, for which existing methods can be applied. Specifically, we used binary sub-events in $S(K)$ (Section 3.3) for distant supervision, and evaluated on classifying test sentences. This would enable an interesting comparison with GUSPEE, as the latter also derived indirect supervision from $S(K)$ alone. Textual annotations of triggers and nested event structures in GUSPEE output were ignored, and prototypes were not used to enable a fair comparison. For distant supervision, we used the state-of-the-art MultiR system (Hoffmann et al., 2011) with standard lexical and syntactic features (Mintz et al., 2009). MultiR can be used for supervised learning by fixing relations according to the sentence-level annotations, which provides a supervised upper bound.

Table 4 shows the results. GUSPEE outperformed MultiR by a wide margin, improving F1 by 24%. Surprisingly, GUSPEE even surpassed the supervised upper bound of MultiR. This suggests that our semantic parsing formulation not only is superior in representation power, but also facilitates better learning. We also experimented with sharing parameters among related sub-events in a MultiR-like model, but it did not improve the performance. Upon close inspection, we found that MultiR mainly scored on `Binding` events and failed almostly entirely on the more difficult `Regulation` events. GUSPEE was able to extract `Regulation` events, but incurred some precision errors.

Method	Rec.	Prec.	F1 (Class.)
MultiR	11.2	21.7	14.8
MultiR (Super.)	12.1	24.4	16.2
GUSPEE	22.9	15.3	18.4

Table 4: Classification results on GENIA when events are simplified to binary relations for distant supervision.

5 Summary

We generalize distant supervision to complex knowledge extraction and propose the first approach to learn a semantic parser from a database of nested events and unannotated text. Experiments on GENIA event extraction showed that our GUSPEE system could learn from and extract such complex events, and was competitive even among supervised systems after incorporating a few easily-obtainable prototype event trigger words.

Future directions include: PubMed-scale pathway extraction; application to other domains; incorporating additional complex states to address syntax-semantics mismatch; learning vector-space representations for complex states; joint syntactic-semantic parsing; incorporating reasoning and other sources of indirect supervision.

Abstract

When text is translated from one language into another, sentiment is preserved to varying degrees. In this paper, we use Arabic social media posts as stand-in for source language text, and determine loss in sentiment predictability when they are translated into English, manually and automatically. As benchmarks, we use manually and automatically determined sentiment labels of the Arabic texts. We show that sentiment analysis of English translations of Arabic texts produces competitive results, w.r.t. Arabic sentiment analysis. We discover that even though translation significantly reduces the human ability to recover sentiment, automatic sentiment systems are still able to capture sentiment information from the translations.

1 Introduction

Automatic sentiment analysis of text, especially social media posts, has a number of applications in commerce, public health, and public policy development. However, a vast majority of prior research on automatic sentiment analysis has been on English texts. Furthermore, many sentiment resources essential to automatic sentiment analysis (e.g., sentiment lexicons) exist only in English. Thus there is a growing need for effective methods for analyzing text from other languages such as Arabic and Chinese, especially posts on social media. There has also been marked progress in automatic translation of texts, especially from other languages into English. Thus, instead of building source-language specific sentiment analysis systems, one can translate the texts into English and use an English sentiment analysis system. However, it is widely believed that aspects of sentiment may be lost in translation, especially in automatic translation. Though, the extent of this loss, in terms of drop in accuracy of automatic sentiment systems remains undetermined.

This paper analyzes several methods available in annotating non-English texts for sentiment:

- Use a source-language sentiment analysis system.
- Run an English sentiment analysis system on manually created English translations of source language text.
- Run an English sentiment analysis system on automatically generated English translations of source language text.

In our experiments, we use Arabic social media posts as a specific instance of the source language text. We use state-of-the-art Arabic and English sentiment analysis systems as well as a state-of-the-art Arabic-to-English translation system. We outline the advantages and disadvantages of each of the methods listed above, and more importantly conduct experiments to determine accuracy of sentiment labels obtained using each of these methods. As benchmarks we use manually and automatically determined sentiment labels of the Arabic tweets.

These results will help users determine methods best suited for their particular needs. Along the way, we answer several research questions such as:

1. What sentiment prediction accuracy is expected when Arabic blog posts and tweets are

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 767–777,
Denver, Colorado, May 31 – June 5, 2015.

translated into English (using the current state-of-art techniques), and then run through a state-of-the-art English sentiment analysis system?

2. How does this performance compare with that of a current state-of-the-art Arabic sentiment system?
3. What is the loss in sentiment predictability when translating Arabic text into English automatically vs. manually?
4. How difficult is it for humans to determine sentiment of automatically translated text?
5. When dealing with translated text, which is more accurate at determining the sentiment of Arabic text: (1) automatic sentiment analysis of the translated text, or (2) human annotation of the translated text for sentiment?

The inferences drawn from these experiments do not necessarily apply to language pairs other than Arabic–English. Languages can differ significantly in terms of characteristics that impact accuracy of an automatic sentiment analysis system. Our goal here specifically is to understand sentiment predictability of Arabic dialectal text on translation. However, a similar set of experiments can be used for other language pairs as well to determine the impact of translation on sentiment.

Through our experiments on two different datasets, we show that sentiment analysis of English translations of Arabic texts produces competitive results, w.r.t. Arabic sentiment analysis. We also show that translation (both manual and automatic) introduces marked changes in sentiment carried by the text; positive and negative texts can often be translated into texts that are neutral. We also find that certain attributes of automatically translated text that mislead humans with regards to the true sentiment of the source text, do not seem to affect the automatic sentiment analysis system.

In the process of developing these experiments to study how translation alters sentiment, we created a state-of-the-art Arabic sentiment analysis system by porting NRC-Canada's competition winning system (Kiritchenko et al., 2014) to Arabic. We also created a substantial amount of sentiment labeled data pertaining to Arabic social media texts and their English translations which is made freely available.[1] This is the first such resource where text in one language and its translations into another language (both manually and automatically produced) are each manually labeled for sentiment.

2 Related Work

2.1 Sentiment Analysis of English Social Media

Sentiment analysis systems have been applied to many different kinds of texts including customer reviews, newspaper headlines (Bellegarda, 2010), novels (Boucouvalas, 2002; Mohammad and Yang, 2011), emails (Liu et al., 2003; Mohammad and Yang, 2011), blogs (Neviarouskaya et al., 2011), and tweets (Mohammad, 2012). Often these systems have to cater to the specific needs of the text such as formality versus informality, length of utterances, etc. Sentiment analysis systems developed specifically for tweets include those by Go et al. (2009), Pak and Paroubek (2010), Agarwal et al. (2011), and Thelwall et al. (2011). A survey by Martínez-Cámara et al. (2012) provides an overview of the research on sentiment analysis of tweets. In the last two years, several shared tasks on sentiment analysis were organized by the Conference on Semantic Evaluation Exercises (SemEval), which allowed for comparison of different approaches on common datasets from different domains (Wilson et al., 2013; Rosenthal et al., 2014; Pontiki et al., 2014). The NRC-Canada system (Kiritchenko et al., 2014) ranked first in these competitions, and we use it in our experiments. Details of the system are described in Section 6.

2.2 Sentiment Analysis of Arabic Social Media

Sentiment analysis of Arabic social media texts has several challenges. The text is often in a regional Arabic dialect rather than Modern Standard Arabic (MSA). Unlike MSA which is a standardized form of Arabic, dialectal Arabic is the spoken form of Arabic and lacks strict writing standards. The text often includes words from languages other than Arabic and multiple scripts may be used to express Arabic and foreign words. In addition, Arabic is a morphologically complex language, thus having a lexicon of word-sentiment associations that covers all different surface forms becomes a cumbersome task. Negation in MSA is expressed through negation par-

ticles, but in some dialects (Egyptian) it is expressed using suffixes at the end of the word. We refer the reader to Mourad and Darwish (2013) for more details on these issues.

There have been a few studies tackling sentiment analysis of Arabic texts (Ahmad et al., 2006; Badaro et al., 2014). The ones most closely related to our work are the studies of sentiment analysis of Arabic social media (Al-Kabi et al., 2013; El-Beltagy and Ali, 2013; Mourad and Darwish, 2013; Abdul-Mageed et al., 2014). Here we review existing Arabic sentiment analysis systems that were designed specifically for Arabic social media datasets. Abdul-Mageed et al. (2014) trained an SVM classifier on a manually labeled dataset and applied a two-stage classification that first separates subjective from objective sentences and then classifies the subjective into positive or negative instances. The authors have compiled several datasets from multiple social media resources that include chatroom messages, tweets, forum posts, and Wikipedia Talk pages. However, these resources have not been made publicly available yet.

Mourad and Darwish (2013) trained SVM and Naive Bayes classifiers on Arabic tweets annotated by two native Arabic speakers. We compare our system's performance to theirs in Section 7.

Refaee and Rieser (2014b) manually annotated tweets for sentiment by two native Arabic speakers. They used an SVM to classify tweets in a two-stage approach, polar vs neutral, then positive vs. negative. The authors shared their data with us and we test our system on their dataset. However, the dataset they provided us is a larger superset than the one they had originally used (Refaee and Rieser, 2014a). Thus, the results of sentiment systems on the two sets are not directly comparable.

2.3 Multilingual Sentiment Analysis

Work on multilingual sentiment analysis has mainly addressed mapping sentiment resources from English into morphologically complex languages. Mihalcea et al. (2007) used English resources to automatically generate a Romanian subjectivity lexicon using an English–Romanian dictionary. The generated lexicon is then used to classify Romanian text. Wan (2008) translated Chinese customer reviews to English using a machine translation system. The translated reviews are then classified with a rule-based system that relies on English lexicons. A higher accuracy is achieved by using ensemble methods and combining knowledge from Chinese and English resources. Balahur and Turchi (2014) conducted a study to assess the performance of statistical sentiment analysis techniques on machine-translated texts. Opinion-bearing phrases from the *New York Times* text corpus (2002–2005) were automatically translated using publicly available machine-translation engines (Google, Bing, and Moses). Then, the accuracy of a sentiment analysis system trained on original English texts was compared to the accuracy of the system trained on automatic translations to German, Spanish, and French. The authors concluded that the quality of machine translation is sufficient for sentiment analysis to be performed on automatically translated texts without a substantial loss in accuracy. Contrary to that work, our study uses both manual and automatic translations as well as both manual and automatic sentiment assignments to systematically examine the effect of translation on sentiment. Additionally, we deal with noisy social media texts as opposed to more polished news media texts. There exists research on using sentiment analysis to improve machine translation (Chen and Zhu, 2014), but that is beyond the scope of this paper.

3 Method for Determining Sentiment Predictability on Translation

In order to systematically study the impact of translation on sentiment analysis, we propose the following experimental setup:

- Identify or compile an Arabic social media dataset. We will refer to it as *Ar*. (*Ar* comes from the first two letter of Arabic.)
- Manually translate *Ar* into English. We will refer to these English translations as *En(Manl.Trans.)* [*Manl.* is for manual, and *Trans.* is for translations.]
- Automatically translate *Ar* into English. We will refer to these English translations as *En(Auto.Trans.)* [*Auto.* is for automatic.]
- Manually annotate Ar. for sentiment. We will refer to the sentiment-labeled dataset as *Ar(Manl.Sent.)*

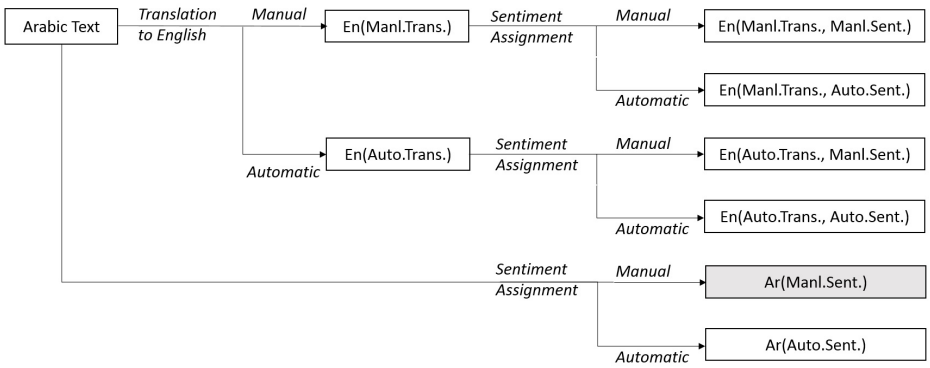

Figure 1: Experimental setup to determine the impact of translation on sentiment. We compare sentiment labels between Ar(Manl.Sent.) (shown in a shaded box) and other datasets shown on the right side of the figure. Ar(Manl.Sent.) is the original Arabic text manually annotated for sentiment.

- Manually annotate all English datasets [*En(Manl.Trans.)* and *En(Auto.Trans.)*] for sentiment, creating *En(Manl.Trans., Manl.Sent.)* and *En(Auto.Trans., Manl.Sent.)*, respectively.
- Run a state-of-the-art Arabic sentiment analysis system on *Ar*, creating *Ar(Auto.Sent.)*
- Run a state-of-the-art English sentiment analysis system on all the English datasets [*En(Manl.Trans.)* and *En(Auto.Trans.)*], creating *En(Manl.Trans., Auto.Sent.)* and *En(Auto.Trans., Auto.Sent.)*, respectively.

Figure 1 depicts this setup. Once the various sentiment-labeled datasets are created, we can compare pairs of datasets to draw inferences. For example, comparing the labels for *Ar(Manl.Sent.)* and *En(Manl.Trans., Manl.Sent.)* will show how different the sentiment labels tend to be when text is translated from Arabic to English. The comparison will also show, for example, whether positive tweets tend to often be translated into neutral tweets, and to what extent. The results will also show how feasible it is to first translate Arabic text into English and then use automatic sentiment analysis (*Ar(Manl.Sent.)* vs. *En(Auto.Trans., Auto.Sent.)*). In Section 8, we provide an analysis of several such comparisons for two different Arabic social media datasets.

DATA: Since manual translation of text from Arabic to English is a costly exercise, we chose, for our experiments, an existing Arabic social media dataset that has already been translated – the BBN Arabic-Dialect/English Parallel Text (Zbib et al., 2012).[2] It contains about 3.5 million tokens of Arabic dialect sentences and their English translations. We use a randomly chosen subset of 1200 Levantine dialectal sentences, which we will refer to as the *BBN posts* or *BBN dataset*, in our experiments. Additionally, we also conduct experiments on a dataset of 2000 tweets originating from Syria (a country where Levantine dialectal Arabic is commonly spoken). These tweets were collected in May 2014 by polling the Twitter API. We will refer to this dataset as the *Syrian tweets* or *Syrian dataset*. Note, however, that manual translations of the Syrian dataset are not available.

The experimental setup described above involves several component tasks: generating translations manually and automatically (Section 4), manually annotating Arabic and English texts for sentiment (Section 5), automatic sentiment analysis of English texts (Section 6), and automatic sentiment analysis of Arabic texts (Section 7).

4 Generating English Translations

The BBN dialectal Arabic dataset comes with manual translations into English. We generate automatic translations of the Arabic BBN posts and the Syrian tweets, by training a multi-stack phrase-based machine translation system to translate from Arabic to English. Our in-house system is quite similar to Cherry and Foster (2012). This statistical machine translation (SMT) system is trained on data from OpenMT 2012. We preprocess the training data by

[2] https://catalog.ldc.upenn.edu/LDC2012T09

segmenting the Arabic source side of the training data with MADA 3.2 (Habash et al., 2009), using Penn Arabic Treebank (PATB) segmentation scheme as recommended by El Kholy and Habash (2012). The Arabic script is further normalized by converting different forms of Alif إ أ آ ا and Ya ى ي to bare Alif ا and dotless Ya ى. The different forms are used interchangeably, and normalization decreases the sparcity of Arabic tokens and improves translation. The English side of the training data is lowercased and tokenized by stripping punctuation marks. We set the decoder's stack size to 10000 and distortion limit to 7. We replace the *out-of-vocabulary* words in the translated text with *UNKNOWN* token (which is shown to the annotators). The decoder's log-linear model is tuned with MIRA (Chiang et al., 2008; Cherry and Foster, 2012). A KN-smoothed 5-gram language model is trained on the English Gigaword and the target side of the parallel data.

5 Creating sentiment labeled data in Arabic and English

Manual sentiment annotations were performed on the crowdsourcing platform CrowdFlower[3] for three BBN datasets and two Syrian datasets:

1. Original Arabic posts (BBN and Syria datasets), annotated by Arabic speakers.
2. Manual English translations of Arabic posts, annotated by English speakers (only for BBN dataset).
3. Automatic English translations of Arabic posts (BBN and Syria datasets), annotated by English speakers.

Each post was annotated by at least ten annotators and the majority sentiment label was chosen. Table 1 shows the class distribution of sentiment labels in various datasets. Observe from rows *a* and *d* that neutral tweets constitute only about 10% of the data in both BBN and Syria datasets. The Syrian tweets have a much higher percentage of negative posts, whereas in the BBN data, the percentages of positive and negative posts are comparable. (Arabic tweets in general tend to be much more skewed to the negative class than Arabic blog post sentences.) Rows b, c, and e show that translated texts tend to lose some of the sentiment information and there is a relatively higher percentage of neutral instances in the translated text than in the original text.

For each post, we determine the count of the most frequent annotation divided by the total number of annotations. This score is averaged for all posts to determine the inter-annotator agreement shown in the last column of Table 1. We use this agreement score as benchmark to compare performance of automatic sentiment systems (described below).

6 English Sentiment Analysis

We use the English-language sentiment analysis system developed by NRC-Canada (Kiritchenko et al., 2014) in our experiments. This system obtained highest scores in two recent international competitions on sentiment analysis of tweets –SemEval-2013 Task 2 and SemEval-2014 Task 9 (Wilson et al., 2013; Rosenthal et al., 2014). We briefly describe the system below; for more details, we refer the reader to Kiritchenko et al. (2014).

A linear-kernel Support Vector Machine (Chang and Lin, 2011) classifier is trained on the available training data. The classifier leverages a variety of surface-form, semantic, and sentiment lexicon features described below. The sentiment lexicon features are derived from existing, general-purpose, manual lexicons, namely NRC Emotion Lexicon (Mohammad and Turney, 2010; Mohammad and Turney, 2013), Bing Liu's Lexicon (Hu and Liu, 2004), and MPQA Subjectivity Lexicon (Wilson et al., 2005), as well as automatically generated, tweet-specific lexicons, Hashtag Sentiment Lexicon and Sentiment140 Lexicon (Kiritchenko et al., 2014).[4]

6.1 Generating English Sentiment Lexicon

Ablation experiments in Mohammad et al. (2013) showed that their sentiment system benefited most from the use of the Hashtag Sentiment Lexicon. The lexicon was created as follows. A list of 77 seed words, which are synonyms of *positive* and *negative*, was compiled from the Roget's Thesaurus. Then, the Twitter API was polled to collect tweets that had these words as hashtags. A tweet is considered positive if it has a positive hashtag and negative if it

	positive	negative	neutral	agreement
BBN data				
a. Ar(Manl.Sent)	41.50	47.92	10.58	73.80
b. En(Manl.Trans., Manl.Sent)	35.00	43.25	21.75	68.00
c. En(Auto.Trans., Manl.Sent)	36.17	36.50	27.34	65.70
Syria data				
d. Ar(Manl.Sent)	22.40	67.50	10.10	79.00
e. En(Auto.Trans., Manl.Sent)	14.25	66.15	19.60	76.10

Table 1: Class distribution (in percentage) of the sentiment annotated datasets.

has a negative hashtag. For each term in the tweet set, a sentiment score is computed by measuring the PMI (pointwise mutual information) between the term and the positive and negative categories:

$$SenScore\,(w) = PMI(w, pos) - PMI(w, neg) \quad (1)$$

where w is a term in the lexicon. $PMI(w, pos)$ is the PMI score between w and the positive class, and $PMI(w, neg)$ is the PMI score between w and the negative class. A positive *SenScore* (w) suggests that the word is associated with positive sentiment and a negative score suggests that the word is associated with negative sentiment. The magnitude indicates the strength of the association.

6.2 Pre-processing and Feature Generation

The following pre-processing steps are performed. URLs and user mentions are normalized to http://someurl and @someuser, respectively. Tweets are tokenized and part-of-speech tagged with the CMU Twitter NLP tool (Gimpel et al., 2011). Then, each tweet is represented as a feature vector.

The features:
- Word and character ngrams;
- POS: # occurrences of each part-of-speech tag;
- Negation: # negated contexts. Negation also affects the ngram features: a word w becomes w_NEG in a negated context;
- Automatic sentiment lexicons: For each token w occurring in a tweet, its sentiment score $score(w)$ is used to compute: # tokens with $score(w) \neq 0$; the total score = $\sum_{w \in tweet} score(w)$; the maximal score = $max_{w \in tweet} score(w)$; the score of the last token in the tweet.
- Manually created sentiment lexicons: For each of the three manual sentiment lexicons, the following features are computed: the sum of positive and the sum of negative scores for tweet tokens in affirmative contexts and in negated contexts, separately.

7 Arabic Sentiment Analysis

7.1 Building an Arabic Sentiment System

We built an Arabic sentiment analysis system by reconstructing the NRC-Canada English system to deal with Arabic text. It extracts the same feature set as described in Section 6.2. We also generated a word-sentiment association lexicon as described in Section 6.1, but for Arabic words from Arabic tweets (more details in sub-section below). We pre-process Arabic text by tokenizing with CMU Twitter NLP tool to deal with specific tokens such as URLs, usernames, and emoticons. Then we use MADA to generate lemmas. Finally, we normalize different forms of Alif and Ya to bare Alif and dotless Ya to decrease token sparcity in Arabic datasets.

7.1.1 Generating Arabic Sentiment Lexicon

We translated 77 positive and negative seed words used to generate the English NRC Hashtag Sentiment Lexicon into Arabic using Google Translate. Among the several translations provided by it, we chose words that were less ambiguous and tended to have strong sentiment in Arabic texts. To increase the coverage of our seed list, we manually added different inflections for these translations.

We polled the Twitter API for the period of June to August 2014 and collected tweets with *#(keyword)*. After filtering out duplicate tweets and retweets, we ended up with 163,944 positive unique tweets and 37,848 negative unique tweets. Then for each word w, *SenScore* (w) was calculated just as described in Section 6.1.

Arabic Sentiment Labeled Dataset	**MD**	**RR**	**BBN**	**Syria**

Table 3: Class distribution (in percentage) resulting from automatic sentiment analysis.

7.2 Evaluation

We tested the Arabic sentiment system on two existing Arabic datasets (Mourad and Darwish (2013) (MD) and Refaee and Rieser (2014a) (RR)) and two newly sentiment-annotated Arabic datasets (BBN and Syria). Table 2 shows results of ten-fold cross-validation experiments on each of the datasets. For MD and RR, the presented results are for the two-class problem (positive vs. negative) to allow for comparison with prior published results. For BBN and Syria, the results are shown for the case where the system has to identify one of three classes: positive, negative, or neutral. Human agreement scores are shown where available.

Note that the accuracy of our system is higher than previously published results on the MD dataset. The only previously published results on the RR dataset are on a small subset (about 1000 instances) for which Refaee and Rieser (2014a) obtained an accuracy of 87%. The results in Table 2 are for a larger dataset and so not directly comparable.

8 Sentiment After Translation

Using the methods and systems described in Sections 4, 5, 6, and 7, we generated all the manually and automatically labeled datasets mentioned in Section 3's Experimental Setup. Table 3 shows the distribution of positive, negative, and neutral classes in datasets that have been automatically labeled with sentiment. These percentages can be compared with those in Table 1 (rows a and d) which show the true sentiment distribution in the BBN and Syria datasets. Observe that the automatic system has difficulty in assigning neutral class to posts. This is probably because of the small percentage (about 10%) of neutral tweets in the training data. Also notice that the system predominantly guesses negative, which is also a reflection of the distribution in the training data. The strong bias to negatives is lessened in the English translations.

Main Result: Tables 4 and 5 show how similar the sentiment labels are across various pairs of datasets for the BBN posts and the Syrian posts, respectively. For example, row a. in Table 4 shows the comparison between Arabic tweets that were manually annotated for sentiment and those that were automatically labeled for sentiment by our Arabic sentiment analysis system. Column 2 shows the percentage of instances where the sentiment labels match across the two datasets being compared. For row a. the match percentage of 63.89% represents the accuracy of the automatic sentiment analysis system on the Arabic BBN posts.

Row b. shows the difference in labels when text is manually translated from Arabic to English, even though sentiment labeling in both Arabic and English is done manually. Observe that the two labels match only 71.31% of the time. However, the agreement among human sentiment annotators on original Arabic texts was only 73.8%. So, the English translation does affect sentiment, but not dramatically.

Row c. shows results for when the manually translated text is run through an English sentiment analysis system and the labels are compared against *Ar(Manl.Sent.)* Observe that the match for this pair is 68.65%, which is not too much lower than 71.31% obtained by manual sentiment labeling. This shows

Data Pair	Match %
a. Ar(Manl.Sent) - Ar(Auto.Sent)	63.89
b. Ar(Manl.Sent) - En(Manl.Trans., Manl.Sent)	71.31
c. Ar(Manl.Sent) - En(Manl.Trans., Auto.Sent)	68.65
d. Ar(Manl.Sent) - En(Auto.Trans., Manl.Sent)	57.21
e. Ar(Manl.Sent) - En(Auto.Trans., Auto.Sent)	62.49
f. En(Manl.Trans., Manl.Sent) - En(Auto.Trans., Manl.Sent)	60.08
g. En(Manl.Trans., Manl.Sent) - En(Manl.Trans., Auto.Sent)	66.51
h. En(Auto.Trans., Manl.Sent) - En(Auto.Trans., Auto.Sent)	69.58

Table 4: Match percentage between pairs of sentiment labelled BBN datasets.

Data Pair	Match %
a. Ar(Manl.Sent) - Ar(Auto.Sent)	78.65
b. Ar(Manl.Sent) - En(Auto.Trans., Manl.Sent)	71.05
c. Ar(Manl.Sent) - En(Auto.Trans.-Auto.Sent)	78.11
d. En(Auto.Trans, Manl.Sent) - En(Auto.Trans., Auto.Sent)	78.80

Table 5: Match percentage between pairs of sentiment labelled Syria datasets.

that the English sentiment system is performing rather well. (One would not expect it to get a match greater than 71.31%.) More importantly, the English sentiment system shows a competitive result of 62.49% when run on the automatically translated text (row e.), which makes this choice a viable option for sentiment analysis of non-English texts. This result is inline with previous findings in Information Retrieval (Nie et al., 1999) and Text Classification (Amini and Goutte, 2010).

Rows d. and e. compare *Ar(Manl.Sent.)* with manual and automatic sentiment labeling of automatic translations. Since automatic translation from Arabic to English is fairly difficult, we expect these match percentages to be lower than those in rows b. and c., and that is exactly what we observe. However, it is unexpected to find the number for row e. to be higher than that of row d. We find the same pattern for corresponding data pairs in the Syrian tweets as well (rows b. and c. in Table 6). This suggests that certain attributes of automatically translated text mislead humans with regards to the true sentiment of the source text. However, these same attributes do not seem to affect the automatic sentiment analysis system as much. Since the NRC sentiment analysis system is largely reliant on word-sentiment associations and does not use syntax-based features, it is possible that syntactic abnormalities introduced by automatic translation impact human perception of sentiment. However, this supposition needs to be validated by future work.

Row f. shows that manual and automatic translation lead to only about 60% match in manually annotated sentiment labels with each other. Row g. shows accuracy of the English automatic sentiment analysis system on the manually translated text (assuming the English sentiment labels as gold). The result of 66.51% is very close to human agreement on manually translated data (68%), which demonstrates the high quality of the English sentiment analysis system. Row h. shows accuracy of the English automatic sentiment analysis system on the automatically translated text (assuming the English sentiment labels as gold). In this case, the system's accuracy of 69.58% is higher than the human agreement on automatically translated text (65.7%), which again shows that automatic translation greatly impacts sentiment perceived by humans.

We manually examined several tweets from the BBN dataset to understand why humans incorrectly annotate a tweet's automatic translation. Most of the cases were due to bad translation where sentiment words either disappeared or were replaced with words of opposite sentiment. In some cases, the translation was affected by typos on the Arabic side. Table 6 shows some examples. Often the mistranslations occurred due to word sense ambiguity. For example, عقارب has two meanings: *scorpions* and *clock arms*. In example 1 (metaphorically stating that relatives can hurt like scorpion bites), the word is mistranslated, leading to neutral (instead of negative) sentiment.

1. Bad auto. translation: mistranslation of ambiguous words		
Post	الدنيا علمتني ان اكثر الاقارب عقارب	negative
Auto.Trans.	the minimum taught me that more relatives clock	neutral
Manl.Trans.	Life has taught me that most of the relatives are scorpions	negative
2. Bad auto. translation: mistranslation of ambiguous words		
Post	ليتنى اعيش في مكان لا تنقطع عنه الثلوج	positive
Auto.Trans.	i wish i live in a place not cut off by snow	negative
Manl.Trans.	I wish I live in a place where snow never stops falling	positive
3. Bad auto. translation: sarcasm is hard to translate		
Post	لسه الخير لقدام تسرب المي موجودة من زمان	negative
Auto.Trans.	you're still good in front of the leakage of water existed from time	positive
Manl.Trans.	Expect more good to come, water has been leaking since a long time	negative

Table 6: Examples where the automatic translation was annotated a sentiment different from the sentiment of the original Arabic tweet, but whose original sentiment was correctly predicted by the English sentiment system. The manual translations are also listed for reference.

One reason why the automatic sentiment analysis system correctly annotates several automatically translated instances (where manual annotations of the translation may fail), is that the system can learn an appropriate model even from mistranslated text — especially when automatic translation makes consistent errors. For example, اللهم انصر (*Oh God grant victory to*) has been consistently translated to *God forsake*. All tweets having this phrase are correctly annotated as positive by our system, but were marked negative by the human annotators.

Caveats: The automatic systems employed in these experiments, i.e., Arabic sentiment analysis, English sentiment analysis, and SMT systems, exhibit state-of-the-art performance; nevertheless, further improvements are possible. The Arabic sentiment system will benefit from extended sentiment lexicons and features derived specifically for the Arabic language. The English sentiment analysis system can be further adapted to the peculiarities of machine-translated texts, which are notably different from regular English. The current translation system has been trained on non-tweet data that results in a high percentage of out-of-vocabulary words on our datasets. In our experiments, we assumed that all texts are written in Levantine dialect of the Arabic language. However, tweets can have a mixture of dialects or even a mixture of languages (e.g., Arabic and English). Addressing these factors will give even more insight on how sentiment is altered on translation, in specific contexts.

9 Conclusions

We presented a set of experiments to systematically study the impact of English translation (manual and automatic) on sentiment analysis of Arabic social media posts. Our experiments show that automatic sentiment analysis of English translations (even of automatic translations) can lead to competitive results—results that are similar to that obtained by current state-of-the-art Arabic sentiment analysis systems. Our results also show that automatic sentiment analysis of automatic translations outperforms the manual sentiment annotations of the automatically translated text. This suggests that SMT errors impact human perception of sentiment markedly more than automatic sentiment systems. This is an interesting avenue for future exploration. We also show that translated texts tend to lose some of the sentiment information and there is a relatively higher percentage of neutral instances in the translated text than in the original dataset. The resources created as part of this project (Arabic sentiment lexicons, Arabic sentiment annotations of social media posts, and English sentiment annotations of their translations) are made freely available.[5]

Abstract

Some state-of-the-art summarization systems use integer linear programming (ILP) based methods that aim to maximize the important concepts covered in the summary. These concepts are often obtained by selecting bigrams from the documents. In this paper, we improve such bigram based ILP summarization methods from different aspects. First we use syntactic information to select more important bigrams. Second, to estimate the importance of the bigrams, in addition to the internal features based on the test documents (e.g., document frequency, bigram positions), we propose to extract features by leveraging multiple external resources (such as word embedding from additional corpus, Wikipedia, Dbpedia, WordNet, SentiWordNet). The bigram weights are then trained discriminatively in a joint learning model that predicts the bigram weights and selects the summary sentences in the ILP framework at the same time. We demonstrate that our system consistently outperforms the prior ILP method on different TAC data sets, and performs competitively compared to other previously reported best results. We also conducted various analyses to show the contributions of different components.

1 Introduction

Extractive summarization is a sentence selection problem: identifying important summary sentences from one or multiple documents. Many methods have been developed for this problem, including supervised approaches that use a classifier to predict whether or not a sentence is in the summary, or unsupervised methods such as graph-based approaches to rank the sentences. Recently global optimization methods such as integer linear programming (ILP) have been shown to be quite powerful for this task. For example, Gillick et al. (2009) used ILP to achieve the best result in the TAC 09 summarization task. The core idea of this summarization method is to select the summary sentences by maximizing the sum of the weights of the language concepts that appear in the summary. Bigrams are often used as these language concepts because Gillick et al. (2009) stated that the bigrams gave consistently better performance than unigrams or trigrams for a variety of ROUGE measures. The association between the language concepts and sentences serves as the constraints. This ILP method is formally represented as below (see (Gillick et al., 2009) for more details):

$$\max \quad \sum_i w_i c_i \tag{1}$$
$$s.t. \quad s_j Occ_{ij} \leq c_i \tag{2}$$
$$\sum_j s_j Occ_{ij} \geq c_i \tag{3}$$
$$\sum_j l_j s_j \leq L \tag{4}$$
$$c_i \in \{0,1\}\ \forall i \tag{5}$$
$$s_j \in \{0,1\}\ \forall j \tag{6}$$

c_i and s_j are binary variables that indicate the presence of a concept and a sentence respectively. l_j is the sentence length and L is maximum length of the generated summary. w_i is a concept's weight and Occ_{ij} means the occurrence of concept i in sentence j. Inequalities (2)(3) associate the sentences

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 778–787,
Denver, Colorado, May 31 – June 5, 2015.

and concepts. They ensure that selecting a sentence leads to the selection of all the concepts it contains, and selecting a concept only happens when it is present in at least one of the selected sentences.

In such ILP-based summarization methods, how to determine the concepts and measure their weights is the key factor impacting the system performance. Intuitively, if we can successfully identify the important key bigrams to use in the ILP system, or assign large weights to those important bigrams, the system generated summary sentences will contain as many important bigrams as possible. The oracle experiment in (Gillick et al., 2008) showed that if they just use the bigrams extracted from human generated summaries as the input of the ILP system, much better ROUGE scores can be obtained than using the automatically selected bigrams.

In this paper, we adopt the ILP summarization framework, but make improvement from three aspects. First, we use the part-of-speech tag and constituent parse information to identify important bigram candidates: bigrams from base NP (noun phrases) and bigrams containing verbs or adjectives. This bigram selection method allows us to keep the important bigrams and filter useless ones. Second, to estimate the bigrams' weights, in addition to using information from the test documents, such as document frequency, syntactic role in a sentence, etc., we utilize a variety of external resources, including a corpus of news articles with human generated summaries, Wiki documents, description of name entities from DBpedia, WordNet, and SentiWordNet. Discriminative features are computed based on these external resources with the goal to better represent the importance of a bigram and its semantic similarity with the given query. Finally, we propose to use a joint bigram weighting and sentence selection process to train the feature weights. Our experimental results on multiple TAC data sets show the competitiveness of our proposed methods.

2 Related Work

Optimization methods have been widely used in extractive summarization lately. McDonald (2007) first introduced the sentence level ILP for summarization. Later Gillick et al. (2009) revised it to concept-based ILP, which is similar to the Budgeted Maximal Coverage problem in (Khuller et al., 1999). The concept-based ILP system performed very well in the TAC 2008 and 2009 summarization task (Gillick et al., 2008; Gillick et al., 2009). After that, the global optimization strategy attracted increasing attention in the summarization task. Lin and Bilmes (2010) treated the summarization task as a maximization problem of submodular functions. Davis et al. (2012) proposed an optimal combinatorial covering algorithm combined with LSA to measure the term weight for extractive summarization. Takamura and Okumura (2009) also defined the summarization problem as a maximum coverage problem and used a branch-and-bound method to search for the optimal solution. Li et al. (2013b) used the same ILP framework as (Gillick et al., 2009), but incorporated a supervised model to estimate the bigram frequency in the final summary.

Similar optimization methods are also widely used in the abstractive summarization task. Martins and Smith (2009) leveraged ILP technique to jointly select and compress sentences for multi-document summarization. A novel summary guided sentence compression was proposed by (Li et al., 2013a) and it successfully improved the summarization performance. Woodsend and Lapata (2012) and Li et al. (2014) both leveraged constituent parser trees to help sentence compression, which is also modeled in the optimization framework. But these kinds of work involve using complex linguistic information, often based on syntactic analysis.

Since the language concepts (or bigrams) can be considered as key phrases of the documents, the other line related to our work is how to extract and measure the importance of key phrases from documents. In particular, our work is related to key phrase extraction by using external resources. A survey by (Hasan and Ng, 2014) showed that using external resources to extract and measure key phrases is very effective. In (Medelyan et al., 2009), Wikipedia-based key phrases are determined based on a candidate's document frequency multiplied by the ratio of the number of Wikipedia articles containing the candidate as a link to the number of articles containing the candidate. Query logs were also used as another external resource by (Yih et al., 2006) to exploit the observation that a candidate is potentially important if it was used as a search

query. Similarly terminological databases have been exploited to encode the salience of candidate key phrases in scientific papers (Lopez and Romary, 2010). In summarization, external information has also been used to measure word salience. Some TAC systems like (Kumar et al., 2010; Jia et al., 2010) used Wiki as an important external resource to measure the words' importance, which helped improve the summarization results. Hong and Nenkova (2014) introduced a supervised model for predicting word importance that incorporated a rich set of features. Tweets information is leveraged by (Wei and Gao, 2014) to help generate news highlights.

In this paper our focus is on choosing useful bigrams and estimating accurate weights to use in the concept-based ILP methods. We explore many external resources to extract features for bigram candidates, and more importantly, propose to estimate the feature weights in a joint process via structured perceptron learning that optimizes summary sentence selection.

3 Summarization System

In this study we use the ILP-based summarization framework (Formulas 1-6) that tries to maximize the weights of the selected concepts (bigrams) under the summary length constraint. Our focus is on better selection of the bigrams and estimation of the bigram weights. We use syntax tree and POS of tokens to help filter some useless bigrams. Then supervised methods are applied to predict the bigram weights. The rich set of features we use is introduced in Section 4. In the following we describe how to select important bigrams and how the feature weights are trained.

3.1 Bigram Selection

In (Gillick et al., 2009), bigrams whose document frequency is higher than a predefined threshold (df=3 in previous work) are used as the concepts in the ILP model. The weight for these bigrams in the ILP optimization objective function (Formula 1) is simply set as their document frequency. Although this setting has been demonstrated to be quite effective, its gap with the oracle experiment (using bigrams that appear in the human summaries) is still very large, suggesting potential gains by using better bigrams/concepts in the ILP optimization method. Details are described in (Gillick et al., 2009).

In this paper, rather than considering all the bigrams, we propose to utilize syntactic information to help select important bigrams. Intuitively bigrams containing content words carry more topic related information. As proven in (Klavans and Kan, 1998), nouns, verbs, and adjectives were indeed beneficial in document analysis. Therefore we focus on choosing bigrams containing these words. First, we use a bottom-up strategy to go through the constituent parse tree and identify the 'NP' nodes in the lowest level of the tree. Then all the bigrams in these base NPs are kept as candidates. Second, we find the verbs and adjectives from the sentence based on the POS tags, and construct bigrams by concatenating the previous or the next word of that verb or adjective. If these bigrams are not included in those already found from the base NPs, they are added to the bigram candidates. After the above filtering, we further drop bigrams if both words are stop words, as previous work in (Gillick et al., 2009).

3.2 Weight Training

We propose to train the feature weights in a joint learning fashion. In the ILP summarization framework, we use the following new objective function:

$$\max \quad \sum_i (\theta \cdot \mathbf{f}(b_i)) c_i \tag{7}$$

We replace the w_i in Formula 1 with a vector inner product of bigram features and their corresponding weights. Constraints remain the same as those in Formula 2 to 6.

To train the model (feature weights), we leverage structured perceptron strategy (Collins, 2002) to update the feature weights whenever the hypothesis offered by the ILP decoding process is incorrect. Binary class labels are used for bigrams in the learning process, that is, we only consider whether a bigram is in the system generated summary or human summaries, not their term or document frequency. During perceptron training, a fixed learning rate is used and parameters are averaged to prevent overfitting.

4 Features for Bigrams

We use a rich set of features to represent each bigram candidate, including internal features based on

the test documents, and features extracted from external resources. The goal is to better predict the importance of a bigram, which we expect will help the ILP module better determine whether to include the bigram in the summary.

4.1 Internal Features

These features are generated from the provided test documents (note our task is multi-document summarization, and there is a given query topic. See Section 5 for the description of tasks and data).

- Frequency of the bigram in the entire set.
- Frequency of the bigram in related sentences.[1]
- Document frequency of the bigram in the entire set.
- Is this bigram in the first 1/2/3 sentence?
- Is this bigram in the last 1/2/3 sentence?
- Similarity with the topic title, calculated by the number of common tokens in these two strings, divided by the length of the longer string.

4.2 Importance Score based on Language Models

The idea is to train two language models (LMs), one from the original documents, and the other one from the summaries, and compare the likelihood of a bigram generated by these two LMs, which can indicate how often a bigram is used in a summary. Similar to previous work in (Hong and Nenkova, 2014), we leveraged The New York Times Annotated Corpus (LDC Catalog No: LDC2008T19), which has the original news articles and human generated abstracts. We build two language models, from the news articles and the corresponding summaries respectively. We used about 160K abstract-original pairs. The KL scores for a bigram are defined as follows:

$$KL(LM_A|LM_O)(b) = Pr_A(b) * ln\frac{Pr_A(b)}{Pr_O(b)} \quad (8)$$

$$KL(LM_O|LM_A)(b) = Pr_O(b) * ln\frac{Pr_O(b)}{Pr_A(b)} \quad (9)$$

[1]Note that we do not use all the sentences in the ILP module. The 'relevant' sentences are those that have at least one bigram with document frequency larger than or equal to three.

where (LM_A) and (LM_O) are the LMs from the abstracts and the original news articles. Note that one difference from (Hong and Nenkova, 2014) is that we calculate these scores for a bigram, not a word. As (Hong and Nenkova, 2014) showed, a higher value from the score in Formula 8 means the words are favored in the summaries, and vice verse in Formula 9. In addition to the above features, we also include the likelihood $Pr_A(b)$ and $Pr_O(b)$ based on the two LMs, and the absolute and relative difference between them: $Pr_A(b) - Pr_O(b), Pr_A(b)/Pr_O(b)$.

4.3 Similarity based on Word Embedding Representation

Given the recent success of the continuous representation for words, we propose to use an unsupervised method to induce dense real-valued low dimensional word embedding, and then use the inner product as a measure of semantic similarity between two strings. In the word embedding model, every word can be represented by a vector $\vec{w}$. We define the similarity between two sequences $S1 = x_1, x_2, ...x_k$ and sequence $S2 = y_1, y_2, ...y_l$ as the average pairwise similarity between any two words in them:

$$Sim(S1, S2) = \frac{\sum_{i=1}^{k}\sum_{j=1}^{l}\vec{x}_i \cdot \vec{y}_j}{k * l} \quad (10)$$

Based on such word embedding models, we derive two similarity features: (1) similarity between a bigram and the topic query, and (2) similarity between a bigram and top-k most frequent unigrams in this topic. We trained two word embedding models, from the abstract and news article collections in the New York Times Annotated Corpus, and thus have two sets of the above similarity features. We use the continuous bag-of-words model introduced by (Mikolov et al., 2013), and the tool word2vec[2] to obtain the word embeddings.

4.4 Similarity based on WordNet[3]

Similar to the above method, here we still focus on measuring the similarity between a bigram and the topic query, but based on WordNet. We use WordNet to identify the synonyms of nouns, verbs,

[2]https://code.google.com/p/word2vec/

[3]http://wordnet.princeton.edu/

and adjectives from each bigram and the query of the topic. Then every bigram and sentence can be represented as a bag of synonyms of the original words. Finally based on these synonyms we leverage the following four similarity measurements: Lin Similarity (Lin, 1998), Wu-Palmer Similarity (Wu and Palmer, 1994), Jiang-Conrath Similarity (Jiang and Conrath, 1997), and Resnik Similarity (Resnik, 1995). These four similarity measurements are all implemented in the NLTK toolkit[4]. We expect that these features would improve the estimation accuracy because they can overcome the ambiguity and the diversity of the vocabulary.

4.5 Importance based on Wikipedia

Wikipedia is a very popular resource used in many different tasks. In order to obtain more precise external information from Wikipedia for our task, we collect the articles from Wikipedia by two steps. If the query is already the title of a wiki page, we will not further gather other wiki pages for this topic. Otherwise, we first search for the wiki pages for the given topic query and description (if available) using Google advanced search function to find pages from http://en.wikipedia.org/. For each returned wiki page, we further calculate its similarity between its abstract and the test documents' top k frequent words. We select 3 most similar pages as the external Wiki resource for this topic. For these wikipages, we split into two parts: abstract and content.[5] The features are the following: For each bigram, we collect its tf*idf score from the abstract and content part respectively, and the average tf*idf value of the unigrams in the bigram candidate. In addition, we design two boolean features that represent whether a bigram is the top-k most frequent ones in the abstract or the content part of the Wikepages.

4.6 DBpedia[6] for Extending Name Entity

DBpedia is a crowd-sourced community effort to extract structured information from Wikipedia and its Spotlight Service[7] is an entity linking tool to connect free text to DBpedia through the recognition and disambiguation of entities and concepts from the DBpedia Knowledge Base. We use this service to extract the entity from each sentence, and if the recognized entity is also identified as a named entity by Stanford CoreNLP[8], we use this entity's DBpedia abstract content to extend the bigrams. For example, in the bigram 'Kashmir area', the word 'Kashmir' is recognized as an entity by both (Stanford CoreNLP and DBpedia Spotlight service), then we use the description for 'Kashmir' from DBpedia[9] to extend this bigram, and calculate the cosine similarity between this description and the topic query and top-k most frequent unigrams in the documents.

4.7 Sentiment Feature from SentiWordNet[10]

SentiWordNet (Baccianella et al., 2010) is an extension on WordNet and it further assigns to each synset of WordNet three sentiment scores: positivity, negativity, objectivity. The sentiment score of a bigram is the average score of the two words in the bigram.

To sum up, the features we use include the internal features, and external ones derived from various resources: news article corpus with summaries, Wikipeida, DBpedia, WordNet and SentiWordNet. Some external features represent the inherent importance of bigrams. For example, features extracted from the news article corpus and wikipedia are used to represent how often bigrams are used in summary/abstract compared to the entire document. Some external features are used to better compute semantic similarity, for example, features from the word embedding methods, DBpedia, and WordNet.

5 Experiments

5.1 Data and Experiment Setup

We evaluate our methods using several recent TAC data sets, from 2008 to 2011. The TAC summarization task is to generate at most 100 words summaries from 10 documents for a given topic query

[4]http://www.nltk.org/

[5]Every Wikipage has a table of contents. The part before that is considered as abstract and the part after that is the content of that page.

[6]http://dbpedia.org/About

[7]http://blog.dbpedia.org/2014/07/21/dbpedia-spotlight-v07-released/

[8]http://nlp.stanford.edu/software/corenlp.shtml

[9]The Indian subcontinent is a southerly region of Asia, mostly situated on the Indian Plate and projecting southward into the Indian Ocean. Definitions of the extent of the Indian subcontinent differ but it usually includes the core lands of India, Pakistan, and Bangladesh

[10]http://sentiwordnet.isti.cnr.it/

consisting of a title and more detailed description (this is unavailable in 2010 and 2011 data). When evaluating on one TAC data set, we use the data from the other three years as the training set. All the summaries are evaluated using ROUGE (Lin, 2004; Owczarzak et al., 2012). In all of our experiments, we use Stanford CoreNLP toolkit to tokenize the sentences, extract name entities and POS tags. Berkeley Parser (Petrov et al., 2006) is used to get the constituent parse tree for every sentence. An academic free solver [11] does all the ILP decoding.

5.2 Results and Analysis

5.2.1 Summarization Results

Table 1 shows the ROUGE-2 results of our proposed joint system, the ICSI system (which uses document frequency threshold to select bigram concepts and uses df as weights), the best performing system in the NIST TAC evaluation, and the state of the art performance we could find. The result of our proposed method is statistically significantly better than that of ICSI ILP ($p < 0.05$ based on paired t-test). It is also statistically significantly ($p < 0.05$) better than that of TAC Rank1 except 2011, and previous best in 2008 and 2010. The 2011 previous best results from (Ng et al., 2012) involve some rule-based sentence compression, which improves the ROUGE value. If we apply the same or similar rule-based sentence compression on our results, and the ROUGE-2 of our proposed method improves to 14.38.

	2008	2009	2010	2011
ICSI ILP	10.23	11.60	10.03	12.71
TAC Rank1	10.38	12.16	9.57	13.44
Previous Best	10.76†	12.46†	10.8‡	13.93∗
Proposed Method	**11.84**	**12.77**	**11.78**	**13.97**

Table 1: ROUGE-2 summarization results.† is from (Li et al., 2013b), ‡ is from (Davis et al., 2012), and ∗ is from (Ng et al., 2012).

5.2.2 The Effect of Bigram Selection

In our experiments, the document frequency threshold used to filter the bigrams is 3, the same as that in (Gillick et al., 2009), in order to make a better comparison with previous work. Figure 1 shows the percentage of the correct bigrams (those in the human reference summaries) by our proposed selection method and the original ICSI system which just used document frequency based selection. We can see that our selection method yields a higher percent of the correctly chosen bigrams. Since our proposed method is slightly aggressive when filtering bigrams, the absolute number of the correct bigrams decreased. However, our filtering method successfully removes more useless bigrams, resulting in a higher percentage of the correct bigrams.

Table 2 shows the summarization results when using different bigrams: the method used in the ICSI ILP system, that is, document frequency based selection/filtering and our selection method. Both of them use document frequency as the bigram weight in the ILP summarization module. The results show that just by changing the input bigrams, our method has already outperformed the ICSI system, which means the selection of bigram indeed has an impact on summarization results.

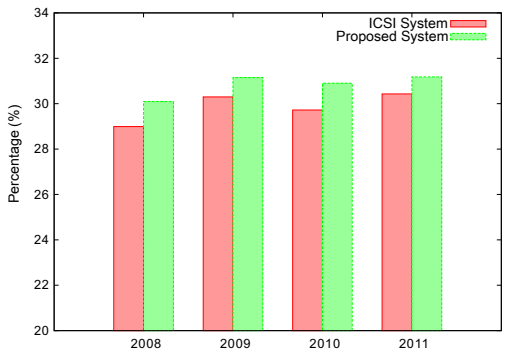

Figure 1: Percentage of correct bigrams in the selected bigrams from ICSI and our proposed system.

	2008	2009	2010	2011
ICSI ILP	10.23	11.60	10.03	12.71
Ours	10.26	11.65	10.25	12.75

Table 2: ROUGE-2 summarization results when using different bigrams, both using document frequencies as weights.

[11] http://www.gurobi.com

5.2.3 The Effect of Features

Next we evaluate the contributions of different features. We show results for four experiments: (i) use just one type of features; (ii) combine the internal features with features from just one external resource; (iii) incrementally add external resources one by one; (iv) leave out each feature type.

Table 3 shows the ROUGE-2 results when we only apply one type of features. First, we can see that the system with the internal features has already outperformed the baseline which used document frequency as the weight. It shows that the other chosen internal features (beyond document frequency) are useful. Second, when we use the features from only one external resource, the results from some resources are competitive compared to that from the system using internal features. In particular, when using the LM scores, Wiki or Word Embedding features, the results are slightly better than the internal features. Using DBpedia or SentiWordNet has worse results than the internal features. This is because the SentiWordNet features themselves are not very discriminative. For DBpedia, since it only has feature values for the bigrams containing name entities, it will only assign weights for those bigrams. Therefore, only considering DBpedia features means that the ILP decoder would prefer to choose bigrams that are name entities with positive weights.

	2008	2009	2010	2011
Internal	10.40	11.76	10.42	12.91
LM	10.58	11.86	10.48	12.94
Word Embedding	10.67	11.96	10.58	13.02
Wikipedia	10.61	11.90	10.52	13.00
DBpedia	8.35	9.85	9.46	11.00
WordNet	10.39	11.76	10.40	12.86
SentiwordNet	9.90	10.80	10.08	12.50

Table 3: ROUGE-2 results using one feature type.

Table 4 shows the results when combining the internal features with features from one external resource. We can see that the features from Word Embedding model outperform others, suggesting the effectiveness of this semantic similarity measure. Features from the LM scores and Wiki are also quite useful. Wiki pages are extracted for the test topic itself, therefore they provide topic relevant background information. The LM score features are extracted from large amounts of news article data, and are good representation of the general importance of bigrams for the test domain. In contrast, WordNet information is collected from a more general aspect, which may not be a very good choice for this task. Also notice that even though the features from DBpedia and sentiwordnet do not perform well by themselves, after the combination with internal features, there is significant improvement. This proves that the features from DBpedia and sentiwordnet provide additional information not captured by the internal features from the documents.

	2008	2009	2010	2011
Internal	10.40	11.76	10.42	12.91
+LM	10.76	12.03	10.80	13.11
+Word Embedding	10.92	12.12	10.85	13.24
+Wikipedia	10.81	12.08	10.76	13.17
+WordNet	10.68	11.96	10.71	12.99
+SentiwordNet	10.60	11.96	10.63	12.96
+DBpedia	10.69	12.00	10.70	13.07

Table 4: ROUGE-2 results using internal features combined with features from just one external resource.

Table 5 shows the results when adding features one by one. The order is based on its individual impact when combined with internal features. The results show that Wiki, LM and DBpedia features give more improvement than WordNet and SentiWordNet features. This shows the different impact of the external resources. We can see there is consistent improvement when more features are added.

	2008	2009	2010	2011
1: Internal +Word Embedding	10.92	12.12	10.85	13.24
2: 1+Wiki	11.22	12.25	11.15	13.47
3: 2+LM	11.41	12.41	11.37	13.68
4: 3+DBpedia	11.65	12.60	11.61	13.77
5: 4+WordNet	11.75	12.67	11.70	13.90
6: 5+SentiWordNet	11.84	12.77	11.78	13.97

Table 5: ROUGE-2 results using features incrementally combined.

Table 6 shows the feature ablation results, that is, each row means that the corresponding features are

excluded and the system uses all the other features. This set of experiments again shows that the external features like Word Embedding model based on large corpus and Wiki resource are very useful. Without using them, the system has the biggest performance degradation compared to the best result.

	2008	2009	2010	2011
-Internal	11.34	12.41	11.42	13.71
-Word Embedding	11.29	12.25	11.36	13.55
-Wiki	11.35	12.38	11.38	13.58
-LM	11.40	12.39	11.42	13.61
-DBpedia	11.50	12.47	11.47	13.71
-WordNet	11.67	12.64	11.64	13.80
-SentiWordNet	11.75	12.67	11.70	13.90

Table 6: ROUGE-2 results when leaving out each feature type.

5.2.4 Distribution of Correct Bigrams After Feature Weighting

In the next experiment we analyze the distribution of the correct bigrams from the ranked bigrams using different features in order to better evaluate their impact on bigram weighting. We rank all the bigrams in descending order according to the estimated weight, then calculate the number of correct bigrams (i.e., the bigrams in human generated summary) in Top10, 30, 50 and 80. The more correct bigrams appear on the top of the list, the better our features estimate the importance of the bigrams. We conducted this experiment using four systems: the system only with internal features, only with Word Embedding features, with combination of internal and Word Embedding features, and with all the features. Figure 2 shows the results of this experiment on TAC 2008 data. The pattern is similar on the other three years' data. The results show that systems with better ROUGE-2 value indeed can assign higher weights to correct bigrams, allowing the ILP decoding process to select these bigrams, which leads to a better sentence selection.

5.2.5 Joint Learning Results

Finally we evaluate the effectiveness of our proposed joint learning approach. For comparison, we implement a pipeline method, where we use the bigram's document frequency as the target value to train a regression model, and during testing use the model's predicted value as the weight in the ILP framework. Table 7 compares the results using the joint learning method and this pipeline approach. We only show the results using the system with all the features due to limited space. We can see that our joint method outperforms the pipeline system based on ROUGE-2 measurement, indicating that weights are better learned in the joint process that takes into account both bigram and sentence selection.

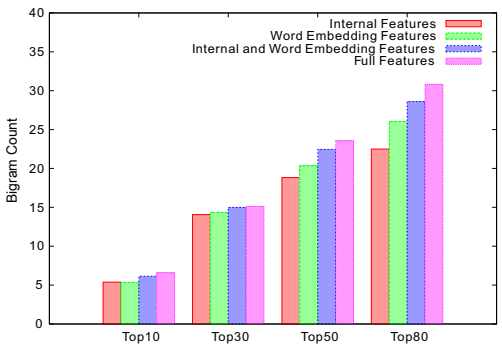

Figure 2: Distribution of correct bigrams in Top-n weighted bigrams from four systems.

System	2008	2009	2010	2011
Pipeline System	11.60	12.64	11.56	13.65
Joint Model	11.84	12.77	11.78	13.97

Table 7: ROUGE-2 results using different training strategies.

6 Conclusions

In this paper, we adopt the ILP based summarization framework, and propose methods to improve bigram concept selection and weighting. We use syntactic information to filter and select bigrams, various external resources to extract features, and a joint learning process for weight training. Our experiments in the TAC data sets demonstrate that our proposed methods outperform other state-of-the-art results. Through the analysis, we found the external resources are helpful to estimate the bigram importance and thus improve the summarization performance. While in summarization research, optimization-based methods have already rivaled other approaches in performance, the task is

far from being solved. Our analysis revealed that there are at least three points worth mentioning. First, using external resources contributes to the improved performance of our method compared to others that only use internal features. Second, employing and designing sophisticated features, especially those that encode background knowledge or semantic relationship like the word embedding features from a large corpus we used, will enable language concepts to be distinguished more easily in the presence of a large number of candidates. Third, one limitation of the use of the external resources is that they are not always available, such as the pairwise news articles along with the human generated summaries, and the relevant Wiki pages. While much recent work has focused on algorithmic development, the summarization task needs to have a deeper "understanding" of a document in order to reach the next level of performance. Such an understanding can be facilitated by the incorporation of background knowledge, which can lead to significant summarization performance improvement, as demonstrated in this study.

Acknowledgments

Abstract

We present a new algorithm for transforming dependency parse trees into phrase-structure parse trees. We cast the problem as structured prediction and learn a statistical model. Our algorithm is faster than traditional phrase-structure parsing and achieves 90.4% English parsing accuracy and 82.4% Chinese parsing accuracy, near to the state of the art on both benchmarks.

1 Introduction

Natural language parsers typically produce phrase-structure (constituent) trees or dependency trees. These representations capture some of the same syntactic phenomena, and the two can be produced jointly (Klein and Manning, 2002; Hall and Nivre, 2008; Carreras et al., 2008; Rush et al., 2010). Yet it appears to be completely unpredictable which will be preferred by a particular subcommunity or used in a particular application. Both continue to receive the attention of parsing researchers.

Further, it appears to be a historical accident that phrase-structure syntax was used in annotating the Penn Treebank, and that English dependency annotations are largely derived through mechanical, rule-based transformations (reviewed in Section 2). Indeed, despite extensive work on direct-to-dependency parsing algorithms (which we call *d-parsing*), the most accurate dependency parsers for English still involve phrase-structure parsing (which we call *c-parsing*) followed by rule-based extraction of dependencies (Kong and Smith, 2014).

What if dependency annotations had come first? Because d-parsers are generally much faster than c-parsers, we consider an alternate pipeline (Section 3): d-parse first, then transform the dependency representation into a phrase-structure tree constrained to be consistent with the dependency parse. This idea was explored by Xia and Palmer (2001) and Xia et al. (2009) using hand-written rules. Instead, we present a data-driven algorithm using the structured prediction framework (Section 4). The approach can be understood as a specially-trained coarse-to-fine decoding algorithm where a d-parser provides "coarse" structure and the second stage refines it (Charniak and Johnson, 2005; Petrov and Klein, 2007).

Our lexicalized phrase-structure parser, PAD, is asymptotically faster than parsing with a lexicalized context-free grammar: $O(n^2)$ plus d-parsing, vs. $O(n^5)$ worst case runtime in sentence length n, with the same grammar constant. Experiments show that our approach achieves linear observable runtime, and accuracy similar to state-of-the-art phrase-structure parsers without reranking or semi-supervised training (Section 7).

2 Background

We begin with the conventional development by first introducing c-parsing and then defining d-parses through a mechanical conversion using head rules. In the next section, we consider the reverse transformation.

2.1 CFG Parsing

The phrase-structure trees annotated in the Penn Treebank are derivation trees from a context-free grammar. Define a binary[1] context-free grammar

[1]For notational simplicity, we defer discussion of non-binary rules to Section 3.3.

(CFG) as a 4-tuple $(\mathcal{N}, \mathcal{G}, \mathcal{T}, r)$ where $\mathcal{N}$ is a set of nonterminal symbols (e.g. NP, VP), $\mathcal{T}$ is a set of terminal symbols, consisting of the words in the language, $\mathcal{G}$ is a set of binary rules of the form $A \rightarrow \beta_1\ \beta_2$, and $r \in \mathcal{N}$ is a distinguished root nonterminal symbol.

Given an input sentence $x_1, \ldots, x_n$ of terminal symbols from $\mathcal{T}$, define the set of c-parses for the sentence as $\mathcal{Y}(x)$. This set consists of all binary ordered trees with fringe $x_1, \ldots, x_n$, internal nodes labeled from $\mathcal{N}$, all tree productions $A \rightarrow \beta_1\ \beta_2$ consisting of members of $\mathcal{G}$, and root label r.

For a c-parse $y \in \mathcal{Y}(x)$, we further associate a span $\langle v_{\Leftarrow}, v_{\Rightarrow} \rangle$ with each vertex in the tree. This specifies the subsequence $\{x_{v_{\Leftarrow}}, \ldots, x_{v_{\Rightarrow}}\}$ of the sentence covered by this vertex.

2.2 Dependency Parsing

Dependency parses provide an alternative, and in some sense simpler, representation of sentence structure. These d-parses can be derived through mechanical transformation from context-free trees. There are several popular transformations in wide use; each provides a different representation of a sentence's structure (Collins, 2003; De Marneffe and Manning, 2008; Yamada and Matsumoto, 2003; Johansson and Nugues, 2007).

We consider the class of transformations that are defined through local *head rules*. For a binary CFG, define a collection of head rules as a mapping from each CFG rule to a head preference for its left or right child. We use the notation $A \rightarrow \beta_1^*\ \beta_2$ and $A \rightarrow \beta_1\ \beta_2^*$ to indicate a left- or right-headed rule, respectively.

The head rules can be used to map a c-parse to a dependency tree (d-parse). In a d-parse, each word in the sentence is assigned as a dependent to a head word, $h \in \{0, \ldots, n\}$, where 0 is a special symbol indicating the pseudo-root of the sentence. For each h we define $\mathcal{L}(h) \subset \{1, \ldots, h-1\}$ as the set of left dependencies of h, and $\mathcal{R}(h) \subset \{h+1, \ldots, n\}$ as the set of right dependencies.

A d-parse can be constructed recursively from a c-parse and the head rules. For each c-parse vertex v with potential children v_{L} and v_{R} in bottom-up order, we apply the following procedure to both assign heads to the c-parse and construct the d-parse:

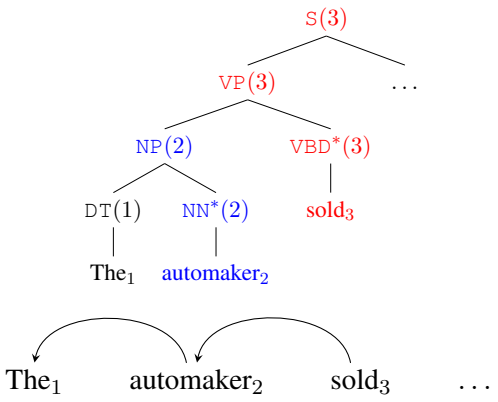

Figure 1: Illustration of c-parse to d-parse conversion with head rules $\{\texttt{VP} \rightarrow \texttt{NP VBD}^*, \texttt{NP} \rightarrow \texttt{DT NN}^*, \ldots\}$. The c-parse is an ordered tree with fringe $x_1, \ldots, x_n$. Each vertex is annotated with a terminal or nonterminal symbol and a derived head index. The blue and red vertices have the words $\texttt{automaker}_2$ and $\texttt{sold}_3$ as heads respectively. The vertex $\texttt{VP}(3)$ implies that $\texttt{automaker}_2$ is a left-dependent of $\texttt{sold}_3$, and that $2 \in \mathcal{L}(3)$ in the d-parse.

1. If the vertex is leaf x_m, then $\mathrm{head}(v) = m$.
2. If the next rule is $A \rightarrow \beta_1^*\ \beta_2$ then $\mathrm{head}(v) = \mathrm{head}(v_{\mathrm{L}})$ and $\mathrm{head}(v_{\mathrm{R}}) \in \mathcal{R}(\mathrm{head}(v))$, i.e. the head of the right-child is a dependent of the head word.
3. If the next rule is $A \rightarrow \beta_1\ \beta_2^*$ then $\mathrm{head}(v) = \mathrm{head}(v_{\mathrm{R}})$ and $\mathrm{head}(v_{\mathrm{L}}) \in \mathcal{L}(\mathrm{head}(v))$, i.e. the head of the left-child is a dependent of the head word.

Figure 1 shows an example conversion of a c-parse to d-parse using this procedure.

By construction, these dependencies form a directed tree with arcs (h, m) for all $h \in \{0, \ldots, n\}$ and $m \in \mathcal{L}(h) \cup \mathcal{R}(h)$. While this tree differs from the original c-parse, we can relate the two trees through their spans. Define the dependency tree span $\langle h_{\Leftarrow}, h_{\Rightarrow} \rangle$ as the contiguous sequence of words reachable from word h in this tree.[2] This span is equivalent to the maximal span $\langle v_{\Leftarrow}, v_{\Rightarrow} \rangle$ of any c-parse vertex with $\mathrm{head}(v) = h$. This property will be important for the parsing algorithm presented in the next section.

[2]The conversion from a standard CFG tree to a d-parse preserves this sequence property, known as *projectivity*. We leave the question of non-projective d-parses and the related question of traces and co-indexation in c-parses to future work.

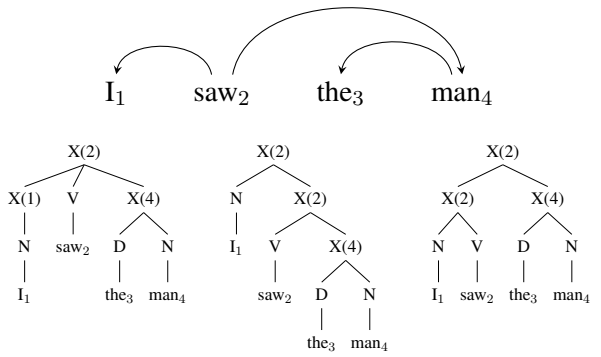

Figure 2: [Adapted from (Collins et al., 1999).] A d-parse (left) and several c-parses consistent with it (right). Our goal is to select the best parse from this set.

3 Parsing Dependencies

Now we consider flipping this setup. There has been significant progress in developing efficient direct-to-dependency parsers. These d-parsers are trained only on dependency annotations and do not require full phrase-structure trees.[3] Some prefer this setup, since it allows easy selection of the specific dependencies of interest in a downstream task (e.g., information extraction), and perhaps even training specifically for those dependencies. Other applications make use of phrase structures, so c-parsers enjoy wide use as well.

With these latter applications in mind, we consider the problem of converting a fixed d-parse into a c-parse, with the intent of using off-the-shelf d-parsers for constructing phrase-structure parses. Since this problem is more challenging than its inverse, we use a structured prediction setup: we learn a function to score possible c-parse conversions, and then generate the highest-scoring c-parse given a d-parse. A toy example of the problem is shown in Figure 2.

3.1 Parsing Algorithm

Consider the classical problem of predicting the best c-parse under a CFG with head rules, known as lexicalized context-free parsing. Assume that we are given a binary CFG defining a set of valid c-parses $\mathcal{Y}(x)$. The parsing problem is to find the highest-scoring parse in this set, i.e. $\arg\max_{y \in \mathcal{Y}(x)} s(y; x)$ where s is a scoring function that factors over lexicalized tree productions.

This problem can be solved by extending the CKY algorithm to propagate head information. The algorithm can be compactly defined by the productions in Figure 3 (left). For example, one type of production is of the form

$$\frac{(\langle i, k\rangle, m, \beta_1) \quad (\langle k+1, j\rangle, h, \beta_2)}{(\langle i, j\rangle, h, A)}$$

for all rules $A \rightarrow \beta_1\ \beta_2^* \in \mathcal{G}$ and spans $i \leq k < j$. This particular production indicates that rule $A \rightarrow \beta_1\ \beta_2^*$ was applied at a vertex covering $\langle i, j\rangle$ to produce two vertices covering $\langle i, k\rangle$ and $\langle k+1, j\rangle$, and that the new head is index h has dependent index m. We say this production "completes" word m since it can no longer be the head of a larger span.

Running the algorithm consists of bottom-up dynamic programming over these productions. However, applying this version of the CKY algorithm requires $O(n^5|\mathcal{G}|)$ time (linear in the number of productions), which is not practical to run without heavy pruning. Most lexicalized parsers therefore make further assumptions on the scoring function which can lead to asymptotically faster algorithms (Eisner and Satta, 1999).

Instead, we consider the same objective, but constrain the c-parses to be consistent with a given d-parse, d. By "consistent," we mean that the c-parse will be converted by the head rules to this exact d-parse.[4] Define the set of consistent c-parses as $\mathcal{Y}(x, d)$ and the constrained search problem as $\arg\max_{y \in \mathcal{Y}(x,d)} s(y; x, d)$.

Figure 3 (right) shows the algorithm for this new problem. The algorithm has several nice properties. All rules now must select words h and m that are consistent with the dependency parse (i.e., there is an arc (h, m)) so these variables are no longer free. Furthermore, since we have the full d-parse, we can precompute the dependency span of each word $\langle m_{\Leftarrow}, m_{\Rightarrow}\rangle$. By our definition of consistency, this gives us the c-parse span of m before it is completed, and fixes two more free variables. Finally the head item must have its alternative side index match

[3] For English these parsers are still often trained on trees converted from c-parses; however, for other languages, dependency-only treebanks of directly-annotated d-parses are common.

[4] An alternative, soft version of consistency, might enforce that the c-parse is close to the d-parse. While this allows the algorithm to potentially correct d-parse mistakes, it is much more computationally expensive.

Premise:

$$(\langle i, i\rangle, i, A) \quad \forall i \in \{1 \dots n\}, A \in \mathcal{N}$$

Rules:

For $i \leq h \leq k < m \leq j$, and rule $A \rightarrow \beta_1^* \ \beta_2$,

$$\frac{(\langle i, k\rangle, h, \beta_1) \quad (\langle k+1, j\rangle, m, \beta_2)}{(\langle i, j\rangle, h, A)}$$

For $i \leq m \leq k < h \leq j$, rule $A \rightarrow \beta_1 \ \beta_2^*$,

$$\frac{(\langle i, k\rangle, m, \beta_1) \quad (\langle k+1, j\rangle, h, \beta_2)}{(\langle i, j\rangle, h, A)}$$

Goal:

$$(\langle 1, n\rangle, m, r) \text{ for any } m$$

Premise:

$$(\langle i, i\rangle, i, A) \quad \forall i \in \{1 \dots n\}, A \in \mathcal{N}$$

Rules:

For all h, $m \in \mathcal{R}(h)$, rule $A \rightarrow \beta_1^* \ \beta_2$,
and $i \in \{m'_{\Leftarrow} : m' \in \mathcal{L}(h)\} \cup \{h\}$,

$$\frac{(\langle i, m_{\Leftarrow} - 1\rangle, h, \beta_1) \quad (\langle m_{\Leftarrow}, m_{\Rightarrow}\rangle, m, \beta_2)}{(\langle i, m_{\Rightarrow}\rangle, h, A)}$$

For all h, $m \in \mathcal{L}(h)$, rule $A \rightarrow \beta_1 \ \beta_2^*$,
and $j \in \{m'_{\Rightarrow} : m' \in \mathcal{R}(h)\} \cup \{h\}$,

$$\frac{(\langle m_{\Leftarrow}, m_{\Rightarrow}\rangle, m, \beta_1) \quad (\langle m_{\Rightarrow} + 1, j\rangle, h, \beta_2)}{(\langle m_{\Leftarrow}, j\rangle, h, A)}$$

Goal:

$$(\langle 1, n\rangle, m, r) \text{ for any } m \in \mathcal{R}(0)$$

Figure 3: The two algorithms written as deductive parsers. Starting from the *premise*, any valid application of *rules* that leads to a *goal* is a valid parse. Left: lexicalized CKY algorithm for CFG parsing with head rules. For this algorithm there are $O(n^5|\mathcal{G}|)$ rules where n is the length of the sentence. Right: the constrained CKY parsing algorithm for $\mathcal{Y}(x, d)$. The algorithm is nearly identical except that many of the free indices are now fixed given the dependency parse. Finding the optimal c-parse with the new algorithm now requires $O\left((\sum_h |\mathcal{L}(h)||\mathcal{R}(h)|)|\mathcal{G}|\right)$ time where $\mathcal{L}(h)$ and $\mathcal{R}(h)$ are the left and right dependents of word h.

a valid dependency span. For example, if for a word h there are $|\mathcal{L}(h)| = 3$ left dependents, then when taking the next right-dependent there can only be 4 valid left boundary indices.

The runtime of the final algorithm reduces to $O(\sum_h |\mathcal{L}(h)||\mathcal{R}(h)||\mathcal{G}|)$. While the terms $|\mathcal{L}(h)|$ and $|\mathcal{R}(h)|$ could in theory make the runtime quadratic, in practice the number of dependents is almost always constant in the length of the sentence. This leads to linear observed runtime in practice as we will show in Section 7.

3.2 Pruning

In addition to constraining the number of c-parses, the d-parse also provides valuable information about the labeling and structure of the c-parse. We can use this information to further prune the search space. We employ two pruning methods:

Method 1 uses the part-of-speech tag of x_h, $\text{tag}(h)$, to limit the possible rule productions at a given span. We build tables $\mathcal{G}_{\text{tag}(h)}$ and restrict the search to rules seen in training for a particular part-of-speech tag.

Method 2 prunes based on the order in which dependent words are added. By the constraints of the algorithm, a head word x_h must combine with each of its left and right dependents. However, the order of combination can lead to different tree structures (as illustrated in Figure 2). In total there are $|\mathcal{L}(h)| \times |\mathcal{R}(h)|$ possible orderings of dependents.

In practice, though, it is often easy to predict which side, left or right, will come next. We do this by estimating the distribution,

$$p(\text{side} \mid \text{tag}(h), \text{tag}(m), \text{tag}(m')),$$

where $m \in \mathcal{L}(h)$ is the next left dependent and $m' \in \mathcal{R}(h)$ is the next right dependent. If the conditional probability of left or right is greater than a threshold parameter γ, we make a hard decision to combine with that side next. This pruning further reduces the impact of outliers with multiple dependents on both sides.

We empirically measure how these pruning methods affect observed runtime and oracle parsing performance (i.e., how well a perfect scoring function could do with a pruned $\mathcal{Y}(x, d)$). Table 1 shows a comparison of these pruning methods on development data. The constrained parsing algorithm is much faster than standard lexicalized parsing, and

Model	Complexity	Sent./s.	Ora. F_1
LEX CKY*	$n^5\|\mathcal{G}\|$	0.25	100.0
DEP CKY	$\sum_h \|\mathcal{L}(h)\|\|\mathcal{R}(h)\|\|\mathcal{G}\|$	71.2	92.6
PRUNE1	$\sum_h \|\mathcal{L}(h)\|\|\mathcal{R}(h)\|\|\mathcal{G}_{\mathrm{T}}\|$	336.0	92.5
PRUNE2	–	96.6	92.5
PRUNE1+2	–	425.1	92.5

Table 1: Comparison of three parsing setups: LEX CKY* is the complete lexicalized c-parser on $\mathcal{Y}(x)$, but limited to only sentences less than 20 words for tractability, DEP CKY is the constrained c-parser on $\mathcal{Y}(x, d)$, PRUNE1, PRUNE2, and PRUNE1+2 are combinations of the pruning methods described in Section 3.2. The oracle is the best labeled F_1 achievable on the development data (§22, see Section 7).

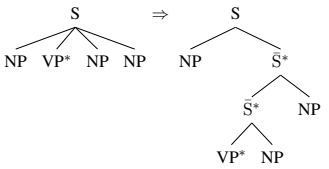
pruning contributes even greater speed-ups. The oracle experiments show that the d-parse constraints do contribute a large drop in oracle accuracy, while pruning contributes a relatively small one. Still, this upper-bound on accuracy is high enough to make it possible to still recover c-parses at least as accurate as state-of-the-art c-parsers. We will return to this discussion in Section 7.

3.3 Binarization and Unary Rules

We have to this point developed the algorithm for a strictly binary-branching grammar; however, we need to produce trees have rules with varying size. In order to apply the algorithm, we binarize the grammar and add productions to handle unary rules.

Consider a non-binarized rule of the form $A \rightarrow \beta_1 \dots \beta_m$ with head child β_k^*. Relative to the head child β_k the rule has left-side $\beta_1 \dots \beta_{k-1}$ and right-side $\beta_{k+1} \dots \beta_m$. We replace this rule with new binary rules and non-terminal symbols to produce each side independently as a simple chain, left-side first. The transformation introduces the following new rules:[5] $A \rightarrow \beta_1\ \bar{A}^*$, $\bar{A} \rightarrow \beta_i\ \bar{A}^*$ for $i \in \{2, \dots, k\}$, and $\bar{A} \rightarrow \bar{A}^*\ \beta_i$ for $i \in \{k, \dots, m\}$.

As an example consider the transformation of a rule with four children:



These rules can then be reversed deterministically to produce a non-binary tree.

[5]These rules are slightly modified when $k = 1$.

We also explored binarization using horizontal and vertical markovization to include additional context of the tree, as found useful in unlexicalized approaches (Klein and Manning, 2003). Preliminary experiments showed that this increased the size of the grammar, and the runtime of the algorithm, without leading to improvements in accuracy.

Phrase-structure trees also include unary rules of the form $A \rightarrow \beta_1^*$. To handle unary rules we modify the parsing algorithms in Figure 3 to include a unary completion rule,

$$\frac{(\langle i, j \rangle, h, \beta_1)}{(\langle i, j \rangle, h, A)}$$

for all indices $i \leq h \leq j$ that are consistent with the dependency parse. In order to avoid unary recursion, we limit the number of applications of this rule at each span (preserving the runtime of the algorithm). Preliminary experiments looked at collapsing the unary rules into the nonterminal symbols, but we found that this hurt performance compared to explicit unary rules.

4 Structured Prediction

We learn the d-parse to c-parse conversion using a standard structured prediction setup. Define the linear scoring function s for a conversion as $s(y; x, d, \theta) = \theta^\top f(x, d, y)$ where θ is a parameter vector and $f(x, d, y)$ is a feature function that maps parse productions to sparse feature vectors. While the parser only requires a d-parse at prediction time, the parameters of this scoring function are learned directly from a treebank of c-parses and a set of head rules. The structured prediction model, in effect, learns to invert the head rule transformation.

4.1 Features

The scoring function requires specifying a set of parse features f which, in theory, could be directly adapted from existing lexicalized c-parsers. However, the structure of the dependency parse greatly limits the number of decisions that need to be made, and allows for a smaller set of features.

We model our features after two bare-bones parsing systems. The first set is the basic arc-factored features used by McDonald (2006). These features include combinations of: rule and top nonterminal,

For a production $\dfrac{(\langle i,k\rangle, m, \beta_1) \quad (\langle k+1,j\rangle, h, \beta_2)}{(\langle i,j\rangle, h, A)}$

Nonterm Features
(A, β_1) $(A, \beta_1, \text{tag}(m))$
(A, β_2) $(A, \beta_2, \text{tag}(h))$

Span Features
(rule, x_i) (rule, x_{i-1})
(rule, x_j) (rule, x_{j+1})
(rule, x_k) (rule, x_{k+1})
$(\text{rule}, \text{bin}(j-i))$

Rule Features
(rule)
$(\text{rule}, x_h, \text{tag}(m))$
$(\text{rule}, \text{tag}(h), x_m)$
$(\text{rule}, \text{tag}(h), \text{tag}(m))$
(rule, x_h)
$(\text{rule}, \text{tag}(h))$
(rule, x_m)
$(\text{rule}, \text{tag}(m))$

Figure 4: The feature templates used in the function $f(x, d, y)$. For the span features, the symbol rule is expanded into both $A \rightarrow B\ C$ and backoff symbol A. The function $\text{bin}(i)$ partitions a span length into one of 10 bins.

modifier word and part-of-speech, and head word and part-of-speech.

The second set of features is modeled after the span features described in the X-bar-style parser of Hall et al. (2014). These include conjunctions of the rule with: first and last word of current span, preceding and following word of current span, adjacent words at split of current span, and binned length of the span.

The full feature set is shown in Figure 4. After training, there are a total of around 2 million non-zero features. For efficiency, we use lossy feature hashing. We found this had no impact on parsing accuracy but made the parsing significantly faster.

4.2 Training

The parameters θ are estimated using a structural support vector machine (Taskar et al., 2004). Given a set of gold-annotated c-parse examples, $(x^1, y^1), \ldots, (x^D, y^D)$, and d-parses $d^1 \ldots d^D$ induced from the head rules, we estimate the parameters to minimize the regularized empirical risk

$$\min_\theta \sum_{i=1}^{D} \ell(x^i, d^i, y^i, \theta) + \lambda ||\theta||_1$$

where we define ℓ as $\ell(x, d, y, \theta) = -s(y) + \max_{y' \in \mathcal{Y}(x,d)} (s(y') + \Delta(y, y'))$ and where Δ is a problem specific cost-function. In experiments, we use a Hamming loss $\Delta(y, y') = |y - y'|$ where y is an indicator for production rules firing over pairs of adjacent spans (i.e., i, j, k).

Model	PTB §22 Prec.	Rec.	F_1
Xia et al. (2009)	88.1	90.7	89.4
PAD (§19)	95.9	95.9	95.9
PAD (§2–21)	97.5	97.8	97.7

Table 2: Comparison with the rule-based system of Xia et al. (2009). Results are shown using gold-standard tags and dependencies. Xia et al. report results consulting only §19 in development and note that additional data had little effect. We show our system's results using §19 and the full training set.

The objective is optimized using AdaGrad (Duchi et al., 2011). The gradient calculation requires computing a loss-augmented max-scoring c-parse for each training example which is done using the algorithm of Figure 3 (right).

5 Related Work

The problem of converting dependency to phrase-structured trees has been studied previously from the perspective of building multi-representational treebanks. Xia and Palmer (2001) and Xia et al. (2009) develop a rule-based system for the conversion of human-annotated dependency parses. This work focuses on modeling the conversion decisions made and capturing how researchers annotate specific phenomena. Our work focuses on a different problem of learning a data-driven structured prediction model that is also able to handle automatically predicted dependency parses as input. While the aim is different, Table 2 does give a direct comparison of our system to that of Xia et al. (2009) on gold d-parse data.

An important line of previous work also uses dependency parsers to produce phrase-structure trees. In particular Hall et al. (2007) and Hall and Nivre (2008) develop a specialized dependency label set to encode phrase-structure information in the d-parse. After predicting a d-parse this label information can be used to assemble a predicted c-parse. Our work differs in that it does not make any assumptions on the labeling of the dependency tree used and it uses structured prediction to produce the final c-parse.

Very recently, Fernández-González and Martins (2015) also show that an off-the-shelf, trainable, dependency parser is enough to build a highly-competitive constituent parser. They proposed

a new intermediate representation called "head-ordered dependency trees", which encode head ordering information in dependeny labels. Their algorithm is based on a reduction of the constituent parsing to dependency parsing of such trees.

There has been successful work combining dependency and phrase-structure information to build accurate c-parsers. Klein and Manning (2002) construct a factored generative model that scores both context-free syntactic productions and semantic dependencies. Carreras et al. (2008) construct a state-of-the-art parser that uses a dependency parsing model both for pruning and within a richer lexicalized parser. Similarly, Rush et al. (2010) use dual decomposition to combine a powerful dependency parser with a lexicalized phrase-structure model. This work differs in that we treat the dependency parse as a hard constraint, hence largely reduce the runtime of a fully lexicalized phrase structure parsing model while maintaining the ability, at least in principle, to generate highly accurate phrase-structure parses.

Finally there have also been several papers that use ideas from dependency parsing to simplify and speed up phrase-structure prediction. Zhu et al. (2013) build a high-accuracy phrase-structure parser using a transition-based system. Hall et al. (2014) use a stripped down parser based on a simple X-bar grammar and a small set of lexicalized features.

6 Methods

We ran a series of experiments to assess the accuracy, efficiency, and applicability of our parser, PAD, to several tasks. These experiments use the following setup.

For English experiments we use the standard Penn Treebank (PTB) experimental setup (Marcus et al., 1993). Training is done on §2–21, development on §22, and testing on §23. We use the development set to tune the regularization parameter, $\lambda = 1e-8$, and the pruning threshold, $\gamma = 0.95$.

For Chinese experiments, we use version 5.1 of the Penn Chinese Treebank 5.1 (CTB) (Xue et al., 2005). We followed previous work and used articles 001–270 and 440–1151 for training, 301–325 for development, and 271–300 for test. We also use the development set to tune the regularization parameter, $\lambda = 1e-3$.

Part-of-speech tagging is performed for all models using TurboTagger (Martins et al., 2013). Prior to training the d-parser, the training sections are automatically processed using 10-fold jackknifing (Collins and Koo, 2005) for both dependency and phrase structure trees. Zhu et al. (2013) found this simple technique gives an improvement to dependency accuracy of 0.4% on English and 2.0% on Chinese in their system.

During training, we use the d-parses induced by the head rules from the gold c-parses as constraints. There is a slight mismatch here with test, since these d-parses are guaranteed to be consistent with the target c-parse. We also experimented with using 10-fold jacknifing of the d-parser during training to produce more realistic parses; however, we found that this hurt performance of the parser.

Unless otherwise noted, in English the test d-parsing is done using the RedShift implementation[6] of the parser of Zhang and Nivre (2011), trained to follow the conventions of Collins head rules (Collins, 2003). This parser is a transition-based beam search parser, and the size of the beam k controls a speed/accuracy trade-off. By default we use a beam of $k = 16$. We found that dependency labels have a significant impact on the performance of the RedShift parser, but not on English dependency conversion. We therefore train a labeled parser, but discard the labels.

For Chinese, we use the head rules compiled by Ding and Palmer (2005)[7]. For this data-set we trained the d-parser using the YaraParser implementation[8] of the parser of Zhang and Nivre (2011), because it has a better Chinese implementation. We use a beam of $k = 64$. In experiments, we found that Chinese labels were quite helpful, and added four additional features templates conjoining the label with the non-terminals of a rule.

Evaluation for phrase-structure parses is performed using the `evalb`[9] script with the standard setup. We report labeled F_1 scores as well as recall and precision. For dependency parsing, we report

Table 4: The effect of d-parsing accuracy (PTB §22) on PAD and an oracle converter. Runtime includes d-parsing and c-parsing. Inputs include MaltParser (Nivre et al., 2006), the RedShift and the Yara implementations of the parser of Zhang and Nivre (2011) with various beam size, and three versions of TurboParser trained with projective constraints (Martins et al., 2013).

unlabeled accuracy score (UAS).

We implemented the grammar binarization, head rules, and pruning tables in Python, and the parser, features, and training in C++. Experiments are performed on a Lenovo ThinkCentre desktop computer with 32GB of memory and Core i7-3770 3.4GHz 8M cache CPU.

7 Experiments

We ran experiments to assess the accuracy of the method, its runtime efficiency, the effect of dependency parsing accuracy, and the effect of the amount of annotated phrase-structure data.

Parsing Accuracy Table 3 compares the accuracy and speed of the phrase-structure trees produced by the parser. For these experiments we treat our system and the Zhang-Nivre parser as an independently trained, but complete end-to-end c-parser. Runtime for these experiments includes both the time for d-parsing and conversion. Despite the fixed dependency constraints, the English results show that the parser is comparable in accuracy to many widely-used systems, and is significantly faster. The parser most competitive in both speed and accuracy is that of Zhu et al. (2013), a fast shift-reduce phrase-structure parser.

Furthermore, the Chinese results suggest that, even without making language-specific changes in the feature system we can still achieve competitive parsing accuracy.

Effect of Dependencies Table 4 shows experiments comparing the effect of different input d-parses. For these experiments we used the same version of PAD with 11 different d-parsers of varying quality and speed. We measure for each parser: its UAS, speed, and labeled F_1 when used with PAD and with an oracle converter.[10] The paired figure

[10] For a gold parse y and predicted dependencies $\hat{d}$, define the oracle parse as $y' = \arg\min_{y' \in \mathcal{Y}(x,\hat{d})} \Delta(y, y')$

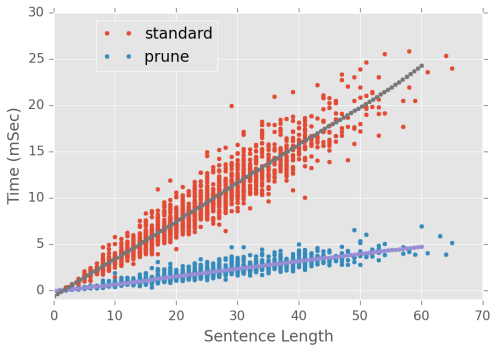

Figure 5: Empirical runtime of the parser on sentences of varying length, with and without pruning. Despite a worst-case quadratic complexity, observed runtime is linear.

Class			Results	
Dep. (h, m)	Span $\langle i, j \rangle$	Split k	Count	Acc. A
+	+	+	32853	97.9
–	+	+	381	69.3
+	+	–	802	83.3
–	+	–	496	85.9
+	–	–	1717	0.0
–	–	–	1794	0.0

Table 5: Error analysis of binary CFG rules. Rules used are split into classes based on correct (+) identification of dependency (h, m), span $\langle i, j \rangle$, and split k. "Count" is the size of each class. "Acc." is the accuracy of span nonterminal identification.

shows that there is a direct correlation between the UAS of the inputs and labeled F_1.

Runtime In Section 3 we considered the theoretical complexity of the parsing model and presented the main speed results in Table 1. Despite having a quadratic theoretical complexity, the practical runtime was quite fast. Here we consider the empirical complexity of the model by measuring the time spent on individual sentences. Figure 5 shows parser speed for sentences of varying length for both the full algorithm and with pruning. In both cases the observed runtime is linear.

Recovering Phrase-Structure Treebanks Annotating phrase-structure trees is often more expensive and slower than annotating unlabeled dependency trees (Schneider et al., 2013). For low-resource languages, an alternative approach to developing fully annotated phrase-structure treebanks might be to label a small amount of c-parses and a large amount of cheaper d-parses. Assuming this setup, we ask how many c-parses would be necessary to obtain reasonable performance?

For this experiment, we train PAD on only 5% of the PTB training set and apply it to predicted d-parses from a fully-trained model. Even with this small amount of data, we obtain a parser with development score of $F_1 = 89.1\%$, which is comparable to Charniak (2000) and Stanford PCFG (Klein and Manning, 2003) trained on the complete c-parse training set. Additionally, if the gold dependencies are available, PAD with 5% training achieves $F_1 = 95.8\%$ on development, demonstrating a strong ability to recover the phrase-structure trees from dependency annotations.

Analysis Finally we consider an internal error analysis of the parser. For this analysis, we group each binary rule production selected by the parser by three properties: Is its dependency (h, m) correct? Is its span $\langle i, j \rangle$ correct? Is its split k correct? The first property is fully determined by the input d-parse, the others are partially determined by PAD itself.

Table 5 shows the breakdown. The conversion is almost always accurate ($\sim$98%) when the parser has correct span and dependency information. As expected, the difficult cases come when the dependency was fully incorrect, or there is a propagated span mistake. As dependency parsers improve, the performance of PAD should improve as well.

8 Conclusion

With recent advances in statistical dependency parsing, we find that fast, high-quality phrase-structure parsing is achievable using dependency parsing first, followed by a statistical conversion algorithm to fill in phrase-structure trees. Our implementation is available as open-source software at `https://github.com/ikekonglp/PAD`.

Abstract

Discourse relation classification is an important component for automatic discourse parsing and natural language understanding. The performance bottleneck of a discourse parser comes from implicit discourse relations, whose discourse connectives are not overtly present. Explicit discourse connectives can potentially be exploited to collect more training data to collect more data and boost the performance. However, using them indiscriminately has been shown to hurt the performance because not all discourse connectives can be dropped arbitrarily. Based on this insight, we investigate the interaction between discourse connectives and the discourse relations and propose the criteria for selecting the discourse connectives that can be dropped independently of the context without changing the interpretation of the discourse. Extra training data collected only by the freely omissible connectives improve the performance of the system without additional features.

1 Introduction

The analysis of discourse-level structure has received increasing attention from the field in recent years (Feng and Hirst, 2012; Patterson and Kehler, 2013; Li et al., 2014). Discourse-level analysis is typically concerned with relations between clauses and sentences, linguistic units that go beyond sentence boundaries. There are a few conceptions of the discourse structure representation of a text such as a tree (Mann and Thompson, 1988), or a graph (Wolf et al., 2005). In the work we describe here, we adopt the view of the Penn Discourse Treebank (PDTB) (Prasad et al., 2008), which views a text as a series of local discourse relations, each of which consists of a discourse connective as a predicate taking two arguments. Syntactically, these two arguments are typically realized as clauses or sentences. The discourse connective (underlined) can either be *explicit*, as in (1), or *implicit*, as in (2):

(1) [The city's Campaign Finance Board has refused to pay Mr Dinkins $95,142 in matching funds]$_{Arg1}$ <u>because</u> [his campaign records are incomplete]$_{Arg2}$.

(2) [So much of the stuff poured into its Austin, Texas, offices that its mail rooms there simply stopped delivering it]$_{Arg1}$. <u>Implicit=so</u> [Now, thousands of mailers, catalogs and sales pitches go straight into the trash]$_{Arg2}$.

Determining the sense of an explicit discourse relation such as (1) is straightforward since "because" is a strong indicator that the relation between the two arguments is CONTINGENCY.CAUSE. This task effectively amounts to disambiguating the sense of discourse connective, which can be done with high accuracy (Pitler et al., 2008).

However, in the absence of an explicit discourse connective, inferring the sense of a discourse relation has proved to a very challenging task (Park and Cardie, 2012; Rutherford and Xue, 2014). The sense is no longer localized on one or two discourse connectives and must now be inferred solely based on its two textual arguments. Given the limited amount of annotated data in comparison to the number of features needed, the process of building a classifier is plagued by the data sparsity problem (Li and Nenkova, 2014). As a result, the classification accuracy of implicit discourse relations remains much

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 799–808,
Denver, Colorado, May 31 – June 5, 2015.

lower than that of explicit discourse relations (Pitler et al., 2008).

One potential method for reducing the data sparsity problem is through a distantly supervised learning paradigm, which is the direction we take in this work. Distant supervision approaches make use of prior knowledge or heuristics to cheaply obtain *weakly labeled data*, which potentially contain a small number of false labels. Weakly labeled data can be collected from unannotated data and incorporated in the model training process to supplement manually labeled data. For our task, we can collect instances of explicit discourse relations from unannotated data by some simple heuristics. After dropping the discourse connectives, we should be able to treat them as additional implicit discourse relations.

The approach assumes that when the discourse connective is omitted, the discourse relation remains the same, which is a popular assumption in discourse analysis (Fraser, 2006; Schourup, 1999). This assumption turns out to be too strong in many cases as illustrated in (3):

(3) [I want to go home for the holiday]$_{Arg1}$. Nonetheless, [I will book a flight to Hawaii]$_{Arg2}$.

If "Nonetheless" is dropped in (3), one can no longer infer the COMPARISON relation. Instead, one would naturally infer a CONTINGENCY relation. Dropping the connective and adding the relation as a training sample adds noise to the training set and can only hurt the performance. In addition, certain types of explicit discourse relations have no corresponding implicit discourse relations. For example, discourse relations of the type CONTINGENY.CONDITION are almost always expressed with an explicit discourse connective and do not exist in implicit relations. We believe this also explains the lack of success in previous attempts to boost the performance of implicit discourse relation detection with this approach. (Biran and McKeown, 2013; Pitler et al., 2009). This suggests that in order for this approach to work, we need to identify instances of explicit discourse relations that closely match the characteristics of implicit discourse relations.

In this paper, we propose two criteria for selecting such explicit discourse relation instances: *omission rate* and *context differential*. Our selection criteria first classify discourse connectives by their distributional properties and suggest that not all discourse connectives are truly optional and not all implicit and explicit discourse relations are equivalent, contrary to commonly held beliefs in previous studies of discourse connectives. We show that only the freely omissible discourse connectives gather additional training instances that lead to significant performance gain against a strong baseline. Our approach improves the performance of implicit discourse relations without additional feature engineering in many settings and opens doors to more sophisticated models that require more training data.

The rest of the paper is structured as follows. In Section 2, we describe the discourse connective selection criteria. In Section 3, we present our discourse connective classification method and experimental results that demonstrate its impact on inferring implicit discourse relations. We discuss related work and conclude our findings in Section 4 and 5 respectively.

2 Discourse Connective Classification and Discourse Relation Extraction

2.1 Datasets used for selection

We use two datasets for the purposes of extracting and selecting weakly labeled explicit discourse relation instances: the Penn Discourse Treebank 2.0 (Prasad et al., 2008) and the English Gigaword corpus version 3 (Graff et al., 2007).

The Penn Discourse Treebank (PDTB) is the largest manually annotated corpus of discourse relations on top of one million word tokens from the Wall Street Journal (Prasad et al., 2008; Prasad et al., 2007). Each discourse relation in the PDTB is annotated with a semantic sense in the PDTB sense hierarchy, which has three levels: CLASS, TYPE and SUBTYPE. In this work, we are primarily concerned with the four top-level CLASS senses: EXPANSION, COMPARISON, CONTINGENCY, and TEMPORAL. The distribution of top-level senses of implicit discourse relations is shown in Table 2. The spans of text that participate in the discourse relation are also explicitly annotated. These are called ARG1 or ARG2, depending on its relationship with the discourse connective.

The PDTB is our corpus of choice for its lexical

groundedness. The existence of a discourse relation must be linked or grounded to a discourse connective. More importantly, this applies to not only explicit discourse connectives that occur naturally as part of the text but also to implicit discourse relations where a discourse connective is added by annotators during the annotation process. This is crucial to the work reported here in that it allows us to compare the distribution of the same connective in explicit and implicit discourse relations. In the next subsection, we will explain in detail how we compute the comparison measures and apply them to the selection of explicit discourse connectives that can be used for collecting good weakly labeled data.

We use the Gigaword corpus, a large unannotated newswire corpus, to extract and select instances of explicit discourse discourse relations to supplement the manually annotated instances from the PDTB. The Gigaword corpus is used for its large size of 2.9 billion words and its similarity to the Wall Street Journal data from the PDTB. The source of the corpus is drawn from six distinct international sources of English newswire dating from 1994 - 2006. We use this corpus to extract weakly labeled data for the experiment.

2.2 Discourse relation extraction pattern

We extract instances of explicit discourse relations from the Gigaword Corpus that have the same patterns as the implicit discourse relations in the PDTB, using simple regular expressions. We first sentence-segment the Gigaword Corpus using the NLTK sentence segmenter (Bird, 2006). We then write a set of rules to prevent some common erroneous cases such as *because* vs *because of* from being included.

If a discourse connective is a subordinating conjunction, then we use the following pattern:

```
(Clause 1) (connective) (clause 2).
```

Clause 1 and capitalized clause 2 are then used as *Arg1* and *Arg2* respectively.

If a discourse connective is a coordinating conjunction or discourse adverbial, we use the following pattern:

```
(Sentence 1). (Connective),(clause 2).
```

Sentence 1 and Clause 2 with the first word capitalized are used as *Arg1* and *Arg2* respectively.

Although there are obviously many other syntactic patterns associated with explicit discourse connectives, we use these two patterns because these are the only patterns that are also observed in the implicit discourse relations. We want to select instances of explicit discourse relations that match the argument patterns of implicit discourse relations as much as possible. As restrictive as this may seem, these two patterns along with the set of rules allow us to extract more than 200,000 relation instances from the Gigaword corpus, so the coverage is not an issue.

2.3 Discourse connective selection and classification criteria

We hypothesize that connectives that are omitted often and in a way that is insensitive to the semantic context are our ideal candidates for extracting good weakly labeled data. We call this type of connectives *freely omissible discourse connectives*. To search for this class of connectives, we need to characterize connectives by the rate at which they are omitted and by the similarity between their context, in this case their arguments, in explicit and implicit discourse relations. This is possible because implicit discourse connectives are inserted during annotation in the PDTB. For each discourse connective, we can compute *omission rate* and *context differential* from annotated explicit and implicit discourse relation instances in the PDTB and use those measures to classify and select discourse connectives.

2.3.1 Omission rate (OR)

We use *omission rates* (OR) to measure the level of optionality of a discourse connective. The omission rate of a type of discourse connective (DC) is defined as:

$$\frac{\text{\# occurrences of DC in implicit relations}}{\text{\# total occurrences of DC}}$$

Our intuition is that the discourse connectives that have a high level of omission rate are more suitable as supplemental training data to infer the sense of implicit discourse relations.

2.3.2 Context differential

The omission of a freely omissible discourse connective should also be context-independent. If the omission of a discourse connective leads to a different interpretation of the discourse relation, this means that the explicit and implicit discourse relations bound by this discourse connective are not equivalent, and the explicit discourse relation instance cannot be used to help infer the sense of the implicit discourse relation. Conversely, if the contexts for the discourse connective in explicit and implicit discourse relations do not significantly differ, then the explicit discourse relation instance can be used as weakly labeled data.

To capture this intuition, we must quantify the context differential of explicit and implicit discourse relations for each discourse connective. We represent the

semantic context of a discourse connective through a unigram distribution over words in its two arguments, with Arg1 and Arg2 combined. We use Jensen-Shannon Divergence (JSD) as a metric for measuring the difference between the contexts of a discourse connective in implicit and explicit discourse relations. Computing a context differential of the discourse connective therefore involves fitting a unigram distribution from all implicit discourse relations bound by that discourse connective and fitting another from all explicit discourse relations bound by the same discourse connective. We choose this method because it has been shown to be exceptionally effective in capturing similarities of discourse connectives (Hutchinson, 2005) and statistical language analysis in general (Lee, 2001; Ljubesic et al., 2008).

The Jensen-Shannon Divergence (JSD) metric for difference between P_o, the semantic environments (unigram distribution of words in Arg1 and Arg2 combined) in implicit discourse relations, and P_r, the semantic environments in explicit discourse relations, is defined as:

$$JSD(P_o||P_r) = \frac{1}{2}D(P_o||M) + \frac{1}{2}D(P_r||M)$$

where $M = \frac{1}{2}(P_o + P_r)$ is a mixture of the two distributions and $D(.||.)$ is Kullback-Leibler divergence function for discrete probability distributions:

$$D(P||Q) = \sum_i \ln(\frac{P(i)}{Q(i)})P(i)$$

2.4 Discourse Connective Classification

Using the two metrics, we can classify discourse connectives into the following classes:

1. Freely omissible: High OR and low JSD
2. Omissible: Low non-zero OR and low JSD.
3. Alternating I: High OR and high JSD.
4. Alternating II: Low non-zero OR and high JSD.
5. Non-omissible: Zero OR. JSD cannot be computed because the connectives are never found in any implicit discourse relations.

Classifying the connectives into these classes allow us to empirically investigate which explicit discourse relations are useful as supplemental training data for determining the sense of implicit discourse relations. We discuss each type of connectives below.

2.4.1 Freely omissible discourse connectives

These are connectives whose usage in implicit and explicit discourse relations is indistinguishable and therefore suitable as a source of supplemental training data. These connectives are defined as having high omission rate and low context differential. This definition implies that the omission is frequent and insensitive to the context. "Because" and "in particular" in (4) and (5) are such connectives. Dropping them has minimal impact on the understanding the discourse relation between their two arguments and one might argue they even make the sentences sound more natural.

(4) We cleared up questions and inconsistencies very quickly because the people who had the skills and perspective required to resolve them were part of the task team. (WSJ0562)

(5) Both companies are conservative marketers that rely on extensive market research. P&G, in particular, rarely rolls out a product nationally before extensive test-marketing. (WSJ0589)

2.4.2 Omissible discourse connectives

They are connectives whose usage in implicit and explicit discourse relations is indistinguishable, yet they are not often omitted because the discourse relation might be hard to interpret without them. These connectives are defined as having low omission rate and low context differential. For example,

(6) Such problems will require considerable skill to resolve. However, neither Mr. Baum nor Mr. Harper has much international experience. (WSJ0109)

One can infer from the discourse that the problems require international experience, but Mr. Baum and Mr. Harper don't have that experience even without the discourse connective "however". In other words, the truth value of this proposition is not affected by the presence or absence of this discourse connective. The sentence might sound a bit less natural, and the discourse relation seems a bit more difficult to infer if "however" is omitted.

2.4.3 Alternating discourse connectives

They are connectives whose usage in implicit and explicit discourse relations is substantially different and they are defined as having high context differential. Having high context differential means that the two arguments of an explicit discourse connective differ substantially from those of an implicit discourse. An example of such discourse connectives is "nevertheless" in (7). If the discourse connective is dropped, one might infer EXPANSION or CONTINGENCY relation instead of COMPARISON indicated by the connective.

(7) Plant Genetic's success in creating genetically engineered male steriles doesn't automatically mean it would be simple to create hybrids in all crops. Nevertheless, he said, he is negotiating with Plant Genetic to acquire the technology to try breeding hybrid cotton. (WSJ0209)

We hypothesize that this type of explicit discourse relations would not be useful as extra training instances for inferring implicit discourse relations because they will only add noise to the training set.

2.4.4 Non-omissible discourse connectives

They are defined as discourse connectives whose omission rate is close to zero as they are never found in implicit discourse relations. For example, conditionals can not be easily expressed without the use of an explicit discourse connective like "if". We hypothesize that instances of explicit discourse relations with such discourse connectives would not be useful as additional training data for inferring implicit discourse relations because they represent discourse relation senses that do not exist in the implicit discourse relations.

3 Experiments

3.1 Partitioning the discourse connectives

We only include the discourse connectives that appear in both explicit and implicit discourse connectives in the PDTB to make the comparison and classification possible. As a result, we only analyze 69 out of 134 connectives for the purpose of classification. We also leave out 15 connectives whose most frequent sense acccounts for less than 90% of their instances. For example, *since* can indicate a TEMPORAL sense or a CONTINGENCY sense of almost equal chance, so it is not readily useful for gathering weakly labeled data. Ultimately, we have 54 connectives as our candidates for freely omissible discourse connectives.

We first classify the discourse connectives based on their omission rates and context differentials as discussed in the previous section and partition all of the explicit discourse connective instances based on this classification. The distributions of omission rates and context differentials show substantial amount of variation among different connectives. Many connectives are rarely omitted and naturally form its own class of non-omissible discourse connectives (Figure 1). We run the agglomerative hierchical clustering algorithm using Euclidean distance on the rest of the connectives to divide them into two groups: high omission and low omission rates. The boundary between the two groups is around 0.65.

The distribution of discourse connectives with respect to the context differential suggests two distinct groups across the two corpora (Figure 2). The analysis only includes connectives that are omitted at least twenty times in the PDTB corpus, so that JSD can be computed. The hierarchical clustering algorithm divides the connectives into two groups with the boundary at around 0.32, as should be apparent from the histogram. The JSD's computed from the explicit discourse relations from the two

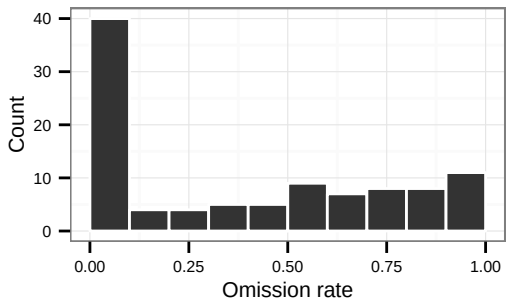

Figure 1: Omission rates of the discourse connective types vary drastically, suggesting that connectives vary in their optionality. Some connectives are never omitted.

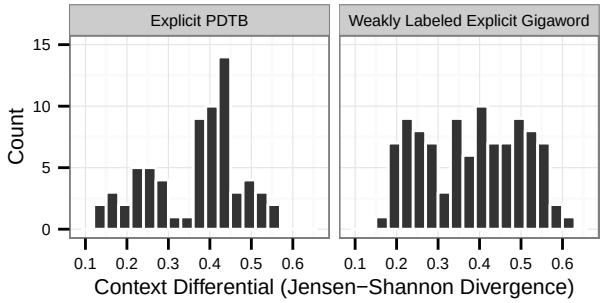

Figure 2: The distributions of Jensen-Shannon Divergence from both corpora shows two potential distinct clusters of discourse connectives.

corpora are highly correlated ($\rho = 0.80$, $p < 0.05$), so we can safely use the Gigaword corpus for the analysis and evaluation.

The omission rate boundary and context differential boundary together classify the discourse connectives into four classes in addition to the non-omissible connectives. When plotted against each other, omission rates and context differential together group the discourse connectives nicely into clusters (Figure 3). For the purpose of evaluation, we combine Alternating I and II into one class because each individual class is too sparse on its own. The complete discourse connective classification result is displayed in Table 1.

Sense	Train	Dev	Test
Comparison	1855	189	145
Contingency	3235	281	273
Expansion	6673	638	538
Temporal	582	48	55
Total	12345	1156	1011

Table 2: The distribution of senses of implicit discourse relations in the PDTB

Class Name	OR	JSD	Connectives
Alternating I	High	High	further, in sum, in the end, overall, similarly, whereas
Alternating II	Low	High	earlier, in turn, nevertheless, on the other hand, ultimately

3.2 Evaluation results

We formulate the implicit relation classification task as a 4-way classification task in a departure from previous practice where the task is usually set up as four *one vs other* binary classification tasks so that the effect of adding the distant supervision from the weakly labeled data can be more easily studied. We also believe this setup is more natural in realistic settings. Each classification instance consists of the two arguments of an implicit discourse relation, typically adjacent pairs of sentences in a text. The distribution of the sense labels is shown in Table 2. We follow the data split used in previous work for a consistent comparison (Rutherford and Xue, 2014). The PDTB corpus is split into a training set, development set, and test set. Sections 2 to 20 are used to train classifiers. Sections 0 and 1 are used for developing feature sets and tuning models. Section 21 and 22 are used for testing the systems.

To evaluate our method for selecting explicit discourse relation instances, we extract weakly labeled discourse relations from the Gigaword corpus for each class of discourse connective such that the discourse connectives are equally represented within the class. We train and test Maximum Entropy classifiers by adding varying number (1000, 2000, ..., 20000) of randomly selected explicit discourse discourse relation instances to the manually annotated implicit discourse relations in the PDTB as training data. We do this for each class of discourse connectives as presented in Table 1. We perform 30 trials of this experiment and compute average accuracy rates to smooth out the variation from random shuffling of the weakly labeled data.

The statistical models used in this study are from the MALLET implementation with its default setting (McCallum, 2002). Features used in all experiments are taken from the state-of-the-art implicit discourse relation classification system (Rutherford and Xue, 2014). The feature set consists of combinations of various lexical features, production rules, and Brown cluster pairs. These features are described in greater detail by Pitler et al. (2009) and Rutherford and Xue (2014).

Instance reweighting is required when using weakly labeled data because the training set no longer represents the natural distribution of the labels. We reweight each instance such that the sums of the weights of all the instances of the same label are equal. More precisely, if an instance i is from class j, then the weight for the instance w_{ij} is equal to the inverse proportion of class j:

$$w_{ij} = \frac{\text{Number of total instances}}{\text{Size of class } j \cdot \text{Number of classes}} = \frac{\sum_{j'}^{k} c_{j'}}{c_j \cdot k} = \frac{n}{c_j \cdot k}$$

where c_j is the total number of instances from class j and k is the number of classes in the dataset of size n. It is trivial to show that the sum of the weights for all instances from class j is exactly $\frac{n}{k}$ for all classes.

The impact of different classes of weakly labeled explicit discourse connective relations is illustrated in Figure 4. The results show that expicit discourse relations with freely omissible discourse connectives (high OR and low JSD) improve the performance on the standard test set and outperform the other classes of discourse connectives and the naive approach where all of the discourse

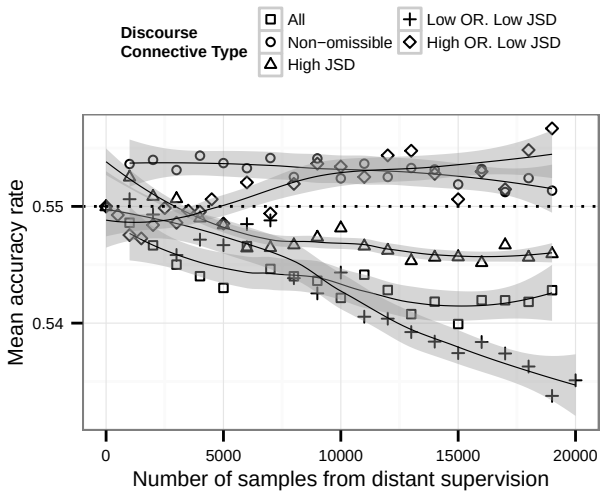

Figure 4: Discourse connectives with high omission rates and low context differentials lead to highest performance boost over the state-of-the-art baseline (dotted line). Each point is an average over multiple trials. The solid lines are LOESS smoothing curves.

connectives are used. In addition, it shows that on average, the system with weakly labeled data from freely omissible discourse connectives continues to rise as we increase the number of samples unlike the other classes of discourse connectives, which show the opposite trend. This suggests that discourse connectives must have both high omission rates and low context differential between implicit and explicit use of the connectives in order to be helpful to the inference of implicit discourse relations.

Table 3 presents results that show, overall, our best performing system, the one using distant supervision from freely omissible discourse connectives, raises the accuracy rate from 0.550 to 0.571 ($p < 0.05$; bootstrap test) and the macro-average F_1 score from 0.384 to 0.405. We achieve such performance after we tune the subset of weakly labeled data to maximize the performance on the development set. Our distant supervision approach improves the performance by adding more weakly labeled data and no additional features.

For a more direct comparison with previous results, we also replicated the state-of-the-art system described in Rutherford and Xue (2014), who follows the practice of the first work on this topic (Pitler et al., 2009) in setting up the task as four binary one vs. other classifiers. The results are presented in Table 4. The results show that the extra data extracted from the Gigaword Corpus is particularly helpful for minority classes such as *Comparison vs. Others* and *Temporal vs Others*, where our current system significantly outperforms that of Rutherford and Xue (2014). Interestingly, the *Expansion vs. Others* classifier

		Baseline features	Baseline + extra data
Expansion	Precision	0.608	0.614
	Recall	0.751	0.788
	F_1	0.672	0.691
Comparison	Precision	0.398	0.449
	Recall	0.228	0.276
	F_1	0.290	0.342
Contingency	Precision	0.465	0.493
	Recall	0.418	0.396
	F_1	0.440	0.439
Temporal	Precision	0.263	0.385
	Recall	0.091	0.091
	F_1	0.135	0.147
Accuracy		0.550	**0.571**
Macro-Average F_1		0.384	**0.405**

Table 3: Our current 4-way classification system outperforms the baseline overall. The difference in accuracy is statistically significant ($p < 0.05$; bootstrap test).

	R&X (2014)	Baseline + extra data	Baseline
Comparison vs Others	0.397	**0.410**	0.380
Contingency vs Others	0.544	0.538	0.539
Expansion vs Others	0.702	0.694	0.679
Temporal vs Others	0.287	**0.333**	0.246

did not improve as the *Expansion* class in the four-way classification (Table 3).

3.3 Just how good is the weakly labeled data?

We performed additional experiments to get a sense of just how good the weakly labeled data extracted from an unlabeled corpus are. Table 5 presents four-way classification results using just the weakly labeled data from the Gigaword Corpus. The results show that the same trend holds when the implicit relations from the PDTB are not included in the training process. The freely omissible discourse connectives achieves the accuracy rate of 0.505, which is significantly higher than the other classes, but they are weaker than the manually labeled data, which achieves the accuracy rate of 0.550 for the same number of training instances.

Weakly labeled data are not perfectly equivalent to the true implicit discourse relations, but they do provide strong enough additional signal. Figure 5 presents experimental results that compare the impact of weakly labeled data from Gigaword Corpus vs gold standard data from the PDTB for the freely omissible class. The mean accuracy rates from the PDTB data are significantly higher than those from the Gigaword Corpus (p <0.05; t-test

Class	Gigaword only	Gigaword + Implicit PDTB
Freely omissible	**0.505**	**0.571**
Omissible	0.313	0.527
Alternating I + II	0.399	0.546
Non-Omissible	0.449	0.554
All of above	0.490	0.547

Table 5: The accuracy rates for the freely omissible class are higher than the ones for the other classes both when using the Gigaword data alone and when using it in conjunction with the implicit relations in the PDTB.

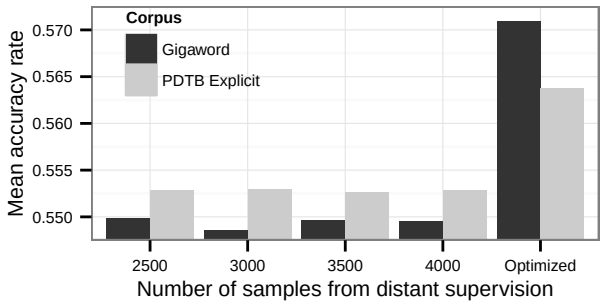

Figure 5: The PDTB corpus leads to more improvement for the same amount of the data. However, Gigaword corpus achieves significantly better performance ($p < 0.05$; bootstrap test) when both models are tuned on the developement set.

and bootstrap test) for the same number of training instances combined with the implicit discourse relations. However, when the number of introduced weakly labeled data exceeds a certain threshold of around 12,000 instances, the performance of the Gigaword corpus rises significantly above the baseline and the explicit PDTB (Figure 4).

The relative superiority of our approach derives precisely from the two selection criteria that we propose. The performance gain does not come from the fact that freely omissible discourse connectives have better coverage of all four senses (Table 6). When all classes are combined equally, the system performs worse as we add more samples although all four senses are covered. The coverage of all four senses is not sufficient for a class of discourse connectives to boost the performance. The two selection criteria are both necessary for the success of this paradigm.

4 Related work

Previous work on implicit discourse relation classification have focused on supervised learning approaches (Lin et al., 2010; Rutherford and Xue, 2014), and the distantly supervised approach using explicit discourse relations

Class	Sense			
	Comp.	Cont.	Exp.	Temp.
Freely omissible	2	6	10	1
Omissible	4	2	5	3
Alternating I	1	0	5	0
Alternating II	2	0	0	3
Non-omissible	0	3	3	2

Table 6: The sense distribution by connective class.

has not shown satisfactory results (Pitler et al., 2009; Park and Cardie, 2012; Wang et al., 2012; Sporleder and Lascarides, 2008) Explicit discourse relations have been used to remedy the sparsity problem or gain extra features with limited success (Biran and McKeown, 2013; Pitler et al., 2009). Our heuristics for extracting discourse relations has been explored in the unsupervised setting (Marcu and Echihabi, 2002), but it has never been evaluated on the gold standard data to show its true efficacy. Our distant supervision approach chooses only certain types of discourse connectives to extract weakly labeled data and is the first of its kind to improve the performance in this task tested on the manually annotated data.

Distant supervision approaches have recently been explored in the context of natural language processing due to the recent capability to process large amount of data. These approaches are known to be particularly useful for relation extraction tasks because training data provided do not suffice for the task and are difficult to obtain (Riloff et al., 1999; Yao et al., 2010). For example, Mintz et al. (2009) acquire a large amount of weakly labeled data based on the Freebase knowledge base and improves the performance of relation extraction. Distantly supervised learning has also recently been demonstrated to be useful for text classification problems (Speriosu et al., 2011; Marchetti-Bowick and Chambers, 2012). For example, Thamrongrattanarit et al. (2013) use simple heuristics to gather weakly labeled data to perform text classification with no manually annotated training data.

Discourse connectives have been studied and classified based on their syntactic properties such subordinating conjunction, adverbials, etc. (Fraser, 2006; Fraser, 1996). While providing a useful insight into how discourse connectives fit into utterances, the syntactic classification does not seem suitable for selecting useful discourse connectives for our purposes of distant supervision for our task.

5 Conclusion and Future Directions

We propose two selection criteria for discourse connectives that can be used to gather weakly labeled data for implicit discourse relation classifiers and improve the performance of the state-of-the-art system without further feature engineering. As part of this goal, we classify dis-

course connectives based on their distributional semantic properties and found that certain classes of discourse connectives cannot be omitted in every context, which plague the weakly labeled data used in previous studies. Our discourse connective classification allows for the better selection of data points for distant supervision.

More importantly, this work presents a new direction in distantly supervised learning paradigm for implicit discourse relation classification. This virtual dramatic increase in the training set size allows for more feature engineering and more sophisticated models. Implicit discourse relation classification is now no longer limited to strictly supervised learning approaches.

Solving Hard Coreference Problems

Abstract

Coreference resolution is a key problem in natural language understanding that still escapes reliable solutions. One fundamental difficulty has been that of resolving instances involving pronouns since they often require deep language understanding and use of background knowledge. In this paper we propose an algorithmic solution that involves a new representation for the knowledge required to address hard coreference problems, along with a constrained optimization framework that uses this knowledge in coreference decision making. Our representation, Predicate Schemas, is instantiated with knowledge acquired in an unsupervised way, and is compiled automatically into constraints that impact the coreference decision. We present a general coreference resolution system that significantly improves state-of-the-art performance on hard, *Winograd*-style, pronoun resolution cases, while still performing at the state-of-the-art level on standard coreference resolution datasets.

1 Introduction

Coreference resolution is one of the most important tasks in *Natural Language Processing* (NLP). Although there is a plethora of works on this task (Soon et al., 2001a; Ng and Cardie, 2002a; Ng, 2004; Bengtson and Roth, 2008; Pradhan et al., 2012; Kummerfeld and Klein, 2013; Chang et al., 2013), it is still deemed an unsolved problem due to intricate and ambiguous nature of natural language text. Existing methods perform particularly poorly on pronouns, specifically when gender or plurality information cannot help. In this paper, we aim to improve coreference resolution by addressing these hard problems. Consider the following examples:

Ex.1 *[A bird]$_{e_1}$ perched on the [limb]$_{e_2}$ and [it]$_{pro}$ bent.*

Ex.2 *[Robert]$_{e_1}$ was robbed by [Kevin]$_{e_2}$, and [he]$_{pro}$ is arrested by police.*

In both examples, one cannot resolve the pronouns based on only gender or plurality information. Recently, Rahman and Ng (2012) gathered a dataset containing 1886 sentences of such challenging pronoun resolution problems (referred to later as the *Winograd* dataset, following Winograd (1972) and Levesque et al. (2011)). As an indication to the difficulty of these instances, we note that a state-of-the-art coreference resolution system (Chang et al., 2013) achieves precision of 53.26% on it. A special purpose classifier (Rahman and Ng, 2012) trained on this data set achieves 73.05%. The key contribution of this paper is a general purpose, state-of-the-art coreference approach which, at the same time, achieves precision of 76.76% on these hard cases.

Addressing these hard coreference problems requires significant amounts of background knowledge, along with an inference paradigm that can make use of it in supporting the coreference decision. Specifically, in Ex.1 one needs to know that "a limb bends" is more likely than "a bird bends". In Ex.2 one needs to know that the *subject* of the verb "rob" is more likely to be the *object* of "arrest" than the *object* of the verb "rob" is. The knowledge required is, naturally, centered around

Denver, Colorado, May 31 – June 5, 2015.

the key predicates in the sentence, motivating the central notion proposed in this paper, that of *Predicate Schemas*. In this paper, we develop the notion of *Predicate Schemas*, instantiate them with automatically acquired knowledge, and show how to compile it into constraints that are used to resolve coreference within a general *Integer Linear Programming* (ILP) driven approach to coreference resolution. Specifically, we study two types of Predicate Schemas that, as we show, cover a large fraction of the challenging cases. The first specifies one predicate with its subject and object, thus providing information on the subject and object preferences of a given predicate. The second specifies two predicates with a semantically shared argument (either subject or object), thus specifies role preferences of one predicate, among roles of the other. We instantiate these schemas by acquiring statistics in an unsupervised way from multiple resources including the Gigaword corpus, Wikipedia, Web Queries and polarity information.

A lot of recent work has attempted to utilize similar types of resources to improve coreference resolution (Rahman and Ng, 2011a; Ratinov and Roth, 2012; Bansal and Klein, 2012; Rahman and Ng, 2012). The common approach has been to inject knowledge as features. However, these pieces of knowledge provide relatively strong evidence that loses impact in standard training due to sparsity. Instead, we compile our Predicate Schemas knowledge automatically, at inference time, into constraints, and make use of an ILP driven framework (Roth and Yih, 2004) to make decisions. Using constraints is also beneficial when the interaction between multiple pronouns is taken into account when making global decisions. Consider the following example:

Ex.3 *[Jack]$_{e_1}$ threw the bags of [John]$_{e_2}$ into the water since [he]$_{pro_1}$ mistakenly asked [him]$_{pro_2}$ to carry [his]$_{pro_3}$ bags.*

In order to correctly resolve the pronouns in Ex.3, one needs to have the knowledge that "*he* asks *him*" indicates that *he* and *him* refer to different entities (because they are subject and object of the same predicate; otherwise, *himself* should be used instead of *him*). This knowledge, which can be easily represented as constraints during inference, then impacts other pronoun decisions in a global decision with respect to all pronouns: pro_3 is likely to be different from pro_2, and is likely to refer to e_2. This type of inference can be easily represented as a constraint during inference, but hard to inject as a feature.

We then incorporate all constraints into a general coreference system (Chang et al., 2013) utilizing the mention-pair model (Ng and Cardie, 2002b; Bengtson and Roth, 2008; Stoyanov et al., 2010). A classifier learns a pairwise metric between mentions, and during inference, we follow the framework proposed in Chang et al. (2011) using ILP.

The main contributions of this paper can be summarized as follows:

1. We propose the Predicate Schemas representation and study two specific schemas that are important for coreference.
2. We show how, in a given context, Predicate Schemas can be automatically compiled into constraints and affect inference.
3. Consequently, we address hard pronoun resolution problems as a standard coreference problem and develop a system[1] which shows significant improvement for hard coreference problems while achieving the same state-of-the-art level of performance on standard coreference problems.

The rest of the paper is organized as follows. We describe our Predicate Schemas in Section 2 and explain the inference framework and automatic constraint generation in Section 3. A summary of our knowledge acquisition steps is given in Section 4. We report our experimental results and analysis in Section 5, and review related work in Section 6.

2 Predicate Schema

In this section we present multiple kinds of knowledge that are needed in order to improve hard coreference problems. Table 1 provides two example sentences for each type of knowledge. We use m to refer to a mention. A mention can either be an entity e or a pronoun pro. $pred_m$ denotes the predicate of m (similarly, $pred_{pro}$ and $pred_e$ for pronouns and entities, respectively). For instance, in sentence 1.1 in Table 1, the predicate of e_1 and e_2

[1] Available at http://cogcomp.cs.illinois.edu/page/software_view/Winocoref

Category	#	Sentence
1	1.1	*[The bird]$_{e_1}$ perched on the [limb]$_{e_2}$ and [it]$_{pro}$ bent.*
	1.2	*[The bee]$_{e_1}$ landed on [the flower]$_{e_2}$ because [it]$_{pro}$ had pollen.*
2	2.1	*[Bill]$_{e_1}$ was robbed by [John]$_{e_2}$, so the officer arrested [him]$_{pro}$.*
	2.2	*[Jimbo]$_{e_1}$ was afraid of [Bobbert]$_{e_2}$ because [he]$_{pro}$ gets scared around new people.*
3	3.1	*[Lakshman]$_{e_1}$ asked [Vivan]$_{e_2}$ to get him some ice cream because [he]$_{pro}$ was hot.*
	3.2	*Paula liked [Ness]$_{e_1}$ more than [Pokey]$_{e_2}$ because [he]$_{pro}$ was mean to her.*

Table 1: Example sentences for each schema category. The annotated entities and pronouns are hard coreference problems.

Type	Schema form	Explanation of examples from Table 1
1	$pred_m\,(m, a)$	Example 1.2: It is enough to know that: $\mathcal{S}\,(\text{have}\,(m = [\text{the flower}], a = [\text{pollen}])) >$ $\mathcal{S}\,(\text{have}\,(m = [\text{the bee}], a = [\text{pollen}]))$
2	$pred_m\,(m, a)\,\|\widehat{pred}_m\,(m, \widehat{a})\,, cn$	Example 2.2: It is enough to know that: $\mathcal{S}\,(\textit{be afraid of}\,(m = *, a = *)\,\|\textit{get scared}\,(m = *, \widehat{a} = *)\,, \text{because}) >$ $\mathcal{S}\,(\textit{be afraid of}\,(a = *, m = *)\,\|\textit{get scared}\,(m = *, \widehat{a} = *)\,, \text{because})$

Table 2: Predicate Schemas and examples of the logic behind the schema design. Here $*$ indicates that the argument is dropped, and $\mathcal{S}(.)$ denotes the scoring function defined in the text.

Type 1	$\mathcal{S}\,(pred_m\,(m, a))$ $\mathcal{S}\,(pred_m\,(a, m))$ $\mathcal{S}\,(pred_m\,(m, *))$ $\mathcal{S}\,(pred_m\,(*, m))$
Type 2	$\mathcal{S}\left(pred_m\,(m, a)\,\|\widehat{pred}_m\,(m, \widehat{a})\,, cn\right)$ $\mathcal{S}\left(pred_m\,(a, m)\,\|\widehat{pred}_m\,(m, \widehat{a})\,, cn\right)$ $\mathcal{S}\left(pred_m\,(m, a)\,\|\widehat{pred}_m\,(\widehat{a}, m)\,, cn\right)$ $\mathcal{S}\left(pred_m\,(a, m)\,\|\widehat{pred}_m\,(\widehat{a}, m)\,, cn\right)$ $\mathcal{S}\left(pred_m\,(m, *)\,\|\widehat{pred}_m\,(m, *)\,, cn\right)$ $\vdots$

Table 3: Possible variations for scoring function statistics. Here $*$ indicates that the argument is dropped.

is $pred_{e_1} = pred_{e_2} =$"perch on". cn refers to the discourse connective (cn="and" in sentence 1.1). a denotes an argument of $pred_m$ other than m. For example, in sentence 1.1, assuming that $m = e_1$, the corresponding argument is $a = e_2$.

We represent the knowledge needed with two types of Predicate Schemas (as depicted in Table 2). To solve the assignment of [it]$_{pro}$ in sentence 1.1, as mentioned in Section 1, we need the knowledge that "a limb bends" is more reasonable than "a bird bends". Note that the predicate of the pronoun is playing a key role here. Also the entity mention itself is essential. Similarly, for sentence 1.2, to resolve [it]$_{pro}$, we need the knowledge that "bee had pollen" is more reasonable than "flower had pollen". Here, in addition to entity mention and the predicate (of the pronoun), we need the argument which shares the predicate with the pronoun. To formally define the type of knowledge needed we denote it with "$\boldsymbol{pred_m(m, a)}$" where m and a are a mention and an argument, respectively[2]. We use $\mathcal{S}(.)$ to denote the score representing how likely the combination of the predicate-mention-argument is. For each schema, we use several variations by either changing the order of the arguments (*subj.* vs *obj.*) or dropping either of them. We score the various Type 1 and Type 2 schemas (shown in Table 3) differently. The first row of Table 2 shows how Type 1 schema is being used in the case of Sentence 1.2.

For sentence 2.2, we need to have the knowledge that the *subject* of the verb phrase "be afraid of" is more likely than the *object* of the verb phrase "be afraid of" to be the *subject* of the verb phrase "get scared". The structure here is more complicated than that of Type 1 schema. To make it clearer, we analyze sentence 2.1. In this sentence, the *object* of "be robbed by" is more likely than the *subject*

[2]Note that the order of m and a relative to the predicate is a critical issue. To keep things general in the schemas definition, we do not show the ordering; however, when using scores in practice the order between a mention and an argument is a critical issue.

of the verb phrase "be robbed by" to be the *object* of "the officer arrest". We can see in both examples (and for the Type 2 schema in general), that both predicates (the entity predicate and the pronoun predicate) play a crucial role. Consequently, we design the Type 2 schema to capture the interaction between the entity predicate and the pronoun predicate. In addition to the predicates, we may need mention-argument information. Also, we stress the importance of the discourse connective between entity mention and pronoun; if in either sentence 2.1 or 2.2, we change the discourse connective to "although", the coreference resolution will completely change. Overall, we can represent the knowledge as "$\boldsymbol{pred_m}\,(\boldsymbol{m}, \boldsymbol{a})\,|\widehat{\boldsymbol{pred_m}}\,(\boldsymbol{m}, \widehat{\boldsymbol{a}})\,, \boldsymbol{cn}$". Just like for Type 1 schema, we can represent Type 2 schema with a score function for different variations of arguments (lower half of Table 3). In Table 2, we exhibit this for sentence 2.2.

Type 3 contains the set of instances which cannot be solved using schemas of Type 1 or 2. Two such examples are included in Table 1. In sentence 3.1 and 3.2, the context containing the necessary information goes beyond our triple representation and therefore this instance cannot be resolved with either of the two schema types. It is important to note that the notion of Predicate Schemas is more general than the Type 1 and Type 2 schemas introduced here. Designing more informative and structured schemas will be essential to resolving additional types of hard coreference instances.

3 Constrained ILP Inference

Integer Linear Programming (ILP) based formulations of NLP problems (Roth and Yih, 2004) have been used in a board range of NLP problems and, particularly, in coreference problems (Chang et al., 2011; Denis and Baldridge, 2007). Our formulation is inspired by Chang et al. (2013). Let $\mathcal{M}$ be the set of all mentions in a given text snippet, and $\mathcal{P}$ the set of all pronouns, such that $\mathcal{P} \subset \mathcal{M}$. We train a coreference model by learning a pairwise mention scoring function. Specifically, given a mention-pair $(u, v) \in \mathcal{M}$ (u is the antecedent of v), we learn a left-linking scoring function $f_{u,v} = \mathbf{w}^\top \phi(u, v)$, where $\phi(u, v)$ is a pairwise feature vector and $\mathbf{w}$ is the weight vector. We then follow the *Best-Link* approach (Section 2.3 from Chang et al. (2011)) for inference. The ILP problem that we solve is formally defined as follows:

$$\begin{cases} \arg\max\limits_{y} \sum\limits_{u\in\mathcal{M}, v\in\mathcal{M}} f_{u,v} y_{u,v} \\ \text{s.t. } y_{u,v} \in \{0,1\}, \quad \forall u, v \in \mathcal{M} \\ \quad \sum_{u<v, u\in\mathcal{M}} y_{u,v} \leq 1, \quad \forall v \in \mathcal{M} \\ \quad \text{Constraints from Predicate Schemas Knowledge} \\ \quad \text{Constraints between pronouns.} \end{cases}$$

Here, u, v are mentions and $y_{u,v}$ is the decision variable to indicate whether or not mention u and mention v are coreferents. As the first constraint shows, $y_{u,v}$ is a binary variable. $y_{u,v}$ equals 1 if u, v are coreferents and 0 otherwise. The second constraint indicates that we only choose at most one antecedent to be coreferent with each mention v. ($u < v$ represents that u appears beore v, thus u is an antecedent of v.) In this work, we add constraints from Predicate Schemas Knowledge and between pronouns.

The Predicate Schemas knowledge provides a vector of score values $\mathcal{S}(u, v)$ for mention pairs $\{(u, v)|(u \in \mathcal{M}, v \in \mathcal{P}\}$, which concatenates all the schemas involving u and v. Entries in the score vector are designed so that the larger the value is, the more likely u and v are to be coreferents. We have two ways to use the score values: 1) Augumenting the feature vector $\phi(u, v)$ with these scores. 2) Casting the scores as constraints for the coreference resolution ILP in one of the following forms:

$$\begin{cases} \text{if } s_i(u, v) \geq \alpha_i s_i(w, v) \Rightarrow y_{u,v} \geq y_{w,v}, \\ \text{if } s_i(u, v) \geq s_i(w, v) + \beta_i \Rightarrow y_{u,v} \geq y_{w,v}, \end{cases} \quad (1)$$

where $s_i(.)$ is the i-th dimension of the score vector $\mathcal{S}(.)$ corresponding to the i-th schema represented for a given mention pair. α_i and β_i are threshold values which we tune on a development set.[3] If an inequality holds for all relevant schemas (that is, all the dimensions of the score vector), we add an inequality between the corresponding indicator variables inside the ILP.[4] As we increase the value of a

[3] For the i_{th} dimension of the score vector, we choose either α_i or β_i as the threshold.

[4] If the constraints dictated by any two dimensions of $\mathcal{S}$ are contradictory, we ignore both of them.

threshold, the constraints in (1) become more conservative, thus it leads to fewer but more reliable constraints added into the ILP. We tune the threshold values such that their corresponding scores attain high enough accuracy, either in the multiplicative form or the additive form.[5] Note that, given a pair of mentions and context, we automatically instantiate a collection of relevant schemas, and then generate and evaluate a set of corresponding constraints. To the best of our knowledge, this is the first work to use such automatic constraint generation and tuning method for coreference resolution with ILP inference. In Section 4, we describe how we acquire the score vectors $\mathcal{S}(u, v)$ for the Predicate Schemas in an unsupervised fashion.

We now briefly explain the pre-processing step required in order to extract the score vector $\mathcal{S}(u, v)$ from a pair of mentions. Define a triple structure $t_m \triangleq \textit{pred}_m(m, a_m)$ for any $m \in \mathcal{M}$. The subscript m for *pred* and a, emphasizes that they are extracted as a function of the mention m. The extraction of triples is done by utilizing the dependency parse tree from the Easy-first dependency parser (Goldberg and Elhadad, 2010). We start with a mention m, and extract its related predicate and the other argument based on the dependency parse tree and part-of-speech information. To handle multiword predicates and arguments, we use a set of hand-designed rules. We then get the score vector $\mathcal{S}(u, v)$ by concatenating all scores of the Predicate Schemas given two triples t_u, t_v. Thus, we can expand the score representation for each type of Predicate Schemas given in Table 2: 1) For Type 1 schema, $\mathcal{S}(u, v) \equiv \mathcal{S}(pred_v(m = u, a = a_v))$ [6] 2) For Type 2 schema, $\mathcal{S}(u, v) \equiv \mathcal{S}(pred_u(m = u, a = a_u)|\widehat{pred}_v(m = v, a = a_v), cn)$.

In additional to schema-driven constraints, we also apply constraints between pairs of pronouns within a fixed distance[7]. For two pronouns that are semantically different (e.g. *he* vs. *it*), they must refer to different antecedents. For two non-possesive pronouns that are related to the same predicate (e.g. *saw him*), they must refer to different antecedents.[8]

4 Knowledge Acquisition

One key point that remains to be explained is how to acquire the knowledge scores $\mathcal{S}(u, v)$. In this section, we propose multiple ways to acquire these scores. In the current implementation, we make use of four resources. Each of them generates its own score vector. Therefore, the overall score vector is the concatenation of the score vector from each resource: $\mathcal{S}(u, v) = [\mathcal{S}_{giga}(u, v)\ \mathcal{S}_{wiki}(u, v)\ \mathcal{S}_{web}(u, v)\ \mathcal{S}_{pol}(u, v)]$.

4.1 Gigaword Co-occurence

We extract triples $t_m \triangleq \textit{pred}_m(m, a_m)$ (explained in Section 3) from Gigaword data (4,111,240 documents). We start by extracting noun phrases using the Illinois-Chunker (Punyakanok and Roth, 2001). For each noun phrase, we extract its head noun and then extract the associated predicate and argument to form a triple.

We gather the statistics for both schema types after applying lemmatization on the predicates and arguments. Using the extracted triples, we get a score vector from each schema type: $\mathcal{S}_{giga} = [\mathcal{S}^{(1)}_{giga}\ \mathcal{S}^{(2)}_{giga}]$.

To extract scores for Type 1 Predicate Schemas, we create occurence counts for each schema instance. After all scores are gathered, our goal is to query $\mathcal{S}^{(1)}_{giga}(u, v) \equiv \mathcal{S}(pred_v(m = u, a = a_v))$ from our knowledge base. The returned score is the $log(.)$ of the number of occurences.

For Type 2 Predicate Schemas, we gather the statistics of triple co-occurence. We count the co-occurrence of neighboring triples that share at least one linked argument. We consider two triples to be neighbors if they are within a distance of three sentences. We use two heuristic rules to decide whether a pair of arguments between two neighboring triples are coreferents or not: 1) If the head noun of two arguments can match, we consider them coreferents. 2) If one argument in the first triple is a person name and there is a compatible pronoun (based on its gender and plurality information) in the second triple, they are also labeled as coreferents. We also extract the discourse connectives between triples (*because*,

[5] The choice is made based on the performance on the development set.

[6] In $pred_v(m = u, a = a_v)$ the argument and the predicate are extracted relative to v but the mention m is set to be u.

[7] We set the distance to be 3 sentences.

[8] Three cases are considered: *he-him*, *she-her*, *they-them*

$$s_{pol}(u,v) = \begin{bmatrix} \mathbf{1}\{Po(p_u) = + \text{ AND } Po(p_v) = +\} & \text{OR} & \mathbf{1}\{Po(p_u) = - \text{ AND } Po(p_v) = -\} \\ \mathbf{1}\{Po(p_u) = + \text{ AND } Po(p_v) = +\} & & \\ \mathbf{1}\{Po(p_u) = - \text{ AND } Po(p_v) = -\} & & \end{bmatrix}$$

Table 4: Extrating the polarity score given polarity information of a mention-pair (u, v). To be brief, we use the shorthand notation $p_v \triangleq pred_v$ and $p_u \triangleq pred_u$. $\mathbf{1}\{\cdot\}$ is an indicator function. $s_{pol}(u, v)$ is a binary vector of size three.

therefore, etc.) if there are any. To avoid sparsity, we only keep the mention roles (only *subj* or *obj*; no exact strings are kept). Two triple-pairs are considered different if they have different predicates, different roles, different coreferred argument-pairs, or different discourse connectives. The co-occurrence counts extracted in this form correspond to Type 2 schemas in Table 2. During inference, we match a Type 2 schema for $\mathcal{S}^{(2)}_{giga}(u, v) \equiv \mathcal{S}(pred_u(m = u, a = a_u)|\widehat{pred}_v(m = u, a = a_v), cn)$.

Our method is related, but different from the proposal in Balasubramanian et al. (2012), who suggested to extract triples using an OpenIE system (Mausam et al., 2012). We extracted triples by starting from a mention, then extract the predicate and the other argument. An OpenIE system does not easily provide this ability. Our Gigaword counts are gathered also in a way similar to what has been proposed in Chambers and Jurafsky (2009), but we gather much larger amounts of data.

4.2 Wikipedia Disambiguated Co-occurence

One of the problems with blindly extracting triple counts is that we may miss important semantic information. To address this issue, we use the publicly avaiable Illinois Wikifier (Cheng and Roth, 2013; Ratinov et al., 2011), a system that disambiguates mentions by mapping them into correct Wikipedia pages, to process the Wikipedia data. We then extract from the Wikipedia text all entities, verbs and nouns, and gather co-occurrence statistics with these syntactic *variations*: 1) *immediately after* 2) *immediately before* 3) *before* 4) *after*. For each of these variations, we get the probability and count[9] of a pair of words (e.g. probability[10]/count for "bend" *immediately following* "limb") as separate dimensions of the score vector.

[9]We use the $log(.)$ of the counts here.

[10]Conditional probability of "limb" immediately following the given verb "bend".

Given the co-occurrence information, we get a score vector $\mathcal{S}_{wiki}(u, v)$ corresponding to Type 1 Predicate Schemas, and hence $\mathcal{S}(u, v)_{wiki} \equiv \mathcal{S}(pred_v(m = u, a = a_v))$.

4.3 Web Search Query Count

Our third source of score vectors is web queries that we implement using Google queries. We extract a score vector $\mathcal{S}_{web}(u, v) \equiv \mathcal{S}(pred_v(m = u, a = a_v))$ (Type 1 Predicate Schemas) by querying for 1) "u a_v" 2) "u $pred_v$" 3) "u $pred_v$ a_v" 4) "a_v u"[11]. For each variation of nouns (plural and singular) and verbs (different tenses) we create a different query and average the counts over all queries. Concatenating the counts (each is a separate dimension) would give us the score vector $\mathcal{S}_{web}(u, v)$.

4.4 Polarity of Context

Another rich source of information is the polarity of context, which has been previously used for Winograd schema problems (Rahman and Ng, 2012). Here we use a slightly modified version. The polarity scores are used for Type 1 Predicate Schemas and therefore we want to get $\mathcal{S}_{pol}(u, v) \equiv \mathcal{S}(pred_v(m = u, a = a_v))$. We first extract polarity values for *Po*$(pred_u)$ and *Po*$(pred_v)$ by repeating the following procedures for each of them:

- We extract initial polarity information given the predicate (using the data provided by Wilson et al. (2005)).
- If the role of the mention is *object*, we negate its polarity.
- If there is a polarity-reversing discourse connective (such as "but") preceding the predicate, we reverse the polarity.
- If there is a negative comparative adverb (such as "less", "lower") we reverse the polarity.

[11]We query this only when a_v is an adjective and $pred_v$ is a to-be verb.

	# Doc	# Train	# Test	# Mention	# Pronoun	# Predictions for Pronoun
Winograd	1886	1212	674	5658	1886	1348
WinoCoref	1886	1212	674	6404	2595	2118
ACE	375	268	107	23247	3862	13836
OntoNotes	3150	2802	348	175324	58952	37846

Table 5: Statistics of *Winograd*, *WinoCoref*, *ACE* and *OntoNotes*. We give the total number of mentions and pronouns, while the number of predictions for pronoun is specific for the test data. We added 746 mentions (709 among them are pronouns) to *WinoCoref* compared to *Winograd*.

Given the polarity values *Po*($pred_u$) and *Po*($pred_v$), we construct the score vector $\mathcal{S}_{pol}(u, v)$ following Table 4.

5 Experiments

In this section, we evaluate our system for both hard coreference problems and general coreference problems, and provide detailed anaylsis on the impact of our proposed Predicate Schemas. Since we treat resolving hard pronouns as part of the general coreference problems, we extend the *Winograd* dataset with a more complete annotation to get a new dataset. We evaluate our system on both datasets, and show significant improvemnt over the baseline system and over the results reported in Rahman and Ng (2012). Moreover, we show that, at the same time, our system achieves the state-of-art performance on standard coreference datasets.

5.1 Experimental Setup

Datasets: Since we aim to solve hard coreference problems, we choose to test our system on the *Winograd* dataset[12] (Rahman and Ng, 2012). It is a challenging pronoun resolution dataset which consists of sentence pairs based on Winograd schemas. The original annotation only specifies one pronoun and two entites in each sentence, and it is considered as a binary decision for each pronoun. As our target is to model and solve them as general coreference problems, we expand the annotation to include all pronouns and their linked entities as mentions (We call this new re-annotated dataset *WinoCoref*[13]). Ex.3 in Section 1 is from the *Winograd* dataset. It originally only specifies *he* as the pronoun in question, and we added *him* and *his* as additional target pronouns. We also use two standard coreference resolution datasets *ACE*(2004) (NIST, 2004) and *OntoNotes-5.0* (Pradhan et al., 2011) for evaluation. Statistics of the datasets are provided in Table 5.

Systems	Learning Method	Inference Method
Illinois	BLMP	BLL
IlliCons	BLMP	ILP
KnowFeat	BLMP+SF	BLL
KnowCons	BLMP	ILP+SC
KnowComb	BLMP+SF	ILP+SC

Table 6: Summary of learning and inference methods for all systems. SF stands for schema features while SC represents constraints from schema knowledge.

Baseline Systems: We use the state-of-art Illinois coreference system as our baseline system (Chang et al., 2013). It includes two different versions. One employs *Best-Left-Link* (BLL) inference method (Ng and Cardie, 2002b), and we name it *Illinois*[14]; while the other uses ILP with constraints for inference, and we name it *IlliCons*. Both systems use *Best-Link Mention-Pair* (BLMP) model for training. On *Winograd* dataset, we also treat the reported result from Rahman and Ng (2012) as a baseline.

Developed Systems: We present three variations of the Predicate Schemas based system developed here. We inject Predicate Schemas knowledge as mention-pair features and retrain the system (*KnowFeat*). We use the original coreference model and Predicate Schemas knowledge as constraints during inference (*KnowCons*). We also have a combined system (*KnowComb*), which uses the schema knowledge to add features for learning as well as constraints for inference. A summary of all systems is provided in Table 6.

[12] Available at http://www.hlt.utdallas.edu/~vince/data/emnlp12/

[13] Available at http://cogcomp.cs.illinois.edu/page/data/

[14] In implementation, we use the L^3M model proposed in Chang et al. (2013), which is slightly different. It can be seen as an extension of BLL inference method.

Dataset	Metric	Illinois	IlliCons	Rahman and Ng (2012)	KnowFeat	KnowCons	KnowComb
Winograd	Precision	51.48	53.26	73.05	71.81	74.93	**76.41**
WinoCoref	AntePre	68.37	74.32	—	88.48	88.95	**89.32**

Table 7: Performance results on *Winograd* and *WinoCoref* datasets. All our three systems are trained on *WinoCoref*, and we evaluate the predictions on both datasets. Our systems improve over the baselines by over than 20% on *Winograd* and over 15% on *WinoCoref*.

Evaluation Metrics: When evaluating on the full datasets of *ACE* and *OntoNotes*, we use the widely recoginzed metrics MUC (Vilain et al., 1995), BCUB (Bagga and Baldwin, 1998), Entity-based CEAF (CEAF$_e$) (Luo, 2005) and their average. As *Winograd* is a pronoun resolution dataset, we use precision as the evaluation metric. Although *WinoCoref* is more general, each coreferent cluster only contains 2-4 mentions and all are within the same sentence. Since traditional coreference metrics cannot serve as good metrics, we extend the precision metric and design a new one called *AntePre*. Suppose there are k pronouns in the dataset, and each pronoun has $n_1, n_2, \cdots, n_k$ antecedents, respectively. We can view predicted coreference clusters as binary decisions on each antecedent-pronoun pair (linked or not). The total number of binary decisions is $\sum_{i=1}^{k} n_i$. We then meaure how many binary decisions among them are correct; let m be the number of correct decisions, then *AnrePre* is computed as: $\frac{m}{\sum_{i=1}^{k} n_i}$.

5.2 Results for Hard Coreference Problems

Performance results on *Winograd* and *WinoCoref* datasets are shown in Table 7. The best performing system is *KnowComb*. It improves by over 20% over a state-of-art general coreference system on *Winograd* and also outperforms Rahman and Ng (2012) by a margin of 3.3%. On the *WinoCoref* dataset, it improves by 15%. These results show significant performance improvement by using Predicate Schemas knowledge on hard coreference problems. Note that the system developed in Rahman and Ng (2012) cannot be used on the *WinoCoref* dataset. The results also show that it is better to compile knowledge into constraints when the knowledge quality is high than add them as features.

5.3 Results for Standard Coreference Problems

Performance results on standard *ACE* and *OntoNotes* datasets are shown in Table 8. Our *KnowComb* system achieves the same level of performance as does the state-of-art general coreference system we base it on. As hard coreference problems are rare in standard coreference datasets, we do not have significant performance improvement. However, these results show that our additional Predicate Schemas do not harm the predictions for regular mentions.

System	MUC	BCUB	CEAFe	AVG
ACE				
IlliCons	**78.17**	81.64	**78.45**	**79.42**
KnowComb	77.51	**81.97**	77.44	78.97
OntoNotes				
IlliCons	84.10	**78.30**	**68.74**	**77.05**
KnowComb	**84.33**	78.02	67.95	76.76

Table 8: Performance results on *ACE* and *OntoNotes* datasets. Our system gets the same level of performance compared to a state-of-art general coreference system.

Category	Cat1	Cat2	Cat3
Size	317	1060	509
Portion	16.8%	56.2%	27.0%

Table 9: Distribution of instances in *Winograd* dataset of each category. Cat1/Cat2 is the subset of instances that require Type 1/Type 2 schema knowledge, respectively. All other instances are put into Cat3. Cat1 and Cat2 instances can be covered by our proposed Predicate Schemas.

5.4 Detailed Analysis

To study the coverage of our Predicate Schemas knowledge, we label the instances in *Winograd* (which also applies to *WinoCoref*) with the type of Predicate Schemas knowledge required. The distribution of the instances is shown in Table 9. Our proposed Predicate Schemas cover 73% of the instances.

We also provide an ablation study on the

Schema	AntePre(Test)	AntePre(Train)
Type 1	76.67	86.79
Type 2	79.55	88.86
Type 1 (Cat1)	90.26	93.64
Type 2 (Cat2)	83.38	92.49

Table 10: Ablation Study of Knowledge Schemas on *WinoCoref*. The first line specifies the preformance for *KnowComb* with only Type 1 schema knowledge tested on all data while the third line specifies the preformance using the same model but tested on Cat1 data. The second line specifies the preformance results for *KnowComb* system with only Type 2 schema knowledge on all data while the fourth line specifies the preformance using the same model but tested on Cat2 data.

WinoCoref dataset in Table 10. These results use the best performing *KnowComb* system. They show that both Type 1 and Type 2 schema knowledge have higher precision on Category 1 and Category 2 data instances, respectively, compared to that on full data. Type 1 and Type 2 knowledge have similiar performance on full data, but the results show that it is harder to solve instances in category 2 than those in category 1. Also, the performance drop between Cat1/Cat2 and full data indicates that there is a need to design more complicated knowledge schemas and to refine the knowledge acquisition for further performance improvement.

6 Related Work

Winograd Schema: Winograd (1972) showed that small changes in context could completely change coreference decisions. Levesque et al. (2011) proposed to assemble a set of sentences which comply with Winograd's schema. Specifically, there are pairs of sentences which are identical except for minor differences which lead to different references of the same pronoun in both sentences. These references can be easily solved by humans, but are hard, he claimed, for computer programs.

Anaphora Resolution: There has been a lot of work on anaphora resolution in the past two decades. Many of the early rule-based systems like Hobbs (1978) and Lappin and Leass (1994) gained considerable popularity. The early designs were easy to understand and the rules were designed manually. With the development of machine learning based models (Connolly et al., 1994; Soon et al., 2001b; Ng and Cardie, 2002a), attention shifted to solving standard coreference resolution problems. However, many hard coreference problems involve pronouns. As Winograd's schema shows, there is still a need for further investigation in this subarea.

World Knowledge Acquisition: Many tasks in NLP (such as Textual Entailment, Question Answering, etc.) require *World Knowledge*. Although there are many existing works on acquiring them (Schwartz and Gomez, 2009; Balasubramanian et al., 2013; Tandon et al., 2014), there is still no consensus on how to represent, gather and utilize high quality *World Knowledge*. When it comes to coreference resolution, there are a handful of works which either use web query information or apply alignment to an external knowledge base (Rahman and Ng, 2011b; Kobdani et al., 2011; Ratinov and Roth, 2012; Bansal and Klein, 2012; Zheng et al., 2013). With the introduction of Predicate Schema, our goal is to bring these different approaches together and provide a coherent view.

Abstract

This paper presents an in-depth investigation on integrating neural language models in translation systems. Scaling neural language models is a difficult task, but crucial for real-world applications. This paper evaluates the impact on end-to-end MT quality of both new and existing scaling techniques. We show when explicitly normalising neural models is necessary and what optimisation tricks one should use in such scenarios. We also focus on scalable training algorithms and investigate noise contrastive estimation and diagonal contexts as sources for further speed improvements. We explore the trade-offs between neural models and back-off n-gram models and find that neural models make strong candidates for natural language applications in memory constrained environments, yet still lag behind traditional models in raw translation quality. We conclude with a set of recommendations one should follow to build a scalable neural language model for MT.

1 Introduction

Language models are used in translation systems to improve the fluency of the output translations. The most popular language model implementation is a back-off n-gram model with Kneser-Ney smoothing (Chen and Goodman, 1999). Back-off n-gram models are conceptually simple, very efficient to construct and query, and are regarded as being extremely effective in translation systems.

Neural language models are a more recent class of language models (Bengio et al., 2003) that have been shown to outperform back-off n-gram models using intrinsic evaluations of heldout perplexity (Chelba et al., 2013; Bengio et al., 2003), or when used in addition to traditional models in natural language systems such as speech recognizers (Mikolov et al., 2011a; Schwenk, 2007). Neural language models combat the problem of data sparsity inherent to traditional n-gram models by learning distributed representations for words in a continuous vector space.

It has been shown that neural language models can improve translation quality when used as additional features in a decoder (Vaswani et al., 2013; Botha and Blunsom, 2014; Baltescu et al., 2014; Auli and Gao, 2014) or if used for n-best list rescoring (Schwenk, 2010; Auli et al., 2013). These results show great promise and in this paper we continue this line of research by investigating the trade-off between speed and accuracy when integrating neural language models in a decoder. We also focus on how effective these models are when used as the sole language model in a translation system. This is important because our hypothesis is that most of the language modelling is done by the n-gram model, with the neural model only acting as a differentiating factor when the n-gram model cannot provide a decisive probability. Furthermore, neural language models are considerably more compact and represent strong candidates for modelling language in memory constrained environments (e.g. mobile devices, commodity machines, etc.), where back-off n-gram models trained on large amounts of data do not fit into memory.

Our results show that a novel combination of noise contrastive estimation (Mnih and Teh, 2012)

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 820–829,
Denver, Colorado, May 31 – June 5, 2015.

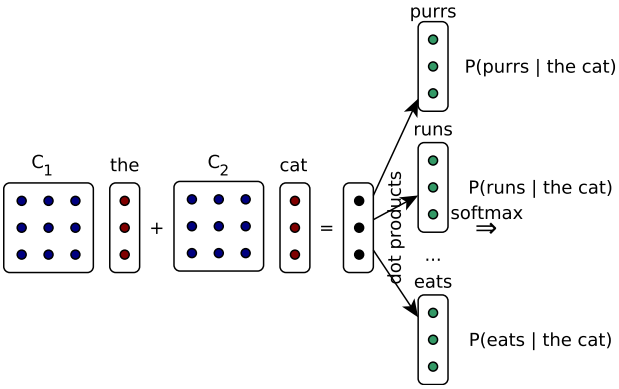

Figure 1: A 3-gram neural language model is used to predict the word following the context *the cat*.

and factoring the softmax layer using Brown clusters (Brown et al., 1992) provides the most pragmatic solution for fast training and decoding. Further, we confirm that when evaluated purely on BLEU score, neural models are unable to match the benchmark Kneser-Ney models, even if trained with large hidden layers. However, when the evaluation is restricted to models that match a certain memory footprint, neural models clearly outperform the n-gram benchmarks, confirming that they represent a practical solution for memory constrained environments.

2 Model Description

As a basis for our investigation, we implement a probabilistic neural language model as defined in Bengio et al. (2003).[1] For every word w in the vocabulary V, we learn two distributed representations $\mathbf{q}_w$ and $\mathbf{r}_w$ in $\mathbb{R}^D$. The vector $\mathbf{q}_w$ captures the syntactic and semantic role of the word w when w is part of a conditioning context, while $\mathbf{r}_w$ captures its role as a prediction. For some word w_i in a given corpus, let h_i denote the conditioning context $w_{i-1}, \ldots, w_{i-n+1}$. To find the conditional probability $P(w_i|h_i)$, our model first computes a context projection vector:

$$\mathbf{p} = f\left(\sum_{j=1}^{n-1} \mathrm{C}_j \mathbf{q}_{h_{ij}}\right),$$

where $\mathrm{C}_j \in \mathbb{R}^{D\times D}$ are context specific transformation matrices and f is a component-wise *rectified linear* activation. The model computes a set of similarity scores measuring how well each word $w \in V$ matches the context projection of h_i. The similarity score is defined as $\phi(w, h_i) = \mathbf{r}_w^{\mathrm{T}}\mathbf{p} + b_w$, where b_w is a bias term incorporating the prior probability of the word w. The similarity scores are transformed into probabilities using the softmax function:

$$P(w_i|h_i) = \frac{\exp(\phi(w_i, h_i))}{\sum_{w\in V}\exp(\phi(w, h_i))},$$

The model architecture is illustrated in Figure 1. The parameters are learned with gradient descent to maximize log-likelihood with L_2 regularization.

Scaling neural language models is hard because any forward pass through the underlying neural network computes an expensive softmax activation in the output layer. This operation is performed during training and testing for all contexts presented as input to the network. Several methods have been proposed to alleviate this problem: some applicable only during training (Mnih and Teh, 2012; Bengio and Senecal, 2008), while others may also speed up arbitrary queries to the language model (Morin and Bengio, 2005; Mnih and Hinton, 2009).

In the following subsections, we present several extensions to this model, all sharing the goal of reducing the computational cost of the softmax step. Table 1 summarizes the complexities of these methods during training and decoding.

Model	Training	Exact Decoding
Standard	$O(\|V\| \times D)$	$O(\|V\| \times D)$
Class Factored	$O(\sqrt{\|V\|} \times D)$	$O(\sqrt{\|V\|} \times D)$
Tree Factored	$O(\log \|V\| \times D)$	$O(\log \|V\| \times D)$
NCE	$O(k \times D)$	$O(\|V\| \times D)$

Table 1: Training and decoding complexities for the optimization tricks discussed in section 2.

2.1 Class Based Factorisation

The time complexity of the softmax step is $O(|V| \times D)$. One option for reducing this excessive amount of computation is to rely on a class based factorisation trick (Goodman, 2001). We partition the vocabulary into K classes $\{\mathcal{C}_1, \ldots, \mathcal{C}_K\}$ such that $V = \bigcup_{i=1}^{K} \mathcal{C}_i$ and $\mathcal{C}_i \cap \mathcal{C}_j = \varnothing, \forall 1 \leq i < j \leq K$.

[1] Our goal is to release a scalable neural language modelling toolkit at the following URL: `http://www.example.com`.

We define the conditional probabilities as:

$$P(w_i|h_i) = P(c_i|h_i)P(w_i|c_i, h_i),$$

where c_i is the class the word w_i belongs to, i.e. $w_i \in \mathcal{C}_{c_i}$. We adjust the model definition to also account for the class probabilities $P(c_i|h_i)$. We associate a distributed representation $\mathbf{s}_c$ and a bias term t_c to every class c. The class conditional probabilities are computed reusing the projection vector $\mathbf{p}$ with a new scoring function $\psi(c, h_i) = \mathbf{s}_c^{\mathrm{T}}\mathbf{p} + t_c$. The probabilities are normalised separately:

$$P(c_i|h_i) = \frac{\exp(\psi(c_i, h_i))}{\sum_{j=1}^{K} \exp(\psi(c_j, h_i))}$$
$$P(w_i|c_i, h_i) = \frac{\exp(\phi(w_i, h_i))}{\sum_{w \in \mathcal{C}_{c_i}} \exp(\phi(w, h_i))}$$

When $K \approx \sqrt{|V|}$ and the word classes have roughly equal sizes, the softmax step has a more manageable time complexity of $O(\sqrt{|V|} \times D)$ for both training and testing.

2.2 Tree Factored Models

One can take the idea presented in the previous section one step further and construct a tree over the vocabulary V. The words in the vocabulary are used to label the leaves of the tree. Let $n_1, \ldots, n_k$ be the nodes on the path descending from the root (n_1) to the leaf labelled with w_i (n_k). The probability of the word w_i to follow the context h_i is defined as:

$$P(w_i|h_i) = \prod_{j=2}^{k} P(n_j|n_1, \ldots, n_{j-1}, h_i).$$

We associate a distributed representation $\mathbf{s}_n$ and bias term t_n to each node in the tree. The conditional probabilities are obtained reusing the scoring function $\psi(n_j, h_i)$:

$$P(n_j|n_1, \ldots, n_{j-1}, h_i) = \frac{\exp(\psi(n_j, h_i))}{\sum_{n \in \mathcal{S}(n_j)} \exp(\psi(n, h_i))},$$

where $\mathcal{S}(n_j)$ is the set containing the siblings of n_j and the node itself. Note that the class decomposition trick described earlier can be understood as a tree factored model with two layers, where the first layer contains the word classes and the second layer contains the words in the vocabulary.

The optimal time complexity is obtained by using balanced binary trees. The overall complexity of the normalisation step becomes $O(\log |V| \times D)$ because the length of any path is bounded by $O(\log |V|)$ and because exactly two terms are present in the denominator of every normalisation operation.

Inducing high quality binary trees is a difficult problem which has received some attention in the research literature (Mnih and Hinton, 2009; Morin and Bengio, 2005). Results have been somewhat unsatisfactory, with the exception of Mnih and Hinton (2009), who did not release the code they used to construct their trees. In our experiments, we use Huffman trees (Huffman, 1952) which do not have any linguistic motivation, but guarantee that a minimum number of nodes are accessed during training. Huffman trees have depths that are close to $\log |V|$.

2.3 Noise Contrastive Estimation

Training neural language models to maximise data likelihood involves several iterations over the entire training corpus and applying the backpropagation algorithm for every training sample. Even with the previous factorisation tricks, training neural models is slow. We investigate an alternative approach for training language models based on noise contrastive estimation, a technique which does not require normalised probabilities when computing gradients (Mnih and Teh, 2012). This method has already been used for training neural language models for machine translation by Vaswani et al. (2013).

The idea behind noise contrastive training is to transform a density estimation problem into a classification problem, by learning a classifier to discriminate between samples drawn from the data distribution and samples drawn for a known noise distribution. Following Mnih and Teh (2012), we set the unigram distribution $P_n(w)$ as the noise distribution and use k times more noise samples than data samples to train our models. The new objective is:

$$J(\theta) = \sum_{i=1}^{m} \log P(C = 1|\theta, w_i, h_i) + \sum_{i=1}^{m} \sum_{j=1}^{k} \log P(C = 0|\theta, n_{ij}, h_i),$$

where n_{ij} are the noise samples drawn from $P_n(w)$. The posterior probability that a word is generated

Language pairs	# tokens	# sentences
fr→en	113M	2M
en→cs	36.5M	733.4k
en→de	104.9M	1.95M

Table 2: Statistics for the parallel corpora.

Language	# tokens	Vocabulary
English (en)	2.05B	105.5k
Czech (cs)	566M	214.9k
German (de)	1.57B	369k

Table 3: Statistics for the monolingual corpora.

from the data distribution given its context is:

$$P(C = 1|\theta, w_i, h_i) = \frac{P(w_i|\theta, h_i)}{P(w_i|\theta, h_i) + kP_n(w_i)}.$$

Mnih and Teh (2012) show that the gradient of $J(\theta)$ converges to the gradient of the log-likelihood objective when $k \rightarrow \infty$.

When using noise contrastive estimation, additional parameters can be used to capture the normalisation terms. Mnih and Teh (2012) fix these parameters to 1 and obtain the same perplexities, thereby circumventing the need for explicit normalisation. However, this method does not provide any guarantees that the models are normalised at test time. In fact, the outputs may sum up to arbitrary values, unless the model is explicitly normalised.

Noise contrastive estimation is more efficient than the factorisation tricks at training time, but at test time one still has to normalise the model to obtain valid probabilities. We propose combining this approach with the class decomposition trick resulting in a fast algorithm for both training and testing. In the new training algorithm, when we account for the class conditional probabilities $P(c_i|h_i)$, we draw noise samples from the class unigram distribution, and when we account for $P(w_i|c_i, h_i)$, we sample from the unigram distribution of only the words in the class $\mathcal{C}_{c_i}$.

3 Experimental Setup

In our experiments, we use data from the 2014 ACL Workshop in Machine Translation.[2] We train standard phrase-based translation systems for French → English, English → Czech and English → German using the `Moses` toolkit (Koehn et al., 2007).

We used the `europarl` and the `news commentary` corpora as parallel data for training the translation systems. The parallel corpora were tokenized, lowercased and sentences longer than 80 words were removed using standard text processing tools.[3] Table 2 contains statistics about the training corpora after the preprocessing step. We tuned the translation systems on the `newstest2013` data using minimum error rate training (Och, 2003) and we used the `newstest2014` corpora to report uncased BLEU scores averaged over 3 runs.

The monolingual training data used for training language models consists of the `europarl`, `news commentary` and the `news crawl 2007-2013` corpora. The corpora were tokenized and lowercased using the same text processing scripts and the words not occuring the in the target side of the parallel data were replaced with a special `<unk>` token. Statistics for the monolingual data after the preprocessing step are reported in Table 3.

Throughout this paper we report results for 5-gram language models, regardless of whether they are back-off n-gram models or neural models. To construct the back-off n-gram models, we used a compact trie-based implementation available in `KenLM` (Heafield, 2011), because otherwise we would have had difficulties with fitting these models in the main memory of our machines. When training neural language models, we set the size of the distributed representations to 500, we used diagonal context matrices and we used 10 negative samples for noise contrastive estimation, unless otherwise indicated. In cases where we perform experiments on only one language pair, the reader should assume we used French→English data.

4 Normalisation

The key challenge with neural language models is scaling the softmax step in the output layer of the

[2]The data is available here: `http://www.statmt.org/wmt14/translation-task.html`.

[3]We followed the first two steps from `http://www.cdec-decoder.org/guide/tutorial.html`.

Model	fr→en	en→cs	en→de
KenLM	33.01 (120.446)	19.11	19.75
NLM	31.55 (115.119)	18.56	18.33

Table 4: A comparison between standard back-off n-gram models and neural language models. The perplexities for the English language models are shown in parentheses.

network. This operation is especially problematic when the neural language model is incorporated as a feature in the decoder, as the language model is queried several hundred thousand times for any sentence of average length.

Previous publications on neural language models in machine translation have approached this problem in two different ways. Vaswani et al. (2013) and Devlin et al. (2014) simply ignore normalisation when decoding, albeit Devlin et al. (2014) alter their training objective to learn self-normalised models, i.e. models where the sum of the values in the output layer is (hopefully) close to 1. Vaswani et al. (2013) use noise contrastive estimation to speed up training, while Devlin et al. (2014) train their models with standard gradient descent on a GPU.

The second approach is to explicitly normalise the models, but to limit the set of words over which the normalisation is performed, either via class-based factorisation (Botha and Blunsom, 2014; Baltescu et al., 2014) or using a shortlist containing only the most frequent words in the vocabulary and scoring the remaining words with a back-off n-gram model (Schwenk, 2010). Tree factored models follow the same general approach, but to our knowledge, they have never been investigated in a translation system before. These normalisation techniques can be successfully applied both when training the models and when using them in a decoder.

Table 4 shows a side by side comparison of out of the box neural language models and back-off n-gram models. We note a significant drop in quality when neural language models are used (roughly 1.5 BLEU for fr→en and en→de and 0.5 BLEU for en→ cs). This result is in line with Zhao et al. (2014) and shows that by default back-off n-gram models are much more effective in MT. An interesting observation is that the neural models have lower perplexities than the n-gram models, implying that BLEU scores and perplexities are only loosely correlated.

Normalisation	fr→en	en→cs	en→de
Unnormalised	33.89	20.06	20.25
Class Factored	33.87	19.96	20.25
Tree Factored	33.69	19.52	19.87

Table 5: Qualitative analysis of the proposed normalisation schemes *with* an additional back-off n-gram model.

Normalisation	fr→en	en→cs	en→de
Unnormalised	30.98	18.57	18.05
Class Factored	31.55	18.56	18.33
Tree Factored	30.37	17.19	17.26

Table 6: Qualitative analysis of the proposed normalisation schemes *without* an additional back-off n-gram model.

Table 5 and Table 6 show the impact on translation quality for the proposed normalisation schemes with and without an additional n-gram model. We note that when `KenLM` is used, no significant differences are observed between normalised and unnormalised models, which is again in accordance with the results of Zhao et al. (2014). However, when the n-gram model is removed, class factored models perform better (at least for fr→en and en→de), despite being only an approximation of the fully normalised models. We believe this difference in not observed in the first case because most of the language modelling is done by the n-gram model (as indicated by the results in Table 4) and that the neural models only act as a differentiating feature when the n-gram models do not provide accurate probabilities. We conclude that some form of normalisation is likely to be necessary whenever neural models are used alone. This result may also explain why Zhao et al. (2014) show, perhaps surprisingly, that normalisation is important when reranking n-best lists with recurrent neural language models, but not in other cases. (This is the only scenario where they use neural models without supporting n-gram models.)

Table 5 and Table 6 also show that tree factored models perform poorly compared to the other candidates. We believe this is likely to be a result of the artificial hierarchy imposed by the tree over the vocabulary.

Normalisation	Clustering	BLEU
Class Factored	Brown clustering	31.55
Class Factored	Frequency binning	31.07
Tree Factored	Huffman encoding	30.37

Table 7: Qualitative analysis of clustering strategies on fr→en data.

Model	Average decoding time
KenLM	1.64 s
Unnormalised NLM	3.31 s
Class Factored NLM	42.22 s
Tree Factored NLM	18.82 s

Table 8: Average decoding time per sentence for the proposed normalisation schemes.

Table 7 compares two popular techniques for obtaining word classes: Brown clustering (Brown et al., 1992; Liang, 2005) and frequency binning (Mikolov et al., 2011b). From these results, we learn that the clustering technique employed to partition the vocabulary into classes can have a huge impact on translation quality and that Brown clustering is clearly superior to frequency binning.

Another thing to note is that frequency binning partitions the vocabulary in a similar way to Huffman encoding. This observation implies that the BLEU scores we report for tree factored models are not optimal, but we can get an insight on how much we expect to lose in general by imposing a tree structure over the vocabulary (on the fr→en setup, we lose roughly 0.7 BLEU points). Unfortunately, we are not able to report BLEU scores for factored models using Brown trees because the time complexity for constructing such trees is $O(|V|^3)$.

We report the average time needed to decode a sentence for each of the models described in this paper in Table 8. We note that factored models are slow compared to unnormalised models. One option for speeding up factored models is using a GPU to perform the vector-matrix operations. However, GPU integration is architecture specific and thus against our goal of making our language modelling toolkit usable by everyone.

Training	Perplexity	BLEU	Duration
SGD	116.596	31.75	9.1 days
NCE	115.119	31.55	1.2 days

Model	Training time
Unnormalised NCE	1.23 days
Class Factored NCE	1.20 days
Tree Factored SGD	1.4 days

Table 10: Training times for neural models on fr→en data.

5 Training

In this section, we are concerned with finding scalable training algorithms for neural language models. We investigate noise contrastive estimation as a much more efficient alternative to standard maximum likelihood training via stochastic gradient descent. Class factored models enable us to conduct this investigation at a much larger scale than previous results (e.g. the WSJ corpus used by Mnih and Teh (2012) has slightly over 1M tokens), thereby gaining useful insights on how this method truly performs at scale. (In our experiments, we use a 2B words corpus and a 100k vocabulary.) Table 9 summarizes our findings. We obtain a slightly better BLEU score with stochastic gradient descent, but this is likely to be just noise from tuning the translation system with MERT. On the other hand, noise contrastive training reduces training time by a factor of 7.

Table 10 reviews the neural models described in this paper and shows the time needed to train each one. We note that noise contrastive training requires roughly the same amount of time regardless of the structure of the model. Also, we note that this method is at least as fast as maximum likelihood training even when the latter is applied to tree factored models. Since tree factored models have lower quality, take longer to query and do not yield any substantial benefits at training time when compared to unnormalised models, we conclude they represent a suboptimal language modelling choice

Contexts	Perplexity	BLEU	Training time
Full	114.113	31.43	3.64 days
Diagonal	115.119	31.55	1.20 days

for machine translation.

6 Diagonal Context Matrices

In this section, we investigate diagonal context matrices as a source for reducing the computational cost of calculating the projection vector. In the standard definition of a neural language model, this cost is dominated by the *softmax* step, but as soon as tricks like noise contrastive estimation or tree or class factorisations are used, this operation becomes the main bottleneck for training and querying the model. Using diagonal context matrices when computing the projection layer reduces the time complexity from $O(D^2)$ to $O(D)$. A similar optimization is achieved in the backpropagation algorithm, as only $O(D)$ context parameters need to be updated for every training instance.

Devlin et al. (2014) also identified the need for finding a scalable solution for computing the projection vector. Their approach is to cache the product between every word embedding and every context matrix and to look up these terms in a table as needed. Devlin et al. (2014)'s approach works well when decoding, but it requires additional memory and is not applicable during training.

Table 11 compares diagonal and full context matrices for class factored models. Both models have similar BLEU scores, but the training time is reduced by a factor of 3 when diagonal context matrices are used. We obtain similar improvements when decoding with class factored models, but the speed up for unnormalised models is over 100x!

7 Quality vs. Memory Trade-off

Neural language models are a very appealing option for natural language applications that are expected to run on mobile phones and commodity computers, where the typical amount of memory available is limited to 1-2 GB. Nowadays, it is becoming more and more common for these devices to include reasonably powerful GPUs, supporting the idea that further scaling is possible if necessary. On the other hand, fitting back-off n-gram models on such devices is difficult because these models store the probability of every n-gram in the training data. In this section, we seek to gain further understanding on how these models perform under such conditions.

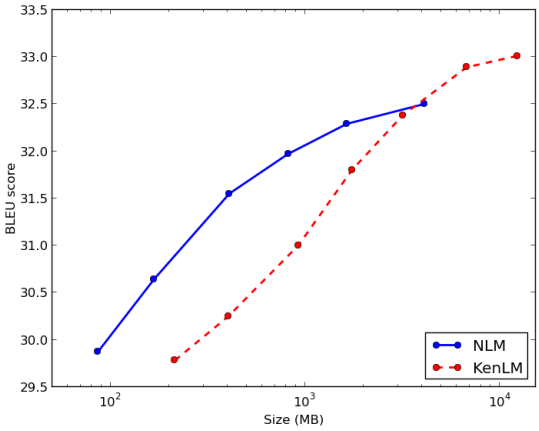

Figure 2: A graph highlighting the quality vs. memory trade-off between traditional n-gram models and neural language models.

In this analysis, we used Heafield (2011)'s trie-based implementation with quantization for constructing memory efficient back-off n-gram models. A 5-gram model trained on the English monolingual data introduced in section 3 requires 12 GB of memory. We randomly sampled sentences with an acceptance ratio ranging between 0.01 and 1 to construct smaller models and observe their performance on a larger spectrum. The BLEU scores obtained using these models are reported in Figure 2. We note that the translation quality improves as the amount of training data increases, but the improvements are less significant when most of the data is used.

The neural language models we used to report results throughout this paper are roughly 400 MB in size. Note that we do not use any compression techniques to obtain smaller models, although this is technically possible (e.g. quantization). We are interested to see how these models perform for various memory thresholds and we experiment with setting the size of the word embeddings between 100

and 5000. More importantly, these experiments are meant to give us an insight on whether very large neural language models have any chance of achieving the same performance as back-off n-gram models in translation tasks. A positive result would imply that significant gains can be obtained by scaling these models further, while a negative result signals a possible inherent inefficiency of neural language models in MT. The results are shown in Figure 2.

From Figure 2, we learn that neural models perform significantly better (over 1 BLEU point) when there is under 1 GB of memory available. This is exactly the amount of memory generally available on mobile phones and ordinary computers, confirming the potential of neural language models for applications designed to run on such devices. However, at the other end of the scale, we can see that back-off models outperform even the largest neural language models by a decent margin and we can expect only modest gains if we scale these models further.

8 Conclusion

This paper presents an empirical analysis of neural language models in machine translation. The experiments presented in this paper help us draw several useful conclusions about the ideal usage of these language models in MT systems.

The first problem we investigate is whether normalisation has any impact on translation quality and we survey the effects of some of the most frequently used techniques for scaling neural language models. We conclude that normalisation is not necessary when neural models are used in addition to back-off n-gram models. This result is due to the fact that most of the language modelling is done by the n-gram model. (Experiments show that out of the box n-gram models clearly outperform their neural counterparts.) The MT system learns a smaller weight for neural models and we believe their main use is to correct the inaccuracies of the n-gram models.

On the other hand, when neural language models are used in isolation, we observe that normalisation does matter. We believe this result generalizes to other neural architectures such as neural translation models (Sutskever et al., 2014; Cho et al., 2014). We observe that the most effective normalisation strategy in terms of translation quality is the class-based decomposition trick. We learn that the algorithm used for partitioning the vocabulary into classes has a strong impact on the overall quality and that Brown clustering (Brown et al., 1992) is a good choice. Decoding with class factored models can be slow, but this issue can be corrected using GPUs, or if a comprise in quality is acceptable, unnormalised models represent a much faster alternative. We also conclude that tree factored models are not a strong candidate for translation since they are outperformed by unnormalised models in every aspect.

We introduce noise contrastive estimation for class factored models and show that it performs almost as well as maximum likelihood training with stochastic gradient descent. To our knowledge, this is the first side by side comparison of these two techniques on a dataset consisting of a few billions of training examples and a vocabulary with over 100k tokens. On this setup, noise contrastive estimation can be used to train standard or class factored models in a little over 1 day.

We explore diagonal context matrices as an optimization for computing the projection layer in the neural network. The trick effectively reduces the time complexity of this operation from $O(D^2)$ to $O(D)$. Compared to Devlin et al. (2014)'s approach of caching vector-matrix products, diagonal context matrices are also useful for speeding up training and do not require additional memory. Our experiments show that diagonal context matrices perform just as well as full matrices in terms of translation quality.

We also explore the trade-off between neural language models and back-off n-gram models. We observe that in the memory range that is typically available on a mobile phone or a commodity computer, neural models outperform n-gram models with more than 1 BLEU point. On the other hand, when memory is not a limitation, traditional n-gram models outperform even the largest neural models by a sizable margin (over 0.5 BLEU in our experiments).

Our work is important because it reviews the most important scaling techniques used in neural language modelling for MT. We show how these methods compare to each other and we combine them to obtain neural models that are fast to both train and test. We conclude by exploring the strengths and weaknesses of these models into greater detail.

Abstract

The *Bechdel test* is a sequence of three questions designed to assess the presence of women in movies. Many believe that because women are seldom represented in film as strong leaders and thinkers, viewers associate weaker stereotypes with women. In this paper, we present a computational approach to automate the task of finding whether a movie passes or fails the Bechdel test. This allows us to study the key differences in language use and in the importance of roles of women in movies that pass the test versus the movies that fail the test. Our experiments confirm that in movies that fail the test, women are in fact portrayed as less-central and less-important characters.

1 Introduction

The Bechdel test is a series of three questions, which originated from Alison Bechdel's comic "Dykes to Watch Out For" (Bechdel, 1986). The three questions (or tests) are as follows: (T1) are there at least two named women in the movie? (T2) do these women talk to each other? and (T3) do these women talk to each other about something besides a man? If after watching a movie, the viewers answer "yes" to all three questions, that movie is said to pass the Bechdel test.

[†]These authors contributed equally. The work was done while Jiehan Zheng was at Peddie School and Sriram Balasubramanian was at Columbia University.

The test was designed to assess the presence of women in movies. Some researchers have embraced the test as an effective primary detector for male bias (Scheiner-Fisher and Russell III, 2012). Due to its generality, the Bechdel test has also been used to assess the presence of women in dialogues held on social media platforms such as MySpace and Twitter (Garcia et al., 2014). Several researchers have noted that gender inequality roots itself in both the subconscious of individuals and the culture of society as a whole (Žižek, 1989; Michel et al., 2011; García and Tanase, 2013). Therefore, combining the Bechdel test with computational analysis can allow for the exposure of gender inequality over a large body of films and literature, thus having the potential to alert society of the necessity to challenge the status quo of male dominance.

In this paper, we investigate the task of automating the Bechdel test. In doing so, we aim to study the effectiveness of various linguistic and social network analysis features developed for conducting this task. Our results show that the features based on social network analysis metrics (such as betweenness centrality) are most effective. More specifically, in movies that fail the test, women are significantly less centrally connected as compared to movies that pass the test. This finding provides support for the long held belief that women are seldom portrayed as strong leaders and thinkers in popular media. Our results also show that word unigrams, topic modeling features, and features that capture mentions of men in conversations are less effective. This may look like a rather surprising result since the question,

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 830–840,
Denver, Colorado, May 31 – June 5, 2015.

(T3) do these women talk to each other about something besides a man? seems to be one that linguistic features should be able to answer. A closer analysis suggests why this may be the case. Consider the screenplay excerpt in Figure 1 (on the next page). This excerpt is from the movie *Hannah and Her Sisters*, which passes the Bechdel test. Even though the conversation between named women *Mickey* and *Gail* mentions a man (*He*), the conversation is not *about* a man. The conversation is about *Mickey's* brain tumor. Now consider the following (contrived) conversation between the same characters:

> *Mickey*: Ssssss, if i'm in love, I don't know what I'm gonna do.
> *Gail*: You're not in love. Didn't he tell you that it was over.
> *Mickey*: No, naturally

This conversation is clearly about a man (or being in love with a man). Much like the original conversation, this conversation mentions a man only once. The linguistic phenomena that allows us to infer that this contrived conversation is about a man is quite complex; it requires a deeper semantic analysis and world knowledge. First, we need to infer that *it being over* refers to a relationship. Relationships typically have two participants. In order to identify the participants, we need to use world knowledge that relationships can end and that the person ending the relationship was once part of the relationship, and so on. Eventually, we are able to conclude that one of the main participants of the conversation or the event being discussed is a man.

As a first attempt to automate the test, we only experiment with basic linguistic features. However, we believe that the task itself offers an opportunity for the development of— and subsequent evaluation of— rich linguistic features that may be better equipped for determining the *aboutness* of conversations.

The rest of the paper is structured as follows. Section 2 reviews the related literature. Section 3 introduces the terminology regarding movie screenplays that we use throughout the paper. Section 4 describes the data and gold standard used for the purposes of automating the test. Sections 5, 6, and 7 present our approach, evaluation and results for the three Bechdel tests, respectively. We conclude and present future direction for research in Section 8.

2 Related

There has been much work in the computational sciences community on studying gender differences in the way language is used by men versus women (Peersman et al., 2011; Mohammad and Yang, 2011; Bamman et al., 2012; Schwartz et al., 2013; Bamman et al., 2014; Prabhakaran et al., 2014). In fact, researchers have proposed linguistic features for supervised classifiers that predict the gender of authors given their written text (Koppel et al., 2002; Corney et al., 2002; Cheng et al., 2011). There has also been a growth in research that utilizes computational techniques and big data for quantifying existing gender biases in society (Sugimoto et al., 2013; Garcia et al., 2014; Wagner et al., 2015).

More closely related to our application is the ongoing work in the social sciences community regarding the study of gender biases in movie scripts and books (Weitzman et al., 1972; Clark et al., 2003; Gooden and Gooden, 2001; McCabe et al., 2011; Chick and Corle, 2012; Smith et al., 2013). This work has largely depended on manual effort. McCabe et al. (2011) analyzed the presence of male and female characters in titles, and their centralities, in 5,618 children's books. The authors employed multiple human coders for obtaining the relevant annotations. Smith et al. (2013) employed 71 research assistants to evaluate 600 films to study gender prevalence in their scripts. Our work offers computational techniques that may help reduce the manual effort involved in carrying out similar social science studies.

Recently, Garcia et al. (2014) used 213 movie screenplays for evaluating the correlation of two novel scores with whether or not movies passed the Bechdel test. However, the main focus of their work was not to automate the test. The focus of their work was to study gender biases in MySpace and Twitter (using these scores). Nonetheless, we experiment with these scores and in fact they provide a strong baseline for automating the task. Furthermore, we use our previous work (Agarwal et al., 2014b) to *clean* noisy screenplays found on the web and carry out the study on a larger data-set of 457 screenplays.

Figure 1: A scene from the movie *Hannah and Her Sisters*. The scene shows *one* conversation between two *named women Mickey* and *Gail*. Tag S denotes scene boundary, C denotes character mention, D denotes dialogue, N denotes scene description, and M denotes meta-data.

Researchers in the Natural Language Processing (NLP) community have used movie screenplays for a number of different applications. Ye and Baldwin (2008) used movie screenplays for evaluating word sense disambiguation in an effort to automatically generate animated storyboards. Danescu-Niculescu-Mizil and Lee (2011) utilized movie screenplays for studying the coordination of linguistic styles in dialogues. Bamman et al. (2013) used movie plot summaries for finding personas of film characters. Agarwal et al. (2014c) used screenplays for automatically creating the *xkcd* movie narrative charts. In this paper, we use movie screenplays for yet another novel NLP task: automating the Bechdel test.

3 Terminology Related to Screenplays

Turetsky and Dimitrova (2004) described the structure of a movie screenplay as follows: a screenplay describes a story, characters, action, setting and dialogue of a film. The content of a screenplay follows a (semi) regular format. Figure 1 shows a snippet of a screenplay from the film *Hannah and Her Sisters*. A scene (tag "S") starts with what is called the *slug line* (or scene boundary). The slug line indicates whether the scene is to take place inside or outside (INT, EXT), the name of the location ("MICKEY'S OFFICE"), and can potentially specify the time of day (e.g. DAY or NIGHT). Following the scene boundary, is a scene description (tag "N"). A scene description is followed by a character name (tag "C"), which is followed by dialogues (tag "D"). Screenplays also have directions for the camera, such as "CUT TO:, DISSOLVE TO:". For lack of a better name, we refer to these as meta-data (tag "M").

Screenplays are expected to conform to a strict grammar – scene boundaries should be capitalized and start with markers such as INT./EXT., character names should be capitalized with an optional (V.O.) for "Voice Over" or (O.S.) for "Off-screen.", dialogues and scene descriptions should be *indented*[1] at a unique level (i.e. nothing else in the screenplay is indented at this level). However, screenplays found on the web have *anomalies* in their structures (Gil et al., 2011). In order to parse screenplays found on the web, we presented a supervised machine learning approach in Agarwal et al. (2014b). By parsing we mean assigning each line of the screenplay one of the following five tags: {S, N, C, D, M}. We showed that a rule based system, often used in

[1] By level of indentation we mean the number of spaces from the start of the line to the first non-space character.

the literature (Turetsky and Dimitrova, 2004; Weng et al., 2009; Gil et al., 2011), is not well equipped to handle anomalies in the structure of screenplays. Our supervised models outperformed the regular expressions based baseline by a large and significant margin (0.69 versus 0.96 macro-F1 measure for the five classes). We use these parsed screenplays for the purposes of this paper.

Many of our features designed to automate the Bechdel test rely on the definition of a scene and a conversation. We define them here:

Scene: A scene is the span of screenplay that lies between two scene boundaries (tag "S").

Conversation: A conversation between two or more characters is defined as their dialogue exchange in *one* scene.

4 Data

The website `bechdeltest.com` has reviewed movies from as long ago as 1892 and as recent as 2015. Over the years, thousands of people have visited the website and assigned ratings to thousands of movies: movies that fail the first test are assigned a rating of 0, movies that pass the first test but fail the second test are assigned a rating of 1, movies that pass the second test but fail the third test are assigned a rating of 2, and movies that pass all three tests are assigned a rating of 3. Any visitor who adds a new movie to the list gets the opportunity to rate the movie. Subsequent visitors who disagree with the rating may leave comments stating the reason for their disagreement. The website has a *webmaster* with admin rights to update the visitor ratings. If the webmaster is unsure or the visitor comments are inconclusive, she sets a flag (called the "dubious" flag) to *true*. For example, *niel (webmaster)* updated the rating for the movie *3 Days to Kill* from 1 to 3.[2] The dubious flag does not show up on the website interface but is available as a meta-data field. Over the course of the project, we noticed that the dubious flag for the movie *Up in the Air* changed from false to true.[3] This provided evidence that the website is actively maintained and moderated by its owners.

	Train & Dev. Set		Test Set	
	Fail	Pass	Fail	Pass
B. Test 1	26	341	5	85
B. Test 2	128	213	32	53
B. Test 3	60	153	15	38
Overall	214	153	52	38

Table 1: Distribution of movies for the three tests over the training/development and test sets. B. stands for Bechdel.

We crawled a total of 964 movie screenplays from the Internet Movie Script Database (IMSDB). Out of these, only 457 were assigned labels on `bechdeltest.com`. We decided to use 367 movies for training and development and 90 movies (about 20%) for testing. Table 1 presents the distribution of movies that pass/fail the three tests in our training and test sets. The distribution shows that a majority of movies fail the test. In our collection, 266 fail while only 191 pass the Bechdel test.

5 Test 1: are there at least two named women in the movie?

A movie passes the first test if there are two or more *named women* in the movie. We experiment with several name-to-gender resources for finding the character's gender. If, after analyzing all the characters in a movie, we find there are two or more *named women*, we say the movie passes the first test, otherwise it does not.

5.1 Resources for Determining Gender

IMDB_GMAP: The Internet Movie Database (IMDB) provides a full list of the cast and crew for movies. This list specifies a one-to-one mapping from character names to the actors who perform that role. Actors are associated with their gender through a meta-data field. Using this information, we created an individual dictionary for each movie that mapped character names to their genders.

SSA_GMAP: The Social Security Administration (SSA) of the United States has created a publicly available list of first names given to babies born in a given year, with counts, separated by gender.[4] Sugimoto et al. (2013) used this resource for assigning genders to authors of scientific articles. Prabhakaran

[4] http://www.ssa.gov/oact/babynames/limits.html

STAN_GMAP+ IMDB_GMAP	0.52	0.55	**0.54**	0.97	0.96	**0.96**	**0.75**

Table 2: Results for **Test 1**: "are there at least two named women in the movie".

et al. (2014) used this resource for assigning gender to sender and recipients of emails in the Enron email corpus. The authors noted that a first name may appear several times with conflicting genders. For example, the first name *Aidyn* appears 15 times as a male and 15 times as a female. For our purposes, we removed such names from the original list. The resulting resource had 90,000 names, 33,000 with the gender male and 57,000 with the gender female.

STAN_GMAP: In our experiments, we found both IMDB_GMAP and SSA_GMAP to be insufficient. We therefore devised a simple technique for assigning genders to named entities using the context of their appearance. This technique is general (not specific to movie screenplays) and may be used for automatically assigning genders to named characters in literary texts. The technique is as follows: (1) run a named entity coreference resolution system on the text, (2) collect all third person pronouns (*she, her, herself, he, his, him, himself*) that are resolved to each entity, and (3) assign a gender based on the gender of the third person pronouns.

We used Stanford's named entity coreference resolution system (Lee et al., 2013) for finding coreferences. Note that the existing coreference systems are not equipped to resolve references within a conversation. For example, in the conversation between *Mickey* and *Gail* (see Figure 1) "He" refers to *Mickey's* doctor, *Dr. Wilkes*, who is mentioned by name in an earlier scene (almost 100 lines before this conversation). To avoid incorrect coreferences, we therefore ran the coreference resolution system only on the scene descriptions of screenplays.

5.2 Results and Discussion

Table 2 presents the results for using various name to gender mapping resources for the first test. Since it is important for us to perform well on both classes (fail and pass), we report the macro-F1 measure; macro-F1 measure weights the classes equally unlike micro-F1 measure (Yang, 1999).

The results show that SSA_GMAP performs significantly[5] worse than all the other name-to-gender resources. One reason is that movies have a number of named characters that have gender different from the common gender associated with their names. For example, the movie *Frozen* (released in 2010) has two named women: *Parker* and *Shannon*. According to SSA_GMAP, *Parker* is a male, which leads to an incorrect prediction (fail when the movie actually passes the first test).

The results show that a combination of STAN_GMAP and IMDB_GMAP outperforms all the individual resources by a significant margin. We combined the resources by taking their union. If a name appeared in both resources with conflicting genders, we retained the gender recorded in IMDB_GMAP. Note that the precision of IMDB_GMAP is significantly higher than the precision of STAN_GMAP for the class Fail (0.35 versus 0.22). This has to do with coverage: STAN_GMAP is not able to determine the gender of a number of characters and predicts fail when the movie actually passes the test. We expected this behavior as a result of being able to run the coreference resolution tool only on the scene descriptions. Not all characters are mentioned in scene descriptions.

Also note that the precision of IMDB_GMAP is significantly lower than the precision of STAN_GMAP for the class Pass (0.97 versus 0.996). Error analysis revealed two problems with IMDB_GMAP. First, it lists non-named characters (such as *Stewardess*) along with the named characters in the credit list. So while the movie *A*

[5]We use McNemars test with $p < 0.05$ to report significance throughout the paper.

	Fail Test 2			Pass Test 2			
Network	P	R	F1	P	R	F1	Macro-F1
CLIQUE	0.55	0.20	0.29	0.65	0.92	0.76	0.57
CONSECUTIVE	0.63	0.28	**0.39**	0.67	0.90	**0.77**	**0.62**

Table 3: Results for **Test 2**: "do these women talk to each other?"

Space Odyssey actually fails the test (it has only one named woman, *Elena*), IMDB_GMAP incorrectly detects *Stewardess* as another named woman and makes an incorrect prediction. Second, certain characters are credited with a name different from the way they appear in the screenplay. Following is a user comment from `bechdeltest.com` on the movie *Up in the Air* that highlights this second limitation:

> Natalie refers to Karen Barnes as "Miss Barnes" when they first meet. She is also named later. Despite the fact that she's credited as "Terminated employee", she's definitely a named female character.

The methodology used for finding named women directly impacts the performance of our classifiers on the next two tests. For instance, if a methodology under-predicts the number of named women in a movie, its chances of failing the next two tests increase. In fact, we experimented with all combinations and found the combination STAN_GMAP+ IMDB_GMAP to outperform other gender resources for the next two tests. Due to space limitations, we do not present these results in the paper. We use the lists of named women and named men generated by STAN_GMAP+ IMDB_GMAP for the next two tests.

6 Test 2: Do these women talk to each other?

So far, we have parsed screenplays for identifying character mentions, scene boundaries, and other elements of a screenplay (see Figure 1). We have also identified the gender of named characters. For automating the second test (*do these women talk to each other?*) we experimented with two techniques for creating *interaction* networks of characters. Consider the following sequence of tagged lines in a screenplay: {S1, C1, C2, C3, S2, C1, ...}. S1 denotes the first scene boundary, C1 denotes the first speaking character in the first scene, C2 the second speaking character, and so on. One way of creating an *interaction* network is to connect all the characters that appear between two scene boundaries (Weng et al., 2009). Since the characters C1, C2, and C3 appear between two scene boundaries (S1 and S2), we connect all the three characters with pair-wise links. We call this the CLIQUE approach. Another way of connecting speaking characters is to connect only the ones that appear consecutively (C1 to C2 and C2 to C3, no link between C1 and C3). We call this the CONSECUTIVE approach.

Results presented in Table 3 show that the CONSEQUITIVE approach performs significantly better than the CLIQUE approach.

We investigated the reason for an overall low performance for this test. One reason was the over-prediction of named women by our gender resource (labeling *Stewardess* as a named woman). Another reason was the inconsistent use of scene descriptions in screenplays. Consider the sequence of scene boundaries, characters, and scene descriptions: {S1, N1, C1, C2, N2, C3, C4, S2, ...}. While for some screenplays N2 divided the scene between S1 and S2 into two scenes (S1-N2 and N2-S2), for other screenplays it did not. For the screenplays that it did, our CONSECUTIVE approach incorrectly connected the characters C2 and C3, which led to an over-prediction of characters that talk to each other. Both these reasons contributed to the low recall for the Fail class.

7 Test 3: Do these women talk to each other about something besides a man?

For the third Bechdel test, we experimented with machine learning models that utilized linguistic features as well as social network analysis features derived from the interaction network of characters.

7.1 Feature Set

We considered four broad categories of features: word unigrams (BOW), distribution of conversa-

tions over topics (TOPIC), linguistic features that captured mentions of *men* in dialogue (LING), and social network analysis features (SNA). We additionally experimented with the two scores proposed by Garcia et al. (2014).

For BOW, we collected all the words that appeared in conversations between pairs of women and normalized the binary vector by the number of pairs of named women and by the number of conversations they had in a screenplay. BOW was a fixed feature vector of length 18,889.

The feature set LING consisted of the following features: (1) the average length of conversations between each pair of named women (2) the number of conversations between each pair of named women, (3) a binary feature that recorded if *all* conversations between a particular pair of named women mentioned a man, and (4) a binary feature that recorded if *any* conversation between a particular pair of named women mentioned a man. Let us denote these feature vectors by $\{v_1, v_2, v_3, v_4\}$. Note that the length of these features vectors ($|v_i| \leq \binom{n}{2}$, where n is the number of named women in a movie) may vary from one movie to the other. We converted these variable length vectors into fixed length vectors of length four by using a function, GET_MIN_MAX_MEAN_STD(VECTOR), that returned the minimum, maximum, mean, and standard deviation for each vector. In all, we had $4 * 4 = 16$ LING features for each movie.

We found multiple instances of conversations that were about men but did not explicitly mention a man. For example, *don't we all fall for those pricks?* and *which one did you fall in love with?*. We also found conversations that mentioned a man explicitly and were around the same topic (say, *love*). For example, *I'm not in love with him, okay!*. In an attempt to capture possible correlations between general topics and conversations in which women talked about men, we decided to experiment with features derived from topic models. We trained a topic model on all the conversations between named women (Blei et al., 2003; McCallum, 2002). Before training the topic model, we converted all the mentions of men to a fixed tag "MALE" and all the mentions of women to a fixed tag "FEMALE". For each conversation between every pair of women, we queried the topic model for its distribution over the k topics. Since the number of pairs of women and the number of conversations between them could vary from one movie to the other, we took the average of the k-length topic distributions. We experimented with $k = 2$, 20, and 50. Thus the length of the TOPIC feature vector was 72.

While the Bechdel test was originally designed to assess the presence of women, it has subsequently been used to comment on the importance of roles of women in movies. But does *talking about men* correlate with the importance of their roles? To study this correlation we designed the following set of SNA features. We created variable length feature vectors (length equal to number of women) for several social network analysis metrics (Wasserman and Faust, 1994), all appropriately normalized: (1) degree centrality, (2) closeness centrality, (3) betweenness centrality, (4) the number of men a woman was connected to, and (5) the number of other women a woman was connected to. We created two other variable length feature vectors (length equal to the number of pairs of women) that recorded (6) the number of men in common between two women and (7) the number of women in common between two women. We converted these variable length feature vectors to fixed length vectors of length four by using the GET_MIN_MAX_MEAN_STD(VECTOR) function described above. This constituted $7 * 4 = 28$ of our SNA features. We additionally experimented with the following features: (8) the ratio of the number of women to the number of men, (9) the ratio of the number of women to the total number of characters, (10) the percentage of women that formed a 3-clique with a man and another woman, (11, 12, 13) the percentage of women in the list of five *main* characters (main based on each of the three notions of centralities), (14, 15, 16) three boolean features recording whether the main character was a women, (17, 18, 19) three boolean features recording whether any woman connected another woman to the main man, and (20, 21, 23) the percentage of women that connected the main man to another woman. In all we had 28 + 15 = 43 SNA features.

As a baseline, we experimented with the features proposed by Garcia et al. (2014). The authors proposed two scores: B_F and B_M. B_F was the ratio of {dialogues between female characters that did not contain mentions of men} over {the total num-

ber of dialogues in a movie$\}$. B_M was the ratio of $\{$dialogues between male characters that did not contain mentions of women$\}$ over $\{$the total number of dialogues in a movie$\}$.

7.2 Evaluation and Results

There were 60 movies that failed and 153 movies that passed the third test (see Table 1). We experimented with Logistic Regression and Support Vector Machines (SVM) with the linear and RBF kernels. Out of these SVM with linear and RBF kernels performed the best. Table 4 reports the averaged 5-fold cross-validation F1-measures for the best combinations of classifiers and feature sets. For each fold, we penalized a mistake on the minority class by a factor of 2.55 (153/60), while penalizing a mistake on the majority class by a factor of 1. This was an important step and as expected had a significant impact on the results. A binary classifier that uses a 0-1 loss function optimizes for accuracy. In a skewed data distribution scenario where F1-measure is a better measure to report, classifiers optimizing for accuracy tend to learn a trivial function that classifies all examples into the same class as the majority class. By penalizing mistakes on the minority class more heavily, we forced the classifier to learn a non-trivial function that achieved a higher F1-measure.

Results in Table 4 show that the features derived from social network analysis metrics (SNA) outperform linguistic features (BOW, LING, and TOPIC) by a significant margin. SNA features also outperform the features proposed by Garcia et al. (2014) by a significant margin (0.68 versus 0.62). Various feature combinations did not outperform the SNA features. In fact, all the top feature combinations that performed almost as well as the SNA features included SNA as one of the feature sets.

7.3 Evaluation on the End Task

We used the IMDB_GMAP + STAN_GMAP gender resource for the first test, the CONSECUTIVE approach for creating an interaction network for the second test, and compared the performance of the baseline versus the best feature set for the third test. Table 5 presents the results for the evaluation on our unseen test set of 52 movies that failed and 38 movies that passed the Bechdel test. As the results show, our best feature and classifier combination outperforms the baseline by a significant margin (0.73 versus 0.80). Note that the end evaluation is easier than the evaluation of each individual test. Consider a movie that fails the first test (and thus fails the Bechdel test). At test time, lets say, the movie is mis-predicted and passes the first two tests. However, the classifier for the third test correctly predicts the movie to fail the Bechdel test. Even though the errors propagated all the way to the third level, these errors are not penalized for the purposes of evaluating on the end task.

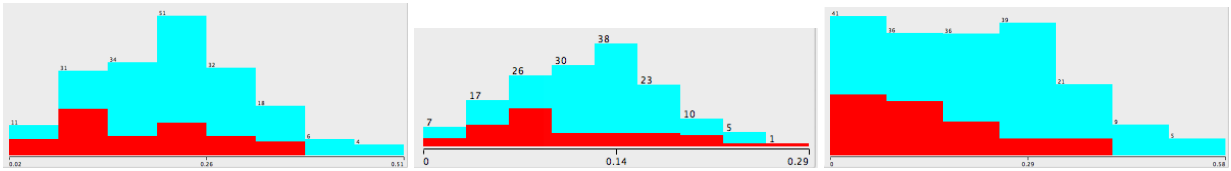

Figure 2: Distribution of three SNA features (left to right): mean degree centrality, mean closeness centrality, and mean betweenness centrality of named women. Red histogram is for movies that fail and the Blue histogram is for movies that pass the third Bechdel Test. The histograms show that the average centralities of women are higher for movies that pass the Bechdel test.

7.4 Discussion

We studied the correlation of our SNA features and the features proposed by Garcia et al. (2014) with the gold class on the set of 183 movies that pass or fail the third test in our training set. The most correlated SNA feature was the one that calculated the percentage of women who formed a 3-clique with a man and another woman ($r = 0.34$). Another highly correlated SNA feature was the binary feature that was true when the main character was a woman in terms of betweenness centrality ($r = 0.32$). Several other SNA features regarding the different notions of centralities of women were among the top. The feature suggested by Garcia et al. (2014), B_F and B_M, were also significantly correlated, with $r = 0.27$ and $r = -0.23$ respectively.

Figure 2 shows the distribution of three of our SNA features: mean degree centrality, mean closeness centrality, and mean betweenness centrality of named women. As the distributions show, most of the mass for movies that fail the test is towards the left of the plot, while most of the mass for movies that pass is towards the right. So movies that fail the test tend to have lower centrality measures as compared to movies that pass the test. Using our classification results, correlation analysis, and visualizations of the distributions of the SNA features, we conclude that in fact, movies that fail the test are highly likely to have less centrally connected women.

8 Conclusion and Future Work

In this paper, we introduced a novel NLP task of automating the Bechdel test. We utilized and studied the effectiveness of a wide range of linguistic features and features derived from social network analysis metrics for the task. Our results revealed that the question, *do women talk to each other about something other than a man*, is best answered by network analysis features derived from the interaction networks of characters in screenplays. We were thus able to show a significant correlation between the importance of roles of women in movies with the Bechdel test. Indeed, movies that fail the test tend to portray women as less-important and peripheral characters.

To the best of our knowledge, there is no large scale empirical study on quantifying the percentage of children's books and novels that fail the Bechdel test. In the future, we hope to combine some of the ideas from this work with our past work on social network extraction from literary texts (Agarwal and Rambow, 2010; Agarwal et al., 2012; Agarwal et al., 2013a; Agarwal et al., 2013b; Agarwal et al., 2014a) for presenting a large scale study on children's book and novels.

Acknowledgments

Abstract

Dialogue systems that support users in complex problem solving must interpret user utterances within the context of a dynamically changing, user-created problem solving artifact. This paper presents a novel approach to semantic grounding of noun phrases within tutorial dialogue for computer programming. Our approach performs joint segmentation and labeling of the noun phrases to link them to attributes of entities within the problem-solving environment. Evaluation results on a corpus of tutorial dialogue for Java programming demonstrate that a Conditional Random Field model performs well, achieving an accuracy of 89.3% for linking semantic segments to the correct entity attributes. This work is a step toward enabling dialogue systems to support users in increasingly complex problem-solving tasks.

1 Introduction

In the dialogue systems research community, there is growing recognition that dialogue systems need to support users in increasingly complex tasks. To move in this direction, dialogue systems must perform natural language understanding within richer and richer contexts, and this understanding includes semantic interpretation of user utterances (Traum, et al., 2012, Rudnicky, et al., 1999). Previous approaches for semantic interpretation include domain-specific grammars (Lemon et al., 2001) and open-domain parsers together with a domain-specific lexicon (Rosé, 2000). However, existing techniques are not sufficient to support increasingly complex problem-solving dialogues due to several challenges. For example, domain-specific grammars become intractable when applied to more ill-formed domains, and open-domain parsers may not perform well across domains (McClosky et al., 2010).

The call for addressing these limitations is particularly strong for dialogue systems that help people learn, such as *tutorial dialogue systems*. Today's tutorial dialogue systems engage in natural language dialogue in support of tasks such as solving qualitative physics problems (VanLehn et al., 2002), understanding computer architecture and physics (Graesser et al., 2004), and predicting behavior of electrical circuits (Dzikovska et al., 2011). Although these systems differ in many ways, they have an important commonality: in order to semantically interpret user dialogue utterances, these systems ground the utterances in a fixed domain description that is an integral part of the engineered system. This characteristic is shared by most dialogue systems, which ground their dialogue in manually defined domain-specific ontologies, such as for the task of booking flights (Allen, et al., 2001), checking bus schedules (Raux, 2004), and finding restaurants (Young et al., 2007).

These task-oriented domains, though they present a rich set of research challenges, stand in stark contrast to a *complex problem-solving* domain in which the user is creating an artifact to solve a problem. Yet the psychology literature tells us that complex problem solving is an essential activity in human learning (Greiff et al., 2013; Mayer et al., 2006; Funke, 2010). In such a domain, understanding user dialogue utterances involves grounding them within an infinite set of possible user-created

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 841–850,
Denver, Colorado, May 31 – June 5, 2015.

artifacts, not within a system ontology. This paper focuses on the complex problem-solving domain of introductory computer programming. In this domain the user might say, for example, "Is `myVariable` supposed to be an `int`?" where `myVariable` refers to the name of a variable within the computer program that the user has created. The semantic interpretation task in this case is akin to situated dialogue where user utterances must be grounded within a physical environment (Liu et al., 2014, Gorniak et al., 2007). However, even these situated dialogue models typically rely on a world defined by a limited number of entities (e.g., a chair or a cup).

To address these challenges, this paper presents a step toward semantic grounding for complex problem-solving dialogues, in which the number of potential entities (e.g., a Java variable or a piece of code) is infinite. The present work focuses on the semantic understanding of *noun phrases*, which tend to bear significant semantic information for each utterance. Although noun phrases are typically small in their number of tokens, their complexity and semantics vary in important ways. For example, in the domain of computer programming, two similar noun phrases such as "the 2 dimensional array" and "the 3 dimensional array" refer to two different entities within the problem-solving artifact. Inferring the semantic structure of the noun phrases is necessary to differentiate these two references within a dialogue, to ground them in the task, and to respond to them appropriately.

This noun phrase grounding task is similar to coreference resolution, which discovers the relationship between pairs of noun phrases in a piece of natural language text (Culotta, Wick, & Mccallum, 2007; Lappin & Leass, 1994). However, different from coreference resolution, noun phrase grounding links natural language expressions to entities in a real world environment. The current approach leverages the structure of noun phrases, mapping their segments to attributes of entities to which they should be semantically linked. In order to overcome the limitation of needing to fully enumerate the entities in the environment, we represent the entities as automatically extracted vectors of attributes. We then perform joint segmentation and labeling of the noun phrases in user utterances to map them to the entity vectors (used to describe entities within the environment). This mapping of noun phrases to real-world attributes is the grounding task focused on in this work. The results show that a Conditional Random Field performs well for this task, achieving 89.3% accuracy. Moreover, even in the absence of lexical features (using only dependency parse features and parts of speech), the model achieves 71.3% accuracy, indicating that it may be tolerant to unseen words. The flexibility of this approach is due in part to the fact that it does not rely on a syntactic parser's ability to accurately segment within noun phrases, but rather includes parse features as just one type of feature among several made available to the model. Finally, in contrast to methods based on bag-of-words such as latent semantic analysis, the proposed approach models the structure of noun phrases to facilitate specific grounding within an artifact.

The remainder of this paper is structured as follows. Section 2 presents related work on semantic interpretation and on natural language interpretation for tutorial dialogue. Section 3 describes the corpus and highlights some of the characteristics of dialogue for complex problem solving. The semantic interpretation approach is introduced in Section 4, with the experiments and results presented in Section 5. Section 6 concludes with important directions for future work.

2 Related Work

The approach presented in this paper draws upon a rich foundation of research in semantic interpretation and specifically upon dialogue interpretation for tutorial dialogues. Each of these areas of related work is discussed in turn.

2.1 Semantic Interpretation

The current work is closely related to several well-established research directions within the computational linguistics literature: semantic role labeling, semantic parsing, and language grounding. Semantic tagging assigns a semantic role label to text segments in a sentence (Pradhan, et. al, 2004). The set of semantic roles are relatively coarse-grained, not mapping to specific entities within the world. In contrast, the approach used in this paper does perform semantic role labeling, but the semantic grounding of these text segments are extracted at the same time. Semantic parsing addresses a more complex problem than semantic role labeling: in-

terpreting the semantic structure of a sentence. Supervised semantic parsing requires a target logical form for each sentence, which is costly (Zettlemoyer et. al, 2012). Unsupervised methods rely on accurate dependency parsing, and the semantics learned with unsupervised methods are not directly grounded in a domain (Poon et al., 2009). Our approach does not require a logical form or accurate parse in order to train the model.

Another aspect of semantic interpretation involves language grounding, which links natural language to representations of entities in the (often physical) world directly. Matuszek et al. (2012) propose a joint language/perception model to learn attribute names in a physical environment. Barnard et al. (2003) learn interpretation of segments of images in words with a number of models. Liu et al. (2014) label the referential entities in a collaborative discourse with graph mapping. All of these approaches work in scenarios in which the number of entities is limited. This is different from the case of a complex problem-solving domain in which there could be infinitely many combinations of entities and surface forms of the problem-solving artifact. Thus, building an entity graph to model the relationships between entities would be intractable. Grounding based on semantic interpretation using our approach will address this problem since it first narrows down the category of entity for a noun phrase and then grounds within a family of factorized vectors.

2.2 Language Understanding in Tutorial Dialogue Systems

All dialogue systems employ some form of semantic interpretation. Within tutorial dialogue, some dialogue interpretation relies on a manually defined domain-specific grammar and lexicon (Lemon et al., 2001, Evens et al., 2005). CIRCSIM-Tutor (Evens et al., 2005), a tutorial dialogue system in the domain of cardiovascular physiology, uses a set of finite state transducers and a domain-specific lexicon. Such domain-specific grammars are successful within well-formed domains but become unwieldy in larger or ill-defined domains.

Another approach is to employ an open-domain parser in combination with domain-specific knowledge. CARMEL (Rosé, 2000) is a natural language understanding component that has been used in multiple dialogue systems (Zinn et al., 2000; Litman, 2004; VanLehn et al., 2002). CARMEL uses a semantic interpretation framework that performs semantic interpretation with semantic constructor functions during syntactic parsing. The semantic interpretation employs encoded domain-specific semantic knowledge and a frame-based representation.

Dzikovska et al. (2007) proposed an approach that divides the logical form representation of utterances and the knowledge representation ontology in order to make a NLU component adaptable for multiple domains. The logical form representation contains high-level word sense and semantic role labels. Then, a contextual interpreter is employed for mapping between the logical form and the domain ontology. This work still relies on an open domain parser to generate the logical forms.

Different from all of the approaches mentioned above, AutoTutor (Graesser et al., 2004) uses latent semantic analysis (LSA) to evaluate students' utterances by comparing them to a handcrafted expected answer. LSA represents semantics as a high-dimensional vector and computes similarity between pieces of text. As a bag-of-words approach, LSA does not capture the kind of semantic structure that facilitates specific language grounding in an environment.

3 Corpus of Complex Problem Solving Dialogue

Complex problem solving is defined within the psychology literature as the process of reaching a goal state by applying multiple problem solving skills, when the desired goal state cannot simply be reached by applying one from a set of existing solution patterns (Greiff et al., 2013; Mayer et al., 2006; Funke, 2010). Dialogue surrounding complex problem solving is therefore grounded within a problem-solving artifact that could have infinitely many surface forms. The complex problem-solving domain that is the focus of this paper is computer programming, specifically Java programming, and the corpus under consideration reflects textual tutorial dialogue exchanged between two humans in support of that problem solving.

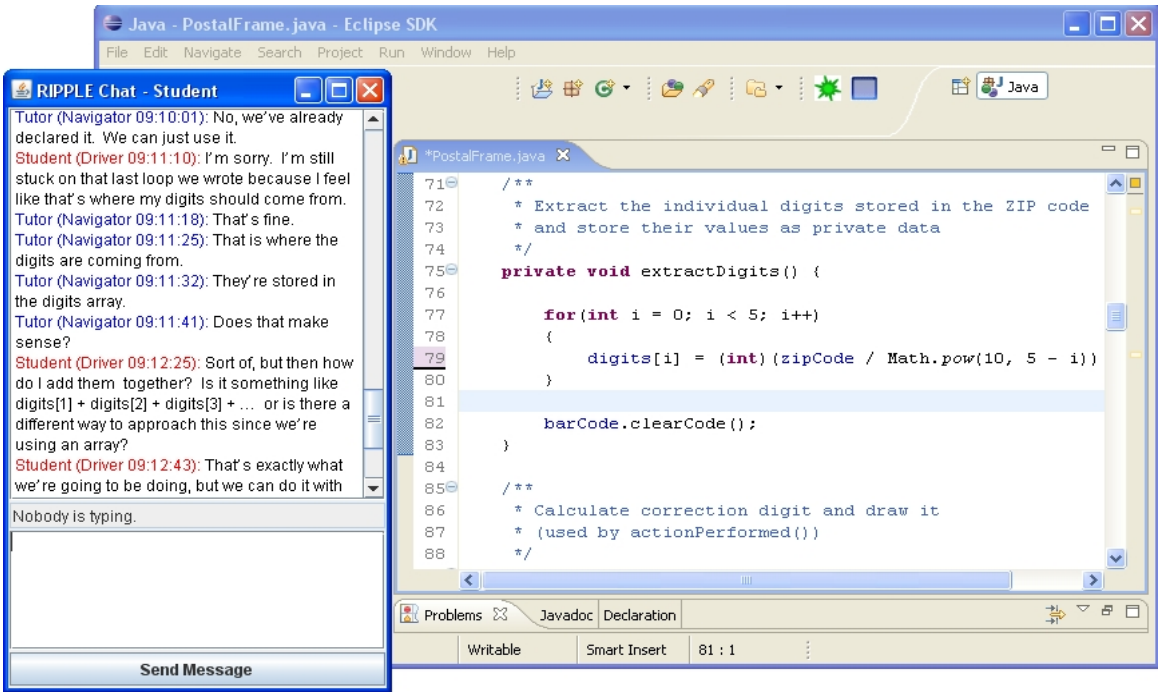

Figure 1. Tutorial dialogue interface.

The corpus was collected within a tutorial dialogue study in which human tutors and students interacted through a tutorial dialogue interface that supported remote textual communication (Boyer et al., 2011) The tutorial dialogue interface (Figure 1) consists of two windows that display interactive components: the student's Java code, the compilation or execution output associated with the code, and the textual dialogue messages between the student and tutor. All of the information in these two windows was synchronized between the student's screen and tutor's screen in real time.

The corpus contains 45 Java programming tutorial sessions from student-tutor pairs, with a total of 4857 utterances, an average of 108 utterances per session. For the current work, six of these tutorial sessions were manually annotated for their semantic grounding (as described in Section 5), a total of 758 utterances. The problem students solved during this tutorial dialogue involved creating, traversing, and modifying parallel arrays. This task was challenging for students and represented a complex problem-solving effort since the students were novices who were enrolled in an introductory computer programming class.

The dialogues within this domain are characterized by situated features that pertain to the programming task. A portion of user utterances refer to general Java knowledge, and in these cases semantic interpretation can be accomplished by mapping to a domain-specific ontology (e.g., Dzikovska et al., 2007). In contrast, many utterances refer to concrete entities within the dynamically changing, user-created programing artifact. Identifying these entities correctly is crucial for generating specific tutorial dialogue moves. A dialogue excerpt is shown in Figure 2.

4 Methodology

To ground the dialogue utterances as described in the previous section, our approach focuses first upon noun phrases, which contain rich semantic information. This section introduces the approach, based on Conditional Random Fields, to jointly segment the noun phrases and link those segments to entities within the domain.

4.1 Noun Phrases in Domain Language

A noun phrase is defined as "a phrase which has a noun (or indefinite pronoun) as its head word, or which performs the same grammatical function as such a phrase" (Crystal, 1997). The syntactic structure of a noun phrase consists of dependents which could include determiners, adjectives, prepositional phrases, or even a clause. For example, let us con-

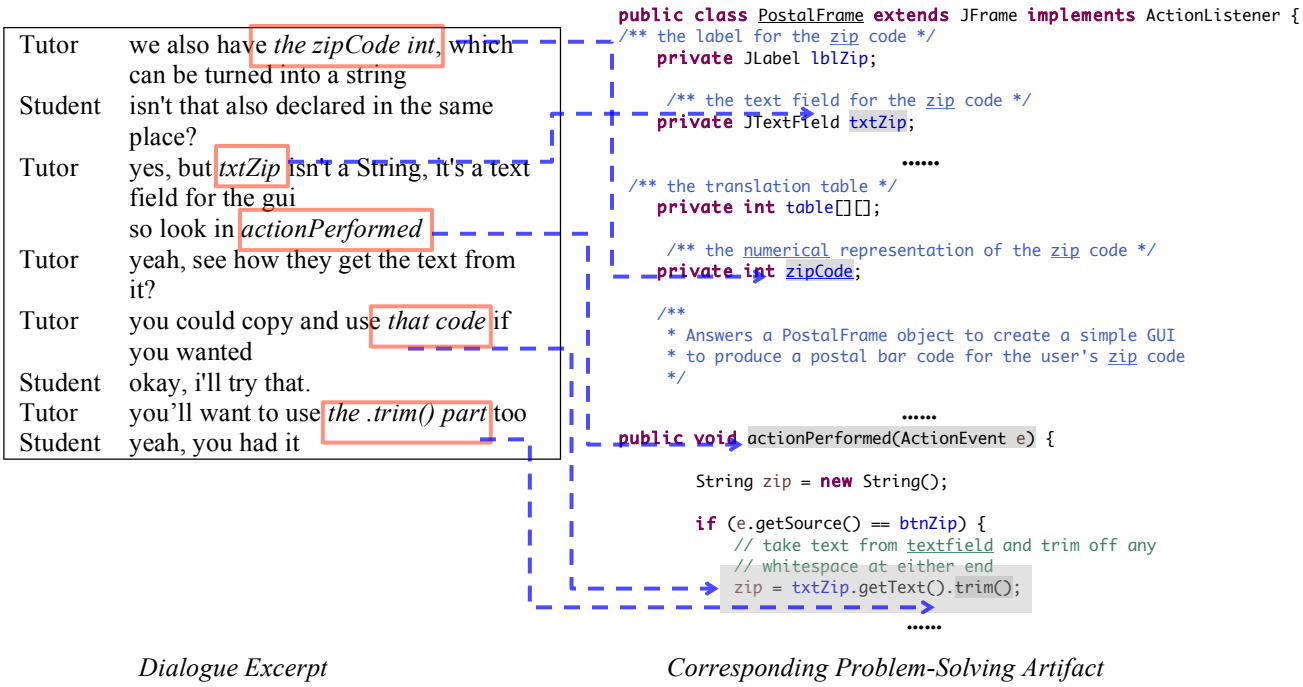

Figure 2. Dialogue excerpt from the corpus.

sider the noun phrase *"a 2 dimensional array"*. Its head is *"array"* and its dependents are *"a"* as the determiner and "2 dimensional" as an adjective phrase. In this simple case the syntactic boundaries also indicate semantic segments, as these dependents indicate one or more attributes of the head. If this relationship were always true, the semantic structure understanding task would be a labeling task that only requires assigning a semantic tag to each syntactic segment of the noun phrase. But this is not always true, in part because a syntactic parser trained on an open-domain corpus will not necessarily perform well on domain language (McClosky et al., 2010). For example, in the noun phrase *"the outer for loop,"* which also occurs in the Java programming corpus, the head of the noun phrase is "*for loop*," but the syntactic parse (generated by the Stanford parser) of this noun phrase understandably (but incorrectly) identifies this head as part of a prepositional phrase (Figure 3).

To address this challenge, this paper utilizes a joint segmentation and semantic labeling approach that does not rely on accurate syntactic parsing within noun phrases. In this approach the head and dependents of each noun phrase are each referred to as a *segment,* with exactly one segment per dependent, and one or more words per segment. Identifying these segments correctly is essential to correct assignment of semantic tags. Pipeline methods for semantic segmentation rely on stable performance of an open domain parser, but as described above, this assumption is not desirable for grounding some domain language. We therefore utilize joint segmentation and labeling and apply a Conditional Random Field approach (Lafferty, 2001), a natural choice for the sequential data segmentation and labeling problem.

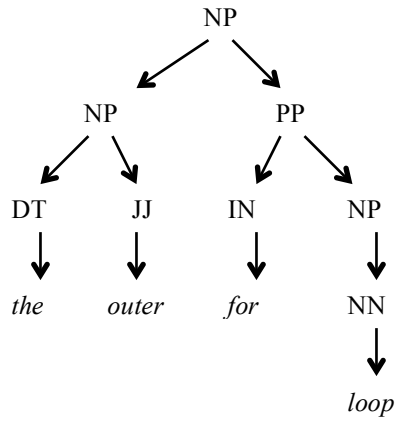

Figure 3. A parse of *"the outer for loop"* from Stanford Parser.

4.2 Description Vector

The goal is to ground each noun phrase to attributes of entities within the problem-solving artifact, which constitutes the "world" in this domain. To do this, we will link each semantic segment in a noun phrase to an attribute of an entity in the world. Because the world can contain any of an infinite set of user-created entities, representation cannot rely upon exhaustively enumerating the entities. To represent an entity in the domain, we define a description vector V which defines the attribute types for entities in the domain. Then, an entity O in the domain is represented uniquely by an instance of V. The values of each V_i indicate the value of the attribute i of O, as illustrated in Table 1. This definition of the description vector relies upon the structure of the domain by factorizing the attributes of entities.

With this representation, grounding a noun phrase involves linking each segment of the noun phrase to an attribute in the description vector. Formally, we represent a noun phrase as a series of segments:

$$NP = < s_1, s_2, ..., s_k >$$

where s_i is the i_{th} segment in this noun phrase. A noun phrase is also a sequence of words:

$$NP = < w_1, w_2, ..., w_n >$$

where each w_j is the j^{th} word in the noun phrase. Therefore each segment is a series of words:

$$s_i = < w_j, w_{j+1}, ..., w_{j+l-1} >$$

where l is the length of semantic segment i.

Given a noun phrase, the segmentation problem is thus choosing a segmentation that maximizes the following conditional probability:

$$p(< s_1, s_2, ..., s_k > \mid < w_1, w_2, ..., w_n >)$$

Complementary to the segmentation problem is the semantic linking problem, which is to link s_i to an attribute a_i, which is the label of the i^{th} attribute in the entity description vector. That is, we wish to maximize the probability of the attribute label sequence a given the segments of the noun phrase:

$$p(< a_1, a_2, ..., a_k > \mid < s_1, s_2, ..., s_k >)$$

Taking consecutive words with the same attribute label as the same semantic segment, the noun phrase segmentation and semantic linking problem is then:

$$\underset{a}{argmax}\, p(< a_1, a_2, ..., a_n > \mid < w_1, w_2, ..., w_n >)$$

In the tag sequence $<a_1, a_2, ..., a_n>$, if a_i and a_{i+1} are the same, then w_i and w_{i+1} are assigned to the same semantic segment with tag a_i. The process of segmentation and semantic linking is illustrated in Figure 4.

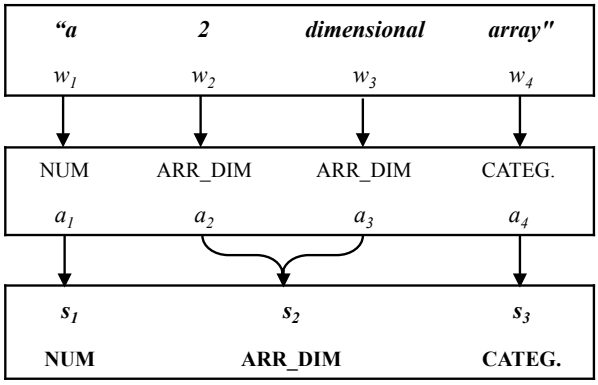

Figure 4. Segmentation and semantic linking of NP *"a 2 dimensional array."*

4.3 Joint Segmentation and Labeling

In order to perform this joint segmentation and labeling, we utilize a Conditional Random Field (CRF), which is a classic approach for sequence segmentation and labeling (Lafferty et al., 2001). Given the linear nature of our data, we employ a linear chain CRF. Specifically, given a sequence of words w, the probability of a label sequence a is defined as

$$p(a \mid w) = \frac{1}{Z(w)} \exp\left(\sum_{i=1}^{n} \sum_{j=1}^{m} \lambda_j f_j(i, w, a_i, a_{i-1})\right)$$

where $f_j(i,w,a_i,a_{i-1})$ is a feature function. The weights λ_j of this feature function are learned within the training process. The normalization function $Z(w)$ is the sum over the weighted feature function for all possible label sequences:

$$Z(w) = \sum_{a} \exp\left(\sum_{i=1}^{n} \sum_{j=1}^{m} \lambda_j f_j(i, w, a_i, a_{i-1})\right)$$

The optimal labeling $\hat{a}$ is the one that maximizes the likelihood of the training set, where K is the number of noun phrases in the corpus.

$$\hat{a} = argmax\left(\sum_{i=1}^{K} \log P(a^{(i)} \mid w^{(i)})\right)$$

4.4 Features

Next, we introduce the features used to train the CRF. The feature function $f_j(i,w,a_i,a_{i-1})$ was defined as a binary function, in which w is a feature value. We use both lexical and syntactic features. In a trained CRF model, the value of $f_i(i,w,a_i,a_{i-1})$ is known given a combination of parameters (i,w,a_i,a_{i-1}). The features used in the CRF model include words themselves, word lemmas, parts of speech, and dependency relationships from the syntactic parse. The word itself, lemmatized words and parts-of-speech have all been shown useful within segmentation and labeling tasks, so they are made available here (Xue et al., 2004). Each of these features is represented as categorical data. For example, a word is represented as its index in a list of all of the words that appeared in the corpus.

The dependency structure of natural language has also been shown to be important in semantic interpretation (Poon et al., 2009). This paper employs a dependency feature vector extracted from dependency parses. The head word of each noun phrase is the root of the dependency tree. Each dependent is a sub-tree directly under the head. We design the dependency feature as a sequence of dependency labels as follows.

Given a dependency tree, words in each semantic segment of the noun phrase are assigned a tag according to the relationship between them and the head. The relationship between each segment and head is defined by the dependency type in the dependency tree. For example, the dependency tree of *"a 2 dimensional array"* is shown in Figure 5. The dependency features are *<det,amod,amod,root>*. In this way, the dependency information from an open-domain parser is encoded as a feature to the semantic grounding model.

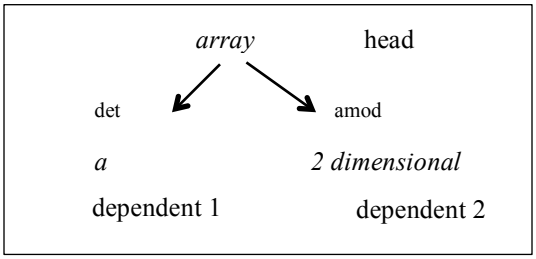

Figure 5. Dependency structure of *"a 2 dimensional array."*

5 Experiments & Results

The goal of the experiments is to determine how well the trained CRF can segment noun phrases and link these segments to the correct attribute of entities in the world. This section presents the experiments using CRFs trained and tested on the Java programming tutorial dialogue corpus. As described below, the results were evaluated by comparing with manually labeled data.

Noun phrases from the tutorial dialogues were first manually extracted and annotated as to their slots in the description vector described in Section

Attributes	**Meaning (in Java programming)**	**Example**
CATEGORY	Category of an entity	`Method, Variable, etc.`
NAME	Variable name; often user-created	`extractDigit`
VAR_TYPE	Type of variable	`int, String, etc.`
NUMBER	Number of entities	`2`
IN_CLASS	The class that contains this entity	`postalFrame`
IN_METHOD	The method that contains this entity	`actionPerformed`
DIR_PARENT	Direct parent entity	`For_Statement, Method`
LINE_NUMBER	Line number	`67`
SUPER_CLASS	Superclass of this entity	`JFrame`
MODIFIER	Access modifier	`public, private, etc.`
ARRAY_TYPE	Type of Array	`int, char, etc.`
ARRAY_DIMENSION	Dimension of array	`2, 1`
OBJ_CLASS	The class an object instantiates	`PostalBarCode`
RETURN_TYPE	Return type	`String, int, etc.`
OTHER	Other attributes	`the, extra, etc.`

Table 1. Elements of entity description vector to which noun phrases are mapped.

4.2. There were 364 grounded noun phrases extracted manually from the six tutorial dialogue sessions used in the current work. Each of these noun phrases extracted has one or multiple corresponding entities in the programming artifact. Since each word in a noun phrase is linked to an element in the description vector, the indices in this vector were used as the label for each word. Annotation of all 346 noun phrases was performed by one annotator, and 20% of the noun phrases (70 noun phrases) were doubly annotated by an independent second annotator. The percent agreement was 85.3% and the Kappa was 0.765.

To extract features, the lemmatization and syntactic parsing were performed with the Stanford CoreNLP toolkit (Manning et al., 2014). Then, a CRF was trained to predict the label for each word in a new noun phrase. The training was performed with the crfChain toolbox (Schmidt, 2008).

We use ten-fold cross-validation to evaluate the performance of the CRF in this problem. Results with different feature combinations are shown in Table 2. Manually labeled data were taken as ground truth for computing accuracy, which is defined as the percentage of segments correctly labeled.

Recall that consecutive words with the same label in a noun phrase are treated as a segment. Therefore, if a segment s_{CRF} identified by the CRF has the same boundary and the same label as a segment s_{Human} in the noun phrase containing s_{CRF}, this segment s_{CRF} will be counted as a correct segment. Otherwise, s_{CRF} will be counted as incorrect. The accuracy is then calculated as the number of correct segments identified by the CRF divided by the number of segments annotated manually. As can be seen in Table 2, all of the models perform substantially better than a minimal majority class baseline of 43%, which would result from taking each word as a segment and assigning it with the most frequent attribute label.

The results demonstrate important characteristics of the segmentation and labeling model. First, unlike most previous semantic interpretation work, our semantic interpretation of noun phrases does not rely on accurate syntactic parse within noun phrases. Rather, we use a dependency parse from an open-domain parser as only one of several types of features provided to the model. These dependency features improved the model in most feature combinations (Table 2). The feature combination of words, lemmas, and dependency parses achieved the best accuracy, which is 4.8% higher than the model that only used word features. This difference is statistically significant (Wilcoxon rank-sum test; n=10; p=0.02).

features	accuracy
word	84.5%
word + lemma	85.5%
Word + Dep	87.22%
lemma + Dep	89.1%
word + lemma + Dep	**89.3%**
word + lemma + POS	86.9%
word + lemma + POS + Dep	88.7%
POS + Dep	71.3%

Table 2. Labeling accuracy.

Notably, the combination of part-of-speech features and dependency parse features still performed at 71.3% accuracy, indicating that to some extent, the method may be tolerant to unseen words.

6 Conclusion and Future Work

This paper has presented a technique for semantic grounding of noun phrases in a complex problem-solving domain, tutorial dialogue for computer programming. By performing joint segmentation and labeling of noun phrases from user utterances, and mapping those segments to attributes of entities within the problem solving artifact, we have made a first step toward grounding complex problem-solving dialogue within a dynamically changing artifact from a potentially infinite set of surface forms. While trained on a small subset of the corpus, the high accuracy of this model indicates that it may be successfully applied to the larger corpus without extensive additional manual annotations.

Several directions of future work are very promising. In order to fully support users in complex problem-solving dialogues, the field must move toward richer grounding of natural language utterances within complex artifacts across many domains. Additionally, generating specific and tailored dialogue feedback grounded in the artifact is a complementary area of research that holds the potential to increase the effectiveness of dialogue systems for supporting problem solving. It is hoped that this line of investigation will lead to dialogue systems that smoothly support a much broader range of human endeavors.

Abstract

We describe how a question-answering system can learn about its domain from conversational dialogs. Our system learns to relate concepts in science questions to propositions in a fact corpus, stores new concepts and relations in a knowledge graph (KG), and uses the graph to solve questions. We are the first to acquire knowledge for question-answering from open, natural language dialogs without a fixed ontology or domain model that predetermines what users can say. Our relation-based strategies complete more successful dialogs than a query expansion baseline, our task-driven relations are more effective for solving science questions than relations from general knowledge sources, and our method is practical enough to generalize to other domains.

1 Introduction

Our goal is a question-answering (QA) system that learns about its domain from users in open, natural language dialogs. Dialog learning interfaces built on top of existing QA systems can complement and refine knowledge acquired from other sources. Even large QA systems such as Watson (Ferrucci et al., 2010) that utilize heavy domain engineering could benefit from focused dialogs to dynamically improve their knowledge.

A successful QA system requires domain knowledge. For example, 4th grade science questions are difficult since they often exclude knowledge necessary to relate answers to known facts. The question in Figure 1 asks if an *iron nail* conducts electricity;

S1: Here's the question: Which object is the best conductor of electricity? (A) a wax crayon (B) a plastic spoon (C) a rubber eraser (D) an iron nail. I'm not sure of the answer. What do you think the answer is?
U1: iron nail
S2: Why do you think the answer is (D) an iron nail?
U2: electricity goes through metal
S3: I know "metals are shiny and good conductors of electricity and heat," does that mean that the answer is (D) an iron nail?
U3: yeah
S4: Okay, great. What's the relationship between 'electricity' and 'iron', if any?
U4: iron conducts electricity because its metal
S5: Okay, great, I get it! The answer is (D) an iron nail

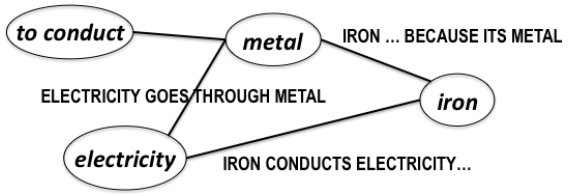

Figure 1: Top: A successful real user dialog. Open-ended prompts (S1&S2) encourage conversational explanations. Focused prompts (S4) target particular relations. Bottom: Corresponding knowledge graph consisting of relations between concepts.

the system only knows that *metal* conducts electricity, and it needs to learn that *iron* is a *metal* in order to answer the question with the relevant fact.

Our dialog system, KNOWBOT, conducts dialogs about science questions and learns how concepts in each question relate to propositions in a corpus of science facts. KNOWBOT presents its user with a question (line S1 in Figure 1), prompts them to choose and explain their answer, and extracts *relations* – any semantic relationship between two con-

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 851–861,
Denver, Colorado, May 31 – June 5, 2015.

cepts, such as *metal* to *iron* (line U4 in Figure 1) – that increase its confidence in the user's answer.

Relation extraction systems such as NELL (Carlson et al., 2010) use ontologies to predetermine valid relation types and arguments, then scan text to fill the ontology with facts. Open Information Extraction (Etzioni et al., 2011) avoids fixed ontologies with domain-independent linguistic features, distant supervision, and redundancy, but requires web-scale text and doesn't improve with interaction. Like Open IE, we extract relations without predetermined types, but are the first to do so from dialog.

KNOWBOT is an *open* dialog system, which means a user utterance may progress the dialog task even if its underlying action is not explicitly represented in a dialog model. This lets KNOWBOT quickly bootstrap domain knowledge from users without significant engineering overhead. Dialog-driven extraction produces effective relations without annotation, improves after each interaction, acquires relations useful on a particular task, and embeds relations in a rich dialog context.

Users successfully correct the system in approximately 50% of dialogs even without a predetermined dialog model. A baseline query expansion (Bast et al., 2007) strategy that bases decisions on the acquisition of new keywords instead of new relations results in only a 5% success rate. In comparison to paraphrase relations from general knowledge bases, relations acquired by our method are more effective as domain knowledge, demonstrating that we successfully learn from real users.

Our contributions include:

1. The first end-to-end system to construct knowledge graphs for question-answering through conversational dialog.

2. A generalizable method to represent the meaning of user utterances without a dialog model when task progression can be computed as a function of extracted relations.

3. A novel data set of real user dialogs in which users correct a QA system's answer, together with knowledge graphs representing the important concepts and relations in each question, labeled with rich dialog features.

2 Conversational extraction for QA

Our QA task consists of 107 science questions from the 4th grade New York Regents exam (Clark et al., 2014).[1] Each question has four possible answers. We convert each of the four question-answer pairs into a true/false *question-answer statement* using a small number of pattern-based transformation rules.

Just as 4th graders read their textbooks for answers, we collect SCITEXT (Clark et al., 2014), a corpus of unlabeled true-false natural language sentences from science textbooks, study guides, and Wikipedia Science. Each question-answer statement is associated with a subset of true/false support sentences from SCITEXT based on positive word overlap between the question-answer pair and the support sentence. The degree to which a SCITEXT sentence supports a question-answer pair is the sentence's *alignment score* (section 2.3).

Initially, the alignment score depends on keyword overlap alone, but SCITEXT needs domain knowledge to answer our questions. For example, the correct question-answer statement to *What form of energy causes an ice cube to melt? (A) mechanical (B) magnetic (C) sound (D) heat* is $Q_{(D)}$, "Heat is a form of energy and heat causes an ice cube to melt." To better align $Q_{(D)}$ to the SCITEXT sentence "A snowball melting in your hand is an example of heat energy," we need to know that *snowballs* are made of *ice*. Figure 2 illustrates this example.

To construct a knowledge base with which to use SCITEXT, we extract *concepts* (section 2.1) from questions and SCITEXT sentences, then use *relations* (section 2.2) between concepts to determine which question-answer statement Q_i is most highly aligned with a supporting SCITEXT sentence.

2.1 Concepts

A *concept keyword* in a sentence or user utterance is any non-stopword of at least three characters. Stopwords are domain-independent, low-information words such as "the."

A *concept* is a set of concept keywords with a common root, e.g. {*melts, melted, melting*} or {*heat, heats, heated*}. We use the Porter algorithm for stemming (Porter, 1997). *Question concepts* ap-

[1] Our dialogs, extractions, and tools are available at `www.cs.washington.edu/research/nlp/knowbot`

pear in a question-answer statement, and *support concepts* appear in a SCITEXT support sentence.

2.2 Relations

A *relation* is any pair of concepts that represents a semantic correspondence. In general, relations can be labeled with any feature that describes the correspondence, such as a particular *type*. For example, the relation between *Obama* and *Hawaii* can be labeled with the type *born-in*.

A predetermined ontology is typically required to label relations with their type. In this work we label acquired relations with dialog-specific features. Our thesis is that user explanations intend to relate concepts together, and the system's task is to determine the user's intent. For example, the user utterance `U: it's melting because of heat` relates the concepts represented by *melt[ing]* and *heat*, with the words `because of` appearing between the two concept keywords. We refer to `because of` as the relation's *intext*.

Relations can be intuitively arranged as a *knowledge graph*, which in this work is any graph whose nodes are concepts and whose edges are relations between those concepts, in the spirit of semantic networks such as ConceptNet (Havasi et al., 2007).

2.3 Sentence alignment

We calculate the alignment score α between the ith question-answer statement Q_i and its jth supporting SCITEXT sentence $S_{i,j}$ as the normalized number of relations between their concepts,

$$\alpha(Q_i, S_{i,j}) = \frac{\|R_{Q_i,S_{i,j}}\|}{\|C_{Q_i} \cup C_{S_{i,j}}\|}, \qquad (1)$$

where C_{Q_i} is the set of concepts in Q_i, $C_{S_{i,j}}$ is the set of concepts in $S_{i,j}$, and $\|R_{Q_i,S_{i,j}}\|$ is the number of relations between C_{Q_i} and $C_{S_{i,j}}$.

Normalized relation count is a practical semantic similarity score that generalizes to different knowledge representations. The dialog in Figure 2 aligns $Q_{(D)}$ with the SCITEXT fact S by learning from the user that, for example, *heat* is related to *melting*.

3 The KNOWBOT dialog system

KNOWBOT grows a knowledge graph of commonsense semantic relations in open, conversational dialog. Figure 2 traces the growth of a knowledge graph over a single dialog. Section 3.1 details how knowledge is extracted from user explanations without a dialog model. Section 3.2 describes dialog strategies that elicit natural language explanations.

KNOWBOT uses task progress to drive natural language understanding. It assumes the user intends to provide one or more novel relations, and uses the constraints described in section 3.1.1 to disambiguate noisy relations. This way, KNOWBOT knows when the dialog progresses because its confidence in the user's chosen answer increases.

3.1 Building knowledge graphs from dialog

KNOWBOT builds KGs at three levels: per utterance, per dialog, and globally over all dialogs. An *utterance-level knowledge graph* (uKG) (Figure 2a) is a fully connected graph whose nodes are all concepts in an utterance. After aggressive pruning (section 3.1.1), remaining edges update a *dialog-level knowledge graph* (dKG) (Figure 2b; section 3.1.2).

Upon dialog termination, the dKG updates the *global knowledge graph* (gKG), which stores relations acquired from all dialogs (section 3.1.3).

3.1.1 Utterance-level KGs

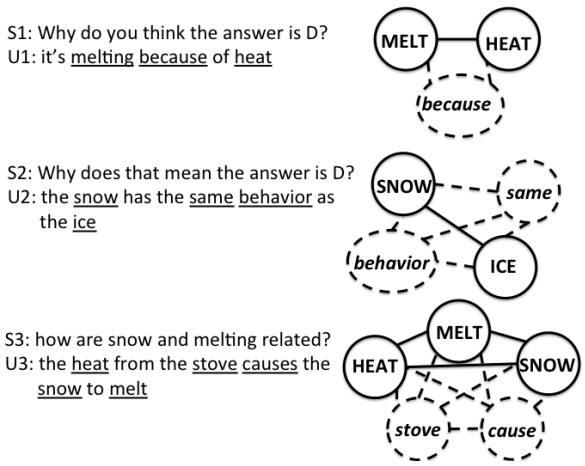
KNOWBOT initially relates every pair of concepts in an utterance, then prunes them based on two constraints: *alignment* and *adjacency*.

Each user explanation is first converted into a fully-connected utterance-level knowledge graph. This uKG is noisy because users don't intend relations between every pair of keywords in their utterance. For example, a typical utterance `U: freezes means it changes water from a liquid to a solid` mentions six concepts, *freezing, meaning, change, water, liquid, solid*, with $\binom{6}{2}$ potential binary relations. Not every relation is salient to the question. To remove noisy relations, edges in the uKG are aggressively pruned with two simple, rational constraints:

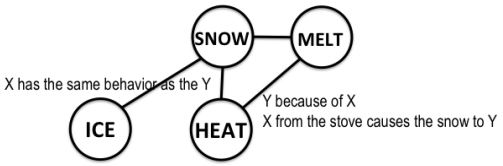
1. *Alignment*. An edge can only relate a question concept to a support concept.

2. *Adjacency*. Edges can't relate concepts whose keywords are adjacent in the utterance.

The intuition for the alignment constraint is that the user intends each explanation to relate the question



(a) utterance-level knowledge graph (uKG)



(b) dialog-level knowledge graph (dKG)

Q = heat is a form of energy and heat causes an ice cube to melt
S = a snowball melting in your hand is an example of heat energy

(c) The dialog goal is to align Q and S

Figure 2: Every pair of concepts in each user utterance is related then aggressively pruned. (a) Utterance-level knowledge graphs represent individual utterances. Concepts (underlined, inset in nodes) are obtained by removing stopwords and stemming. An edge that either doesn't connect a question and support concept or else which connects concepts whose keywords in the user utterance have no intervening words (*intexts*) are pruned, indicated here with dashed lines. (b) The four remaining relations are stored in a dialog-level dKG.

to a known fact, and other relations in the utterance are unintentional. For example, in the uKG for the first utterance in Figure 2(a), the edge between *melt[ing]* and *heat* is an alignment relation because *melt[ing]* is a concept in S and *heat* is a concept in Q. But the edge between *because* and *heat* is pruned (dashed lines) since *because* is not a concept in S.

Adjacency is a simple, practical syntactic feature to reduce spurious relations. Users typically put words or *intexts* between concepts they intend to relate. The edge between *melt[ing]* and *because* is pruned since their keywords are adjacent in `U1: it's melting because of heat`, while `U2` relates *snow* and *ice* with the intext `has the same behavior as the`.

We find these constraints effective in practice, but at this point other pruning constraints can be deployed. A strength of our approach is that it welcomes aggressive pruning: just as in human-human interaction, users who initially fail to communicate their intention can try again later in the dialog.

3.1.2 Dialog-level KGs

Each dialog focuses on a single question. KNOWBOT starts with an empty dialog-level knowledge graph (dKG). After each user turn, edges from that turn's uKG are added to the dKG, and KNOWBOT rescores each of the four answers according to equation (1) where the set of relations $R_{Q_i,S_{i,j}}$ is exactly the set of edges in the dKG. The dialog successfully terminates when the user's answer has the highest alignment score, indicating the "missing knowledge" has been successfully provided by the user.

3.1.3 The global knowledge graph

The *global knowledge graph* (gKG) includes every relation learned from every KNOWBOT dialog.

Because we do not use a fixed ontology or comprehensive dialog model, individual dialogs can result in noisy relations even after aggressive pruning. However, as KNOWBOT conducts more dialogs about the same problem, relations that more often re-occur are more likely to be salient to the problem.

In this work, KNOWBOT takes advantage of redundancy with a simple filter: it ignores *singleton* relations originating in a single user utterance. We find even this simple filter increases performance. As KNOWBOT accumulates more dialogs, frequency can be incorporated in more sophisticated models.

3.2 Dialog strategies for knowledge acquisition

We've described how a user's free text explanations are converted into knowledge graphs. Each user explanation is uttered in response to a system

prompt. A dialog system's *dialog manager* chooses the prompt to say next according to its *dialog strategy*, which maps each system state to an action. An effective dialog strategy guides users to informative explanations that provide novel relations which let KNOWBOT successfully answer the question.

We compare two different strategies. A *user-initiative* strategy always asks open-ended questions to prompt the user for new explanations, e.g. line S2 in Figure 1. These prompts let users introduce salient concepts on their own.

In contrast, a *mixed-initiative* strategy utilizes focused prompts (line S4 in Figure 1) to introduce potentially related concepts. KNOWBOT chooses what pair of concepts to ask about based on how *discriminative* they are. The most discriminative concepts are the pair of question and support concepts that (1) don't already have an edge between them, (2) satisfies the alignment constraint for the user's answer, and (3) satisfies the alignment constraint for the fewest alternative answers. By proposing relations that would lead to a swift completion of the dialog task, KNOWBOT shares the burden of knowledge acquisition with the user.

Both dialog strategies are question-independent, but because we don't use a comprehensive dialog model to represent the state space, we rely on hand built rules instead of optimizing with respect to a reward function. For example, KNOWBOT always starts by asking the user for their answer, and if a new support sentence is found will always immediately present it to the user for confirmation.

4 Evaluation of dialog strategies

Our first experiment compares mixed-initiative and user-initiative strategies (section 3.2) to a baseline interactive query expansion (section 4.1). The purpose of this experiment is to investigate whether users can successfully complete our complex dialog task even though we don't use a trained semantic parser for natural language understanding.

Dialogs were conducted through a web browser. Users were colleagues and interns at the Allen Institute for Artificial Intelligence, and so were familiar with the question-answering task but were not expert annotators. Users were invited to converse with the system of their choice, and to move on to a new question if they felt the dialog was not progressing. Individual dialog sessions were anonymous.

The system starts each dialog with an empty knowledge graph, using only *identity* relations to select its answer. This default answer is correct on 44 of the 107 questions, and an additional 10 questions have no associated supporting sentence for the correct answer in SCITEXT. We run dialogs for the remaining 53 questions, for which each answer candidate has 80 supporting sentences in SCITEXT on average. A successful dialog terminates when the system extracts enough novel relations from the user that the correct answer has the highest alignment score with one of its supporting sentences.

4.1 Baseline: Interactive query expansion

To evaluate whether task-driven relation extraction is an effective method for knowledge acquisition in the absence of an explicit dialog model, we also implement a baseline dialog strategy based on interactive *query expansion* (IQE). This baseline is similar to the recent knowledge acquisition dialog system of Rudnicky and Pappu (2014a; 2014b).

In IQE, new knowledge is learned in the form of novel keywords that are appended to the question-answer statement. For example, the dialog in Figure 1 shows the user teaching KNOWBOT how *metal* relates to *electricity*. KNOWBOT understands that the user intends that relation because it drives the dialog forward. IQE, in contrast, treats the user utterance as an unstructured bag of keywords. The unrecognized word "metal" is added to the bag of keywords representing each of the four alternative answers to form four *augmented* queries, and new overlap scores against sentences from SCITEXT are computed. The dialog progresses whenever a new vocabulary word increases the score for the augmented query for the user's chosen answer.

The intuition behind query expansion is that users will explain their answers with salient keywords missing from the original question sentence. The expanded query will overlap with and uprank a support sentence that contains the acquired keywords.

4.2 Performance metrics

Task completion is the proportion of dialogs that end in agreement. Higher task completion indicates that the dialog system is more successful in acquir-

ing enough knowledge by the end of the dialog to change its answer from incorrect to correct.

Dialog length is the number of system and user turns. Shorter dialogs are more efficient.

Acquisition rate is the number of edges in the dKG at the end of each dialog. Acquisition rate measures two contrasting system features:

(1) how much new knowledge is acquired, and

(2) how much *explanatory effort* users expend.

From the perspective of raw knowledge acquisition, higher acquisition rate is better because each dialog adds more edges to the knowledge graph. From the perspective of usability, lower acquisition rate is better provided it doesn't negatively affect dialog success, because it indicates the user is able to successfully correct the system's answer with a fewer number of explanatory relations.

4.3 Results

Our results (Table 1) show both strategies dramatically outperform the baseline and have comparable success rate and dialog length to each other. User-initiative strategies acquire more knowledge per dialog but require more user effort.

	IQE	U.I.	M.I.
Total dialogs	35	27	57
Task completion rate	5.7%	55.6%	49.1%
Mean Dialog Length	14.1	10.6	10.9
Mean acquisition Rate	N/A	13.5	7.4

Table 1: Comparison of knowledge acquisition strategies. Interactive query expansion (IQE)'s poor task completion indicates keywords can't bridge the knowledge gap. Relations are more successful. User-initiative (U.I.) and mixed-initiative (M.I.) strategies have comparable task completion and dialog length, but U.I. extracts twice the relations before getting the correct answer: more knowledge acquired but at the cost of more explanatory effort. User comments indicate M.I. is more satisfying.

We find that the baseline has a very low completion rate of 5%, and longer dialog lengths of 14 turns on average. Interactive query expansion is a poor knowledge acquisition dialog strategy for our task.

In contrast, users were able to successfully correct our system using both strategies about 50% of the time, even though no in-domain ontology guides extractions and no comprehensive dialog model classifies explanations. The average dialog lengths and completion rate for User Initiative (U.I.) and Mixed Initiative (M.I.) strategies was approximately the same, so that choice of strategy had little impact on overall task success. However, strategy has a great effect on acquisition rate. M.I. cuts the knowledge acquisition rate nearly in half when compared to U.I (7.4 novel relations per dialog to 13.5). M.I. learns fewer new relations per dialog with comparable task success, which means each dialog succeeds with much less explanatory effort by the user but also contributes less to the knowledge graph.

User comments indicated that the mixed-initiative strategy was the most enjoyable system to use. We find that open-ended, user-initiative strategies can acquire more helpful relations in a single dialog but guided, mixed-initiative strategies may be more appropriate when usability is taken into account. Because our goal is lifelong interactive knowledge acquisition, the impact of a single dialog on the total knowledge graph is less important than the individual user effort required, and we conclude that the mixed-initiative strategy is preferable.

5 Evaluation of knowledge quality

Experiment 1 evaluated whether users could successfully complete our dialog task. Next, we evaluate whether the total output of our system, all relations acquired during all 431 conducted dialogs, represents useful domain knowledge on this task. We evaluate on questions for which dialogs have been held to investigate whether it's possible to learn any domain knowledge from natural language conversation without a dialog model, irrespective of overfitting. We then use cross-validation to test if knowledge transfers between questions.

As described in section 2, our QA system decomposes each question/answer pair into a true/false statement and chooses as its answer the statement among the four that has the best supporting sentence in a text corpus. Equation (1) scores each question-answer statement by using domain relations to align question concepts to support concepts. The next section describes sources of domain relations.

5.1 Sources of domain knowledge

We compare relations from five sources:

IDENTITY: An edgeless knowledge graph. The only relations are between identical concepts, equivalent to Jaccard overlap of concept keyword roots.

WORDNET: Paraphrase relations from Wordnet. Wordnet (Fellbaum, 1998) is a lexical database of synonyms and hypernyms common in NLP tasks. For example, Snow et al (2006) use Wordnet as training data for ontology induction. To build WORDNET, we draw an edge between every pair of Wordnet concepts (w_s, w_q) for which the Wu-Palmer Similarity (WUP) (Wu and Palmer, 1994) of the first sense in each concept's synset exceeds 0.9, the best-performing WUP threshold we found. Concepts in the Wordnet hierarchy have a higher WUP when they have a closer common ancestor. If a known fact is *Heat energy causes snow to melt*, but a question asks if *ice* melts, then Wordnet should provide the missing knowledge that *ice* acts like *snow*.

PPDB: Paraphrase relations from PPDB (Ganitkevitch et al., 2013) are derived by aligning bilingual parallel texts. PPDB is divided into subsets where the larger subsets have more paraphrases with less precision. We tried all subsets and found the smallest to give the best results, which we report here. The largest performed the worst of all relation sets we tested. We use the lexical paraphrases, which relates unigrams. Concepts are related when at least one concept keyword for each are paraphrases in PPDB. We obtained better performance by stemming PPDB words: for example, if *snows* and *iced* are paraphrases in PPDB then we also considered *snowing* and *icy* to be in PPDB.

KNOWBOT: Each question is answered using relations pooled from all dialogs about all questions. The goal in each dialog is to acquire knowledge helpful to answer the question. If KNOWBOT leads to an increase in QA accuracy over IDENTITY, then we can successfully use open dialog with a human in the loop to learn knowledge that solves a question.

LEAVE-ONE-OUT: Each question is answered only with relations learned during dialogs for every other question. While KNOWBOT uses relations learned from dialogs about the questions on those same questions, LEAVE-ONE-OUT tests whether knowledge generalizes to questions without dialogs. Generalization is only possible when there are at least two questions involving the same concepts. Due to our small number of questions, in the best case we expect only slight improvement.

	%correct
IDENTITY	41%
WORDNET	34%
PPDB	39%
KNOWBOT	**57%**
LEAVE-ONE-OUT	45%

Table 2: QA accuracy on the 107 questions with different sources of domain knowledge. IDENTITY: identity relations only, e.g. "heats" to "heating." WORDNET: Wordnet-derived pseudo-synonyms, e.g. "eagle" to "owl." KNOWBOT: the full, unablated global KG. LEAVE-ONE-OUT: answers each question while ignoring relations acquired during dialogs on that question.

5.2 Results

The results of QA using the different domain knowledge is shown in Table 2. IDENTITY achieves 41% accuracy on this difficult reasoning task, showing that some questions are answerable by searching SCITEXT for supporting sentences with the same concepts as in the question-answer statement. WORDNET works surprisingly poorly. Examination found WORDNET's relations to be of good quality, yet underperform IDENTITY. PPDB performed better but still underperformed IDENTITY. We conclude that general paraphrase bases introduce too much noise to apply directly without manual curation to our science domain, underscoring the need for domain-specific knowledge acquisition.

KNOWBOT achieves accuracy of 57%, a dramatic improvement over both baselines. Importantly, this value does not test *generalization* to unseen questions, since KNOWBOT has held dialogs on these questions. However, it does show that our system can effectively learn about its domain: a poor dialog extraction system will fail to extract any helpful knowledge from users during a training dialog. This is a significant result because it shows that we successfully acquire knowledge to solve many question through conversational interaction without the overhead of a closed dialog model or fixed ontology.

We also tested how well knowledge generalizes with LEAVE-ONE-OUT. Our question set is less suited to evaluate generalization because it covers a wide range of topics with little overlap between

questions. We still found LEAVE-ONE-OUT to be the second-best performer with accuracy of 45%, a 10% relative improvement versus IDENTITY. Redundancy is an effective noise reduction constraint: when LEAVE-ONE-OUT ignores redundancy and includes singleton relations (those originating in a single dialog utterance), its accuracy reduces to 32%.

6 Related work

Knowledge acquisition in dialog has long been a central goal of AI research. Early dialog systems acquired knowledge through ambitious interaction, but were brittle, required hand-defined dialog models and did not scale. Terry Winograd (1972) presented the first dialog system that acquires knowledge about the block world. TEIRESIAS (Davis, 1977) refines inference rules from terse interaction with experts. CONVINCE (Kim and Pearl, 1987) and its prototypes (Leal and Pearl, 1977) learn decision structures through stylized but conversational dialogs. An interactive interface for CYC (Witbrock et al., 2003) learns from experts but don't use natural language. Fernández et al (2011) argue the importance of interactive language learning for conversational agents. Williams et al (2015) combine active learning and dialog to efficiently label training data for dialog act classifiers.

Relatively little work integrates relation extraction and dialog systems. Attribute-value pairs from restaurant reviews can generate system prompts (Reschke et al., 2013), and single-turn exchanges with search engines can populate a knowledge graph (Hakkani-Tur et al., 2014). Dependency relations extracted from individual dialog utterances by a parser also make effective features for dialog act classification (Klüwer et al., 2010).

The work closest to our own, Pappu and Rudnicky (2014a; 2014b), investigates knowledge acquisition strategies for academic events. Their system asks its users open-ended questions in order to elicit information about academic events of interest. They compare strategies by how many new vocabulary words are acquired, so that the best strategy prompts the user to mention the most OOV words. In their most recent work (2014b), they group the acquired researcher names by their interests to form a bipartite graph, and use acquired keywords for query expansion in a simple information retrieval task. Our present contribution builds on this general idea, but we learn an unlimited number of relations and concepts from open dialogs, whereas they learn a small number of relations belonging to a fixed ontology from closed dialogs. We also show the acquired knowledge is objectively useful for QA.

In *closed* dialog systems, the system's dialog model explicitly represents the meaning of every potential user utterance. Any utterance not represented by this comprehensive model is rejected and the user asked to rephrase. Closed dialog systems work well in practice. For example, in the well-studied *slot-filling* or *frame-filling* model, users fill slots to constrain their goal, and an NLU module decomposes user utterances to known actions, slots, and values. A slot-filling system to find flights might map the utterance `U: Show me a flight from Nashville to Seattle on Sunday` to the action *find-flight* and the filled slots *origin = Nashville, destination = Seattle*, and *time = Sunday*. However, for our domain, each distinct question warrants its own actions, slots, and values. Such a complex model would require abundant training data or laboriously handcrafted interpretation rules.

In contrast, an *open* dialog system can usefully interpret, learn from, and respond to user utterances without a comprehensive dialog model. Domain-independent dialog systems with the flexibility to accept novel user utterances are a longstanding goal in dialog research (Polifroni et al., 2003). Recent work to address more open dialog includes bootstrapping a semantic parser from unlabeled dialogs (Artzi and Zettlemoyer, 2011), extracting potential user goals and system responses from backend databases (Hixon and Passonneau, 2013), and inducing slots and slot-fillers from a corpus of human-human dialogs with the use of FrameNet (Chen et al., 2014). These works focus on systems that learn about their domain prior to any human-system dialog. Our system learns about its domain *during* the dialog. While we rely on a limited number of templates to generate system responses, unscripted user utterances can usefully progress the dialog. This allows relation extraction from complex natural language utterances without a closed set of recognized actions and known slot-value decompositions.

7 Discussion and Future Work

KNOWBOT acquires helpful, task-driven relations from conversational dialogs in a difficult QA domain. A dialog is a success when it produces knowledge to solve the question. Extractions increase QA accuracy on questions for which dialogs have been held, indicating that knowledge acquisition dialogs can succeed without a closed dialog model by using task progress and careful pruning to drive natural language understanding. Our method is general enough to scale to any task in which alternative dialog goals can be presented to a user and the system's confidence in each alternative computed from semantic relations between concepts.

Our focus is on facilitated knowledge acquisition rather than question-answering, so we purposefully keep inference simple. The alignment score is a Jaccard overlap modified to use relations, which makes it fast and practical, but results in many ties which we score as incorrect, and also ignores word order. For example, the bag-of-keywords is identical for contradicting answers "changing from liquid to solid" and "changing from solid to liquid." To make this distinction, we could use an alignment score that is sensitive to word order such as an edit distance. We could expand our simple pruning constraints to take more advantage of syntax, for example by using dependency parsers optimized for conversational language (Kong et al., 2014).

The relational model for reasoning is both flexible and powerful (Liu and Singh, 2004). However, in a small number of cases, relations that align known facts with question-answer statements are unlikely to lead to the correct answer. For example, our question set contains a single math problem, *How long does it take for Earth to rotate on its axis seven times? (A) one day (B) one week (C) one month (D) one year*. The multiplication operation necessary to infer the answer from the SCITEXT fact "The Earth rotates, or spins, on its axis once every 24 hours" is not easily represented by our model and requires other techniques (Hosseini et al., 2014).

We observed only slight transfer of knowledge between questions. A larger question set with multiple questions per topic will allow us to better evaluate knowledge transfer. Our long-term goal is learning through any conversational interaction in a completely open domain, but because the fundamental trick that enables model-free NLU is computing progress towards an explicit dialog goal as a function of possible extractions, our current method is limited to tasks with explicit goals.

The simple redundancy filter we use effectively distinguishes salient from noisy relations, but could be improved with a model of relation frequency. We consider all acquired relations equally salient, but future work will examine how to rank relation saliency. We will also examine how dialog features can help distinguish between paraphrase, entailment, and negative relations.

Our open system acquires relations from a wide variety of user explanations without the bottleneck of a hand-built dialog model, but the tradeoff is that we use relatively simple, templated system prompts. However, our collected corpus of real human-system dialogs can be used to improve our system in further iterations. For example, the knowledge graphs we produce are targeted, question-specific semantic networks, which could be used in lieu of FrameNet to induce domain-specific dialog models (Chen et al., 2014). With a dialog model to represent the state space, reinforcement learning could then be employed to optimize our strategies.

While most question-answering systems focus on factoid questions, reasoning tasks such as ours require different techniques. Our method generalizes to other non-factoid QA tasks which could usefully employ relations, such as arithmetic word problems (Hosseini et al., 2014) and biology reading comprehension questions (Berant et al., 2014).

Acknowledgments

This research was conducted at the Allen Institute for Artificial Intelligence. We'd like to thank Luke Zettlemoyer, Mark Yatskar, Rik Koncel-Kedziorski, Eric Gribkoff, Oren Etzioni and the anonymous reviewers for helpful comments, and AI2 interns and colleagues for their support and participation in the user studies. The first author was supported by the National Science Foundation Graduate Research Fellowship Program under Grant Number DGE-1256082. Abstract

Automatic analysis of impaired speech for screening or diagnosis is a growing research field; however there are still many barriers to a fully automated approach. When automatic speech recognition is used to obtain the speech transcripts, sentence boundaries must be inserted before most measures of syntactic complexity can be computed. In this paper, we consider how language impairments can affect segmentation methods, and compare the results of computing syntactic complexity metrics on automatically and manually segmented transcripts. We find that the important boundary indicators and the resulting segmentation accuracy can vary depending on the type of impairment observed, but that results on patient data are generally similar to control data. We also find that a number of syntactic complexity metrics are robust to the types of segmentation errors that are typically made.

1 Introduction

The automatic analysis of speech samples is a promising direction for the screening and diagnosis of cognitive impairments. For example, recent studies have shown that machine learning classifiers trained on speech and language features can detect, with reasonably high accuracy, whether a speaker has mild cognitive impairment (Roark et al., 2011), frontotemporal lobar degeneration (Pakhomov et al., 2010b), primary progressive aphasia (Fraser et al., 2014), or Alzheimer's disease (Orimaye et al., 2014; Thomas et al., 2005). These studies used manually transcribed samples of patient speech; however, it is clear that for such systems to be practical in the real world they must use automatic speech recognition (ASR). One issue that arises with ASR is the introduction of word recognition errors: insertions, deletions, and substitutions. This problem as it relates to impaired speech has been considered elsewhere (Jarrold et al., 2014; Fraser et al., 2013; Rudzicz et al., 2014), although more work is needed. Another issue, which we address here, is how ASR transcripts are divided into sentences.

> turning to politics for al gore and george w bush another day of rehearsal in just over forty eight hours the two men will face off in their first of three debates for the first time voters will get a live unfiltered view of them together

> Turning to politics, for Al Gore and George W Bush another day of rehearsal. In just over forty-eight hours the two men will face off in their first of three debates. For the first time, voters will get a live, unfiltered view of them together.

Figure 1: ASR text before and after processing.

The raw output from an ASR system is generally a stream of words, as shown in Figure 1. With some effort, it can be transformed into a format which is more readable by both humans and machines. Many algorithms exist for the segmentation of the raw text stream into sentences. However, there has been no previous work on how those algorithms might be applied to impaired speech.

This problem must be addressed for two reasons: first, sentence boundaries are important when analyzing the syntactic complexity of speech, which can be a strong indicator of potential impairment.

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 862–871,
Denver, Colorado, May 31 – June 5, 2015.

Many measures of syntactic complexity are based on properties of the syntactic parse tree (e.g. Yngve depth, tree height), which first require the demarcation of individual sentences. Even very basic measures of syntactic complexity, such as the mean length of sentence, require this information. Secondly, there are many reasons to believe that existing algorithms might not perform well on impaired speech, since assumptions about normal speech do not hold true in the impaired case. For example, in normal speech, pausing is often used to indicate a boundary between syntactic units, whereas in some types of dementia or aphasia a pause may indicate word-finding difficulty instead. Other indicators of sentence boundaries, such as prosody, filled pauses, and discourse markers, can also be affected by cognitive impairments (Emmorey, 1987; Bridges and Van Lancker Sidtis, 2013).

Here we explore whether we can apply standard approaches to sentence segmentation to impaired speech, and compare our results to the segmentation of broadcast news. We then extract syntactic complexity features from the automatically segmented text, and compare the feature values with measurements taken on manually segmented text. We assess which features are most robust to the noisy segmentation, and thus could be appropriate features for future work on automatic diagnostic interfaces.

2 Background

2.1 Automatic sentence segmentation

Many approaches to the problem of segmenting recognized speech have been proposed. One popular way of framing the problem is to treat it as a sequence tagging problem, where each interword boundary must be labelled as either a sentence boundary (B) or not (NB) (Liu and Shriberg, 2007).

Liu et al. (2005) showed that using a conditional random field (CRF) classifier for this problem resulted in a lower error rate than using a hidden Markov model or maximum entropy classifier. They stated that the CRF approach combined the benefits of these two other popular approaches, since it is discriminative, can handle correlated features, and uses a globally optimal sequence decoding.

The features used to train such classifiers fall broadly into two categories: word features and prosodic features. Word features can include word or part-of-speech *n*-grams, keyword identification, and filled pauses (Stevenson and Gaizauskas, 2000; Stolcke and Shriberg, 1996; Gavalda et al., 1997). Prosodic features include measures of pitch, energy, and duration of phonemes around the boundary, as well as the length of the silent pause between words (Shriberg et al., 2000; Wang et al., 2003).

The features which are most discriminative to the segmentation task can change depending on the nature of the speech. One important factor can be whether the speech is prepared or spontaneous. Cuendet et al. (2007) explored three different genres of speech: broadcast news, broadcast conversations, and meetings. They analyzed the effectiveness of different feature sets on each type of data. They found that pause features were the most discriminative across all groups, although the best results were achieved using a combination of lexical and prosodic features. Kolár et al. (2009) also looked at genre effects on segmentation, and found that prosodic features were more useful for segmenting broadcast news than broadcast conversations.

2.2 Primary progressive aphasia

There are many different forms of language impairment that could affect how sentence boundaries are placed in a transcript. Here, we focus on the syndrome of primary progressive aphasia (PPA). PPA is a form of frontotemporal dementia which is characterized by progressive language impairment without other notable cognitive impairment. In particular, we consider two subtypes of PPA: semantic dementia (SD) and progressive nonfluent aphasia (PNFA). SD is typically marked by fluent but empty speech, obvious word finding difficulties, and spared grammar (Gorno-Tempini et al., 2011). In contrast, PNFA is characterized by halting and sometimes agrammatic speech, reduced syntactic complexity, and relatively spared single-word comprehension (Gorno-Tempini et al., 2011). Because syntactic impairment, including reduced syntactic complexity, is a core feature of PNFA, we expect that measures of syntactic complexity would be important for a downstream screening application. Fraser et al. (2013) presented an automatic system for classifying PPA subtypes from ASR transcripts, but they were not able to include any syntactic complexity

metrics because their transcripts did not contain sentence boundaries.

3 Data

3.1 PPA data

Twenty-eight patients with PPA (11 with SD and 17 with PNFA) were recruited through three memory clinics, and 23 age- and education-matched healthy controls were recruited through a volunteer pool. All participants were native speakers of English, or had completed some of their education in English.

To elicit a sample of narrative speech, participants were asked to tell the well-known story of *Cinderella*. They were given a wordless picture book to remind them of the story; then the book was removed and they were asked to tell the story in their own words. This procedure, described in full by Saffran et al. (1989), is commonly used in studies of connected speech in aphasia.

The narrative samples were transcribed by trained research assistants. The transcriptions include filled pauses, repetitions, and false starts. Sentence boundaries were marked by a single annotator according to semantic, syntactic, and prosodic cues. We removed capitalization and punctuation, keeping track of original sentence boundaries for training and evaluation, to simulate a high-quality ASR transcript.

3.2 Broadcast news data

For the broadcast news data, we use a 804,064 word subset of the English section of the TDT4 Multilingual Broadcast News Speech Corpus[1]. Using the annotations in the transcripts, we extracted news stories only (ignoring teasers, miscellaneous text, and under-transcribed segments). The transcriptions were generated by closed captioning services and commercial transcription agencies (Strassel, 2005), and so they are of high but not perfect quality. Again, we remove capitalization and punctuation to simulate the output from an ASR system.

Since the TDT4 corpus is much larger than our PPA data set, we also construct a small news data set by randomly selecting 20 news stories from the TDT4 corpus. This allows us to determine which effects are due to differences in genre and which are due to having a smaller training set.

[1] `catalog.ldc.upenn.edu/LDC2005S11`

4 Methods

4.1 Lexical and POS features

The lexical features are simply the unlemmatized word tokens. We do not consider word *n*-grams due to the small size of our PPA data set. To extract our part-of-speech (POS) features, we first tag the transcripts using the NLTK POS tagger (Bird et al., 2009). We use the POS of the current word, the next word, and the previous word as features.

4.2 Prosodic features

To calculate the prosodic features, we first perform automatic alignment of the transcripts to the audio files. This provides us with a phone-level transcription, with the start and end of each phone linked to a time in the audio file. Using this information, we are able to calculate the length of the pauses between words, which we bin into three categories based on previous work by Pakhomov et al. (2010a). Each interword boundary either contains no pause, a short pause (<400 ms), or a long pause (>400 ms).

We calculate the pitch (Talkin, 1995; Brookes, 1997), energy, and duration of the last vowel before an interword boundary. For each measurement, we compare the value to the average value for that speaker, as well as to the values for the last vowel before the next and previous interword boundaries.

We perform the automatic alignment using the HTK toolkit (Young et al., 1997). Our pronunciation dictionary is based on the CMU dictionary[2], augmented with estimated pronunciations of out-of-vocabulary words using the "g2p" grapheme-to-phoneme toolkit (Bisani and Ney, 2008). We use a generic acoustic model that has been trained on Wall Street Journal text (Vertanen, 2006).

4.3 Classification

We use a conditional random field (CRF) to label each interword boundary as either a sentence boundary (B) or not (NB). We use a CRF implementation called CRFsuite (Okazaki, 2007) with the passive-aggressive learning algorithm. To avoid overfitting, we set the minimum feature frequency cut-off to 20.

To evaluate the performance of our system, we compare the hypothesized sentence boundaries with

[2] `www.speech.cs.cmu.edu/cgi-bin/cmudict`

the manually annotated sentence boundaries and report the F score, where F is the harmonic mean of recall and precision. For the PPA data and the small news data, we assess the system using a leave-one-out cross validation framework, in which each narrative is sequentially held out as test data while the system is trained on the remaining narratives. For the large TDT4 corpus, we randomly hold out 10% of the corpus as test data, and train on the remaining 90%.

4.4 Assessment of syntactic complexity

Once we have segmented the transcripts, we want to assess how the (presumably noisy) segmentation affects our measures of syntactic complexity. Here we consider a number of syntactic complexity metrics that have been previously used in the study of PPA speech (Fraser et al., 2014). The metrics are defined in the first column of Table 3. For the first four metrics, we generated the parse tree for each sentence using the Stanford parser (Klein and Manning, 2003). The Yngve depth is a well-known measure of how left-branching a parse tree is (Sampson, 1997; Yngve, 1960). The remaining metrics in Table 3 were calculated using Lu's Syntactic Complexity Analyzer (SCA) (Lu, 2010). We follow Lu's definitions for the various syntactic units: a *clause* is a structure consisting of at least a subject and a finite verb, a *dependent clause* is a clause which could not form a sentence on its own, a *verb phrase* is a phrase consisting of at least a verb and its dependents, a *complex nominal* is a noun phrase, clause, or gerund that stands in for a noun, a *coordinate phrase* is an adjective, adverb, noun, or verb phrase immediately dominated by a coordinating conjunction, a *T-unit* is a clause and all of its dependent clauses, and a *complex T-unit* is a T-unit which contains a dependent clause.

5 Segmentation results

5.1 Comparison between data sets

Table 1 shows the performance on the different data sets when trained using different combinations of feature types. We also report the chance baseline for comparison.

We first consider the differences in results observed between the two news data sets. The best results are similar in both groups, although, as would be expected, the larger training sample performs better. However, the difference is small, which suggests that the small size of the PPA data set should not greatly hurt the performance. When we compare the performance of these two groups with different sets of training features, we notice that the difference in performance is greatest when training on lexical features. In a small random sample from the TDT4 corpus, it is unlikely that two stories will cover the same topic, and so there will be little overlap in vocabulary. This is reflected in the results showing that lexical features hurt the performance in this small news sample.

Feature set	TDT4	TDT4 (small)	Controls	SD	PNFA
Chance baseline	0.07	0.07	0.05	0.07	0.06
All	**0.61**	0.57	**0.51**	**0.43**	**0.47**
Lexical+prosody	0.57	0.50	0.44	0.30	0.33
Lexical+POS	0.48	0.36	0.36	0.36	0.40
POS+prosody	**0.61**	**0.59**	0.45	0.39	0.45
POS	0.45	0.39	0.28	0.35	0.39
Prosody	0.50	0.48	0.24	0.23	0.25
Lexical	0.26	0.14	0.18	0.17	0.18

Table 1: F score for the automatic segmentation method on each data set. Boldface indicates best in column.

Performance on the news corpus is better than on the PPA data (including the control group). Comparing the small news sample to the PPA controls, we see that this is not simply due to the size of the training set, so we instead attribute the effect to the fact that speech in broadcast news is often prepared, while in the PPA data sets it is spontaneous.

A closer look at the effect of prosodic features in our training data further shows the difference we observe between prepared and spontaneous speech. When trained on the prosodic features alone, the news data set performs relatively well, while performance on the control data is much worse. These results are consistent with the findings of Kolár et al. (2009) regarding the effect of prosodic features in prepared and spontaneous speech.

When comparing the performance on the control group and on the PPA data, we see that generally, the results are better on the controls. This is to be expected, as the speech in the control group has more

complete sentences and fewer disfluencies. However, it is interesting to note that performance on the PNFA and SD groups is not much worse. All three data sets achieved the best results when trained with all feature types. This suggests that standard methods of sentence segmentation for spontaneous speech can be effective on PPA speech as well.

Looking at the PPA and control groups with other feature sets, we see that POS features are more important in the PNFA and SD groups than they are for the control data. A closer look at the transcripts shows us that the PPA participants tend to connect independent clauses with a conjunction more frequently than control participants, and independent clauses are often separated in the manual segmentation. This means that many sentence boundaries in the PPA data are marked by conjunctions. This is discussed further in the next section.

When considering the prosodic and lexical feature sets individually, we see that performance is similar in all three cases (control, SD, and PNFA). However, when we combine prosodic and lexical features together, the performance in the control case increases by a much larger margin than in the two aphasic cases. This suggests that control participants combine words and prosody in a manner that is more predictive of sentence boundaries than in the aphasic case.

TDT-4 (small)	**Control**	**SD**	**PNFA**

a	*of*	*I*	VBD_next
to	*uh*	*a*	*a*

(b) Features associated with a non-boundary

Table 2: The 10 features with the highest weights in each CRF model, indicating either that the following interword boundary is or is not a sentence boundary.

5.2 Important features

In Table 2, we report the 10 features in each data set which are most strongly associated with a boundary or a non-boundary. We consider only the small news corpus, for a fair comparison with the PPA data.

The POS tags shown are the output of the NLTK part of speech tagger, which uses the Penn Treebank Tag Set. We append '_next' and '_prev' to indicate that this is the POS tag of the next and previous word respectively. Italicized words represent lexical items.

We first consider the features that indicate a sentence boundary (see Table 2a). In general, we observe that our minimum frequency cut-off removes many of the lexical features from the top 10. (In the absence of such a cut-off, we observed that very low frequency words can be given deceptively high weights.) The exceptions to this are the words *go* and *her* in the control set. When we look at the data, there are indeed many occurrences of *go* and *her* at the end of sentences, for example, *she was not allowed to go* or *she couldn't go*, and *very mean to her* or *so in love with her*. While these lexical items are not specific to the *Cinderella* story, it seems unlikely that these features would generalize to other story-telling tasks (although we note that the Cinderella story is very widely used in the assessment of aphasia and some types of dementia).

The POS of the given word and its neighbours are generally important features. In all four cases, the next word being a coordinating conjunction or a pronoun is indicative of a boundary. In the three PPA cases, but not the news case, the next word being an adverb is also indicative. Looking at the data, we observe that this very often corresponds to the use of words like *so*, *then*, *well*, *anyway*, etc. This would seem to reflect a difference between the frequent use of discourse markers in spontaneous speech and their relative sparsity in prepared speech.

The POS of the current word is also important. In

all cases, a boundary is associated with the current word being an adverb or a noun. In the control data only, the tag IN, representing either a preposition or a subordinating clause, is also associated with a boundary. Although this seems counter-intuitive, an examination of the data reveals that in almost every case, this corresponds to the phrase *happily ever after*. The fact that this feature does not occur in the other PPA groups could indicate that the patients are less likely to use this phrase, but could also be due to our relatively high frequency cut-off.

Another anomalous result is that the tag VB (verb, base form) is associated with a sentence boundary in the SD case only. Again, examples from the data suggest a probable explanation. In many cases, sentences ending with VB are actually statements about the difficulty of the task, rather than narrative content; e.g., *that's all I can say*, *I can't recall*, or *I don't know*. These statements are consistent with the word-finding difficulties that are a hallmark of SD.

In the prosodic features, we see that long pauses and decreases in pitch and energy are associated with sentence boundaries in the news corpus. However, the results are mixed in the PPA data. This finding is consistent with our results in Section 5.1, and supports the conclusion of Cuendet et al. (2007) and Kolár et al. (2009) that prosodic features are more useful in prepared than spontaneous speech.

We now look briefly at the features which are associated with a non-boundary (Table 2b). Here we see more lexical features in the top 10, mostly function words and filled pauses. These features reflect the reasonable assumption that most sentences do not end with determiners, conjunctions, or subjective pronouns. One feature which occurs in the news data but not the PPA data is the next word being a modal verb (MD). This seems to be a result of the more frequent use of the future tense in the news stories (e.g. *the senator will serve another term*), in contrast to the Cinderella stories, which are generally told in the present or simple past tense.

6 Complexity results

We first compare calculating the syntactic complexity metrics on the manually segmented transcripts and the automatically segmented transcripts. The results are given in Table 3. Metrics for which there is no significant difference between the manual and automatic segmentation are marked with "NS". Of course, we do not claim that there is actually no difference between the values, as can be seen in the table, but we use this as a threshold to determine which features are less affected by the automatic segmentation.

All the features relating to Yngve depth and height of the parse trees are significantly different (in at least one of the three clinical groups). However, of the eight primary syntactic units calculated by Lu's SCA, six show no significant difference when measured on the automatically segmented transcripts. To examine this effect further, we will discuss how each of the eight is affected by the segmentation process.

Although the number of sentences (S) is different, the number of clauses (C) is not significantly affected by the automatic segmentation, which implies that the boundaries are rarely placed within clauses, but rather between clauses. An example of this phenomenon is given in Example 1:

Manual: And then they go off to the ball and then she comes I dunno how she meets up with this um fairy godmother whatever.

Auto: And then they go off to the ball. And then she comes I dunno how she meets up with this um fairy godmother whatever.

Our automatic method inserts a sentence boundary before the second *and*, breaking one sentence into two but not altering the number of clauses. In fact, the proposed boundary seems quite reasonable, although it does not agree with the human annotator. The correlation between the number of clauses counted in the manual and automatic transcripts is 0.99 in all three clinical groups. The counts for dependent clauses (DC) are also relatively unaffected by the automatic segmentation, for similar reasons.

The T-unit count (T) is also not significantly affected by the automatic segmentation. Since a T-unit only contains one independent clause as well as any attached dependent clauses, this suggests that the segmentation generally does not separate dependent clauses from their independent clauses. This also helps explain the lack of difference on complex T-units (CT).

Table 3 also indicates that the number of verb phrases (VP) and complex nominals (CN) is not significantly different in the automatically segmented

Metric	Diff?	Controls		SD		PNFA	
		Manual	Auto	Manual	Auto	Manual	Auto
Max YD maximum Yngve depth		5.10	4.53	4.45	3.87	4.66	3.83
Mean YD mean Yngve depth		2.97	2.72	2.68	2.44	2.77	2.41
Total YD total sum of the Yngve depths		66.92	53.41	42.48	32.95	49.95	32.57
Tree height average parse tree height		12.56	11.30	10.79	9.81	11.25	9.88
S number of sentences		24.35	31.22	27.73	37.36	18.82	25.47
T number of T-units	NS	31.43	35.13	32.55	39.27	23.29	27.41
C number of clauses	NS	61.48	64.48	57.73	62.45	42.94	46.65
DC number of dependent clauses	NS	24.70	27.30	26.27	26.09	16.59	18.88
CN number of complex nominals	NS	41.39	43.52	38.73	39.64	27.12	27.88
VP number of verb phrases	NS	77.00	79.65	72.09	77.00	51.76	55.24
CP number of coordinate phrases		12.39	10.30	11.55	6.91	7.82	4.18
CT number of complex T-units	NS	14.30	13.52	12.00	11.82	9.29	8.71
MLS mean length of sentence		19.79	16.22	14.04	11.25	15.86	11.60
MLT mean length of T-unit		14.92	13.72	12.19	10.46	12.78	10.66
MLC mean length of clause		7.55	7.21	7.13	6.58	6.89	6.39
T/S T-units per sentence		1.34	1.17	1.15	1.06	1.23	1.08
C/S clauses per sentence		2.64	2.25	1.96	1.70	2.28	1.82
DC/T dependent clauses per T-unit	NS	0.80	0.78	0.73	0.63	0.73	0.69
VP/T verb phrases per T-unit		2.47	2.34	2.11	1.92	2.23	1.98
CP/T coordinate phrases per T-unit		0.40	0.33	0.35	0.17	0.35	0.15
CN/T complex nominals per T-unit	NS	1.32	1.26	1.18	1.10	1.17	1.01
C/T clauses per T-unit		1.99	1.91	1.71	1.58	1.86	1.68
CT/T complex T-units per T-unit	NS	0.46	0.40	0.37	0.32	0.39	0.32
DC/C dependent clauses per clause	NS	0.39	0.41	0.42	0.40	0.38	0.41
CP/C coordinate phrases per clause		0.20	0.17	0.20	0.10	0.19	0.09
CN/C complex nominals per clause	NS	0.65	0.65	0.70	0.71	0.63	0.61

Table 3: Mean values of syntactic complexity metrics for the different patient groups. Features which show no significant difference between the manual and automatic segmentation on all three clinical groups are marked as "NS" (not significant).

transcripts. Since these syntactic units are typically sub-clausal, this is not unexpected given the arguments above.

The remaining primary syntactic unit, the coordinate phrase (CP), *is* different in the automatic transcripts. This represents a weakness of our method; namely, it has a tendency to insert a boundary before all coordinating conjunctions, as in Example 2:

Manual: So she is very upset and she's crying and with her fairy godmother who then uh creates a carriage and horses and horsemen and and driver and beautiful dress and magical shoes.

Auto: So she is very upset. And she's crying and with her. Fairy godmother who then uh creates a carriage. And horses and horsemen and and driver. And beautiful dress. And magical shoes.

In this case, the manual transcript has five coordinate phrases, while the automatic transcript has only two.

The mean lengths of sentence (MLS), clause (MLC), and T-unit (MLT) are all significantly different in the automatically segmented transcripts. We ascribe this to the fact that a small change in C or T can lead to a large change in MLC or MLT. The remaining metrics in Table 3 are simply combinations of the primary units discussed above.

Our analysis so far suggests that some syntactic units are relatively impervious to the automatic sentence segmentation, while others are more susceptible to error. However, when we examine the mean values given in Table 3, we observe that even in cases when the complexity metrics are significantly different in the automatic transcripts, the differences appear to be systematic. For example, we know that our segmentation method tends to produce more sentences than appear in the manual transcripts (i.e., S is always greater in the automatic transcripts). If we look at the differences across clinical groups, the same pattern emerges in both the man-

Table 4: Difference between syntactic complexity metrics for each pair of patient groups. A significant difference ($p < 0.05$) is marked with an asterisk.

ual and automatic transcripts: participants with SD produce the most sentences, followed by controls, followed by participants with PNFA. In most applications of these syntactic complexity metrics, what matters most is not the absolute value of the metric, but the relative differences between groups. So, we now ask: which features distinguish between clinical groups in the manually segmented transcripts, and do they still distinguish between the groups in the automatically segmented transcripts?

Our results for this experiment are reported in Table 4. In the case of SD vs. controls, there are 11 features which are significantly different between the two groups in the manual transcripts. Seven of these features are also significantly different between groups in the automatic transcripts, while an additional three features are significant only in the automatic transcripts. In the PNFA vs. controls case, there are 15 distinguishing features in the manual transcripts, and 14 of those are also significantly different in the automatic transcripts. There are four features which are significant only in the automatic case. Finally, in the case of SD vs. PNFA, there is only one distinguishing feature in the manual transcripts, and none in the automatic transcript.

These findings suggest that automatically segmented transcripts can still be useful, even if the complexity metrics have different values from the manual transcripts. Importantly, a comparison of the mean feature values in Table 3 reveals that in 92% of cases, and in every case marked as significant in Table 4 4, the direction of the trend is the same in the manual and automatic transcripts.

For example, in the first column of Table 4, maximum Yngve depth is significantly different between SD participants and controls. In both the manual and automatic transcripts, the controls have a greater maximum depth than SD participants. This is true for every metric that is significant in both the manual and automatic transcripts. This indicates that the metrics are not only significantly different, and therefore useful for machine learning classification or some other downstream application, but that they are interpretable in relation to the specific language impairments that we expect to observe in the patient groups.

7 Discussion

We have introduced the issue of sentence segmentation of impaired speech, and tested the effectiveness of standard segmentation methods on PPA speech samples. We found that, as expected, performance was best on prepared speech from broadcast news, then on healthy controls, and worst on speech samples from PPA patients. However, the results on the PPA data are promising, and suggest that similar methods could be effective for impaired speech. Future work will look at adapting the standard algorithms to improve performance in the impaired case. This would include an evaluation of the forced alignment on impaired speech data, as well as the exploration of new features for the boundary classification.

One limitation of this study is the use of manually transcribed data with capitalization and punctuation removed to simulate perfect ASR data. We expect that real ASR data will contain recognition errors, and it is not clear how these errors will affect the segmentation process. As well, our PPA data set is relatively small from a machine learning perspec-

tive, due to the inherent difficulties associated with collecting clinical data. Furthermore, we assumed that the diagnostic group is known *a priori*, allowing us to train and test on each group separately.

We analyzed our results to see how the noise introduced by our segmentation affects various syntactic complexity measures. Some measures (e.g. T-units) were robust to the noise, while others (e.g. Yngve depth) were not. When using such automatic methods for the analysis of speech data, researchers should be aware of the unequal effects on different complexity metrics.

For the more practical goal of distinguishing between different patient groups, we found that most measures that were significant for this task using the manual transcripts remained so when using the automatically segmented ones, and the direction of the difference was the same in the manual and automatic transcripts. In all cases where a significant difference between the groups was detected, the direction of the difference was the same in the manual and automatic transcripts. These results indicate that imperfect segmentation methods might still be useful for some applications, since they affect the data in a systematic way.

Although we evaluated our methods against human-annotated data, there is some uncertainty about whether a single gold standard for the sentence segmentation of speech truly exists. Miller and Weinert (1998), among others, argue that the concept of a sentence as defined in written language does not necessarily exist in spoken language. In future work, it would useful to compare the inter-annotator agreement between trained human annotators to determine an upper bound for the accuracy.

Abstract

Semantic grammars can be applied both as a language model for a speech recognizer and for semantic parsing, e.g. in order to map the output of a speech recognizer into formal meaning representations. Semantic speech recognition grammars are, however, typically created manually or learned in a supervised fashion, requiring extensive manual effort in both cases. Aiming to reduce this effort, in this paper we investigate the induction of semantic speech recognition grammars under weak supervision. We present empirical results, indicating that the induced grammars support semantic parsing of speech with a rather low loss in performance when compared to parsing of input without recognition errors. Further, we show improved parsing performance compared to applying n-gram models as language models and demonstrate how our semantic speech recognition grammars can be enhanced by weights based on occurrence frequencies, yielding an improvement in parsing performance over applying unweighted grammars.

1 Motivation

Semantic parsers map natural language utterances (*NL*) into formal meaning representations (*MR*), and are applied for both parsing of textual input and in Spoken Language Understanding (SLU). In data-driven SLU research, typically pipeline-based systems are applied in which first an automatic speech recognizer (ASR) is applied to transcribe speech input, and subsequently a semantic parser is applied to map the transcriptions into some semantic form (Deoras et al., 2013). Such systems typically use different models for recognition and understanding. Since ASR yields recognition errors, parsing performance can degrade rapidly compared to parsing performance on written text. While the performance of ASR and parsing components are often optimized independently of each other, in particular in case of the ASR to minimize recognitions errors, research has shown that ASR transcriptions with a lower error rate can in fact yield worse understanding performance (Wang et al., 2003; Bayer and Riccardi, 2012) and that joint approaches to recognition and understanding can yield improved performance (Wang and Acero, 2006b; Deoras et al., 2013). In particular, Wang and Acero (2006b) have shown that applying the same grammar for speech recognition and understanding can yield improved understanding performance compared to applying a standard n-gram model with the ASR, since dependencies between acoustics and semantics can be captured. Their grammars are, however, learned in a supervised setting. In fact, while semantic grammars are often applied for speech recognition and/or understanding, they are often created manually or – as mentioned previously – learned from data containing semantic annotations, which are time-consuming to produce.

In the field of Natural Language Processing (NLP), the development of semantic parsers has received considerable attention. While some researchers have considered fully supervised settings (Wong and Mooney, 2006; Zettlemoyer and Collins, 2007), requiring accurate and complete semantic annota-

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 872–881,
Denver, Colorado, May 31 – June 5, 2015.

tions, others have developed weakly supervised approaches exploiting ambiguous representations of the context in which an utterance is produced instead of accurate and complete annotations (Chen et al., 2010; Börschinger et al., 2011; Chen and Mooney, 2008). In this line, in this paper we explore how an approach that induces semantic parsers in the form of a (semantic) grammar from ambiguous training data can be applied to acquire a language model (LM) for speech recognition as well as a semantic parser for the understanding task at the same time. Making use of a semantic parser as a language model for speech recognition also comes with the advantage that no separate language model must be trained. In our experiments, we compare performance of the induced grammars to the performance of different language models, in particular n-gram models, and we investigate the impact of enhancing induced semantic grammars with weights based on the training data. We present empirical results showing that it is possible to induce semantic grammars with weak supervision that can be applied successfully both as an LM for a speech recognizer and for semantic parsing. We show that with respect to parsing performance, our joint approach in which the same grammar is used for parsing and as an LM yields a higher F_1 (84.46%) compared to an approach in which a standard n-gram based model is used as an LM (78.36%). In addition, our results indicate that enhancing speech recognition grammar rules with weights based on occurrence frequencies can yield improved performance over unweighted grammars (84.46% vs 82.37% for weighted vs unweighted grammars, respectively).

2 Background & related work

In principle, two different types of language models can be applied with an ASR: stochastic LMs – typically n-gram models – and speech recognition grammars. While n-gram models estimate probabilities of word sequences, speech recognition grammars explicitly specify rules defining which words and patterns a user may utter. Further, semantic information can be directly included within the rules. Thus, when applied with an ASR, spoken utterances can be directly transformed into a corresponding semantic representation without producing a sequence of words as intermediate step. This approach is typically taken when building commercial systems (Wang et al., 2011). Such grammars are, however, typically created manually, which is time-consuming and error-prone. Hence, data-driven approaches to automatic grammar induction have been explored (Wang and Acero, 2006b; Wang and Acero, 2005; Wang and Acero, 2003). However, they often rely on fully supervised settings, requiring training data which is annotated at the utterance- or word level, which is costly and time-consuming to produce. In contrast, aiming to reduce the required manual effort, in this paper we explore the utility of weak supervision in the form of ambiguous context information for the induction of grammars applicable for both speech recognition and understanding.

The utility of this kind of weak supervision has been explored previously in the field of semantic parsing (Chen et al., 2010; Börschinger et al., 2011; Chen and Mooney, 2008), and unsupervised approaches to semantic parsing have been proposed as well (Poon and Domingos, 2009; Goldwasser et al., 2011). While such approaches may be applied as parsing components for SLU systems – notice though that the SLU task differs from parsing of written text in that recognition errors and phenomena of spoken language must be handled, and that not all SLU models can be applied as an LM (Wang et al., 2011) – we are not aware of work aiming to transform these parsers into speech recognition grammars or investigating their performance with respect to different LMs applied with an ASR.

Semantic parsers applied in pipeline-based SLU systems are in general usually learned in a supervised fashion. Other than semantic grammar-based approaches, probabilistic models and machine learning techniques have been applied in SLU for conceptual tagging due to their robustness to noise, e.g. Conditional Random Fields (Lafferty et al., 2001) have been applied (e.g. Wang and Acero (2006a; Dinarelli et al. (2012)); He and Young (2005) present an approach based on Hidden Markos Models. However, evaluations have shown that even in case of applying machine learning techniques or probabilistic models, semantic parsing of ASR transcriptions is affected by much more errors compared to parsing of correct transcriptions (De Mori, 2011). In order to reduce annotation costs, work has,

for instance, focused on providing annotation tools (Wang and Acero, 2006b; Wang and Acero, 2005), exploring supervised learning in combination with active learning (Wu et al., 2010) and gaining additional training data, for instance, from the Web using queries generated from a (small) existing grammar (Klasinas et al., 2013). These approaches, however, still assume manual effort and may be somewhat complementary to the one investigated here. Further, data-driven SLU parsers are often based on rather local features, e.g. n-grams, while we explore template-based grammars which can capture long-distance linguistic dependencies.

Several approaches have addressed unsupervised (Solan et al., 2005; van Zaanen and Adriaans, 2001) and semi-supervised (Wong and Meng, 2001; Siu and Meng, 1999; Meng and Siu, 2002) induction of grammars, where the latter may comprise manual post-processing of automatically induced rules. In particular, in order to be applicable as an SLU model, semantic information must be added manually, since only syntactic structures can be induced automatically in this case.

While in data-driven SLU research typically pipeline-based systems are applied, a few joint approaches have been proposed (Deoras et al., 2013; Wang and Acero, 2006b; Bayer and Riccardi, 2012). Specifically, the work presented here is most similar to the approach presented by Wang and Acero (2006b). In particular, we also attempt to learn grammars applicable for both speech recognition and understanding. However, Wang and Acero (2006b) explore a supervised setting based on word-level annotations for slots and induce rather local rules, i.e. based on preambles and postambles for slots, while we explore a template-based approach, capturing long-distance linguistic dependencies.

3 Methodology

In this paper, we explore the induction of semantic grammars under weak supervision provided in the form of ambiguous representations of the semantic context as explored in the NLP field of Semantic Parsing (Chen et al., 2010). In particular, the training data comprises of a set of textual utterances coupled with symbolic context information from which we induce semantic parsers and derive different LMs for application with an ASR. LMs are then applied to transcribe speech data, and the resulting transcriptions are in turn mapped into meaning representations by the learned semantic parsers. In the following, we will first describe the input data and learning scenario and subsequently the semantic parsing approach as well as the creation of language models.

3.1 Learning scenario and input data

Our experiments were performed on the RoboCup soccer corpus (Chen and Mooney, 2008), which is a standard dataset used for the evaluation of semantic parsing algorithms taking written natural language utterances as input. The corpus comprises four RoboCup games. Game events are represented by predicate logic formulas, which represent the ambiguous contextual representations from which semantic parsers are trained in a weakly supervised fashion. The games were commented by humans, yielding examples for *written* natural language utterances (*NL*). In the corpus, each *NL* is paired with a set of possible meaning representations $mr_i \in MR$, each expressing a game action, and *NL* corresponds to at most one them. For example, *pass(purple10,purple7)* represents an *mr* for a passing event which might be commented as "purple10 kicks to purple7". However, there is no direct correspondence between the *NL* comments and their corresponding *mr*s; thus, these correspondences have to be learned.

The corpus also contains a gold standard comprising *NL*s annotated with their correct *mr*s. Several semantic parsers have been evaluated using this dataset by applying the evaluation schema introduced by Chen et al. (2010). The authors performed 4-fold cross-validation on the four games. Training was done on the ambiguous training data, while the gold standard for a fourth game was used for testing. Results were presented by means of the F_1 score. Precision and recall were computed as the percentage of *mr*s produced by the system that were correct and the percentage of *mr*s that the system produced correctly, respectively. A parse was considered as correct if it matched the gold standard exactly (Chen et al., 2010). Recently, this task has been extended to consider speech data, both in learning and applying a parser. In particular, the approach of Gaspers and Cimiano (2014) relied on transcriptions made by a

task-independent phoneme recognizer as input. For this purpose, *NL* comments contained in the dataset were read by a speaker. By contrast, in this paper we explore how grammars for speech recognition and understanding can be built from textual input in a weakly supervised setting, and subsequently be applied for recognition and parsing of speech input. Hence, we explore a 4-fold cross-validation scenario in which for each fold learning is performed using the *written* ambiguous training data for three games, while the *spoken* gold standard of the forth game is used for testing, i.e. for performing both speech recognition and subsequent parsing of the resulting ASR transcriptions; spoken data are the same as in Gaspers and Cimiano (2014). For application with the ASR we normalized training data which mainly comprised lowercasing and replacement of numbers in player names, e.g. "pink4" → "pink four". Some statistics for the normalized dataset are presented in Table 1.[1]

Table 1: Dataset statistics.

Total number of comments	1,872
Comments having correct mr	1,539
Average number of events per comment	2.5
Maximum number of events per comment	12
SD in number of events per comment	1.8
Mean utterance length	7.39
# Types	355
# Tokens	13,838

3.2 The applied semantic parsing algorithm

For semantic parser induction we applied the algorithm presented in Gaspers and Cimiano (2014), which is mainly designed to work with the output of a phoneme recognizer. The algorithm is also applicable to textual input and has been shown to achieve state-of-the-art performance on written input (cf. Gaspers and Cimiano (2014)). The induced parser is represented in the form of a lexicon and an inventory containing syntactic constructions and thus well-suited to be transformed into a rule-based speech recognition grammar. The learned lexicon comprises lexical units, i.e. words or short sequences of words, along with their mapping to semantic referents, e.g. "pink goalie" → $pink1$. Each syntactic construction consists of a syntactic pattern, e.g. "X_1 kicks to X_2", along with an associated semantic frame, e.g. $pass(ARG_1, ARG_2)$, and a mapping which maps slots in the syntactic pattern to argument slots in the semantic frame, e.g. $X_1 \rightarrow ARG_1, X_2 \rightarrow ARG_2$. Slots in syntactic patterns represent positions in which a lexical unit from the parser's lexicon can be inserted. For instance, in the previous pattern "pink goalie" can be inserted at position X_1 or X_2. When applied to written text, parser induction is performed by applying the following learning steps:

1. acquisition of an initial lexicon
2. computation of alignments between *NL*s and ambiguous context representations, and
3. estimation of co-occurrence frequencies at different levels.

This work flow is illustrated in Fig 1.

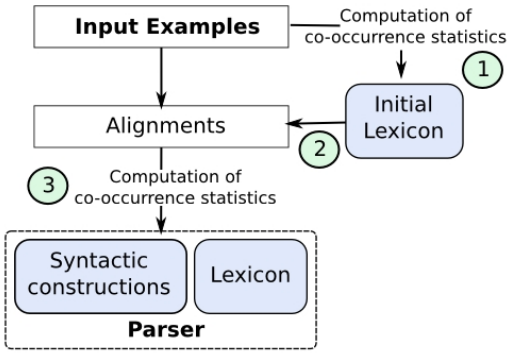

Figure 1: The algorithm's work flow.

In step 1, initial lexical knowledge is learned by computing co-occurrence frequencies between all bi- and unigrams appearing in the *NL* data and all semantic referents appearing in the *MR* data. In step 2, this knowledge is used to compute alignments for each example between its *NL* and all $mr_i \in MR$ observed with it, i.e. lexical knowledge is used to segment *NL* such that all semantic referents observed in an *mr* are expressed by individual sequences, and hypotheses concerning a mapping between *NL* and

[1] Numbers for mean utterance length and number of tokens and types are computed only for comments included in the training dataset. Regarding the total number of comments we use one more per game than Chen et al. (2010) in line with Börschinger et al. (2011).

semantics are created. For instance, given an input example

(1)

NL:	purple eight kicks to purple seven
mr_1:	$playmode(play\_on)$
mr_2:	$pass(purple8, purple7)$
mr_3:	$pass(purple2, purple5)$

the following alignment might be created:

(2)

NL	X_1 kicks to X_2
mr	$pass(ARG_1, ARG_2)$ Mapping: $X_1 \rightarrow ARG_1$, $X_2 \rightarrow ARG_2$
$nl \rightarrow ref$	purple eight $\rightarrow purple8$ purple seven $\rightarrow purple7$

That is, assuming that the algorithm has learned in step 1 that "purple eight" and "purple seven" refer to $purpl8$ and $purple7$, respectively, it may use this knowledge to hypothesize that *NL* is an instantiation of a pattern "X_1 kicks to X_2", which in turn refers to the predicate $pass(ARG_1, ARG_2)$ with a mapping $X_1 \rightarrow ARG_1$, $X_2 \rightarrow ARG_2$.
Alignments are rated, and for each example only those having maximal scores are used for parser induction. By this, lexical knowledge is used to predisambiguate the training data. Given the alignments induced in step 3, a parser is estimated by computing co-occurrence frequencies at different levels. In particular, association scores are computed at three different levels, i.e.

1. $nl \rightarrow ref$: between all lexical units, e.g. "purple eight", and semantic referents, e.g. *purple8*, appearing in alignments,

2. *NL* $\rightarrow mr$: between all syntactic patterns, e.g. "X_1 kicks to X_2", and semantic frames, e.g. $pass(ARG_1, ARG_2)$, appearing in alignments, and

3. mapping: between all slots in a syntactic pattern, e.g. X_1, and argument slots, e.g. ARG_1, specific for each pattern and semantic frame.

Then, the parser's lexicon consists of rules of the form $nl \rightarrow ref$, while the syntactic constructions have the form *NL* $\rightarrow mr$, each coupled with its individual mapping.
Parsing is performed by searching for an appropriate syntactic construction given an input *NL*, and the arguments matching the elements at the slots in the syntactic pattern are inserted into the appropriate argument slots in the associated semantic frame. Approximate matching can be applied during parsing of *NL*s for which no pattern can be found otherwise. In this paper, we always perform approximate matching by searching for a matching syntactic pattern with a Levenshtein distance of 1 if no matching pattern can be found directly, which allows us to parse utterances containing a recognition error. Even though – of course – more than one recognition error might be contained in a given utterance, we do not use greater distance values because this would likely yield parsing errors, as utterances are rather short and most of the words are important for detecting the meaning; leaving out too many words will in general increase the likelihood of matching wrong patterns, thus yielding spurious interpretations. Using the algorithm, for each fold of the RoboCup data set we created a semantic parser using the written training data of three games.

3.3 Creation of language models

Based on the written training data we created different LMs. In particular, we created rule-based recognition grammars using the algorithm and further LMs, such as trigram models, for comparison.

3.3.1 Recognition grammars

We built semantic speech recognition grammars given a semantic parser by transforming all rules with an occurrence greater than one into JSpeech Grammar Format (JSGF)[2]. The resulting grammars consisted of rules representing the parser's inventory of syntactic constructions as well as its lexicon. In case of the inventory of syntactic constructions, alternative expansions of learned syntactic patterns were defined, and in case of the lexicon, alternative expansions of learned lexical units were defined. In particular, with respect to the lexicon we defined a rule <ref> which comprises the learned lexical units. With respect to syntactic constructions we defined a rule <utterance> which comprises the patterns. Further, syntactic slots in patterns were replaced by <ref>, allowing lexical units to appear at those positions. In grammar creation, we also investigated the influence of occurrence frequencies of

[2]http://www.w3.org/TR/jsgf/

syntactic patterns and lexical units to enhance grammatical rules with weights. In particular, we created both weighted and unweighted grammars. When using weights, rules were weighted by using occurrence frequencies, i.e. the frequency which was observed for pattern or lexical unit as aligned by the algorithm during training. Hence, weights for patterns and lexical units aligned less frequently in the training data were smaller, indicating that they were less likely to be spoken. An example illustrating a subset of two (weighted) rules is illustrated in Fig. 2.

Notice that resulting JSGF grammars do not explicitly contain semantic information, but their induction was driven by semantic information. This is the case because a mapping to semantics was not needed during recognition as we explore a two-stage approach where parsing is performed after recognition, allowing the inclusion of further LMs during recognition. However, because both parsing and understanding are performed using the same grammar – where semantic information is ignored by the LM – it would also be possible to induce a semantic grammar that directly maps ASR output into semantic representations.

3.3.2 Baseline language models

We computed different language models for comparison; these were mainly stochastic LMs. In particular, we created standard trigram language models from the written training data without making use of concurrent perceptual context information using SRILM (Stolcke, 2002). Since the RoboCup corpus is rather small and n-gram models are typically learned from large amounts of data, in addition we interpolated the trigram models trained solely on the in-domain RoboCup corpus each with a large background language model trained on a broadcast news corpus, i.e. the HUB4 dataset (Fiscus et al., 1998). We also experimented with class-based models, but automatic induction of classes in an unsupervised fashion did not appear promising and we refrained from manually creating classes since the focus of this paper is on the automatic creation of ASR resources without requiring extensive manual effort. However, an interesting experiment would be to utilize the semantic classes induced by our algorithm in order to create class-based language models.

Moreover, in order to evaluate the utility of ambiguous perceptual context for speech recognition grammar induction, as a fully unsupervised grammar-based baseline, we induced syntactic grammars relying on the ADIOS algorithm (Solan et al., 2005). Notice, however, that it is not common to apply grammars learned in an unsupervised fashion directly for SLU. In particular, with respect to semantic parsing, automatically induced grammars are typically post-processed manually, which we refrained from doing, since the focus of this paper is on the automatic creation of speech recognition and understanding components.

4 Experiments & Results

We evaluated the word error rate (WER) as well as parsing accuracy for different language models and combinations thereof. In particular, in case of applying recognition grammars we applied these also in combination with an n-gram back off LM. In particular, the n-gram model was applied in case of utterances which were rejected by the recognizer as out of grammar (OOG), as these might still be parsed subsequently by applying approximate matching. Notice, however, that for our experiments we did not apply both LMs at a time but combined the output of two recognizers for further processing. Notice further that most speech recognizers can only be applied using either a recognition grammar or an n-gram model at a time, but one can assume that two recognizers might be configured to run in parallel. As mentioned previously, we performed 4-fold cross-validation on the four RoboCup games. For each fold, learning semantic parsers and creation of language models was performed using the ambiguous *written* training data for three games and the *spoken* gold standard for the forth game for testing. In the following, we will discuss results for applying our induced grammars as an LM compared to using standard trigrams models (solely trained on the in-domain data) as a baseline, since these yielded the best results. In particular, we do not discuss the results achieved by the grammars induced in a purely syntactic manner as they performed worse than semantic grammars in all experiments, and we do not discuss the experiments for the interpolated/adapted

Figure 2: A subset of weighted speech recognition grammar rules

```
public <utterance> = /6/ <ref> again passes to <ref> | /199/ <ref> kicks to <ref> | ...
<ref> =  /15/ pink goalie | /132/ pink nine | /10/ pink one | ...
```

trigram models as they performed worse than the in-domain trigram models with the exception of a very slight improvement when applied as a back off model for SLU.[3]

4.1 Speech recognition

Speech recognition was performed using different (combinations of) LMs individually; lexicon and acoustic models were the same in all cases.[4] Speech recognition results with respect to the word error rate averaged over all folds are presented in Table 2.

Table 2: speech recognition results

Applied language model(s)	**WER (%)**
Semantic grammar w/o weights	15.55
Semantic grammar w/o weights + trigram back off	12.63
Semantic grammar inc. weights	17.15
Semantic grammar inc. weights + trigram back off	10.88
Trigram (baseline)	**7.1**

As can be seen, with a rather low error rate of 7.1%, applying trigram language models yields the best results. While in case of applying semantically motivated recognition grammars the WER increases, it must be noted that in cases in which no back off models were applied this is to some extent due to OOG utterances (as these yield several deletions compared to the reference data). Yet, the OOG-rate is rather low, i.e. averaged over all folds 8.6% and 4.1% when using grammars with and without weights, respectively. However, even in cases where OOG utterances are recognized by applying trigram language models, the WER is higher compared to applying trigram language models only. Notably, these results were not consistent across folds. For two folds, the WER actually decreased when combining a semantically motivated grammar including weights with a trigram language model compared to applying the trigram language model only, thus indicating that combining semantically motivated grammars learned with weak supervision with trigram models can also yield improved recognition performance over applying trigram models only in some cases.

4.2 Semantic parsing

For each fold, ASR transcriptions were parsed using the semantic parser learned on the training data for that fold. For comparison, as an upper baseline we computed parsing performance on normalized gold standard data, since typically performance degrades – and often to a large extent – when a semantic parser is applied to ASR transcriptions of speech; recall that the applied algorithm achieves state-of-the-art performance on the dataset.[5] Results are presented in Table 3.

Table 3: Semantic parsing results on written text and on speech transcribed using different language models

Written text (reference)			
	F_1	**Prec.**	**Recall**
Normalized text	87.26	94.28	81.42
Speech			
Applied language model(s)	**F_1**	**Prec.**	**Recall**
Semantic grammar inc. weights	84.18	88.7	80.18
Semantic grammar inc. weights + trigram back off	**84.46**	87.53	81.64
Semantic grammar w/o weights	82.24	84.83	79.84
Semantic grammar w/o weights + trigram back off	82.37	84.67	80.21
Trigram (baseline)	78.36	90.34	69.4

[3]The results were: interpolated/adapted LM: WER: 13.43%, F_1: 71.22%, semantic grammar + interpolated/adapted LM backoff: WER: 13.85, F_1: 84.6%, syntactic recognition grammar: WER: 18.98%, F_1: 70.86%, syntactic recognition grammar + trigram back off: WER: 13.98%, F_1: 71.27%.

[4]We applied Sphinx4 (Walker et al., 2004) using lexicon and acoustic models trained on the HUB4 dataset (Fiscus et al., 1998), which contains broadcast news speech matching our RoboCup data with respect to acoustics in that in both cases read speech is addressed; these resources are available online. We added phonetic transcriptions for out of vocabulary (OOV) to the vocabulary; only two were OOV along with some typos.

[5]While comparison with a manually created gold standard grammar would be interesting as well, a manually created grammar for the utilized dataset is unfortunately not available.

The results reveal that in case of applying trigram LMs F_1 degrades about 9% absolute compared to parsing written text (reference), yielding 78.36% in F_1, even though the WER is rather low with a value of 7.1%. Thus, the trigram seems to "destroy" semantically meaningful sequences while restoring sequences that contain no meaning. By contrast, in case of applying a semantically motivated recognition grammar including weights, performance improves by 6% absolute over the trigram model, even though the WER is higher in this case. Moreover, including weights in the recognition grammars yields improved performance compared to using unweighted grammars.

Notably, the decrease in performance in case of applying a weighted semantically motivated recognition grammar (+ trigram back off) compared to performance on the reference data is mainly due to a decrease in precision. Here it must be noted that the high values in F_1 are achieved without performing any optimization of (recognition) parameters. In the performed experiments, the probability for OOG utterances was rather low, and thus utterances were matched incorrectly by the ASR which were actually not covered by the grammar, yielding both recognition and subsequent parsing errors. However, these parameters can be tuned, likely increasing precision and F_1 even further (and probably also the WER).

Applying a back off trigram model yields only little improvement in parsing performance, although this may to some extent be due to not tuning recognition parameters. That is, if the ASR would be tuned to reject more OOG utterances correctly, these utterances might instead be recognized by a trigram model and probably parsed correctly by applying approximate matching.

5 Discussion

When applying trigram models, even with a rather low error rate of 7.1%, semantic parsing performance degraded about 9% absolute in F_1. Here it must be noted that due to the evaluation schema a single recognition error can yield a completely incorrect parse. Recall that evaluation is performed on the basis of fully correct *mr*s, i.e. all referents and the predicate must be determined correctly in order to yield a correct parse. For instance, if any of the words "purple", "pink", "two" or "five" is deleted or substituted in an utterance "purple two passes to pink five", one of the referents may not be identified (correctly). Similarly, deleting or substituting "passes" may yield an incorrect predicate or no parse at all. Hence, parsing performance can degrade rapidly even on ASR transcriptions containing only few recognition errors.

The results show that, in line with previous research (Wang et al., 2003; Bayer and Riccardi, 2012), a lower WER may not yield better understanding results, i.e. in our case parsing performance is not directly dependent on the WER but rather on the type of errors made. In particular, with respect to semantic parsing it is important that words carrying important meaning are recognized correctly. For instance, a spoken utterance "pink nine passes the ball to pink seven" in which "seven" is incorrectly recognized as "eleven" likely yields a parsing error while a recognition error which substitutes "backward" by "forward" may not prevent correct parsing. This is the case because "forward" and "backward" do not carry any semantics in the data set at hand, while correct identification of numbers is in most cases essential for detecting the correct semantic referents. Applying the semantically motivated grammars may have been beneficial in recognizing the semantic referents correctly because the system can explicitly learn them and their appearances in certain patterns in contrast to the trigram model. In particular, if an utterance "pink nine passes the ball to pink seven" appears during recognition and "pink seven" has not been observed in the context of the preceding words during training, then the n-gram model would assign a low probability, likely leading to a recognition error such as "pink eleven". By contrast, in case of semantic grammars the system can learn that the utterance is an instantiation of a pattern "*player* passes the ball to *player*" and that all players can appear at the contained slots, thus making the appearance of the example utterance more likely. Notably, semantic classes such as *player* can in principle also be modeled in stochastic language models, in particular by applying class-based models, or in syntactically motivated grammars. Recall that we also experimented with syntactically motivated grammars and with class-based models and that neither classes which were auto-induced on the raw text data nor

syntactically motivated grammars yielded promising results. Thus, using weak supervision in the form of perceptual context information appears to be beneficial for detecting semantic classes compared to working with raw text. An interesting point for future work might be to explore whether using semantic groupings induced by our algorithm in a class-based model yields reasonable results, in particular when applied as a back-off model in combination with a semantically motivated recognition grammar. Further, we have also investigated weighting rules for semantically meaningful lexical units, i.e. in this example the probability for the occurrence of players like "pink nine" and "pink seven" can be increased according to their occurrence frequencies, thus making recognizing them more likely. Our results indicate that by weighting semantically meaningful sequences, performance is improved, possibly because more words carrying semantics are recognized correctly, even though words carrying no semantics like "forward" or "backward" might be confused, which, however, may not prevent correct parsing. In general, while in SLU research mainly cascading systems are explored, in line with previous work (Wang et al., 2003; Bayer and Riccardi, 2012), our results indicate that joint models yield improved parsing performance, even though word recognition performance may decrease. Yet, our results indicate that a combination of a semantic grammar with a standard trigram model during speech recognition can also reduce the word error rate in some cases compared to applying the trigram model only. Furthermore, the results emphasize that capturing semantic information in a language model applied during ASR is beneficial for subsequent semantic parsing, since the ASR can be tuned towards recognizing words carrying semantics more precisely, which is important with respect to parsing performance.

6 Conclusion

This work investigated the induction of semantic grammars applicable for both speech recognition and understanding in a weakly supervised setting, i.e. using ambiguous context information. In doing so, we compared parsing the output of speech recognizers applied with different language models. Our results indicate that by applying the same semantically motivated grammar learned with weak supervision for both recognition and parsing, speech can be parsed into formal meaning representations with a rather low loss in performance compared to parsing of data without recognition errors, that is, textual data or manual transcriptions of speech. An improvement in parsing performance was obtained over a cascading approach in which a standard n-gram model is used, and we have shown how learning weights for grammatical rules applied in speech recognition can yield improved subsequent parsing results compared to applying unweighted grammars.

Early Gains Matter: A Case for Preferring Generative over Discriminative Crowdsourcing Models

Paul Felt, Eric Ringger, Kevin Seppi, Kevin Black, Robbie Haertel

Abstract

In modern practice, labeling a dataset often involves aggregating annotator judgments obtained from crowdsourcing. State-of-the-art aggregation is performed via inference on probabilistic models, some of which are data-aware, meaning that they leverage features of the data (e.g., words in a document) in addition to annotator judgments. Previous work largely prefers discriminatively trained conditional models. This paper demonstrates that a data-aware crowdsourcing model incorporating a generative multinomial data model enjoys a strong competitive advantage over its discriminative log-linear counterpart in the typical crowdsourcing setting. That is, the generative approach is better except when the annotators are highly accurate in which case simple majority vote is often sufficient. Additionally, we present a novel mean-field variational inference algorithm for the generative model that significantly improves on the previously reported state-of-the-art for that model. We validate our conclusions on six text classification datasets with both human-generated and synthetic annotations.

1 Introduction

The success of supervised machine learning has created an urgent need for manually-labeled training datasets. Crowdsourcing allows human label judgments to be obtained rapidly and at relatively low cost. Micro-task markets such as Amazon's Mechanical Turk and CrowdFlower have popularized crowdsourcing by reducing the overhead required to distribute a job to a community of annotators (the "crowd"). However, crowdsourced judgments often suffer from high error rates. A common solution to this problem is to obtain multiple redundant human judgments, or annotations,[1] relying on the observation that, in aggregate, the ability of non-experts often rivals or exceeds that of experts by averaging over individual error patterns (Surowiecki, 2005; Snow et al., 2008; Jurgens, 2013).

For the purposes of this paper a *crowdsourcing model* is a model that infers, at a minimum, class labels y based on the evidence of one or more imperfect annotations a. A common baseline method aggregates annotations by *majority vote* but by so doing ignores important information. For example, some annotators are more reliable than others, and their judgments ought to be weighted accordingly. State-of-the-art crowdsourcing methods formulate probabilistic models that account for such side information and then apply standard inference techniques to the task of inferring ground truth labels from imperfect annotations.

Data-aware crowdsourcing models additionally account for the features x comprising each data instance (e.g., words in a document). The data can be modeled generatively by proposing a joint distribution $p(y,x,a)$. However, because of the challenge of accurately modeling complex data x, most previous work uses a discriminatively trained conditional model $p(y,a|x)$, hereafter referred to as a discriminative model. As Ng and Jordan (2001) explain, maximizing conditional log likelihood is a compu-

[1] We use the term *annotation* to identify human judgments and distinguish them from gold standard class *labels*.

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 882–891,
Denver, Colorado, May 31 – June 5, 2015.

tationally convenient approximation to minimizing a discriminative 0-1 loss objective, giving rise to the common practice of referring to conditional models as discriminative.

Contributions. This paper challenges the popular preference for discriminative data models in the crowdsourcing literature by demonstrating that in typical crowdsourcing scenarios a generative model enjoys a strong advantage over its discriminative counterpart. We conduct, on both real and synthetic annotations, the first empirical comparison of structurally comparable generative and discriminative crowdsourcing models. The comparison is made fair by developing similar mean-field variational inference algorithms for both models. The generative model is considerably improved by our variational algorithm compared with the previously reported state-of-the-art for that model.

2 Previous Work

Dawid and Skene (1979) laid the groundwork for modern annotation aggregation by proposing the *item-response* model: a probabilistic crowdsourcing model $p(y,a|\gamma)$ over document labels y and annotations a parameterized by confusion matrices γ for each annotator. A growing body of work extends this model to account for such things as correlation among annotators, annotator trustworthiness, item difficulty, and so forth (Bragg et al., 2013; Hovy et al., 2013; Passonneau and Carpenter, 2013; Pasternack and Roth, 2010; Smyth et al., 1995; Welinder et al., 2010; Whitehill et al., 2009; Zhou et al., 2012).

Of the crowdsourcing models that are data-aware, most model the data discriminatively (Carroll et al., 2007; Liu et al., 2012; Raykar et al., 2010; Yan et al., 2014). A smaller line of work models the data generatively (Lam and Stork, 2005; Simpson and Roberts, In Press). We are aware of no papers that compare a generative crowdsourcing model with a similar discriminative model. In the larger context of supervised machine learning, Ng and Jordan (2001) observe that generative models parameters tend to converge with fewer training examples than their discriminatively trained counterparts, but to lower asymptotic performance levels. This paper explores those insights in the context of crowdsourcing models.

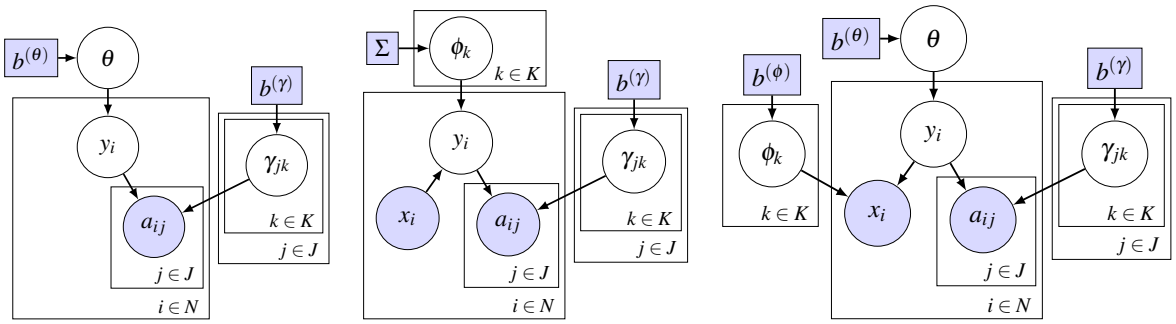
3 Models

At a minimum, a probabilistic crowdsourcing model predicts ground truth labels y from imperfect annotations a (i.e., $\text{argmax}_y\, p(y|a)$). In this section we review the specifics of two previously-proposed data-aware crowdsourcing models. These models are best understood as extensions to a Bayesian formulation of the item-response model that we will refer to as ITEMRESP. ITEMRESP, illustrated in Figure 1a, is defined by the joint distribution

$$p(\theta,\gamma,y,a) \tag{1}$$
$$= p(\theta)\Big[\prod_{j\in J}\prod_{k\in K} p(\gamma_{jk})\Big]\prod_{i\in N} p(y_i|\theta)\prod_{j\in J} p(a_{ij}|\gamma_j,y_i)$$

where J is the set of annotators, K is the set of class labels, N is the set of data instances in the corpus, θ is a stochastic vector in which θ_k is the probability of label class k, γ_j is a matrix of stochastic vector rows in which $\gamma_{jkk'}$ is the probability that annotator j annotates with k' items whose true label is k, y_i is the class label associated with the ith instance in the corpus, and a_{ijk} is the number of times that instance i was annotated by annotator j with label k. The fact that a_{ij} is a count vector allows for the general case where annotators express their uncertainty over multiple class values. Also, $\theta \sim Dirichlet(b^{(\theta)})$, $\gamma_{jk} \sim Dirichlet(b^{(\gamma)}_{jk})$, $y_i|\theta \sim Categorical(\theta)$, and $a_{ij}|y_i,\gamma_j \sim Multinomial(\gamma_{jy_i},M_i)$ where M_i is the number of times annotator j annotated instance i. We need not define a distribution over M_i because in practice $M_i = |a_{ij}|_1$ is fixed and known during posterior inference. A special case of this model formulates a_{ij} as a categorical distribution assuming that annotators will provide at most one annotation per item. All hyperparameters are designated b and are disambiguated with a superscript (e.g., the hyperparameters for $p(\theta)$ are $b^{(\theta)}$). When ITEMRESP parameters are set with uniform θ values and diagonal confusion matrices γ, majority vote is obtained.

Inference in a crowdsourcing model involves a corpus with an annotated portion $N^A = \{i : |a_i|_1 > 0\}$ and also potentially an unannotated portion $N^U = \{i : |a_i|_1 = 0\}$. ITEMRESP can be written as $p(\gamma,y,a) = p(\gamma,y^A,y^U,a)$ where $y^A = \{y_i : i \in N^A\}$ and $y^U = \{y_i : i \in N^U\}$. However, because ITEMRESP has no model of the data x, it receives no benefit from unannotated data N^U.



(a) ITEMRESP (b) LOGRESP (c) MOMRESP

Figure 1: Directed graphical model depictions of the models discussed in this paper. Round nodes are variables with distributions. Rectangular nodes are hyperparameters (without distributions). Shaded nodes have known values (although some a values may be unobserved).

3.1 Log-linear data model (LOGRESP)

One way to make ITEMRESP data-aware is by adding a discriminative log-linear data component (Raykar et al., 2010; Liu et al., 2012). For short, we refer to this model as LOGRESP, illustrated in Figure 1b. Concretely,

$$p(\gamma,\phi,y,a|x) = \Big[\prod_{j\in J}\prod_{k\in K} p(\gamma_{jk})\Big] \prod_{k\in K} p(\phi_k) \prod_{i\in N} p(y_i|x_i,\phi) \prod_{j\in J} p(a_{ij}|\gamma_j,y_i) \quad (2)$$

where x_{if} is the value of feature f in data instance i (e.g., a word count in a text classification problem), ϕ_{kf} is the probability of feature f occurring in an instance of class k, $\phi_k \sim Normal(0,\Sigma)$, and $y_i|x_i,\phi \sim LogLinear(x_i,\phi)$. That is, $p(y_i|x_i,\phi) = \exp[\phi_{y_i}^T x_i] / \sum_k \exp[\phi_k^T x_i]$.

In the special case that each γ_j is the identity matrix (each annotator is perfectly accurate), LOGRESP reduces to a multinomial logistic regression model. Because it is a conditional model, LOGRESP lacks any built-in capacity for semi-supervised learning.

3.2 Multinomial data model (MOMRESP)

An alternative way to make ITEMRESP data-aware is by adding a generative multinomial data component (Lam and Stork, 2005; Felt et al., 2014). We refer to the model as MOMRESP, shown in Figure 1c.

$$p(\theta,\gamma,\phi,y,x,a) = p(\theta)\Big[\prod_{j\in J}\prod_{k\in K} p(\gamma_{jk})\Big] \prod_{k\in K} p(\phi_k) \prod_{i\in N} p(y_i|\theta)p(x_i|y_i,\phi) \prod_{j\in J} p(a_{ij}|\gamma_j,y_i) \quad (3)$$

where ϕ_{kf} is the probability of feature f occurring in an instance of class k, $\phi_k \sim Dirichlet(b_k^{(\phi)})$, $x_i \sim Multinomial(\phi_{y_i}, T_i)$, and T_i is a number-of-trials parameter (e.g., for text classification T_i is the number of words in document i). $T_i = |x_i|_1$ is observed during posterior inference $p(\theta,\gamma,\phi,y|x,a)$.

Because MOMRESP is fully generative over the data features x, it naturally performs semi-supervised learning as data from unannotated instances N^U inform inferred class labels y^A of annotated instances via ϕ. This can be seen by observing that $p(x)$ terms prevent terms involving y^U from summing out of the marginal distribution $p(\theta,\gamma,\phi,y^A,x,a) = \sum_{y^U} p(\theta,\gamma,\phi,y^A,y^U,x,a) = p(\theta,\gamma,\phi,y^A,x^A,a)\sum_{y^U} p(y^U|\theta)p(x^U|y^U)$.

When $N = N^U$ (the unsupervised setting) the posterior distribution $p(\theta,\gamma,\phi,y^U|x,a) = p(\theta,\phi,y^U|x)$ is a mixture of multinomials clustering model. Otherwise, the model resembles a semi-supervised naïve Bayes classifier (Nigam et al., 2006). However, naïve Bayes is supervised by trustworthy labels whereas MOMRESP is supervised by imperfect annotations mediated by inferred annotator error characteristic γ. In the special case that γ is the identity matrix (each annotator is perfectly accurate), MOMRESP reduces to a possibly semi-supervised naïve

Bayes classifier where each annotation is a fully trusted label.

3.3 A Generative-Discriminative Pair

MOMRESP and LOGRESP are a generative-discriminative pair, meaning that they belong to the same parametric model family but with parameters fit to optimize joint likelihood and conditional likelihood, respectively. This relationship is seen via the equivalence of the conditional probability of LOGRESP $p_L(y,a|x)$ and the same expression according to MOMRESP $p_M(y,a|x)$. For simplicity in this derivation we omit priors and consider ϕ, θ, and γ to be known values. Then

$$p_M(y,a|x) = \frac{p(y)p(x|y)p(a|y)}{\sum_{y'}\sum_{a'} p(y')p(x|y')p(a'|y')} \quad (4)$$

$$= \frac{p(y)p(x|y)}{\sum_{y'} p(y')p(x|y')} \cdot p(a|y) \quad (5)$$

$$= \frac{\exp[e^{w_y^T x+z}]}{\sum_k \exp[e^{w_k^T x+z}]} \cdot p(a|y) \quad (6)$$

$$= p_L(y,a|x) \quad (7)$$

Equation 4 follows from Bayes Rule and conditional independence in the model. In Equation 5 $p(a'|y)$ sums to 1. The first term of Equation 6 is the posterior $p(y|x)$ of a naïve Bayes classifier, known to have the same form as a logistic regression classifier where parameters w and z are constructed from ϕ and θ.[2]

4 Mean-field Variational Inference (MF)

In this section we present novel mean-field (MF) variational algorithms for LOGRESP and MOMRESP. Note that Liu et al. (2012) present (in an appendix) variational inference for LOGRESP based on belief propagation (BP). They do not test their algorithm for LOGRESP; however, their comparison of MF and BP variational inference for the ITEMRESP model indicates that the two flavors of variational inference perform very similarly. Our MF algorithm for LOGRESP has not been designed with the idea of outperforming its BP analogue, but rather with the goal of ensuring that the generative and discriminative model use the same inference algorithm. We expect that we would achieve the same results if our comparison used variational BP algorithms for both MOMRESP and LOGRESP, although such an additional comparison is beyond the scope of this work.

Broadly speaking, variational approaches to posterior inference transform inference into an optimization problem by searching within some family of tractable approximate distributions Q for the distribution $q \in Q$ that minimizes distributional divergence from an intractable target posterior p^*. In particular, under the mean-field assumption we confine our search to distributions Q that are fully factorized.

4.1 LOGRESP Inference

We approximate LOGRESP's posterior $p^*(\gamma,\phi,y|x,a)$ using the fully factorized approximation $q(\gamma,\phi,y) = \left[\prod_j \prod_k q(\gamma_{jk})\right] \prod_k q(\phi_k) \prod_i q(y_i)$. Approximate marginal posteriors q are disambiguated by their arguments.

Algorithm. Initialize each $q(y_i)$ to the empirical distribution observed in the annotations a_i. The Kullback-Leibler divergence $KL(q||p^*)$ is minimized by iteratively updating each variational distribution in the model as follows:

$$q(\gamma_{jk}) \propto \prod_{k' \in K} \gamma_{jkk'}^{b_{jkk'}^{(\gamma)} + \sum_{i \in N} a_{ijk'} q(y_i=k) - 1} = Dirichlet(\alpha_{jk}^{(\gamma)})$$

$$q(\phi_k) \propto \exp\left[\phi_k^T \Sigma^{-1} \phi_k + \sum_{i \in N} q(y_i=k) \phi_k^T x_i\right]$$

$$q(y_i) \propto \prod_{k \in K} \exp\Big[\sum_{j \in J} \sum_{k' \in K} a_{ijk'} E_{q(\gamma_{jk})}[\log \gamma_{jkk'}] + \sum_{f \in F} x_{if} E_{q(\phi_k)}[\phi_{kf}]\Big]^{\mathbb{1}(y_i=k)}$$

$$\propto \prod_{k \in K} \alpha_{ik}^{(y)\mathbb{1}(y_i=k)} = Categorical(\alpha_i^{(y)})$$

Approximate distributions are updated by calculating variational parameters $\alpha^{(\cdot)}$, disambiguated by a superscript. Because $q(\gamma_{jk})$ is a Dirichlet distribution the term $E_{q(\gamma_{jk})}[\log \gamma_{jkk'}]$ appearing in $q(y_i)$ is computed analytically as $\psi(\alpha_{jkk'}^{(\gamma)}) - \psi(\sum_{k'} \alpha_{jkk'}^{(\gamma)})$ where ψ is the digamma function.

The distribution $q(\phi_k)$ is a logistic normal distribution. This means that the expectations $E_{q(\phi_k)}[\phi_{kf}]$ that appear in $q(y_i)$ cannot be computed analytically. Following Liu et al. (2012), we approximate the distribution $q(\phi_k)$ with the point estimate

[2] http://cs.cmu.edu/~tom/mlbook/NBayesLogReg.pdf gives a proof of this property in the continuous case and hints about the discrete case proof.

$\hat{\phi}_k = \text{argmax}_{\phi_k} q(\phi_k)$ which can be calculated using existing numerical optimization methods for log-linear models. Such maximization can be understood as embedding the variational algorithm inside of an outer EM loop such as might be used to tune hyperparameters in an empirical Bayesian approach (where ϕ are treated as hyperparameters).

4.2 MOMRESP Inference

MOMRESP's posterior $p^*(y, \theta, \gamma, \phi | x, a)$ is approximated with the fully factorized distribution $q(y, \theta, \gamma, \phi) = q(\theta)\left[\prod_j \prod_k q(\gamma_{jk})\right] \prod_k q(\phi_k) \prod_i q(y_i)$.

Algorithm. Initialize each $q(y_i)$ to the empirical distribution observed in the annotations a_i. The Kullback-Leibler divergence $KL(q||p^*)$ is minimized by iteratively updating each variational distribution in the model as follows:

$$q(\theta) \propto \prod_{k \in K} \theta_k^{b_k^{(\theta)} + \sum_{i \in N} q(y_i = k) - 1} = Dirichlet(\alpha^{(\theta)})$$

$$q(\gamma_{jk}) \propto \prod_{k' \in K} \gamma_{jkk'}^{b_{jkk'}^{(\gamma)} + \sum_{i \in N} a_{ijk'} q(y_i = k) - 1} = Dirichlet(\alpha_{jk}^{(\gamma)})$$

$$q(\phi_k) \propto \prod_{f \in F} \phi_{kf}^{b_{kf}^{(\phi)} + \sum_{i \in N} x_{if} q(y_i = k) - 1} = Dirichlet(\alpha_k^{(\phi)})$$

$$q(y_i) \propto \prod_{k \in K} \exp\Big[\sum_{j \in J} \sum_{k' \in K} a_{ijk'} E_{q(\gamma_{jk})}[\log \gamma_{jkk'}] + E_{q(\theta_k)}[\log \theta_k] + \sum_{f \in F} x_{if} E_{q(\phi_k)}[\log \phi_{kf}] \Big]^{\mathbb{1}(y_i = k)}$$

$$\propto \prod_{k \in K} \alpha_{ik}^{(y) \mathbb{1}(y_i = k)} = Categorical(\alpha_i^{(y)})$$

Approximate distributions are updated by calculating the values of variational parameters $\alpha^{(\cdot)}$, disambiguated by a superscript. The expectations of log terms in the $q(y_i)$ update are all with respect to Dirichlet distributions and so can be computed analytically as explained previously.

4.3 Model priors and implementation details

Computing a lower bound on the log likelihood shows that in practice the variational algorithms presented above converge after only a dozen or so updates. We compute $\text{argmax}_{\phi_k} q(\phi_k)$ for LOGRESP using the L-BFGS algorithm as implemented in MALLET (McCallum, 2002). We choose uninformed priors $b_k^{(\theta)} = 1$ for MOMRESP and identity matrix $\Sigma = \mathbb{1}$ for LOGRESP. We set $b_{kf}^{(\phi)} = 0.1$ for MOMRESP to encourage sparsity in per-class word distributions. Liu et al. (2012) argue that a uniform prior over the entries of each confusion matrix γ_j can lead to degenerate performance. Accordingly, we set the diagonal entries of each $b_j^{(\gamma)}$ to a higher value $b_{jkk}^{(\gamma)} = \frac{1+\delta}{K+\delta}$ and off-diagonal entries to a lower value $b_{jkk'}^{(\gamma)} = \frac{1}{K+\delta}$ with $\delta = 2$.

Both MOMRESP and LOGRESP are given full access to all instances in the dataset, annotated and unannotated. However, as explained in Section 3.1, LOGRESP is conditioned on the data and thus is structurally unable to make use of unannotated data. We experimented briefly with self-training for LOGRESP but it had little effect. With additional effort one could likely settle on a heuristic scheme that allowed LOGRESP to benefit from unannotated data. However, since such an extension is external to the model itself, it is beyond the scope of this work.

5 Experiments with Simulated Annotators

Models which learn from error-prone annotations can be challenging to evaluate in a systematic way. Simulated annotations allow us to systematically control annotator behavior and measure the performance of our models in each configuration.

5.1 Simulating Annotators

We simulate an annotator by corrupting ground truth labels according to that annotator's accuracy parameters. Simulated annotators are drawn from the annotator quality pools listed in Table 1. Each row is a named pool and contains five annotators A1–A5, each with a corresponding accuracy parameter (the number five is chosen arbitrarily). In the pools HIGH, MED, and LOW, annotator errors are distributed uniformly across the incorrect classes. Because there are no patterns among errors, these settings approximate situations in which annotators are ultimately in agreement about the task they are doing, although some are better at it than others. The HIGH pool represents a corpus annotation project with high quality annotators. In the MED and LOW pools annotators are progressively less reliable.

The CONFLICT annotator pool in Table 1 is special in that annotator errors are made systematically rather than uniformly. Systematic errors are

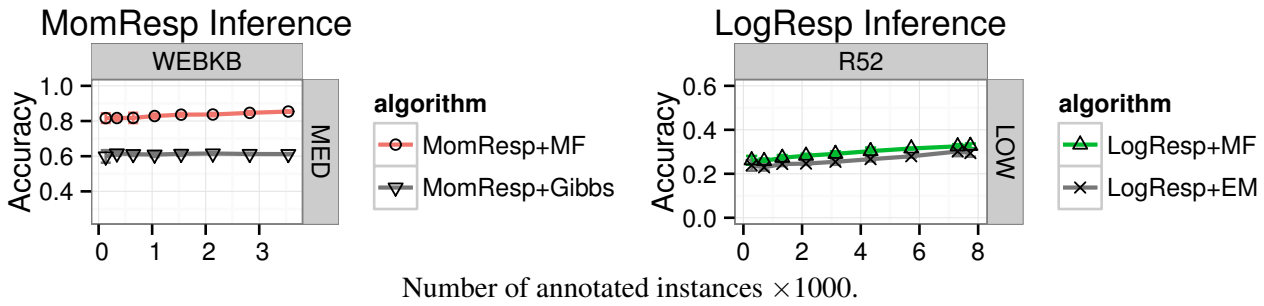


Figure 2: Mean field (MF) variational inference outperforms previous inference methods for both models. *Left*: MOMRESP with MF (MOMRESP+MF) versus with Gibbs sampling (MOMRESP+Gibbs) on the WebKB dataset using annotators from the MED pool. *Right*: LOGRESP with MF (LOGRESP+MF) versus with EM (LOGRESP+EM) on the Reuters52 dataset using annotators from the LOW pool.

produced at simulation time by constructing a per-annotator confusion matrix (similar to γ_j) whose diagonal is set to the desired accuracy setting, and whose off-diagonal row entries are sampled from a symmetric Dirichlet distribution with parameter 0.1 to encourage sparsity and then scaled so that each row properly sums to 1. These draws from a sparse Dirichlet yield consistent error patterns. The CONFLICT pool approximates an annotation project where annotators understand the annotation guidelines differently from one another. For the sake of example, annotator A5 in the CONFLICT setting will annotate documents with the true class *B* as *B* exactly 10% of the time but might annotate *B* as *C* 85% of the time. On the other hand, annotator A4 might annotate *B* as *D* most of the time. We choose low agreement rates for CONFLICT to highlight a case that violates majority vote's assumption that annotators are basically in agreement.

	A1	A2	A3	A4	A5
HIGH	90	85	80	75	70
MED	70	65	60	55	50
LOW	50	40	30	20	10
CONFLICT	50†	40†	30†	20†	10†

Table 1: For each simulated annotator quality pool (HIGH, MED, LOW, CONFLICT), annotators A1-A5 are assigned an accuracy. † indicates that errors are systematically in conflict as described in the text.

5.2 Datasets and Features

We simulate the annotator pools from Table 1 on each of six text classification datasets. The datasets 20 Newsgroups, WebKB, Cade12, Reuters8, and Reuters52 are described by Cardoso-Cachopo (2007). The LDC-labeled Enron emails dataset is described by Berry et al. (2001). Each dataset is preprocessed via Porter stemming and by removal of the stopwords from MALLET's stopword list. Features occurring fewer than 5 times in the corpus are discarded. Features are fractionally scaled so that $|x_i|_1$ is equal to the average document length since document scaling has been shown to be beneficial for multinomial document models (Nigam et al., 2006).

Each dataset is annotated according to the following process: an instance is selected at random (without replacement) and annotated by three annotators selected at random (without replacement). Because annotation simulation is a stochastic process, each simulation is repeated five times.

5.3 Validating Mean-field Variational Inference

Figure 2 compares mean-field variational inference (MF) with alternative inference algorithms from previous work. For variety, the left and right plots are calculated over arbitrarily chosen datasets and annotator pools, but these trends are representative of other settings. MOMRESP using MF is compared with MOMRESP using Gibbs sampling estimating $p(y|x,a)$ from several hundred samples (an improvement to the method used by Felt et al. (2014)).

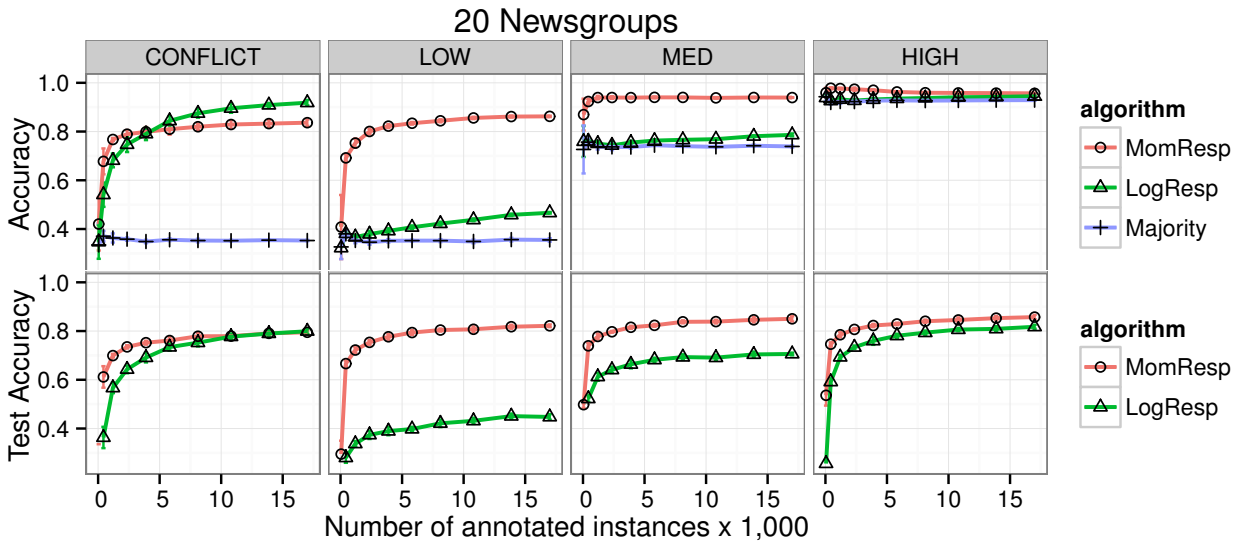

Figure 3: *Top row*: Inferred label accuracy on three-deep annotations. A majority vote baseline is shown for reference. *Bottom row*: Generalization accuracy on a test set. Majority vote is not shown since it does not generate test set predictions. Each column uses the indicated simulated annotator pool.

MOMRESP benefits significantly from MF. We suspect that this disparity could be reduced via hyperparameter optimization as indicated by Asuncion et al. (2009). However, that investigation is beyond the scope of the current work. LOGRESP using MF is compared with LOGRESP using expectation maximization (EM) as in (Raykar et al., 2010). LOGRESP with MF displays minor improvements over LOGRESP with EM. This is consistent with the modest gains that Liu et al. (2012) reported when comparing variational and EM inference for the ITEMRESP model.

5.4 Discriminative (LOGRESP) versus Generative (MOMRESP)

We run MOMRESP and LOGRESP with MF inference on the cross product of datasets and annotator pools. Inferred label accuracy on items that have been annotated is the primary task of crowdsourcing; we track this measure accordingly. However, the ability of these models to generalize on unannotated data is also of interest and allows better comparison with traditional non-crowdsourcing models. Figure 3 plots learning curves for each annotator pool on the 20 Newsgroups dataset; results on other datasets are summarized in Table 2. The first row of Figure 3 plots the accuracy of labels inferred from annotations. The second row of Figure 3 plots generalization accuracy using the inferred model parameters ϕ (and θ in the case of MOMRESP) on held-out test sets with no annotations. The generalization accuracy curves of MOMRESP and LOGRESP may be compared with those of naïve Bayes and logistic regression, respectively. Recall that in the special case where annotations are both flawless and trusted (via diagonal confusion matrices γ) then MOMRESP and LOGRESP simplify to semi-supervised naïve Bayes and logistic regression classifiers, respectively.

Notice that MOMRESP climbs more steeply than LOGRESP in all cases. This observation is in keeping with previous work in supervised learning. Ng and Jordan (2001) argue that generative and discriminative models have complementary strengths: generative models tend to have steeper learning curves and converge in terms of parameter values after only $\log n$ training examples, whereas discriminative models tend to achieve higher asymptotic levels but converge more slowly after n training examples. The second row of Figure 3 shows that even after training on three-deep annotations over the entire 20 newsgroups dataset, LOGRESP's data model does not approach its asymptotic level of performance. The

early steep slope of the generative model is more desirable in this setting than the eventually superior performance of the discriminative model given large numbers of annotations. Figure 4 additionally plots MOMRESPA, a variant of MOMRESP deprived of all unannotated documents, showing that the early generative advantage is not attributable entirely to semi-supervision.

The generative model is more robust to annotation noise than the discriminative model, seen by comparing the LOW, MED, and HIGH columns in Figure 3. This robustness is significant because crowdsourcing tends to yield noisy annotations, making the LOW and MED annotator pools of greatest practical interest. This assertion is borne out by an experiment with CrowdFlower, reported in Section 6.

To validate that LOGRESP does, indeed, asymptotically surpass MOMRESP we ran inference on datasets with increasing annotation depths. Crossover does not occur until 20 Newsgroups is annotated nearly 12-deep for LOW, 5-deep for MED, and 3.5-deep (on average) for HIGH. Additionally, for each combination of dataset and annotator pool except those involving CONFLICT, by the time LOGRESP surpasses MOMRESP, the majority vote baseline is extremely competitive with LOGRESP. The CONFLICT setting is the exception to this rule: CONFLICT annotators are particularly challenging for majority vote since they violate the implicit assumption that annotators are basically aligned with the truth. The CONFLICT setting is of practical interest only when annotators have dramatic deep-seated differences of opinion about what various labels should mean. For most crowdsourcing projects this issue may be avoided with sufficient up-front orientation of the annotators. For reference, in Figure 4 we show that a less extreme variant of CONFLICT behaves more similarly to LOW.

Table 2 reports the percent of the dataset that must be annotated three-deep before LOGRESP's inferred label accuracy surpasses that of MOMRESP. Crossover tends to happen later when annotation quality is low and earlier when annotator quality is high. Cases reported as *NA* were too close to call; that is, the dominating algorithm changed depending on the random run.

Unsurprisingly, MOMRESP is not well suited to all classification datasets. The 0% entries in Table 2 mean that LOGRESP dominates the learning curve for that annotator pool and dataset. These cases are likely the result of the MOMRESP model making the same strict inter-feature independence assumptions as naïve Bayes, rendering it tractable and effective for many classification tasks but ill-suited for datasets where features are highly correlated or for tasks in which class identity is not informed by document vocabulary. The CADE12 dataset, in particular, is known to be challenging. A supervised naïve Bayes classifier achieves only 57% accuracy on this dataset (Cardoso-Cachopo, 2007). We would expect MOMRESP to perform similarly poorly on sentiment classification data. Although we assert that generative models are inherently better suited to crowdsourcing than discriminative models, a sufficiently strong mismatch between model assumptions and data can negate this advantage.

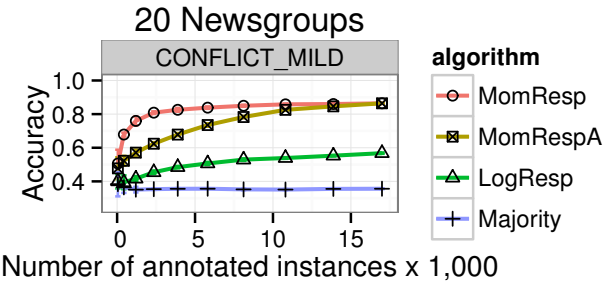

Figure 4: Inferred label accuracy for a variant of the CONFLICT annotator pool in which the off-diagonals of each annotator confusion matrix are drawn from a Dirichlet parameterized by 1 rather than 0.1. Also adds the algorithm MOMRESPA to show the effect of removing MOMRESP's access to unannotated documents.

6 Experiments with Human Annotators

In the previous section we used simulations to control annotator error. In this section we relax that control. To assess the effect of real-world annotation error on MOMRESP and LOGRESP, we selected 1000 instances at random from 20 Newsgroups and paid annotators on CrowdFlower to annotate them with the 20 Newsgroups categories, presented as human-readable names (e.g., "Atheism" for alt.atheism). Annotators were allowed to express uncertainty by

Table 2: The percentage of the dataset that must be annotated (three-deep) before the generative model MOMRESP is surpassed by LOGRESP. ✓indicates that MOMRESP dominates the entire learning curve; 0% indicates that LOGRESP dominates. *NA* indicates high variance cases that were too close to call.

selecting up to three unique categories per document. During the course of a single day we gathered 7,265 annotations, with each document having a minimum of 3 and a mean of 7.3 annotations.[3] Figure 5 shows learning curves for the CrowdFlower annotations. The trends observed previously are unchanged. MOMRESP enjoys a significant advantage when relatively few annotations are available. Presumably LOGRESP would still dominate if we were able to explore later portions of the curve or curves with greater annotation depth.

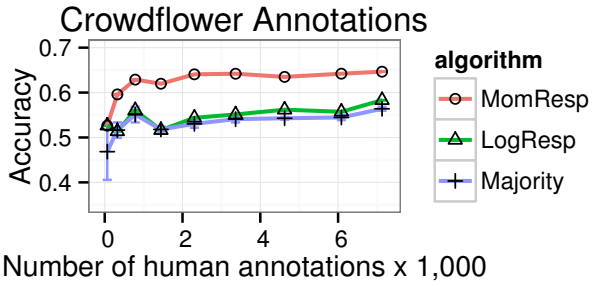

Figure 5: Inferred label accuracy on annotations gathered from CrowdFlower over a subset of 1000 instances of the 20 Newsgroups dataset. At the last plotted point there are $7,265/1,000 \approx 7.3$ annotations per instance.

[3] This dataset and the scripts that produced it are available via git at git://nlp.cs.byu.edu/plf1/crowdflower-newsgroups.git

7 Conclusions and Future Work

We have argued that generative models are better suited than discriminative models to the task of annotation aggregation since they tend to be more robust to annotation noise and to approach their asymptotic performance levels with fewer annotations. Also, in settings where a discriminative model would usually shine, there are often enough annotations that a simple baseline of majority vote is sufficient.

In support of this argument, we developed comparable mean-field variational inference for a generative-discriminative pair of crowdsourcing models and compared them on both crowdsourced and synthetic annotations on six text classification datasets. In practice we found that on classification tasks for which generative models of the data work reasonably well, the generative model greatly outperforms its discriminative log-linear counterpart.

The generative multinomial model we employed makes inter-feature independence assumptions ill suited to some classification tasks. Document topic models (Blei, 2012) could be used as the basis of a more sophisticated generative crowdsourcing model. One might also transform the data to make it more amenable to a simple model using documents assembled from distributed word representations (Mikolov et al., 2013). Finally, although we expect these results to generalize, we have only experimented with text classification. Similar experiments could be performed on other commonly crowdsourced tasks such as sequence labeling.

Abstract

We describe a novel max-margin learning approach to optimize non-linear performance measures for distantly-supervised relation extraction models. Our approach can be generally used to learn latent variable models under multivariate non-linear performance measures, such as F_β-score. Our approach interleaves Concave-Convex Procedure (CCCP) for populating latent variables with dual decomposition to factorize the original hard problem into smaller independent sub-problems. The experimental results demonstrate that our learning algorithm is more effective than the ones commonly used in the literature for distant supervision of information extraction models. On several data conditions, we show that our method outperforms the baseline and results in up to 8.5% improvement in the F_1-score.

1 Introduction

Rich models with latent variables are popular for many problems in natural language processing. In information extraction, for example, one needs to predict the relation labels $\mathbf{y}$ that an entity-pair $\mathbf{x}$ can have based on the hidden relation mentions $\mathbf{h}$, *i.e.*, the relation labels for occurrences of the entity-pair in a given corpus. However, these models are often trained by optimizing performance measures (such as conditional log-likelihood or error rate) that are not directly related to the task-specific non-linear performance measure, *e.g.*, the F_1-score. However, better models may be trained by optimizing the task-specific performance measure while allowing latent variables to adapt their values accordingly.

We present a large-margin method to learn parameters of latent variable models for a wide range of non-linear multivariate performance measures such as F_β. Our method can be applied to learning graphical models that incorporate inter-dependencies among the output variables either directly, or indirectly through hidden variables.

Large-margin methods have been shown to be a compelling approach to learn rich models detailing the inter-dependencies among the output variables, via optimizing loss functions decomposable over the *training instances* (Taskar et al., 2003; Tsochantaridis et al., 2004) or non-decompasable loss functions (Ranjbar et al., 2013; Tarlow and Zemel, 2012; Rosenfeld et al., 2014; Keshet, 2014). They have also been shown to be powerful when applied to latent variable models when optimizing for decomposable loss functions (Wang and Mori, 2011; Felzenszwalb et al., 2010; Yu and Joachims, 2009).

Our large-margin method learns latent variable models via optimizing non-decomposable loss functions. It interleaves the Concave-Convex Procedure (CCCP) (Yuille and Rangarajan, 2001) for populating latent variables with dual decomposition (Komodakis et al., 2011; Rush and Collins, 2012). The latter factorizes the hard optimization problem (encountered in learning) into smaller independent sub-problems over the training instances. We then present linear programming and local search methods for effective optimization of the sub-problems encountered in the dual decomposition. Our local search algorithm leads to a speed up of 7,000 times compared to the exhaustive search used in the literature (Joachims, 2005; Ranjbar et al., 2012).

Our work is the first to make use of max-margin training in distant supervision of relation extraction models. We demonstrate the effectiveness of our proposed method compared to two strong baseline systems which optimize for the error rate and conditional likelihood, including a state-of-the-art system by Hoffmann et al. (2011). On several data conditions, we show that our method outperforms the baseline and results in up to 8.5% improvement in the F_1-score.

2 Preliminaries

2.1 Distant Supervision for Relation Extraction

Our framework is motivated by distant supervision for learning relation extraction models (Mintz et al., 2009). The goal is to learn relation extraction models by aligning facts in a database to sentences in a large unlabeled corpus. Since the individual sentences are not hand labeled, the facts in the database act as "weak" or "distant" labels, hence the learning scenario is termed as distantly supervised.

Prior work casts this problem as a multi-instance multi-label learning problem (Hoffmann et al., 2011; Surdeanu et al., 2012). It is multi-instance since for a given entity-pair, only the label of the bag of sentences containing both entities (aka mentions) is given. It is multi-label since a bag of mentions can have multiple labels. The inter-dependencies between relation labels and (hidden) mention labels are modeled by a Markov Random Field (Figure 1) (Hoffmann et al., 2011). The learning algorithms used in the literature for this problem optimize the (conditional) likelihood, but the evaluation measure is commonly the F-score.

Formally, the training data is $\mathcal{D} := \{(\mathbf{x}_i, \mathbf{y}_i)\}_{i=1}^N$ where $\mathbf{x}_i \in \mathcal{X}$ is the entity-pair, $\mathbf{y}_i \in \mathcal{Y}$ denotes the relation labels, and $\mathbf{h}_i \in \mathcal{H}$ denotes the *hidden* mention labels. The possible relation labels for the entity pair are observed from a given knowledge-base. If there are L candidate relation labels in the knowledge-base, then $\mathbf{y}_i \in \{0,1\}^L$, (e.g. $y_{i,\ell}$ is 1 if the relation ℓ is licensed by the knowledge-base for the entity-pair) and $\mathbf{h}_i \in \{1, .., L, nil\}^{|\mathbf{x}_i|}$ (i.e. each mention realizes one of the relation labels or *nil*).

Notation. In the rest of the paper, we denote the collection of all entity-pairs $\{\mathbf{x}_i\}_{i=1}^N$ by $\mathbf{X} \in \boldsymbol{\mathcal{X}} := \mathcal{X} \times .. \times \mathcal{X}$, the collection of mention relations $\{\mathbf{h}_i\}_{i=1}^N$ by $\mathbf{H} \in \boldsymbol{\mathcal{H}} := \mathcal{H} \times .. \times \mathcal{H}$, and the collection of relation labels $\{\mathbf{y}_i\}_{i=1}^N$ by $\mathbf{Y} \in \boldsymbol{\mathcal{Y}} := \mathcal{Y} \times .. \times \mathcal{Y}$.

The aim is to learn a parameter vector $\mathbf{w} \in \mathbb{R}^d$ by which the relation labels for a new entity-pair $\mathbf{x}$ can be predicted

$$f_{\mathbf{w}}(\mathbf{x}) := \arg\max_{\mathbf{y}} \max_{\mathbf{h}} \mathbf{w} \cdot \Phi(\mathbf{x}, \mathbf{h}, \mathbf{y}) \qquad (1)$$

where $\Phi \in \mathbb{R}^d$ is a feature vector defined according to the Markov Random Field, modeling the inter-dependencies between $\mathbf{x}$ and $\mathbf{y}$ through $\mathbf{h}$ (Figure 1). In training, we would like to minimize the loss function Δ by which the model will be assessed at test time. For the relation extraction task, the loss can be considered to be the negative of the F_β score:

$$F_\beta = \frac{1}{\frac{\beta}{\text{Precision}} + \frac{1-\beta}{\text{Recall}}} \qquad (2)$$

where $\beta = 0.5$ results in optimizing against F_1-score. Our proposed learning method optimizes those loss functions Δ which cannot be decomposed over individual training instances. For example, F_β depends non-linearly on Precision and Recall which in turn require the predictions for *all* the entity pairs in the training set, hence it cannot be decomposed over individual training instances.

2.2 Structured Prediction Learning

The goal of our learning problem is to find $\mathbf{w} \in R^d$ which minimizes the expected loss, aka *risk*, over a

new sample $\mathcal{D}'$ of size N':

$$R^{\Delta}_{f_{\mathbf{w}}} := \int \Delta\Big(\big(f_{\mathbf{w}}(\mathbf{x}'_1), .., f_{\mathbf{w}}(\mathbf{x}'_{N'})\big), \big(\mathbf{y}'_1, .., \mathbf{y}'_{N'}\big)\Big) dPr(\mathcal{D}') \tag{3}$$

Generally, the loss function Δ cannot be decomposed into a linear combination of a loss function δ over individual training samples. However, most discriminative large-margin learning algorithms assume for simplicity that the loss function is decomposable and the samples are i.i.d. (independent and identically distributed), which simplifies the sample risk $R^{\Delta}_{f_{\mathbf{w}}}$ as:

$$R^{\delta}_{f_{\mathbf{w}}} := \int \delta(f_{\mathbf{w}}(\mathbf{x}'), \mathbf{y}') dPr(\mathbf{x}', \mathbf{y}') \tag{4}$$

Often learning algorithms make use of the empirical risk as an approximation of the sample risk:

$$\hat{R}^{\delta}_{f_{\mathbf{w}}} := \frac{1}{N} \sum_{i=1}^{N} \delta(f_{\mathbf{w}}(\mathbf{x}_i), \mathbf{y}_i) \tag{5}$$

For non-decomposable loss functions, such as F_β, Δ cannot be expressed in terms of instance-specific loss function δ to construct the empirical risk of the kind in Eq. (5). Instead, we need to optimize the empirical risk constructed based on the sample loss:

$$\hat{R}^{\Delta}_{f_{\mathbf{w}}} := \Delta\Big(\big(f_{\mathbf{w}}(\mathbf{x}_1), .., f_{\mathbf{w}}(\mathbf{x}_N)\big), \big(\mathbf{y}_1, .., \mathbf{y}_N\big)\Big) \tag{6}$$

or equivalently

$$\hat{R}^{\Delta}_{f_{\mathbf{w}}} := \Delta(f_{\mathbf{w}}(\mathbf{X}), \mathbf{Y}) \tag{7}$$

where $f_{\mathbf{w}}(\mathbf{X}) := (f_{\mathbf{w}}(\mathbf{x}_1), .., f_{\mathbf{w}}(\mathbf{x}_N))$.

Having defined the empirical risk in Eq (7), we formulate the learning problem as a structured prediction problem. Instead of learning a mapping function $f_{\mathbf{w}} : \mathcal{X} \to \mathcal{Y}$ from an individual instance $\mathbf{x} \in \mathcal{X}$ to its label $\mathbf{y} \in \mathcal{Y}$, let us learn a mapping function $\mathbf{f} : \boldsymbol{\mathcal{X}} \to \boldsymbol{\mathcal{Y}}$ from all instances $\mathbf{X} \in \boldsymbol{\mathcal{X}}$ to their labels $\mathbf{Y} \in \boldsymbol{\mathcal{Y}}$. We then define the best labeling using a linear discriminant function:

$$\mathbf{f}(\mathbf{X}) := \arg\max_{\mathbf{Y}' \in \boldsymbol{\mathcal{Y}}} \max_{\mathbf{H} \in \boldsymbol{\mathcal{H}}} \Big\{ \mathbf{w} \cdot \Psi(\mathbf{X}, \mathbf{H}, \mathbf{Y}') \Big\} \tag{8}$$

where $\Psi(\mathbf{X}, \mathbf{H}, \mathbf{Y}') := \sum_{i=1}^{N} \Phi(\mathbf{x}_i, \mathbf{h}_i, \mathbf{y}'_i)$. Based on the margin re-scaling formulation of structured prediction problems (Tsochantaridis et al., 2004), the training objective can be written as the following unconstrained optimization problem:

$$\min_{\mathbf{w}} \frac{1}{2}||\mathbf{w}||_2^2 + C \max_{\mathbf{Y}'} \Big\{ \max_{\mathbf{H}} \mathbf{w} \cdot \Psi(\mathbf{X}, \mathbf{H}, \mathbf{Y}') - \max_{\mathbf{H}} \mathbf{w} \cdot \Psi(\mathbf{X}, \mathbf{H}, \mathbf{Y}) + \Delta(\mathbf{Y}', \mathbf{Y}) \Big\} \tag{9}$$

which is similar to the training objective for the latent SVMs (Yu and Joachims, 2009), with the difference that instance-dependent loss function δ is replaced by the sample loss function Δ. Learning $\mathbf{w}$ by optimizing the above objective function is challenging, and is the subject of the next section.

3 Optimizing the Training Objective

In this section we present our method to learn latent SVMs with non-decomposable loss functions. Our training objective is Eq (9), which can be equivalently expressed as:

$$\min_{\mathbf{w}} \frac{1}{2}||\mathbf{w}||_2^2 + C \max_{\mathbf{y}'_1, .., \mathbf{y}'_N} \Big\{ \Delta\Big((\mathbf{y}_1, .., \mathbf{y}_N), (\mathbf{y}'_1, .., \mathbf{y}'_N)\Big) + \sum_{i=1}^{N} \max_{\mathbf{h}} \mathbf{w} \cdot \Phi(\mathbf{x}_i, \mathbf{h}, \mathbf{y}'_i) - \sum_{i=1}^{N} \max_{\mathbf{h}} \mathbf{w} \cdot \Phi(\mathbf{x}_i, \mathbf{h}, \mathbf{y}_i) \Big\} \tag{10}$$

The training objective is non-convex, since it is the difference of two convex functions. In this section we make use of the CCCP to populate the hidden variables (Yu and Joachims, 2009; Yuille and Rangarajan, 2001), and interleave it with dual decomposition (DD) to solve the resulting intermediate loss-augmented inference problems (Ranjbar et al., 2012; Rush and Collins, 2012; Komodakis et al., 2011).

3.1 Concave-Convex Procedure (CCCP)

The CCCP (Yuille and Rangarajan, 2001) gives a general iterative method to optimize those non-convex objective functions which can be written as the difference of two convex functions $g_1(\mathbf{w}) - g_2(\mathbf{w})$. The idea is to iteratively lowerbound g_2 with a linear function $g_2(\mathbf{w}^{(t)}) + \mathbf{v} \cdot (\mathbf{w} - \mathbf{w}^{(t)})$, and take the following step to update $\mathbf{w}$:

$$\mathbf{w}^{(t+1)} := \arg\min_{\mathbf{w}} \big\{ g_1(\mathbf{w}) - \mathbf{w} \cdot \mathbf{v}^{(t)} \big\} \tag{11}$$

In our case, the training objective Eq (10) is the difference of two convex functions, where the second function g_2 is $C \sum_{i=1}^{N} \max_{\mathbf{h}} \big\{ \mathbf{w} \cdot \Phi(\mathbf{x}_i, \mathbf{h}, \mathbf{y}_i) \big\}$. The

Algorithm 1 The Training Algorithm (Optimizing Eq 10)

procedure OPT-LATENTSVM($\mathbf{X}, \mathbf{Y}$)
  Initialize $\mathbf{w}^{(0)}$ and set $t = 0$
  repeat
    for $i := 1$ to N **do**
      $\mathbf{h}_i^* := \arg\max_{\mathbf{h}} \mathbf{w}^{(t)} \cdot \Phi(\mathbf{x}_i, \mathbf{h}, \mathbf{y}_i)$
    // Optimizing Eq 12
    $\mathbf{w}^{(t+1)} :=$ optSVM($\mathbf{X}, \mathbf{H}^*, \mathbf{Y}$)
    $t := t + 1$
  until some stopping condition is met
  return $\mathbf{w}^{(t)}$

lowerbound of $g_2(\mathbf{w})$ involves populating the hidden variables by:

$$\mathbf{h}_i^* := \arg\max_{\mathbf{h}} \left\{ \mathbf{w}^{(t)} \cdot \Phi(\mathbf{x}_i, \mathbf{h}, \mathbf{y}_i) \right\}.$$

Therefore, in each iteration of our CCCP-based algorithm we need to optimize Eq (12), which is reminiscent of the standard structural SVM without latent variables:

$$\min_{\mathbf{w}} \frac{1}{2}||\mathbf{w}||_2^2 + C \max_{\mathbf{y'}_1,..,\mathbf{y'}_N} \left\{ \Delta\Big((\mathbf{y}_1,..,\mathbf{y}_N), (\mathbf{y'}_1,..,\mathbf{y'}_N) \Big) + \sum_{i=1}^{N} \max_{\mathbf{h}} \mathbf{w} \cdot \Phi(\mathbf{x}_i, \mathbf{h}, \mathbf{y}'_i) - \sum_{i=1}^{N} \mathbf{w} \cdot \Phi(\mathbf{x}_i, \mathbf{h}_i^*, \mathbf{y}_i) \right\} \quad (12)$$

The above objective function can be optimized using the standard cutting-plane algorithms for structural SVM (Tsochantaridis et al., 2004; Joachims, 2005). The cutting-plane algorithm in turn needs to solve the *loss-augmented inference*, which is the subject of the next sub-section. The CCCP-based training algorithm is summarized in Algorithm 1.

3.2 Loss-Augmented Inference

To be able to optimize the training objective Eq (12) encountered in each iteration of Algorithm 1, we need to solve (the so-called) loss-augmented inference:

$$\max_{\mathbf{y}'_1,..,\mathbf{y}'_N} \quad \Delta\Big((\mathbf{y}_1,..,\mathbf{y}_N), (\mathbf{y}'_1,..,\mathbf{y}'_N) \Big) + \sum_{i=1}^{N} \max_{\mathbf{h}} \mathbf{w} \cdot \Phi(\mathbf{x}_i, \mathbf{h}, \mathbf{y}'_i) \quad (13)$$

We make use of the dual decomposition (DD) technique to decouple the two terms of the above objective function, and efficiently find an approximate solution. DD is shown to be an effective technique for loss-augmented inference in structured prediction models *without* hidden variables (Ranjbar et al., 2012).

To apply DD to the loss-augmented inference (13), let us rewrite it as a constrained optimization problem:

$$\max_{\mathbf{y}'_1,..,\mathbf{y}'_N,\mathbf{y}''_1,..,\mathbf{y}''_N} \Delta\Big((\mathbf{y}_1,\ldots,\mathbf{y}_N), (\mathbf{y}'_1,\ldots,\mathbf{y}'_N) \Big) + \sum_{i=1}^{N} \max_{\mathbf{h}} \mathbf{w} \cdot \Phi(\mathbf{x}_i, \mathbf{h}, \mathbf{y}_i{}'')$$

subject to

$$\forall i \in \{1,\ldots,N\}, \forall \ell \in \{1,\ldots,L\}, \quad y'_{i,\ell} = y''_{i,\ell}$$

Introduction of the new variables $(\mathbf{y}''_1, .., \mathbf{y}''_N)$ decouples the two terms in the objective function, and as we will see, leads to an effective optimization algorithm. After forming the Lagrangian, the dual objective function is derived as:

$$L(\mathbf{\Lambda}) := \max_{\mathbf{Y}'} \Delta(\mathbf{Y}, \mathbf{Y}') + \sum_i \sum_\ell \lambda_i(\ell) y'_{i,\ell} + \max_{\mathbf{Y}''} \sum_{i=1}^{N} \max_{\mathbf{h}} \mathbf{w} \cdot \Phi(\mathbf{x}_i, \mathbf{h}, \mathbf{y}_i{}'') - \sum_i \sum_\ell \lambda_i(\ell) y''_{i,\ell}$$

where $\mathbf{\Lambda} := (\boldsymbol{\lambda}_1, .., \boldsymbol{\lambda}_N)$, and $\boldsymbol{\lambda}_i$ is a vector of Lagrange multipliers for L binary variables each of which represent a relation label. The two optimization problems involved in the dual $L(\mathbf{\Lambda})$ are independent and can be solved separately. The dual is an upperbound on the loss-augmented objective function for any value of $\mathbf{\Lambda}$; therefore, we can find the tightest upperbound as an approximate solution:

$$\min_{\mathbf{\Lambda}} L(\mathbf{\Lambda})$$

The dual is non-differentiable at those points $\mathbf{\Lambda}$ where either of the two optimisation problems has multiple optima. Therefore, it is optimized using the subgradient descent method:

$$\Lambda^{(t)} := \Lambda^{(t-1)} - \eta^{(t)} (\mathbf{Y}'_* - \mathbf{Y}''_*)$$

where $\eta^{(t)} = \frac{1}{\sqrt{t}}$ is the step size[1], and

$$\mathbf{Y}'_* := \arg\max_{\mathbf{Y}'} \Delta(\mathbf{Y}, \mathbf{Y}') + \sum_i \sum_\ell \lambda_i^{(t-1)}(\ell) y'_{i,\ell} \quad (14)$$

$$\mathbf{Y}''_* := \arg\max_{\mathbf{Y}''} \sum_{i=1}^{N} \max_{\mathbf{h}} \mathbf{w} \cdot \Phi(\mathbf{x}_i, \mathbf{h}, \mathbf{y}_i{}'') - \sum_i \sum_\ell \lambda_i^{(t-1)}(\ell) y''_{i,\ell} \quad (15)$$

[1]Other (non-increasing) functions of the iteration number t are also plausible, as far as they satisfy the following conditions (Komodakis et al., 2011) needed to guarantee the convergence to the optimal solution in the subgradient descent method: $\eta^{(t)} \geq 0, \lim_{t\to\infty} \eta^{(t)} = 0, \sum_{t=1}^{\infty} \eta^{(t)} = \infty$

Algorithm 2 Loss-Augmented Inference

procedure OPT-LOSSAUG($\mathbf{w}, \mathbf{X}, \mathbf{Y}$)
  Initialize $\mathbf{\Lambda}^{(0)}$ and set $t = 0$
  repeat
    $\mathbf{Y}^{'}_{*} :=$ opt-LossLag($\mathbf{\Lambda}, \mathbf{Y}$) // Eq (14)
    $\mathbf{Y}^{''}_{*} :=$ opt-ModelLag($\mathbf{\Lambda}, \mathbf{X}$) // Eq (15)
    if $\mathbf{Y}^{'}_{*} = \mathbf{Y}^{''}_{*}$ **then**
      return $\mathbf{Y}^{'}_{*}$
    for $i := 1$ to N **do**
      for $\ell := 1$ to L **do**
        $\lambda_i^{(t+1)}(\ell) := \lambda_i^{(t)}(\ell) - \eta^{(t)}(y'_{i,\ell} - y''_{i,\ell})$
  until some stopping condition is met
  return $\mathbf{Y}^{'}_{*}$

The DD algorithm to compute the loss-augmented inference is outlined in Algorithm 2. Now the challenge is how to solve the above two optimization problems, which is the subject of the following section.

3.3 Effective Optimization of the Dual

The two optimization problems involved in the dual are hard in general. More specifically, the optimization of the affine-augmented model score (in Eq. 15) is as difficult as the MAP inference in the underlying graphical model, which can be challenging for loopy graphs. For the graphical model underlying distant supervision of relation extraction (Fig 1), we formulate the inference as an ILP (integer linear program). Furthermore, we relax the ILP to LP to speed up the inference, in the expense of trading exact solutions with approximate solutions[2].

Likewise, the optimization of the affine-augmented multivariate loss (in Eq. 14) is difficult. This is because we have to search over the entire space of $\mathbf{Y}' \in \mathcal{Y}$, which is exponentially large $\mathcal{O}(2^{N*L})$. However, if the loss term Δ can be expressed in terms of some aggregate statistics over $\mathbf{Y}'$, such as false positives (FPs) and false negatives (FNs), the optimization can be performed efficiently. This is due to the fact that the number of FPs can range from zero to the size of negative labels, and the number of FNs can range from zero to the number of positive labels. Therefore, the loss term can take $\mathcal{O}(N^2L^2)$ different values which can be represented on a two-dimensional grid. Fixing FPs and FNs to a grid point, $\mathbf{\Lambda} \cdot \mathbf{Y}'$ is maximized with respect to $\mathbf{Y}'$. The grid point which has the best value for $\Delta(\mathbf{Y}, \mathbf{Y}') + \mathbf{\Lambda} \cdot \mathbf{Y}'$ will then give the optimal solution for Eq (14).

Algorithm 3 Finding $\mathbf{Y}'_*$: Local Search

procedure OPT-LOSSLAG($\mathbf{\Lambda}, \mathbf{Y}$)
  $(idx_1^n \dots idx_{\#neg}^n) \leftarrow$ Sort $\downarrow$ $(\lambda_i(\ell))$ // FPs
  $(idx_1^n \dots idx_{\#pos}^n) \leftarrow$ Sort $\uparrow$ $(\lambda_i(\ell))$ // FNs
  Initialise (fp, fn) on the grid
  repeat
    for $((fp', fn') \in$ `Neigbours`(fp, fn) **do**
      $loss_{(fp',fn')} = \Delta(fp', fn') + \mathbf{\Lambda}_{sorted}$[3]
    $loss_{(fp'',fn'')} = \arg\max_{(fp',fn')} loss_{(fp',fn')}$
    if $loss_{(fp,fn)} > loss_{(fp'',fn'')}$ **then**
      break
    else
      $(fp, fn) = (fp'', fn'')$
  until $loss_{(fp,fn)} \leq loss_{(fp'',fn'')}$
return $\{ \mathbf{Y}'$ corresponding to $(fp, fn) \}$

Exhaustive search in the space of all possible grid points is not efficient as soon as the grid becomes large. Therefore, we have to adapt the techniques proposed in previous work (Ranjbar et al., 2012; Joachims, 2005). We propose a simple but effective *local search* strategy for this purpose. The procedure is outlined in Algorithm 3. We start with a random grid point, and move to the best neighbour. We keep hill climbing until there is no neighbour better than the current point. We define the neighbourhood by a set of exponentially-spaced points in all directions around the current point, to improve the exploration of the search space. We present some analysis on the benefits of using this search strategy vis-a-vis the exhaustive search in the Experiments section.

4 Experiments

Dataset: We use the challenging benchmark dataset created by Riedel et al. (2010) for distant supervision of relation extraction models. It is created by aligning relations from *Freebase*[4] with the sentences in *New York Times* corpus (Sandhaus, 2008). The labels for the datapoints come from the Freebase

[2]We observed in our experiments that relaxing the ILP to LP does not hurt the performance, but significantly speeds up the inference.

[3]For a given (fp, fn), we set $\mathbf{y}'$ by picking the sorted unary terms that maximize the score according to $\mathbf{y}$.

[4]`www.freebase.com`

database but Freebase is incomplete (Ritter et al., 2013). So a data point is labeled *nil* when either no relation exists or the relation is absent in Freebase. To avoid this ambiguity we train and evaluate the baseline and our algorithms on a subset of this dataset which consists of only non-nil relation labeled datapoints (termed as *positive dataset*). For the sake of completeness, we do report the accuracies of the various approaches on the entire evaluation dataset.

Systems and Baseline: Hoffmann et al. (2011) describe a state-of-the-art approach for this task. They use a perceptron-style parameter update scheme adapted to handle latent variables; their training objective is the conditional likelihood. Out of the two implementations of this algorithm, we use the better[5] of these two[6], as our baseline (denoted by `Hoffmann`). For a fair comparison, the training dataset and the set of features defined over it are common to all the experiments.

We discuss the results of two of our approaches. One, is the LatentSVM max-margin formulation with the simple decomposable Hamming loss function which minimizes the error rate (denoted by `MM-hamming`). The other is the LatentSVM max-margin formulation with the non-decomposable loss function which minimizes the negative of F_β score (denoted by `MM-F-loss`)[7].

Evaluation Measure: The performance measure is F_β which can be expressed in terms of false positives (FP) and false negatives (FN) as:

$$F_\beta = \frac{N_p - FN}{\beta(FP - FN) + N_p}$$

where β is the weight assigned to precision (and $1-\beta$ to recall). FP, FN and N_p are defined as :

$$\begin{aligned} FP &= \sum_i \sum_\ell y'_{i,\ell}(1 - y_{i,l}) \\ FN &= \sum_i \sum_\ell y_{i,\ell}(1 - y'_{i,l}) \\ N_p &= \sum_i \sum_\ell y_{i,\ell} \end{aligned}$$

[5]It is not quite clear why the performance of the two implementations are different.

[6]`nlp.stanford.edu/software/mimlre.shtml`

[7]We use a combination of F1 loss and hamming loss, as using only F1-loss overfits the training dataset, as observed from the experiments.

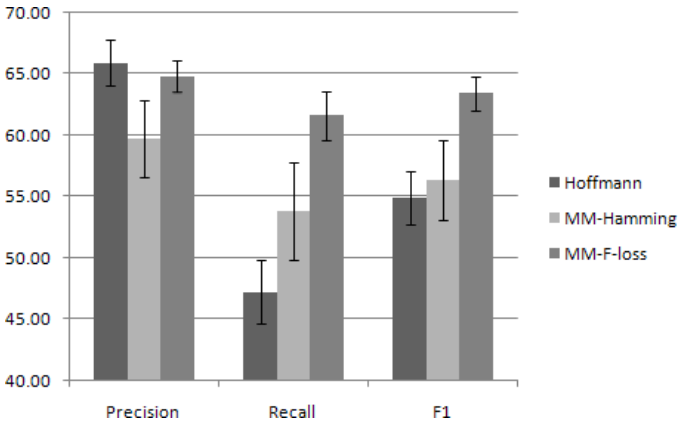

Figure 2: Experiments on 10% Riedel datasets.

	Precision	*Recall*	F_1
Hoffmann	65.93	47.22	54.91
MM-Hamming	59.74	53.81	56.32
MM-F-loss	64.81	61.63	63.44

Table 1: Average results on 10% Riedel datasets.

We use $1-F_\beta$ as the expression for the multivariate-loss.

4.1 Training on Sub-samples of Data

We performed a number of experiments using different randomized subsets of the Riedel dataset (10% of the positive dataset) for training the max-margin approaches. This was done in order to empirically determine a good set of parameters for training. We also compare the results of the approaches with `Hoffmann` trained on the same sub-samples.

Comparison with the Baseline: We report the average over 15 subsets of the dataset with a 90% confidence interval (using student-t distribution). The results of these experiments are shown in Figure 2 and Table 1. We observe that both `MM-hamming` and `MM-F-loss` have higher F_1-score compared to the baseline. There is a significant improvement in F_1-score to the tune of 8.52% for the multivariate performance measure over `Hoffmann`. There is also an improvement of F_1-score of 7.12% compared to `MM-Hamming`. This highlights the importance of using non-linear loss functions compared to simple loss functions like error rate during training.

However, `Hoffmann` has a marginally higher precision of about 1.13%. We noticed that this was

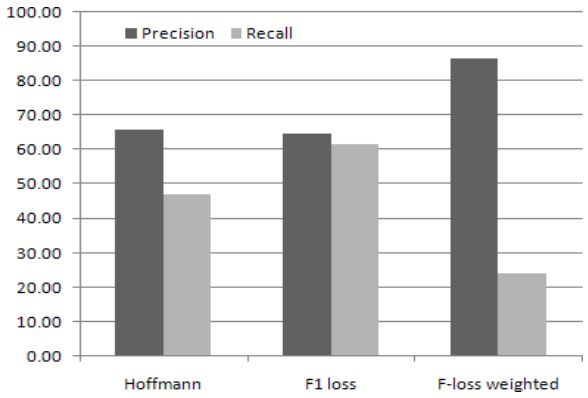

Figure 3: Weighting of Precision and Recall ($\beta = 0.833$)

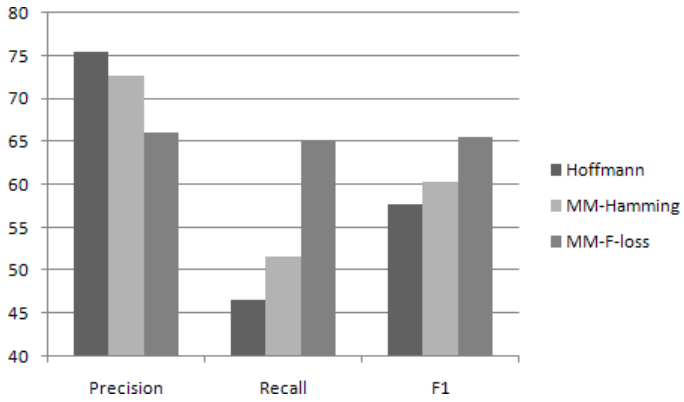

Figure 4: Overall accuracies Riedel dataset

due to over-fitting the data, as the performance on the training datasets were very high. One more interesting observation of `MM-F-loss` is that it is fairly balanced w.r.t both precision and recall which the other approaches do not exhibit.

Tuning towards Precision/Recall: Often we come across situations where either precision or recall is important for a given application. This is modeled by the notion of F_β (van Rijsbergen, 1979). One of the main advantages of using a non-decomposable loss function like F_β is the ability to vary the learning algorithm to factor such situations. For instance we can tune the objective to favor precision more than recall by "up-weighting" precision in the F_β-score.

For instance, in the previous case we observed that `MM-F-loss` has a marginally poorer precision compared to `Hoffmann`. Suppose we increase the weight of precision, $\beta = 0.833$, we observe a dramatic increase in precision from 65.83% to 86.59%. As expected, due to the precision-recall trade-off, we observe a decrease in recall. The results are shown in Figure 3.

Local vs. Exhaustive Grid Search: As we described in Section 3.3, we devise a simple yet efficient local search strategy to search the space of (FP, FN) grid-points. This enables a speed up of three orders of magnitude in solving the dual-optimization problem. In Table 2, we compare the average time per iteration and the F_1-score when each of these techniques is used for training on a sub-sample dataset. We observe that there is a significant decrease in training time when we use local search (almost 7000 times faster), with a negligible decrease in F_1-score (0.073%).

	avg. time per iter.	F_1
Local Search	0.09s	58.322
Exhaustive Search	630s	58.395

Table 2: Local vs. Exhaustive Search.

4.2 The Overall Results

Figure 4 and Table 3 present the overall results of our approaches compared to the baseline on the *positive* dataset. We observe that `MM-F-loss` has an increase in F_1-score to the tune of $\sim$8% compared to the baseline. This confirms our observation on the sub-sample datasets we saw earlier.

By assigning more weight to precision, we are able to improve over the precision of `Hoffmann` by $\sim$1.6% (Table 4). When precision is tuned with a higher weight during training of `MM-F-loss`, we see an improvement in precision without much dip in recall.

	Precision	*Recall*	F_1
Hoffmann	75.436	46.615	57.623
MM-Hamming	76.839	50.462	60.918
MM-F-loss	65.991	65.211	65.598

Table 3: Overal results on the *positive* dataset.

	Precision	*Recall*	F_β
Hoffmann	75.44	46.62	57.62
MM-F-loss-wt	77.04	53.44	63.11

Table 4: Increasing weight on Precision in F_β.

4.3 Discussion

So far we have discussed the performance of various approaches on the *positive* evaluation dataset. Our approach is shown to improve overall F_β-score having better recall than the baseline. By suitably tweaking the F_β we show an improvement in precision as well.

The performance of the approaches when evaluated on the entire test dataset (consisting of both nil and non-nil datapoints) is shown in Table 5. Max-margin based approaches generally perform well when trained only on the *positive* dataset compared to `Hoffmann`. However, our F_1-scores are $\sim$8% less when we train on the entire dataset consisting of both nil and non-nil datapoints.

Trained On$\rightarrow$	*entire dataset*	*positive dataset*
Hoffmann	23.14	3.269
MM-Hamming	13.20	16.26
MM-F-loss	13.94	21.93

Table 5: F_1-scores on the entire test set.

In a recent work, Xu et al. (2013) provide some statistics about the incompleteness of the Riedel dataset. Out of the sampled 1854 sentences from NYTimes corpus most of the entity pairs expressing a relation in Freebase correspond to false negatives. This is one of the reasons why we do not consider nil labeled datapoints during training and evaluation.

MIMLRE (Surdeanu et al., 2012) is another state-of-the-art system which is based on the EM algorithm. Since that system uses an additional set of features for the relation variables $\mathbf{y}$, it is not our primary baseline. On the *positive* dataset, our model `MM-F-loss` achieves a F_1-score of 65.598% compared to 65.341% of MIMLRE. As part of the future work, we would like to incorporate the additional features present in MIMLRE into our approach.

5 Conclusion

In this paper, we described a novel max-margin approach to optimize non-linear performance measures, such as F_β, in distant supervision of information extraction models. Our approach is general and can be applied to other latent variable models in NLP. Our approach involves solving the hard-optimization problem in learning by interleaving Concave-Convex Procedure with dual decomposition. Dual decomposition allowed us to solve the hard sub-problems independently. A key aspect of our approach involves a local-search algorithm which has led to a speed up of 7,000 times in our experiments. We have demonstrated the efficacy of our approach in distant supervision of relation extraction. Under several conditions, we have shown our technique outperforms very strong baselines, and results in up to 8.5% improvement in F_1-score.

For future work, we would like to maximize other performance measures, such as area under the curve, for information extraction models. Furthermore, we would like to explore our approach for other latent variable models in NLP, such as those in machine translation.

Convolutional Neural Network for Paraphrase Identification

Wenpeng Yin and **Hinrich Schütze**

University of Munich, Germany
wenpeng@cis.uni-muenchen.de

Abstract

We present a new deep learning architecture Bi-CNN-MI for paraphrase identification (PI). Based on the insight that PI requires comparing two sentences *on multiple levels of granularity*, we learn multigranular sentence representations using convolutional neural network (CNN) and model interaction features at each level. These features are then the input to a logistic classifier for PI. All parameters of the model (for embeddings, convolution and classification) are directly optimized for PI. To address the lack of training data, we pretrain the network in a novel way using a language modeling task. Results on the MSRP corpus surpass that of previous NN competitors.

1 Introduction

In this paper, we address the problem of paraphrase identification. It is usually formalized as a binary classification task: for two sentences (S_1, S_2), determine whether they roughly have the same meaning.

Inspired by recent successes of deep neural networks (NNs) in fields like computer vision (Neverova et al., 2014), speech recognition (Deng et al., 2013) and natural language processing (Collobert and Weston, 2008), we adopt a deep learning approach to paraphrase identification in this paper.

The key observation that motivates our NN architecture is that the identification of a paraphrase relationship between S_1 and S_2 requires an analysis *at multiple levels of granularity.*

(A1) "Detroit manufacturers have raised vehicle prices by ten percent." – (A2) "GM, Ford and Chrysler have raised car prices by five percent."

Example A1/A2 shows that paraphrase identification requires comparison *at the word level.* A1 cannot be a paraphrase of A2 because the numbers "ten" and "five" are different.

(B1) "Mary gave birth to a son in 2000." – (B2) "He is 14 years old and his mother is Mary."

PI for B1/B2 can only succeed *at the sentence level* since B1/B2 express the same meaning using very different means.

Most work on paraphrase identification has focused on only one level of granularity: either on low-level features (e.g., Madnani et al. (2012)) or on the sentence level (e.g., ARC-I, Hu et al. (2014)).

An exception is the RAE model (Socher et al., 2011). It computes representations on all levels of a parse tree: each node – including nodes corresponding to words, phrases and the entire sentence – is represented as a vector. RAE then computes a $n_1 \times n_2$ comparison matrix of the two trees derived from S_1 and S_2 respectively, where n_1, n_2 are the number of nodes and each comparison is the Euclidean distance between two vectors. This is then the basis for paraphrase classification.

RAE (Socher et al., 2011) is one of three prior NN architectures that we draw on to design our system. It embodies the key insight that paraphrase identification involves analysis of information at multiple levels of granularity. However, relying on parsing has limitations for noisy text and for other applications in which highly accurate parsers are not available. We extend the basic idea of RAE by exploring stacked convolution layers which on one hand use sliding windows to split sentences into flexible phrases, furthermore, higher layers are able to ex-

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 901–911,
Denver, Colorado, May 31 – June 5, 2015.

tract more abstract features of longer-range phrases by combining phrases in lower layers.

A representative way of doing this in deep learning is the work by Kalchbrenner et al. (2014), the second prior NN architecture that we draw on. They use convolution to learn representations at multiple levels (Collobert and Weston, 2008). The motivation for convolution is that natural language consists of long sequences in which many short subsequences contribute in a stable way to the structure and meaning of the long sequence *regardless of the position of the subsequence within the long sequence*. Thus, it is advantageous to learn convolutional filters that detect a particular feature regardless of position. Kalchbrenner et al. (2014)'s architecture extends this idea in two important ways. First, k-max pooling extracts the k top values from a sequence of convolutional filter applications and guarantees a fixed length output. Second, they stack several levels of convolutional filters, thus achieving multigranularity. We incorporate this architecture as the part that analyzes an individual sentence.

The third prior NN architecture we draw on is ARC proposed by Hu et al. (2014) who also attempt to exploit convolution for paraphrase identification. Their key insight is that *we want to be able to directly optimize the entire system for the task we are addressing,* i.e., for paraphrase identification. Hu et al. (2014) do this by adopting a Siamese architecture: their NN consists of two shared-weight sentence analysis NNs that feed into a binary classifier that is directly trained on labeled sentence pairs. As we will show below, this is superior to separating the two steps: first learning sentence representations, then training binary classification for fixed, learned sentence representations as Bromley et al. (1993), Socher et al. (2011) and many others do.

We can now give an overview of our NN architecture (Figure 1). We call it Bi-CNN-MI: "Bi-CNN" stands for double CNNs used in Siamese framework, "MI" for *multigranular interaction* features. Bi-CNN-MI has three parts: (i) the sentence analysis network CNN-SM, (ii) the sentence interaction model CNN-IM and (iii) a logistic regression on top of the network that performs paraphrase identification. We now describe these three parts in detail.

(i) Following Kalchbrenner et al. (2014), we design CNN-SM, a convolutional sentence analysis NN that computes representations at four different levels: word, short ngram, long ngram and sentence. This multigranularity is important because paraphrase identification benefits from analyzing sentences at multiple levels.

(ii) Following Socher et al. (2011), CNN-IM, the interaction model, computes interaction features as $s_1 \times s_2$ matrices, where s_i is the number of items of a certain granularity in S_i. In contrast to Socher et al. (2011), CNN-IM computes these features at fixed levels and only for comparable units; e.g., we do not compare single words with entire sentences.

(iii) Following Hu et al. (2014), we integrate two copies of CNN-SM into a Siamese architecture that allows to optimize all parameters of the NN for paraphrase identification. In our case, these parameters include parameters for word embedding, for convolution filters, and for the classification of paraphrase candidate pairs. In contrast to Hu et al. (2014), the inputs to the final paraphrase candidate pair classification layer are *interaction feature matrices at multiple levels* – as opposed to *single-level features* that do not directly *compare an element of S_1 with a potentially corresponding element of S_2*.

There is one other problem we have to address to get good performance. Training sets for paraphrase identification are small in comparison with the high complexity of the task. Training a complex network like Bi-CNN-MI with a large number of parameters on a small training set is not promising due to sparseness and likely overfitting.

In order to make full use of the training data, we propose a new unsupervised training scheme CNN-LM (CNN Language Model) to pretrain the largest part of the model, the sentence analysis network CNN-SM. The key innovation is that we use a language modeling task in a setup similar to autoencoding for pretraining (see below for details). This means that embedding and convolutional parameters can be pretrained on very large corpora since no human labels are required for pretraining.

We will show below that this pretraining is critical for getting good performance in the paraphrase task. However, the general design principle of this type of unsupervised pretraining should be widely applicable given that next-word prediction training is possible in many NLP applications. Thus, this new way of unsupervised pretraining could be an important

contribution of the paper independent of paraphrase identification.

Section 2 discusses related work. Sections 3 and 4 introduce the sentence model CNN-SM and the sentence interaction model CNN-IM. Section 5 describes the training regime. The experiments are presented in Section 6. Section 7 concludes.

2 Related work

Bi-CNN-MI is closely related to NN models for sentence representations and for text matching.

A pioneering work using CNN to model sentences is (Collobert and Weston, 2008). They conducted convolutions on sliding windows of a sentence and finally use max pooling to form a sentence representation. Kalchbrenner et al. (2014) introduce k-max pooling and stacking of several CNNs as discussed in Section 1.

Lu and Li (2013) developed a deep NN to match short texts, where interactions between components within the two objects were considered. These interactions were obtained via LDA (Blei et al., 2003). A two-dimensional interaction space is formed, then those local decisions will be sent to the corresponding neurons in upper layers to get rounds of fusion, finally logistic regression in the output layer produces the final matching score. Drawbacks of this approach are that LDA parameters are not optimized for the paraphrase task and that the interactions are formed on the level of single words only.

Gao et al. (2014) model *interestingness* between two documents with deep NNs. They map source-target document pairs to feature vectors in a latent space in such a way that the distance between the source document and its corresponding interesting target in that space is minimized. Interestingness is more like topic relevance, based mainly on the aggregate meaning of lots of keywords. Additionally, their model is a document-level model and is not multigranular.

Madnani et al. (2012) treated paraphrase relationship as a kind of mutual translation, hence combined eight kinds of machine translation metrics including BLEU (Papineni et al., 2002), NIST (Doddington, 2002), TER (Snover et al., 2006), TERp (Snover et al., 2009), METEOR (Denkowski and Lavie, 2010), SEPIA (Habash and Elkholy, 2008), BADGER (Parker, 2008) and MAXSIM (Chan and Ng, 2008). These features are not multigranular; rather they are low-level only; high-level features – e.g., a representation of the entire sentence – are not considered.

Bach et al. (2014) claimed that elementary discourse units obtained by segmenting sentences play an important role in paraphrasing. Their conclusion also endorses Socher et al. (2011)'s and our work, for both take similarities between component phrases into account.

We discussed Socher et al. (2011)'s RAE and Hu et al. (2014)'s ARC-I in Section 1. In addition to similarity matrices there are two other important aspects of (Socher et al., 2011). First, the similarity matrices are converted to a fixed size feature vector by *dynamic pooling*. We adopt this approach in Bi-CNN-MI; see Section 4.2 for details.

Second, (Socher et al., 2011) is partially based on parsing as is some other work on paraphrase identification (e.g., Wan et al. (2006), Ji and Eisenstein (2013)). Parsing is a potentially powerful tool for identifying the important meaning units of a sentence, which can then be the basis for determining meaning equivalence. However, reliance on parsing makes these approaches less flexible. For example, there are no high-quality parsers available for some domains and some languages. Our approach is in principle applicable for any domain and language. It is also unclear how we would identify comparable units in the parse trees of S_1 and S_2 if the parse trees have different height and the sentences different lengths. A key property of Bi-CNN-MI is that it is designed to produce units at fixed levels and only units at the same level are compared with each other.

3 Convolution sentence model CNN-SM

Our network Bi-CNN-MI for paraphrase detection (Figure 1) consists of four parts. On the left and on the right there are two multilayer NNs with seven layers, from "initialized word embeddings: sentence 1/2" to "k-max pooling". The weights of these two NNs are shared. This part of Bi-CNN-MI is based on (Kalchbrenner et al., 2014) and we refer to it as convolutional sentence model CNN-SM.

Between the two CNN-SMs there is the interaction model CNN-IM, consisting of four feature ma-

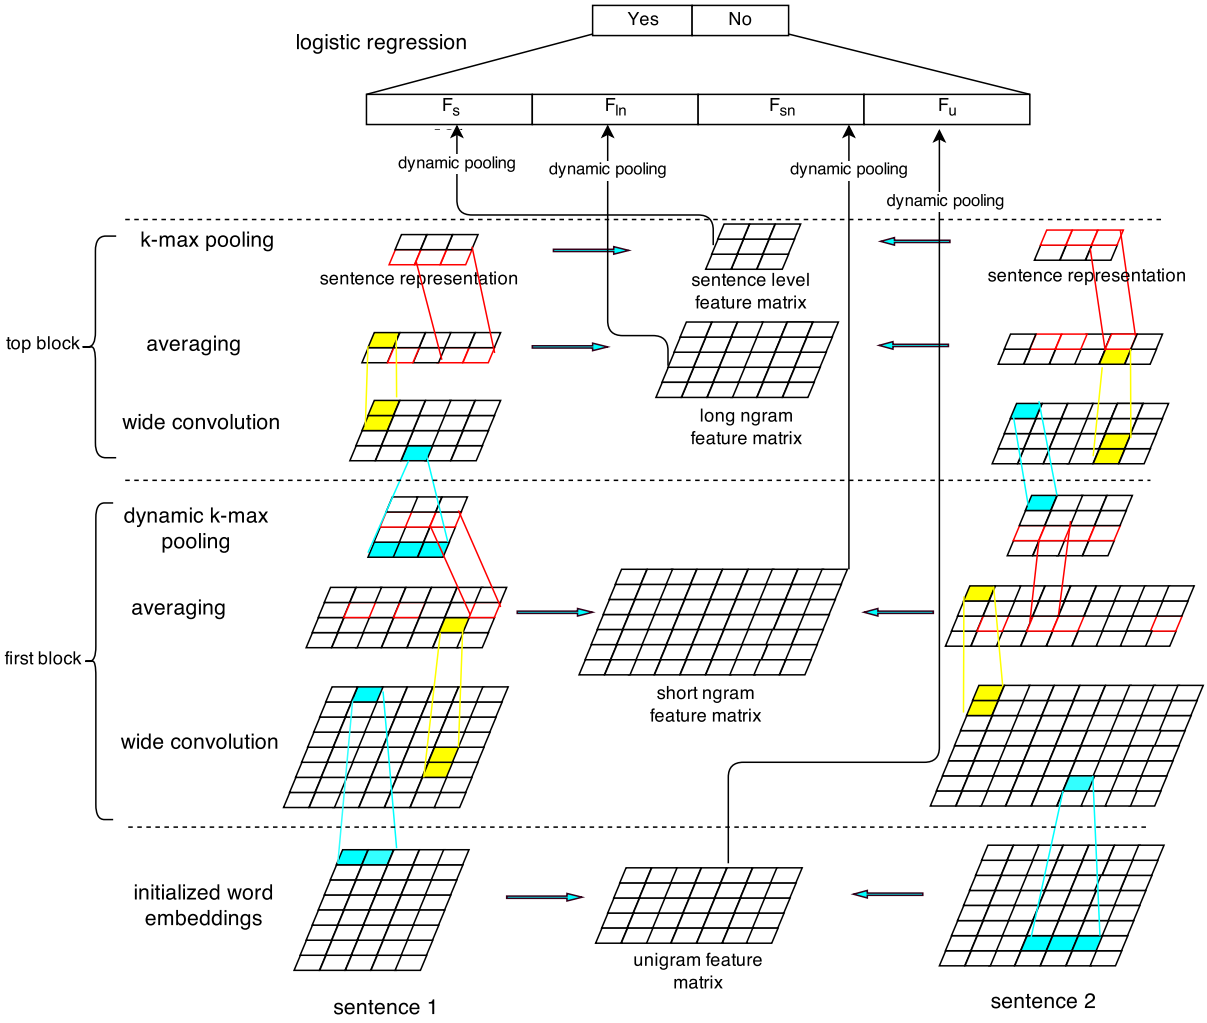

Figure 1: The paraphrase identification architecture Bi-CNN-MI

trices (unigram, short ngram, long ngram, sentence). CNN-IM feeds into a logistic classifier that performs paraphrase detection. See Sections 4 and 5 for these two parts of Bi-CNN-MI.

3.1 Wide convolution

We use Kalchbrenner et al. (2014)'s **wide one-dimensional convolution**. Denoting the number of tokens of S_i as $|S_i|$, we convolve weight matrix $\mathbf{M} \in \mathbb{R}^{d \times m}$ over sentence representation matrix $\mathbf{S} \in \mathbb{R}^{d \times |S_i|}$ and generate a matrix $\mathbf{C} \in \mathbb{R}^{d \times (|S_i|+m-1)}$ each column of which is the representation of an m-gram. d is the dimension of word (and also ngram) embeddings. m is filter width.

Our motivation for using convolution is that after training, a convolutional filter corresponds to a feature detector that learns to recognize a class of m-grams that is useful for paraphrase detection.

3.2 Averaging

After convolution, to build simple relations across rows, each odd row and the row behind immediately are *averaged*, generating matrix $\mathbf{A} \in \mathbb{R}^{\frac{d}{2} \times (|S_i|+m-1)}$. Namely:

$$\mathbf{A} = (\mathbf{C}_{\text{odd}} + \mathbf{C}_{\text{even}})/2 \tag{1}$$

where $\mathbf{C}_{\text{odd}}$, $\mathbf{C}_{\text{even}}$ denote the odd and even rows of $\mathbf{C}$, respectively. Finally, this convolution layer will output matrix $\mathbf{B}$ whose jth column is defined thus:

$$\mathbf{B}_{:,j} = \tanh(\mathbf{A}_{:,j} + \mathbf{b}^T) \quad 0 \leq j < (|S_i| + m - 1) \tag{2}$$

$\mathbf{b}$ is a bias vector with dimension $d/2$, same for each column.

3.3 Dynamic k-max pooling

We use Kalchbrenner et al. (2014)'s **dynamic k-max pooling** to extract features for variable-length sentences. It extracts k_{dy} top values from each dimension after the first layer of averaging and $k_{\text{top}} = 4$ top values after the top layer of averaging. We set

$$k_{\text{dy}} = \max(k_{\text{top}}, |S_i|/2 + 1) \tag{3}$$

Thus, k_{dy} depends on the length of S_i.

The sequence of layers in (Kalchbrenner et al., 2014) is convolution, folding, k-max pooling, $\tanh$. We experimented with this sequence and found that after k-max pooling many $\tanh$ units had an input close to 1, in the nondynamic range of the function (since the input is the addition of several values). This makes learning difficult. We therefore changed the sequence to convolution, averaging, $\tanh$, k-max pooling. This makes it less likely that $\tanh$ units will be saturated.

We have described convolution, averaging and k-max pooling. We can stack several blocks of these three layers to form deep architectures, as the two blocks (marked "first block" and "top block") in Figure 1.

4 Convolution interaction model CNN-IM

After the introduction in the previous section of the CNN-SM part of our architecture for processing an *individual sentence*, we now turn to the CNN-IM interaction model that computes the four feature matrices in Figure 1 to assess the *interactions between the two sentences*.

4.1 Feature matrices

One key innovation of our approach is multigranularity: we compute similarity between the two paraphrase candidates on multiple levels. Specifically, we compute similarity at four levels in this paper: unigram, short ngram, long ngram and sentence. We use notation $l \in \{\text{u}, \text{sn}, \text{ln}, \text{s}\}$ to refer to the four levels, and use $\mathbf{S}^{i,l}$ to denote the matrix representing sentence S_i at level l. For level l, we compute feature matrices $\hat{\mathbf{F}}_l$ as follows:

$$\hat{\mathbf{F}}_l^{ij} = \exp(\frac{-||\mathbf{S}_{:,i}^{1,l} - \mathbf{S}_{:,j}^{2,l}||^2}{2\beta}) \tag{4}$$

where $||\mathbf{S}_{:,i}^{1,l} - \mathbf{S}_{:,j}^{2,l}||^2$ is the Euclidean distance between the representations of the ith item of S_1 and the jth item of S_2 on level l. We set $\beta = 2$ (cf. Wu et al. (2013)).

We do not use cosine because the magnitude of the activations of hidden units is important, not just the overall direction; e.g., if $\mathbf{S}_{:,i}^{1,l}$ and $\mathbf{S}_{:,j}^{2,l}$ point in the same direction, but activations are much larger in $\mathbf{S}_{:,j}^{2,l}$, then the two vectors are very dissimilar.

The lowest level feature matrix ($l = \text{u}$) is the unigram similarity matrix $\hat{\mathbf{F}}_{\text{u}}$. It has size $|S_1| \times |S_2|$. The feature entry $\hat{\mathbf{F}}_{\text{u}}{}^{ij}$ is the similarity between the ith word of S_1 and the jth word of S_2 where each

word is represented by a d-dimensional word embedding ($d = 100$ in our experiments).

The next level feature matrix is the short ngram similarity matrix $\hat{\mathbf{F}}_{\text{sn}}$. It has size $(|S_1| + m_{\text{sn}} - 1) \times (|S_2| + m_{\text{sn}} - 1)$ where $m_{\text{sn}} = 3$ is the filter width in this convolution layer and $|S_i| + m_{\text{sn}} - 1$ is the number of short ngrams in S_i. The feature entry $\hat{\mathbf{F}}_{\text{sn}}{}^{ij}$ is the similarity between two $d/2$-dimensional vectors representing two short ngrams from S_1 and S_2.

We use multiple feature maps to improve the system performance. Different feature maps are expected to extract different kinds of sentence features, and can be implemented in the same convolution layer in parallel. Specifically, we use $f_{\text{sn}} = 6$ feature maps on this level following Kalchbrenner et al. (2014). Thus, we actually compute six feature matrices $\hat{\mathbf{F}}_{\text{sn},i}$ ($i = 1, \cdots, f_{\text{sn}}$), one for each pair of feature maps that share convolution weights while derived from S_1 and S_2 respectively. (Figure 1 only shows one of those six matrices.)

The next level feature matrix is the long ngram similarity matrix $\hat{\mathbf{F}}_{\text{ln}}$. It has size $(k_{\text{dy},1} + m_{\text{ln}} - 1) \times (k_{\text{dy},2} + m_{\text{ln}} - 1)$ where $k_{\text{dy},i}$ (Equation 3) is the k value in dynamic k-max pooling for sentence i, $k_{\text{dy},i} + m_{\text{ln}} - 1$ is the number of long ngrams in S_i and $m_{\text{ln}} = 5$ is the filter width in this convolution layer. The feature entry $\hat{\mathbf{F}}_{\text{ln}}{}^{ij}$ is the similarity between two $d/4$-dimensional vectors representing two long ngrams from S_1 and S_2.

We use $f_{\text{ln}} = 14$ feature maps on this level following Kalchbrenner et al. (2014). Thus, we compute 14 feature matrices $\hat{\mathbf{F}}_{\text{ln},i}$ ($i = 1, \cdots, f_{\text{ln}}$), in a way analogous to the $f_{\text{sn}} = 6$ feature maps $\hat{\mathbf{F}}_{\text{sn},i}$.

The last feature matrix is the sentence similarity matrix $\hat{\mathbf{F}}_{\text{s}}$. It has size $k_{\text{top}} \times k_{\text{top}}$ where $k_{\text{top}} = 4$ is the parameter in k-max pooling at the last max pooling layer. The feature entry $\hat{\mathbf{F}}_{\text{s}}{}^{ij}$ is the similarity between two $d/4$-dimensional vectors computed by max pooling from S_1 and S_2.

For $l = \text{s}$, there are also $f_{\text{ln}} = 14$ feature matrices $\hat{\mathbf{F}}_{\text{s},i}$ ($i = 1, \cdots, f_{\text{ln}}$), analogous to the $f_{\text{ln}} = 14$ feature matrices $\hat{\mathbf{F}}_{\text{ln},i}$.

A general design principle of the architecture is that we compute each interaction feature matrix between two feature maps that share the same convolution weights. Two feature maps learned with the same filter will contain the same kinds of features derived from the input.

4.2 Dynamic pooling of feature matrices

As sentence lengths vary, feature matrices $\hat{\mathbf{F}}_l$ have different sizes, which makes it impossible to use them directly as input of the last layer.

That means we need to map $\hat{\mathbf{F}}_l \in \mathbb{R}^{r \times c}$ into a matrix $\mathbf{F}_l$ of fixed size $r' \times c'$ ($l \in \{\text{u}, \text{sn}, \text{ln}, \text{s}\}$; r', c' are parameters and are the same for all sentence pairs while r, c depend on $|S_1|$ and $|S_2|$). Dynamic pooling divides $\hat{\mathbf{F}}_l$ into $r' \times c'$ nonoverlapping *(dynamic) pools* and copies the maximum value in each dynamic pool to $\mathbf{F}_l$. Our method is similar to (Socher et al., 2011), but preserves locality better.

$\hat{\mathbf{F}}_l$ can be split into equal regions only if r (resp. c) is divisible by r' (resp. c'). Otherwise, for $r > r'$ and if $r \bmod r' = b$, the dynamic pools in the first $r' - b$ splits each have $\lfloor \frac{r}{r'} \rfloor$ rows while the remaining b splits each have $\lfloor \frac{r}{r'} \rfloor + 1$ rows. In Figure 2, a $r \times c = 4 \times 5$ matrix (left) is split into $r' \times c' = 3 \times 3$ dynamic pools (middle): each row is split into [1, 1, 2] and each column is split into [1, 2, 2].

If $r < r'$, we first repeat all rows until no fewer than r' rows remain. Then first r' rows are kept and split into r' dynamic pools. The same principle applies to the partitioning of columns. In Figure 2 (right), the areas with dashed lines and dotted lines are repeated parts for rows and columns, respectively; each cell is its own dynamic pool.

5 Training

5.1 Supervised training

Dynamic pooling gives us fixed size interaction feature matrices for sentence, ngram and unigram levels. As shown in Figure 1, the concatenation of these features ($\mathbf{F}_{\text{s}}$, $\mathbf{F}_{\text{ln}}$, $\mathbf{F}_{\text{sn}}$ and $\mathbf{F}_{\text{u}}$) is the input to a logistic regression layer for paraphrase classification. We have now described all three parts of Bi-CNN-MI: CNN-SM, CNN-IM and logistic regression.

Bi-CNN-MI with all its parameters – including word embeddings and convolution weights – is trained on MSRP. We initialize embeddings with those provided by Turian et al. (2010)[1] (based on Collobert and Weston (2008)). For layer sn, we have $f_{\text{sn}} = 6$ feature maps and set filter width $m_{\text{sn}} = 3$. For layer ln, we have $f_{\text{ln}} = 14$ feature maps and set filter width $m_{\text{ln}} = 5$ and $k_{\text{top}} = 4$. Dynamic pooling

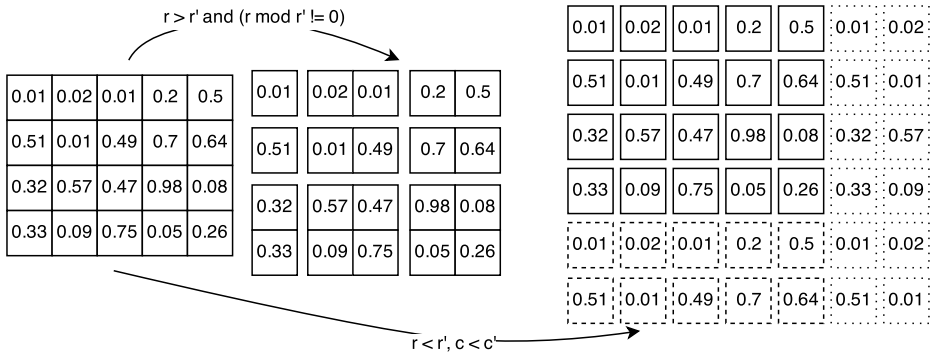

Figure 2: Partition methods in dynamic pooling. Original matrix with size 4×5 is mapped into matrix with size 3×3 and matrix with size 6×7, respectively. Each dynamic pool is distinguished by a border of empty white space around it.

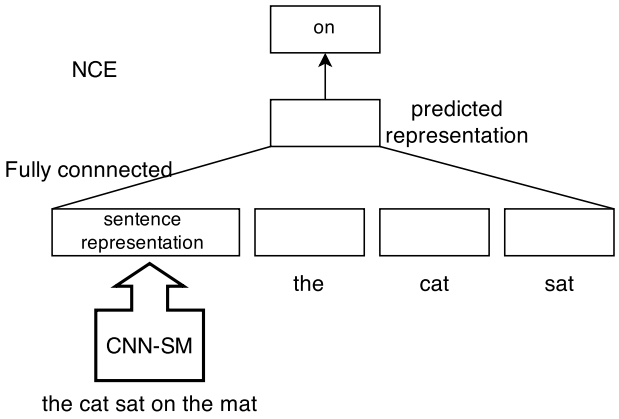

Figure 3: Unsupervised architecture: CNN-LM

sizes are 10×10, 10×10, 6×6, 2×2 for unigram, short ngram, long ngram and sentence, respectively. For training, we employ mini-batch of size 70, L_2 regularization with weight 5×10^{-4} and Adagrad (Duchi et al., 2011).

5.2 Unsupervised pretraining

One of the key contributions of this paper is the architecture CNN-LM shown in Figure 3. CNN-LM is used to pretrain the convolutional filters on unlabeled data. This addresses sparseness and limited training data for paraphrase identification.

The convolution sentence model CNN-SM (Section 3) is part of CNN-LM ("CNN-SM" in Figure 3). The input to CNN-SM is the entire sentence ("the cat sat on the mat"); its output ("sentence representation" in the leftmost rectangle in Figure 3 and the two grids labeled "sentence representation" in the top layer of the top block in Figure 1) is concatenated with a history consisting of the embeddings of the $h = 3$ preceding words ("the", "cat", "sat") as the input of a fully connected layer to generate a predicted representation for the next word ("on"). We employ noise-contrastive estimation (NCE) (Mnih and Teh, 2012; Mnih and Kavukcuoglu, 2013) to compute the cost: the model learns to discriminate between true next words and noise words. NCE allows us to fit unnormalized models making the training time effectively independent of the vocabulary size.

In experiments, CNN-LM is trained on unlabeled MSRP data and an additional 100,000 sentences from English Gigaword (Graff et al., 2003). In principle, sentences from any source, not just English Gigaword, can be used to train this model. In NCE, 20 noise words are sampled for each true example.

So training has two parts: unsupervised, CNN-LM (Figure 3) and supervised, Bi-CNN-MI (Figure 1). In the first phase, the unsupervised training phase, we adopt a language modeling approach because it does not require human labels and can use large corpora to pretrain word embeddings and convolution weights. The goal is to learn sentence features that are unbiased and reflect useful attributes of the input sentence. More importantly, pretraining is useful to relieve overfitting, which is a severe problem when building deep NNs on small corpora like MSRP (cf. Hu et al. (2014)).

In the second phase, the supervised training phase, pretrained word embeddings and convolution

weights are tuned for optimal performance on PI.

In CNN-LM, we have combined several architectural elements to pretrain a high-quality sentence analysis NN despite the lack of training data. (i) Similar to PV-DM (Le and Mikolov, 2014), we integrate global context (CNN-SM) and local context (the history of size h) into one model – although our global context consists only of a sentence, not of a paragraph or document. (ii) Similar to work on autoencoding (Vincent et al., 2010), the output that is to be predicted is part of the input. Autoencoding is a successful approach to learning representations and we adapt it here to pretrain good sentence representations. (iii) A second successful approach to learning embeddings is neural network language modeling (Bengio et al., 2003; Mikolov, 2012). Again, we adopt this by including in CNN-LM an ngram language modeling part to predict the next word. The great advantage of this type of embedding learning is that no labels are needed. (iv) CNN-LM only adds one hidden layer over CNN-SM. It keeps simple architecture like PV-DM (Le and Mikolov, 2014), CBOW (Mikolov et al., 2013) and LBL (Mnih and Teh, 2012), enabling the CNN-SM as main training target.

In summary, the key contribution of CNN-LM is that we pretrain convolutional filters. Architectural elements from the literature are combined to support effective pretraining of convolutional filters.

6 Experiments

6.1 Data set and evaluation metrics

We use the Microsoft Research Paraphrase Corpus (MSRP) (Dolan et al., 2004; Das and Smith, 2009). The training set contains 2753 true and 1323 false paraphrase pairs; the test set contains 1147 and 578 pairs, respectively. For each triple (label, S_1, S_2) in the training set we also add (label, S_2, S_1) to make best use of the training data; these additions are nonredundant because the interaction feature matrices (Section 4.1) are asymmetric. Systems are evaluated by accuracy and F_1.

6.2 Paraphrase detection systems

Since we want to show that Bi-CNN-MI performs better than previous NN work, we compare with three NN approaches: NLM, ARC and RAE (Table 1).[2] We also include the majority baseline ("baseline") and MT (Madnani et al., 2012). **RAE** (Socher et al., 2011) and **MT** were discussed in Sections 1 and 2. We now briefly describe the other prior work.

Blacoe and Lapata (2012) compute the vector representation of a sentence from the neural language model (NLM) embeddings (computed based on (Collobert and Weston, 2008)) of the words of the sentence as the sum of the word embeddings (**NLM+**), as the element-wise multiplication of the word embeddings (**NLM$\odot$**), or by means of the recursive autoencoder (**NLM_RAE**, Socher et al. (2011)). The representations of the two paraphrase candidates are then concatenated as input to an SVM classifier. See Blacoe and Lapata (2012) for details.

The ARC model (Hu et al., 2014) is a convolutional architecture similar to (Collobert and Weston, 2008). **ARC-I** is a Siamese architecture in which two shared-weight convolutional sentence models are trained on the binary paraphrase detection task. Hu et al. (2014) find that ARC-I is suboptimal in that it defers the interaction between S_1 and S_2 to the very end of processing: only after the vectors representing S_1 and S_2 have been computed does an interaction occur. To remedy this problem, they propose **ARC-II** in which the Siamese architecture is replaced by a multilayer NN that processes a single representation produced by interleaving S_1 and S_2.

We also evaluate **Bi-CNN-MI–**, an NN identical to Bi-CNN-MI, except that it is not pretrained in unsupervised training.

6.3 Results

Table 1 shows that Bi-CNN-MI outperforms all other systems. The comparison with Bi-CNN-MI– indicates that this is partly due to one major innovation we introduced: unsupervised pretraining. Bi-CNN-MI–, the model without unsupervised pretraining, performs badly. Thus, unsupervised training is helpful to pretrain parameters in paraphrase

[2] A reviewer suggests an additional experiment to directly evaluate the importance of multigranularity: a "system that puts all unigrams, short ngrams, long ngrams, and sentence representations into one interaction matrix." This would indeed be an interesting baseline, but there is no obvious way to conduct this experiment since vectors from different levels are not comparable; e.g., they have different dimensionality.

method	acc	F_1
baseline	66.5	79.9
NLM+	69.0	80.1
NLM$\odot$	67.8	79.3
NLM_RAE	70.3	81.3
ARC-I	69.6	80.3
ARC-II	69.9	80.9
RAE	76.7	83.6
MT	77.4	84.1
Bi-CNN-MI–	72.5	81.4
Bi-CNN-MI	**78.1**	**84.4**

Table 1: Performance of different systems on MSRP

	features used	acc	F_1
1	no features	66.5	79.9
2	+ u: unigram	68.4	79.7
3	+ sn: short ngram	75.3	82.8
4	+ ln: long ngram	76.2	83.1
5	+ s: sentence	73.4	82.3
6	– u: unigram	77.8	84.3
7	– sn: short ngram	76.3	83.5
8	– ln: long ngram	75.6	83.2
9	– s: sentence	77.6	84.2
10	all features	78.1	84.4

Table 2: Analysis of impact of the four feature classes. Line 1: majority baseline. Line 10: Bi-CNN-MI result from Table 1. Lines 2–5: Bi-CNN-MI when only one feature class is used. Line 6–9: ablation experiment: on each line one feature class is removed.

detection, especially when the training set is small. RAE also uses pretraining, but not as effectively as Bi-CNN-MI as Table 1 indicates. Hu et al. (2014) also suggest that training complex NNs only with supervised training runs the risk of overfitting on the small MSRP corpus.

Table 2 looks at the relative importance of the four feature matrices shown in Figure 1. (The unsupervised part of the training regime is not changed for this experiment.) The results indicate that levels sn and ln are most informative: F_1 scores are highest if only these two levels are used (lines 3&4: 82.8, 83.1) and performance drops most when they are removed (lines 7&8: 83.5, 83.2).

Unigrams contribute little to overall performance (lines 2&6), probably because the paraphrases in the corpus typically do not involve individual words (replacing one word by its synonym); rather, the paraphrase relationship involves larger context, which can only be judged by the higher-level features.

Just using the sentence matrix by itself performs well (line 5), but less well than using only levels sn or ln (lines 3&4). Most prior NN work on PI has taken the sentence-level approach. Our results indicate that combining this with the more fine-grained comparison on the ngram-level is superior.

Removing the sentence matrix results in a small drop in performance (line 9). The reason is that sentence representations are computed by k-max pooling from level ln. Thus, we can roughly view the sentence-level feature matrix $\mathbf{F}_{\text{s}}$ as a subset of $\mathbf{F}_{\text{ln}}$.

Adding (Madnani et al., 2012)'s MT metrics as input to the Bi-CNN-MI logistic regression further improves performance: accuracy of 78.4 and F_1 of 84.6.

7 Conclusion and future work

We presented the deep learning architecture Bi-CNN-MI for paraphrase identification (PI). Based on the insight that PI requires comparing two sentences *on multiple levels of granularity*, we learn multigranular sentence representations using convolution and compute interaction feature matrices at each level. These matrices are then the input to a logistic classifier for PI. All parameters of the model (for embeddings, convolution and classification) are directly optimized for PI. To address the lack of training data, we pretrain the network in a novel way for a language modeling task. Results on MSRP are state of the art.

In the future, we plan to apply Bi-CNN-MI to sentence matching, question answering and other tasks.

Abstract

Methods of deep neural networks (DNNs) have recently demonstrated superior performance on a number of natural language processing tasks. However, in most previous work, the models are learned based on either unsupervised objectives, which does not directly optimize the desired task, or single-task supervised objectives, which often suffer from insufficient training data. We develop a multi-task DNN for learning representations across multiple tasks, not only leveraging large amounts of cross-task data, but also benefiting from a regularization effect that leads to more general representations to help tasks in new domains. Our multi-task DNN approach combines tasks of multiple-domain classification (for query classification) and information retrieval (ranking for web search), and demonstrates significant gains over strong baselines in a comprehensive set of domain adaptation.

1 Introduction

Recent advances in deep neural networks (DNNs) have demonstrated the importance of learning vector-space representations of text, e.g., words and sentences, for a number of natural language processing tasks. For example, the study reported in (Collobert et al., 2011) demonstrated significant accuracy gains in tagging, named entity recognition, and semantic role labeling when using vector space word representations learned from large corpora. Further, since these representations are usually in a low-dimensional vector space, they result in more compact models than those built from surface-form features. A recent successful example is the parser by (Chen and Manning, 2014), which is not only accurate but also fast.

However, existing vector-space representation learning methods are far from optimal. Most previous methods are based on unsupervised objectives such as word prediction for training (Mikolov et al., 2013c; Pennington et al., 2014). Other methods use supervised training objectives on a single task, e.g. (Socher et al., 2013), and thus are often constrained by limited amounts of training data. Motivated by the success of multi-task learning (Caruana, 1997), we propose in this paper a multi-task DNN approach for representation learning that leverages supervised data from many tasks. In addition to the benefit of having more data for training, the use of multi-task also profits from a regularization effect, i.e., reducing overfitting to a specific task, thus making the learned representations universal across tasks.

Our contributions are of two-folds: First, we propose a multi-task deep neural network for representation learning, in particular focusing on semantic classification (query classification) and semantic information retrieval (ranking for web search) tasks. Our model learns to map arbitrary text queries and documents into semantic vector representations in a low dimensional latent space. While the general concept of multi-task neural nets is not new, our model is novel in that it successfully combines tasks as disparate as operations necessary for classifica-

Denver, Colorado, May 31 – June 5, 2015.

tion or ranking.

Second, we demonstrate strong results on query classification and web search. Our multi-task representation learning consistently outperforms state-of-the-art baselines. Meanwhile, we show that our model is not only compact but it also enables agile deployment into new domains. This is because the learned representations allow domain adaptation with substantially fewer in-domain labels.

2 Multi-Task Representation Learning

2.1 Preliminaries

Our multi-task model combines classification and ranking tasks. For concreteness, throughout this paper we will use query classification as the classification task and web search as the ranking task. These are important tasks in commercial search engines:

Query Classification: Given a search query Q, the model classifies in the binary fashion as to whether it belongs to one of the domains of interest. For example, if the query Q is "Denver sushi", the classifier should decide that it belongs to the "Restaurant" domain. Accurate query classification enables a richer personalized user experience, since the search engine can tailor the interface and results. It is however challenging because queries tend to be short (Shen et al., 2006). Surface-form word features that are common in traditional document classification problems tend to be too sparse for query classification, so representation learning is a promising solution. In this study, we classify queries into four domains of interest: ("Restaurant", "Hotel", "Flight", "Nightlife"). Note that one query can belong to multiple domains. Therefore, a set of binary classifiers are built, one for each domain, to perform the classification. We frame the problem as four binary classification tasks. Thus, for domain C_t, our goal is binary classification based on $P(C_t|\ Q)$ ($C_t = \{0, 1\}$). For each domain t, we assume supervised data $(Q, y_t = \{0, 1\}$ with y_t as binary labels.[1]

Web Search: Given a search query Q and a document list $\mathbf{L}$, the model ranks documents in the order of relevance. For example, if the query Q is "Denver sushi", model returns a list of documents that satisfies such information need. Formally, we estimate $P(D_1|Q), P(D_2|Q), \ldots$ for each document D_n and rank according to these probabilities. We assume that supervised data exist; I.e., there is at least one relevant document D_n for each query Q.

[1]One could frame the problem as a a single multi-class classification task, but our formulation is more practical as it allows adding new domains without retraining existing classifiers. This will be relevant in domain adaptation (§3.3).

2.2 The Proposed Multi-Task DNN Model

Briefly, our proposed model maps any arbitrary queries Q or documents D into fixed low-dimensional vector representations using DNNs. These vectors can then be used to perform query classification or web search. In contrast to existing representation learning methods which employ either unsupervised or single-task supervised objectives, our model learns these representations using multi-task objectives.

The architecture of our multi-task DNN model is shown in Figure 1. The lower layers are shared across different tasks, whereas the top layers represent task-specific outputs. Importantly, the input X (either a query or document), initially represented as a bag of words, is mapped to a vector (l_2) of dimension 300. This is the shared semantic representation that is trained by our multi-task objectives. In the following, we elaborate the model in detail:

Word Hash Layer (l_1): Traditionally, each word is represented by a one-hot word vector, where the dimensionality of the vector is the vocabulary size. However, due to the large size of vocabulary in real-world tasks, it is very expensive to learn such kind of models. To alleviate this problem, we adopt the *word hashing* method (Huang et al., 2013). We map a one-hot word vector, with an extremely high dimensionality, into a limited letter-trigram space (e.g., with the dimensionality as low as 50k). For example, word *cat* is hashed as the bag of letter trigram {*#-c-a, c-a-t, a-t-#*}, where # is a boundary symbol. Word hashing complements the one-hot vector representation in two aspects: 1) out of vocabulary words can be represented by letter-trigram vectors; 2) spelling variations of the same word can be mapped to the points that are close to each other in the letter-trigram space.

Semantic-Representation Layer (l_2): This is a shared representation learned across different tasks. this layer maps the letter-trigram inputs into a 300-

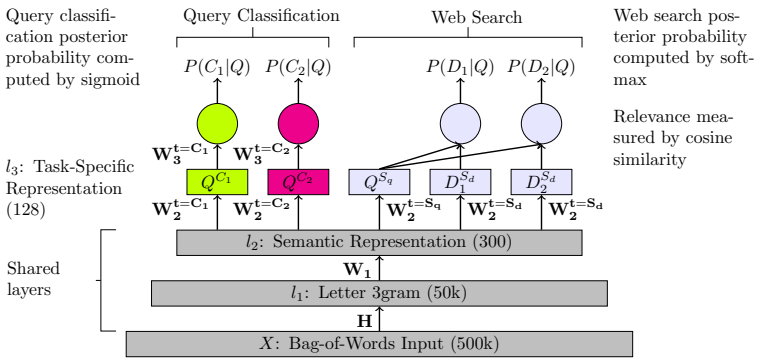

Figure 1: **Architecture of the Multi-task Deep Neural Network (DNN) for Representation Learning:** The lower layers are shared across all tasks, while top layers are task-specific. The input X (either a query or document, with vocabulary size 500k) is first represented as a bag of words, then hashed into letter 3-grams l_1. Non-linear projection W_1 generates the shared semantic representation, a vector l_2 (dimension 300) that is trained to capture the essential characteristics of queries and documents. Finally, for each task, additional non-linear projections W_2^t generate task-specific representations l_3 (dimension 128), followed by operations necessary for classification or ranking.

dimensional vector by

$$l_2 = f(\mathbf{W_1} \cdot l_1) \tag{1}$$

where $f(\cdot)$ is the tanh nonlinear activation $f(z) = \frac{1-e^{-2z}}{1+e^{-2z}}$. This 50k-by-300 matrix $\mathbf{W_1}$ is responsible for generating the cross-task semantic representation for arbitrary text inputs (e.g., Q or D).

Task-Specific Representation (l_3): For each task, a nonlinear transformation maps the 300-dimension semantic representation l_2 into the 128-dimension task-specific representation by

$$l_3 = f(\mathbf{W}_2^t \cdot l_2) \tag{2}$$

where, t denotes different tasks (query classification or web search).

Query Classification Output: Suppose $Q^{C_1} \equiv l_3 = f(\mathbf{W}_2^{t=C_1} \cdot l_2)$ is the 128-dimension task-specific representation for a query Q. The probability that Q belongs to class C_1 is predicted by a logistic regression, with sigmoid $g(z) = \frac{1}{1+e^{-z}}$:

$$P(C_1|Q) = g(\mathbf{W}_3^{t=C_1} \cdot Q^{C_1}) \tag{3}$$

Web Search Output: For the web search task, both the query Q and the document D are mapped into 128-dimension task-specific representations Q^{S_q} and D^{S_d}. Then, the relevance score is computed by cosine similarity as:

$$R(Q, D) = cos(Q^{S_q}, D^{S_d}) = \frac{Q^{S_q} \cdot D^{S_d}}{||Q^{S_q}||||D^{S_d}||} \tag{4}$$

Algorithm 1: Training a Multi-task DNN

Initialize model $\Theta : \{\mathbf{W_1}, \mathbf{W_2^t}, \mathbf{W_3^t}\}$ randomly
for *iteration in* $0...\infty$ **do**
1. Pick a task t randomly
2. Pick sample(s) from task t
   $(Q, y_t = \{0, 1\})$ for query classification
   $(Q, \mathbf{L})$ for web search
3. Compute loss: $L(\Theta)$
   $L(\Theta)$=Eq. 5 for query classification
   $L(\Theta)$=Eq. 6 for web search
4. Compute gradient: $\nabla(\Theta)$
5. Update model: $\Theta = \Theta - \epsilon\nabla(\Theta)$

end

The task t is one of the query classification tasks or web search task, as shown in Figure 1. For query classification, each training sample includes one query and its category label. For web search, each training sample includes query and document list.

2.3 The Training Procedure

In order to learn the parameters of our model, we use mini-batch-based stochastic gradient descent (SGD) as shown in Algorithm 1. In each iteration, a task t is selected randomly, and the model is updated ac-

cording to the task-specific objective. This approximately optimizes the sum of all multi-task objectives. For query classification of class C_t, we use the cross-entropy loss as the objective:

$$-\{y_t \ln P(C_t|Q) + (1-y_t)\ln(1-P(C_t|Q))\} \quad (5)$$

where $y_t = \{0,1\}$ is the label and the loss is summed over all samples in the mini-batch (1024 samples in experiments).

The objective for web search used in this paper follows the pair-wise learning-to-rank paradigm outlined in (Burges et al., 2005). Given a query Q, we obtain a list of documents $\mathbf{L}$ that includes a clicked document D^+ (positive sample), and J randomly-sampled non-clicked documents $\{D_j^-\}_{j=1,..,J}$. We then minimize the negative log likelihood of the clicked document (defined in Eq. 7) given queries across the training data

$$-\log \prod_{(Q,D^+)} P(D^+|Q) \quad (6)$$

where the probability of a given document D^+ is computed

$$P(D^+|Q) = \frac{\exp(\gamma R(Q,D^+))}{\sum_{D' \in \mathbf{L}} \exp(\gamma R(Q,D'))} \quad (7)$$

here, γ is a tuning factor determined on held-out data.

Additional training details: (1) Model parameters are initialized with uniform distribution in the range $(-\sqrt{6/(fan_{in}+fan_{out})}, \sqrt{6/(fan_{in}+fan_{out})})$ (Montavon et al., 2012). Empirically, we have not observed better performance by initialization with layer-wise pre-training. (2) Moment methods and AdaGrad training (Duchi et al., 2011) speed up the convergence speed but gave similar results as plain SGD. The SGD learning rate is fixed at $\epsilon = 0.1/1024$. (3) We run Algorithm 1 for 800K iterations, taking 13 hours on an NVidia K20 GPU.

2.4 An Alternative View of the Multi-Task Model

Our proposed multi-task DNN (Figure 1) can be viewed as a combination of a standard DNN for classification and a Deep Structured Semantic Model (DSSM) for ranking, shown in Figure 2. Other ways to merge the models are possible. Figure 3 shows an alternative multi-task architecture, where only the query part is shared among all tasks and the DSSM

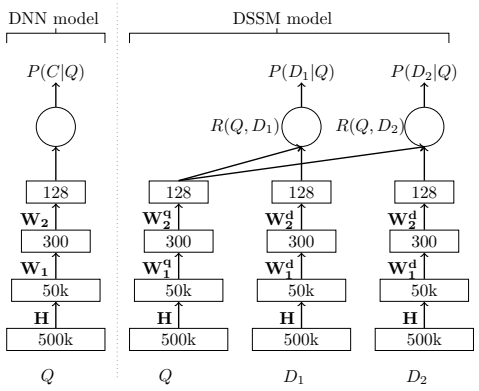

Figure 2: A DNN model for classification and a DSSM model (Huang et al., 2013) for ranking.

retains independent parameters for computing the document representations. This is more similar to the original DSSM. We have attempted training this model using Algorithm 1, but it achieves good results on query classification at the expense of web search. This is likely due to unbalanced updates (i.e. parameters for queries are updated more often than that of documents), and implying that the amount of sharing is an important design choice in multi-task models.

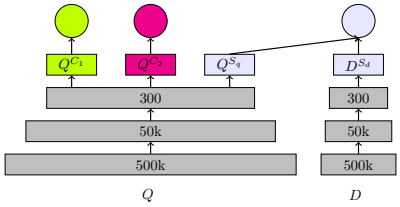

Figure 3: An alternative multi-task architecture. Compared with Figure 1, only the query part is shared across tasks here.

3 Experimental Evaluation

3.1 Data Sets and Evaluation Metrics

We employ large-scale, real data sets in our evaluation. See Table 1 for statistics. The test data for query classification were sampled from one-year log files of a commercial search engine with labels (yes or no) judged by humans. The test data for web search contains 12,071 English queries, where each query-document pair has a relevance label manually annotated on a 5-level relevance scale: *bad*, *fair*,

Task	Query Classification				Web Search
	Restaurant	Hotel	Flight	Nightlife	
Training	1,585K	2,131K	1,880K	1,214K	4,084K queries & click-through documents
Test	3,074	6,307	6,199	298	12,071 queries / 897,770 documents

Table 1: Statistics of the data sets used in the experiments.

good, *excellent* and *perfect*. The evaluation metric for query classification is the Area under of Receiver Operating Characteristic (ROC) curve (AUC) score (Bradley, 1997). For web search, we employ the Normalized Discounted Cumulative Gain (NDCG) (Järvelin and Kekäläinen, 2000).

3.2 Results on Accuracy

First, we evaluate whether our model can robustly improve performance, measured as accuracy across multiple tasks.

Table 2 summarizes the AUC scores for query classification, comparing the following classifiers:

- SVM-Word: a SVM model[2] with unigram, bigram and trigram surface-form word features.
- SVM-Letter: a SVM model with letter trigram features (i.e. l_1 in Figure 1 as input to SVM).
- DNN: single-task deep neural net (Figure 2).
- MT-DNN: our multi-task proposal (Figure 1).

The results show that the proposed MT-DNN performs best in all four domains. Further, we observe:

1. MT-DNN outperforms DNN, indicating the usefulness of the multi-task objective (that includes web search) over the single-task objective of query classification.
2. Both DNN and MT-DNN outperform SVM-Letter, which initially uses the same input features (l_1). This indicates the importance of learning a semantic representation l_2 on top of these letter trigrams.
3. Both DNN and MT-DNN outperform a strong SVM-Word baseline, which has a large feature set that consists of 3 billion features.

Table 3 summarizes the NDCG results on web search, comparing the following models:

[2]In this paper, we use the liblinear to build SVM classifiers and optimize the corresponding parameter C by using 5-fold cross-validation in training data. http://www.csie.ntu.edu.tw/ cjlin/liblinear/

System	Query Classification			
	Restaurant	Hotel	Flight	Nightlife
SVM-Word	90.91	75.82	91.17	91.27
SVM-Letter	88.75	69.65	85.51	87.71
DNN	97.38	76.81	95.58	93.24
MT-DNN	**97.57**	**78.56**	**96.21**	**94.20**

Table 2: Query Classification AUC results.

- Popular baselines in the web search literature, e.g. BM25, Language Model, PLSA
- DSSM: single-task ranking model (Figure 2)
- MT-DNN: our multi-task proposal (Figure 1)

Again, we observe that MT-DNN performs best. For example, MT-DNN achieves NDCG@1=0.334, outperforming the current state-of-the-art single-task DSSM (0.327) and the classic methods like PLSA (0.308) and BM25 (0.305). This is a statistically significant improvement ($p < 0.05$) over DSSM and other baselines.

To recap, our MT-DNN robustly outperforms strong baselines across all web search and query classification tasks. Further, due to the use of larger training data (from different domains) and the regularization effort as we discussed in Section 1, we confirm the advantage of multi-task models over than single-task ones.[3]

3.3 Results on Model Compactness and Domain Adaptation

Important criteria for building practical systems are agility of deployment and small memory footprint and fast run-time. Our model satisfies both with

[3]We have also trained SVM using Word2Vec (Mikolov et al., 2013b; Mikolov et al., 2013a) features. Unfortunately, the results are poor at 60-70 AUC, indicating the sub-optimality of unsupervised representation learning objectives for actual prediction tasks. We optimized the Word2Vec features in the SVM baseline by scaling and normalizing as well, but did not observe much improvement.

Models	NDCG@1	NDCG@3	NDCG@10
TF-IDF model (BM25)	0.305	0.328	0.388
Unigram Language Model (Zhai and Lafferty, 2001)	0.304	0.327	0.385
PLSA(Topic=100) (Hofmann, 1999; Gao et al., 2011)	0.305	0.335	0.402
PLSA(Topic=500) (Hofmann, 1999; Gao et al., 2011)	0.308	0.337	0.402
Latent Dirichlet Allocation (Topic=100) (Blei et al., 2003)	0.308	0.339	0.403
Latent Dirichlet Allocation (Topic=500) (Blei et al., 2003)	0.310	0.339	0.405
Bilingual Topic Model (Gao et al., 2011)	0.316	0.344	0.410
Word based Machine Translation model (Gao et al., 2010)	0.315	0.342	0.411
DSSM, J=50 (Figure 2, (Huang et al., 2013))	0.327	0.359	0.432
MT-DNN (Proposed, Figure 3)	**0.334***	**0.363**	**0.434**

Table 3: Web Search NDCG results. Here, * indicates statistical significance improvement compared to the best baseline (DSSM) measured by t-test at p-value of 0.05.

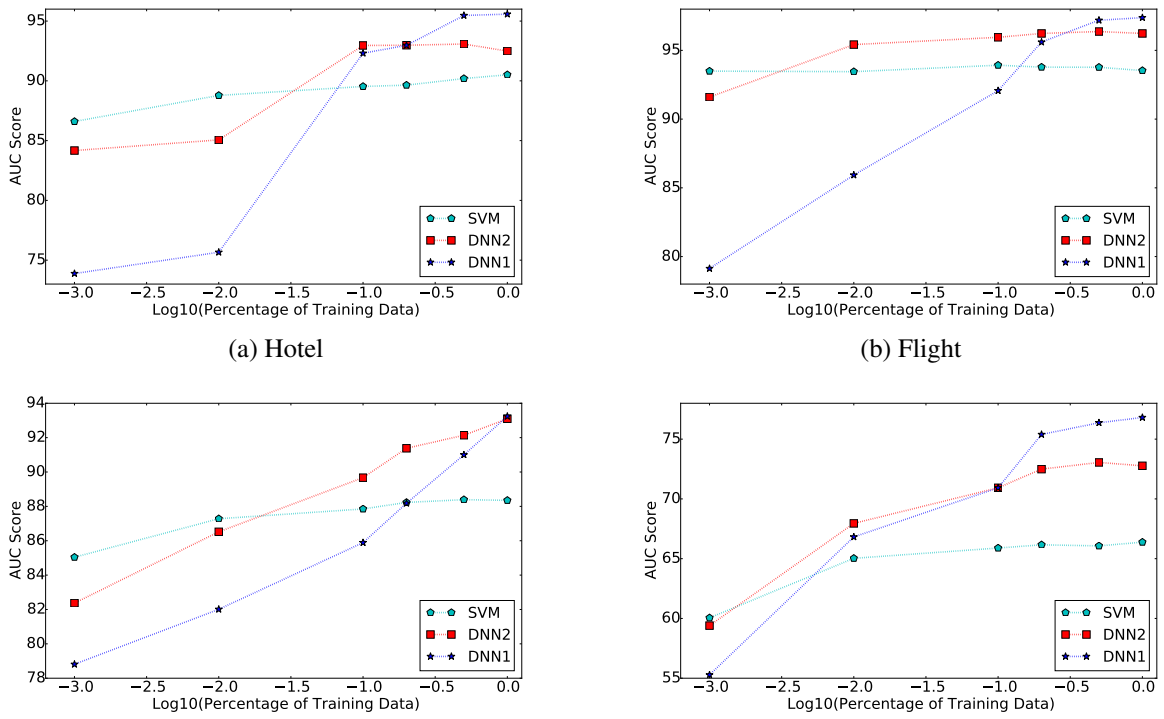
(b) Flight

(c) Restaurant

(d) Nightlife

Figure 4: Domain Adaption in Query Classification: Comparison of features using SVM classifiers. The X-axis indicates the amount of labeled samples used in training the SVM. Intuitively, the three feature representations correspond to different layers in Figure 1. **SemanticRepresentation** is the l_2 layer trained by MT-DNN. **Word3gram** is input X and **Letter3gram** is word hash layer (l_1), both not trained/adapted. Generally, **SemanticRepresentation** performs best for small training labels, indicating its usefulness in domain adaptation. Note that the numbers -3.0, -2.0, -1.0 and 0.0 in x-axis denote 0.1, 1, 10 and 100 percent training data in each domain, respectively.



(a) Hotel (b) Flight

(c) Restaurant (d) Nightlife

Figure 5: Domain Adaptation in Query Classification. Comparison of different DNNs.

high model compactness. The key to the compactness is the aggressive compression from the 500k-dimensional bag-of-words input to 300-dimensional semantic representation l_2. This significantly reduces the memory/run-time requirements compared to systems that rely on surface-form features. The most expensive portion of the model is storage of the 50k-by-300 W_1 and its matrix multiplication with l_1, which is sparse: this is trivial on modern hardware. Our multi-task DNN takes $<$ 150KB in memory whereas e.g. SVM-Word takes about 200MB.

Compactness is particularly important for query classification, since one may desire to add new domains after discovering new needs from the query logs of an operational system. On the other hand, it is prohibitively expensive to collect labeled training data for new domains. Very often, we only have very small training data or even no training data.

To evaluate the models using the above criteria, we perform domain adaptation experiments on query classification using the following procedure: (1) Select one query classification task t^*. Train MT-DNN on the remaining tasks (including Web Search task) to obtain a semantic representation (l_2); (2) Given a fixed l_2, train an SVM on the training data t^*, using varying amounts of labels; (3) Evaluate the AUC on the test data of t^*

We compare three SVM classifiers trained using different feature representations: (1) **SemanticRepresentation** uses the l_2 features generated according to the above procedure. (2) **Word3gram** uses unigram, bigram and trigram word features. (3) **Letter3gram** uses letter-trigrams. Note that **Word3gram** and **Letter3gram** correspond to SVM-Word and SVM-Letter respectively in Table 2.

The AUC results for different amounts of t^* training data are shown in Figure 4. In the Hotel, Flight and Restaurant domains, we observe that our semantic representation dominated the other two feature representations (**Word3gram** and **Letter3gram**) in all cases except the extremely large-data regime (more than 1 million training samples in domain t^*). Given sufficient labels, SVM is able to train well on **Word3gram** sparse features, but for most cases **Se-**

manticRepresentation is recommended.[4]

In a further experiment, we compare the following two DNNs using the same domain adaptation procedure: (1) **DNN1**: DNN where $\mathbf{W}_1$ is randomly initialized and parameters $\mathbf{W}_1, \mathbf{W}_2, \mathbf{W}_3^{t^*}$ are trained on varying amounts of data in t^*; (2) **DNN2**: DNN where $\mathbf{W}_1$ is obtained from other tasks (i.e. **SemanticRepresentation**) and fixed, while parameters $\mathbf{W}_2, \mathbf{W}_3^{t^*}$ are trained on varying amounts of data in t^*. The purpose is to see whether shared semantic representation is useful even under a DNN architecture. Figure 5 show the AUC results of DNN1 vs. DNN2 (the results **SVM** denotes the same system as **SemanticRepresentation** in Figure 4, plotted here for reference). We observe that when the training data is extremely large (millions of samples), one does best by training all parameters from scratch (DNN1). Otherwise, one is better off using a shared semantic representation trained by multi-task objectives. Comparing DNN2 and SVM with **SemanticRepresentation**, we note that SVM works best for training data of several thousand samples; DNN2 works best in the medium data range.

4 Related Work

There is a large body of work on representation learning for natural language processing, sometimes using different terminologies for similar concepts; e.g., feature generation, dimensionality reduction, and vector space models. The main motivation is similar: to abstract away from surface forms in words, sentences, or documents, in order to alleviate sparsity and approximate semantics. Traditional techniques include LSA (Deerwester et al., 1990), ESA (Gabrilovich and Markovitch, 2007), PCA (Karhunen, 1998), and non-linear kernel variants (Schölkopf et al., 1998). Recently, learning-based approaches inspired by neural networks, especially DNNs, have gained in prominence, due to their favorable performance (Huang et al., 2013; Baroni et al., 2014; Milajevs et al., 2014).

Popular methods for learning *word* representations include (Collobert et al., 2011; Mikolov et al., 2013c; Mnih and Kavukcuoglu, 2013; Pennington et al., 2014): all are based on unsupervised objectives of predicting words or word frequencies from raw text. End-to-end neural network models for specific tasks (e.g. parsing) often use these word representations as initialization, which are then iteratively improved by optimizing a supervised objective (e.g. parsing accuracy). A selection of successful applications of this approach include sequence labeling (Turian et al., 2010), parsing (Chen and Manning, 2014), sentiment (Socher et al., 2013), question answering (Iyyer et al., 2014) and translation modeling (Gao et al., 2014a).

Our model takes queries and documents as input, so it learns *sentence/document* representations. This is currently an open research question, the challenge being how to properly model semantic compositionality of words in vector space (Huang et al., 2013; M. Baroni and Zamparelli, 2013; Socher et al., 2013). While we adopt a bag-of-words approach for practical reasons (memory and run-time), our multi-task framework is extensible to other methods for sentence/document representations, such as those based on convolutional networks (Kalchbrenner et al., 2014; Shen et al., 2014; Gao et al., 2014b), parse tree structure (Irsoy and Cardie, 2014), and run-time inference (Le and Mikolov, 2014).

The synergy between multi-task learning and neural nets is quite natural; the general idea dates back to (Caruana, 1997). The main challenge is in designing the tasks and the network structure. For example, (Collobert et al., 2011) defined part-of-speech tagging, chunking, and named entity recognition as multiple tasks in a single sequence labeler; (Bordes et al., 2012) defined multiple data sources as tasks in their relation extraction system. While conceptually similar, our model is novel in that it combines tasks as disparate as classification and ranking. Further, considering that multi-task models often exhibit mixed results (i.e. gains in some tasks but degradation in others), our accuracy improvements across all tasks is a very satisfactory result.

5 Conclusion

In this work, we propose a robust and practical representation learning algorithm based on multi-task objectives. Our multi-task DNN model successfully combines tasks as disparate as classification and ranking, and the experimental results demon-

[4]The trends differ slightly in the Nightlife domain. We believe this may be due to data bias on test data (only 298 samples).

strate that the model consistently outperforms strong baselines in various query classification and web search tasks. Meanwhile, we demonstrated compactness of the model and the utility of the learned query/document representation for domain adaptation.

Our model can be viewed as a general method for learning semantic representations beyond the word level. Beyond query classification and web search, we believe there are many other knowledge sources (e.g. sentiment, paraphrase) that can be incorporated either as classification or ranking tasks. A comprehensive exploration will be pursued as future work.

Abstract

We approach the task of morphological inflection generation as discriminative string transduction. Our supervised system learns to generate word-forms from lemmas accompanied by morphological tags, and refines them by referring to the other forms within a paradigm. Results of experiments on six diverse languages with varying amounts of training data demonstrate that our approach improves the state of the art in terms of predicting inflected word-forms.

infinitive		atmen
present participle		atmend
past participle		geatmet
auxiliary		haben
	indicative	
present	ich atme	wir **atmen**
	du atmest	ihr atmet
	er atmet	sie **atmen**
preterite	ich atmete	wir atmeten
	du atmetest	ihr atmetet
	er atmete	sie atmeten

Figure 1: A partial inflection table for the German verb *atmen* "to breathe" in Wiktionary.

1 Introduction

Word-forms that correspond to the same lemma can be viewed as paradigmatically related instantiations of the lemma. For example, *take, takes, taking, took,* and *taken* are the word-forms of the lemma *take*. Many languages have complex morphology with dozens of different word-forms for any given lemma: verbs inflect for tense, mood, and person; nouns can vary depending on their role in a sentence, and adjectives agree with the nouns that they modify. For such languages, many forms will not be attested even in a large corpus. However, different lemmas often exhibit the same inflectional patterns, called *paradigms*, which are based on phonological, semantic, or morphological criteria. The paradigm of a given lemma can be identified and used to generate unseen forms.

Inflection prediction has the potential to improve Statistical Machine Translation (SMT) into morphologically complex languages. In order to address data sparsity in the training bitext, Clifton and Sarkar (2011) and Fraser et al. (2012) reduce diverse inflected forms in the target language into the corresponding base forms, or lemmas. At test time, they predict an abstract inflection tag for each translated lemma, which is then transformed into a proper word-form. Unfortunately, hand-crafted morphological generators such as the ones that they use for this purpose are available only for a small number of languages, and are expensive to create from scratch. The supervised inflection generation models that we investigate in this paper can instead be trained on publicly available inflection tables.

The task of an inflection generator is to produce an inflected form given a base-form (e.g., an infinitive) and desired inflection, which can be specified as an abstract inflectional tag. The generator is trained on a number of inflection tables, such as the one in Figure 1, which enumerate inflection forms for a given lemma. At test time, the generator predicts inflections for previously unseen base-forms. For example, given the input *atmen* + *1SIA*, where the tag stands for "first person singular indicative preterite," it should output *atmete*.

Recently, Durrett and DeNero (2013) and Ahlberg

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 922–931,
Denver, Colorado, May 31 – June 5, 2015.

et al. (2014) have proposed to model inflection generation as a two-stage process: an input base-form is first matched with rules corresponding to a paradigm seen during training, which is then used to generate all inflections for that base-form simultaneously. Although their methods are quite different, both systems account for paradigm-wide regularities by creating rules that span all inflections within a paradigm. We analyze both approaches in greater detail in Section 2.

In this paper, we approach the task of supervised inflection generation as discriminative string transduction, in which character-level operations are applied to transform a lemma concatenated with an inflection tag into the correct surface word-form. We carefully model the transformations carried out for a single inflection, taking into account source characters surrounding a rule, rule sequence patterns, and the shape of the resulting inflected word. To take advantage of paradigmatic regularities, we perform a subsequent reranking of the top n word-forms produced by the transducer. In the reranking model, soft constraints capture similarities between different inflection slots within a table. Where previous work leveraged large, rigid rules to span paradigms, our work is characterized by small, flexible rules that can be applied to any inflection, with features determining what rule sequence works best for each pairing of a base-form with an inflection.

Since our target application is machine translation, we focus on maximizing inflection form accuracy, rather than complete table accuracy. Unlike previous work, which aims at learning linguistically-correct paradigms from crowd-sourced data, our approach is designed to be robust with respect to incomplete and noisy training data, which could be extracted from digital lexicons and annotated corpora. We conduct a series of experiments which demonstrate that our method can accurately learn complex morphological rules in languages with varying levels of morphological complexity. In each experiment we either match or improve over the state of the art reported in previous work. In addition to providing a detailed comparison of the available inflection prediction systems, we also contribute four new inflection datasets composed of Dutch and French verbs, and Czech verbs and nouns, which are made available for future research.

2 Inflection generation

Durrett and DeNero (2013) formulate the specific task of supervised generation of inflected forms for a given base-form based on a large number of training inflection tables, while Ahlberg et al. (2014) test their alternative method on the same Wiktionary dataset. In this section, we compare their work to our approach with respect to the following three subtasks:

1. character-wise alignment of the word-forms in an inflection table (Section 2.1),
2. extraction of rules from aligned forms (2.2),
3. matching of rules to new base-forms (2.3).

2.1 Table alignment

The first step in supervised paradigm learning is the alignment of related inflected forms in a table. Though technically a multiple-alignment problem, this can also be addressed by aligning each inflected form to a base-form. Durrett & DeNero do exactly this, aligning each inflection to the base with a paradigm-aware, position-dependent edit distance. Ahlberg et al. use finite-state-automata to implement a multiple longest-common-subsequence (LCS) alignment, avoiding the use of an explicit base-form. Both systems leverage the intuition that character alignment is mostly a problem of aligning those characters that remain unchanged throughout the inflection table.

Our alignment approach differs from previous work in that we use an EM-driven, many-to-many aligner. Instead of focusing on unchanged characters within a single paradigm, we look for small multi-character operations that have statistical support across all paradigms. This includes operations that simply copy their source into the target, leaving the characters unchanged.

2.2 Rule extraction

The second step involves transforming the character alignments into inflection rules. Both previous efforts begin addressing this problem in the same way: by finding maximal, contiguous spans of changed characters, in the base-form for Durrett & DeNero, and in the aligned word-forms for Ahlberg et al. Given those spans, the two methods diverge quite substantially. Durrett & DeNero extract a rule for

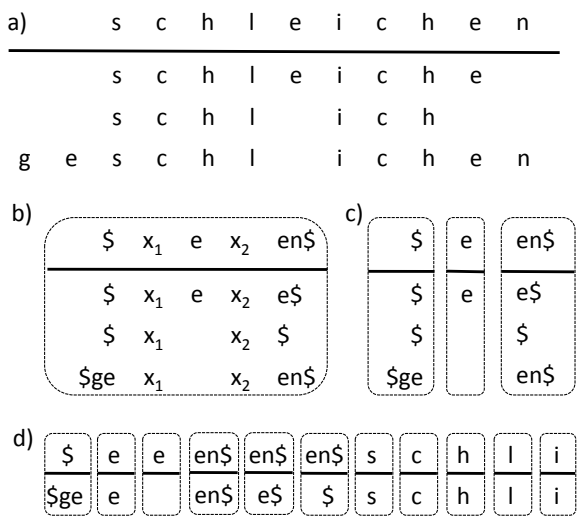

Figure 2: Competing strategies for rule extraction: (a) an aligned table; (b) a table-level rule; (c) vertical rules; (d) atomic rules. $ is a word boundary marker.

each *changed* span, with the rule specifying transformations to perform for each inflection. Ahlberg et al. instead replace each *unchanged* span with a variable, creating a single rule that specifies complete inflections for the entire table. The latter approach creates larger rules, which are easier to interpret for a linguist, but are less flexible, and restrict information sharing across paradigms.

We move in the opposite direction by extracting a rule for each minimal, multi-character transformation identified by our aligner, with no hard constraint on what rules travel together across different inflections. We attempt to learn atomic character transformations, which extends the flexibility of our rules at the cost of reduced interpretability.

The differences in rule granularity are illustrated on the German verb *schleichen* "to sneak" in Figure 2. The single rule of Ahlberg et al. comprises three vertical rules of Durrett & DeNero, which in turn correspond to eleven atomic rules in our system. Note that this is a simplification, as alignments and word boundary markers vary across the three systems.

2.3 Rule selection

The final component of an inflection generation system is a mechanism to determine what rules to apply to a new base-form, in order to generate the inflected forms. The strongest signal for this task comes from learning how the training base-forms use the rules. With their highly restrictive rules, Ahlberg et al. can afford a simple scheme, keeping an index that associates rules with base-forms, and employing a longest suffix match against this index to assign rules to new base-forms. They also use the corpus frequency of the inflections that would be created by their rules as a rule-selection feature. Durrett & DeNero have much more freedom, both in what rules can be used together and in where each rule can be applied. Therefore, they employ a more complex semi-Markov model to assign rules to spans of the base-form, with features characterizing the n-gram character context surrounding the source side of each rule.

Since our rules provide even greater flexibility, we model rule application very carefully. Like Durrett & DeNero, we employ a discriminative semi-Markov model that considers source character context, and like Ahlberg et al., we use a corpus to re-evaluate predictions. In addition, we model rule sequences, and the character-shape of the resulting inflected form. Note that our rules are much more general than those of our predecessors, which makes it easy to get statistical support for these additional features. Finally, since our rules are not bound by paradigm structure, we employ a reranking step to account for intra-paradigm regularities.

3 Discriminative Transduction

In this section, we describe the details of our approach, including the affix representation, the string alignment and transduction, and the paradigm reranking.

3.1 Affix representation

Our inflection generation engine is a discriminative semi-Markov model, similar to a monotonic phrase-based decoder from machine translation (Zens and Ney, 2004). This system cannot insert characters, except as a part of a phrasal substitution, so when inflecting a base form, we add an abstract affix representation to both provide an insertion site and to indicate the desired inflection.

Abstract tags are separated from their lemmas with a single '+' character. Marking the morpheme boundary in such a way allows the transducer to gen-

eralize the context of a morpheme boundary. For example, the third person singular indicative present of the verb *atmen* is represented as *atmen+3SIE*. We use readable tags throughout this paper, but they are presented to the transducer as indivisible units; it cannot translate them character-by-character.

German and Dutch past participles, as well as several Czech inflections, are formed by circumfixation, a special process of simultaneous prefixation and suffixation. We represent such inflections with separate copies of the circumfix tag before and after the lemma. For example, the past participle *gebracht* "brought" is represented as *PPL+bringen+PPL*. In the absence of language-specific information regarding the set of inflections that involve circumfixation, the system can learn to transduce particular affixes into empty strings.

During development, we experimented with an alternative method, in which affixes are represented by a default allomorph. Allomorphic representations have the potential advantage of reducing the complexity of transductions by the virtue of being similar to the correct form of the affix. However, we found that allomorphic affixes tend to obfuscate differences between distinct inflections, so we decided to employ abstract tags instead.

3.2 String transduction

We perform string transduction adapting the tool DIRECTL+, originally designed for grapheme-to-phoneme conversion (Jiampojamarn et al., 2010). DIRECTL+ is a feature-rich, discriminative character transducer, which searches for a model-optimal sequence of character transformation rules for its input. The core of the engine is a dynamic programming algorithm capable of transducing many consecutive characters in a single operation, also known as a semi-Markov model. Using a structured version of the MIRA algorithm (McDonald et al., 2005), training attempts to assign weights to each feature so that its linear model separates the gold-standard derivation from all others in its search space.

DIRECTL+ uses a number of feature templates to assess the quality of a rule: source context, target n-gram, and joint n-gram features. Context features conjoin the rule with indicators for all source character n-grams within a fixed window of where the rule is being applied. Target n-grams provide indicators on target character sequences, describing the shape of the target as it is being produced, and may also be conjoined with our source context features. Joint n-grams build indicators on rule sequences, combining source and target context, and memorizing frequently-used rule patterns. Durrett & DeNero also use source context features, but we are the first group to account for features that consider rule sequences or target word shape.

Following Toutanova and Cherry (2009), we modify the out-of-the-box version of DIRECTL+ by implementing an abstract copy feature that indicates when a rule simply copies its source characters into the target, e.g. $p \rightarrow p$. The copy feature has the effect of biasing the transducer towards preserving the base-form within the inflected form.

In addition to the general model that is trained on all inflected word-forms, we derive tag-specific models for each type of inflection. Development experiments showed the general model to be slightly more accurate overall, but we use both types of models in our reranker.

3.3 String alignment

DIRECTL+ training requires a set of aligned pairs of source and target strings. The alignments account for every input and output character without the use of insertion. Derivations that transform the input substrings into the desired output substrings are then extracted from the alignments.

We induce the alignments by adapting the M2M aligner of (Jiampojamarn et al., 2007), which uses Expectation-Maximization to maximize the joint likelihood of its input under a pairwise alignment scheme. Previous work creates alignments based upon entire inflection tables, while ours considers each inflection paired with its base form independently. M2M goes beyond linking single characters by aligning entire substrings instead. In practice, the base-form serves as a pivot for the entire inflection table, leading to consistent multiple alignments.

We modify the M2M aligner to differentiate between stems and affixes. The alignments between stem letters rarely require more than a 2-2 alignment. A single tag, however, must align to an entire affix, which may be composed of four or more letters. The distinction allows us to set different substring length limits for the two types.

In order to encourage alignments between identical letters, we augment the training set by pairing each inflected form with itself. In addition, we modify the aligner to generalize the identity alignments into a single operation, which corresponds to the copy feature described in Section 3.2.

3.4 Reranking

Morphological processes such as stem changes tend to be similar across different word-forms of the same lemma. In order to take advantage of such paradigmatic consistency, we perform a reranking of the n-best word-forms generated by DIRECTL+. The correct form is sometimes included in the n-best list, but with a lower score than an incorrect form. We propose to rerank such lists on the basis of features extracted from the 1-best word-forms generated for other inflection slots, the majority of which are typically correct.

We perform reranking with the Liblinear SVM (Fan et al., 2008), using the method of Joachims (2002). An initial inflection table, created to generate reranking features, is composed of 1-best predictions from the general model. For each inflection, we then generate lists of candidate forms by taking the intersection of the n-best lists from the general and the tag-specific models.

In order to generate features from our initial inflection table, we make pairwise comparisons between a prediction and each form in the initial table. We separate stems from affixes using the alignment. Our three features indicate whether the compared forms share the same stem, the same affix, and the same surface word-form, respectively. We generate a feature vector for each aligned pair of related word-forms, such as past participle vs. present participle. In addition, we include as features the confidence scores generated by both models.

Two extra features are designed to leverage a large corpus of raw text. A binary indicator feature fires if the generated form occurs in the corpus. In order to model the phonotactics of the language, we also derive a 4-gram character language model from the same corpus, and include as a feature the normalized log-likelihood of the predicted form.

Language / POS	Set	Base forms	Infl.
German Nouns	DE-N	2764	8
German Verbs	DE-V	2027	27
Spanish Verbs	ES-V	4055	57
Finnish Nouns	FI-N	6400[1]	28
Finnish Verbs	FI-V	7249	53
Dutch Verbs	NL-V	11200	9
French Verbs	FR-V	6957	48
Czech Nouns	CZ-N	21830	17
Czech Verbs	CZ-V	4435	54

Table 1: The number of base forms and inflections for each dataset.

4 Experiments

We perform five experiments that differ with respect to the amount and completeness of training data, and whether the training is performed on individual word-forms or entire inflection tables. We follow the experimental settings established by previous work, as much as possible.

The parameters of our transducer and aligner were established on a development set of German nouns and verbs, and kept fixed in all experiments. We limit stem alignments to 2-2, affix alignments to 2-4, source context to 8 characters, joint n-grams to 5 characters, and target Markov features to 2 characters.

4.1 Inflection data

We adopt the Wiktionary inflection data made available by Durrett and DeNero (2013), with the same training, development, and test splits. The development and test sets contain 200 inflection tables each. and the training sets consist of the remaining data. Table 1 shows the total number of tables in each language set. We convert their inflectional information to abstract tags for input to our transducer.

We augment the original five datasets with four new sets: Dutch verbs from the CELEX lexical database (Baayen et al., 1995), French verbs from Verbiste, an online French conjugation dictionary[2], and Czech nouns and verbs from the Prague Dependency Treebank (Böhmová et al., 2003). For each of

[1] Durrett & DeNero report 40589 forms, but only use 6000 for training, and 200 each for development and testing

[2] http://perso.b2b2c.ca/sarrazip/dev/verbiste.html

Case	Singular	Plural
Nominative	Buch	Bücher
Accusative	Buch	Bücher
Dative	Buch	Büchern
Genitive	Buches	Bücher

Table 2: All word-forms of the German noun *Buch*.

these sets, the training data is restricted to 80% of the inflection tables listed in Table 1, with 10% each for development and testing. Each lemma inflects to a finite number of forms that vary by part-of-speech and language (Table 1); German nouns inflect for number and case (Table 2), while French, Spanish, German, and Dutch verbs inflect for number, person, mood, and tense.

We extract Czech data from the Prague Dependency Treebank, which is fully annotated for morphological information. This dataset contains few complete inflection tables, with many lemmas represented by a small number of word-forms. For this reason, it is only suitable for one of our experiments, which we describe in Section 4.5.

Finnish has a morphological system that is unlike any of the Indo-European languages. There are 15 different grammatical cases for nouns and adjectives, while verbs make a number of distinctions, such as conditional vs. potential, and affirmative vs. negative. We derive separate models for two noun classes (singular and plural), and six verb classes (infinitive, conditional, potential, participle, imperative, and indicative). This is partly motivated by the number of individual training instances for Finnish, which is much larger than the other languages, but also to take advantage of the similarities within classes.

For the reranker experiments, we use the appropriate Wikipedia language dump. The number of tokens in the corpora is approximately 77M for Czech, 200M for Dutch, 6M for Finnish, 425M for French, 550M for German, and 400M for Spanish.

4.2 Individual inflections

In the first experiment, we test the accuracy of our basic model which excludes our reranker, and therefore has no access to features based on inflection tables or corpus counts. Table 3 compares our results against the Factored model of Durrett & DeNero (DDN), which also makes an independent prediction for each inflection. The numbers marked with an asterisk were not reported in the original paper, but were generated by running their publicly-available code on our new Dutch and French datasets. For the purpose of quantifying the effectiveness of our reranker, we also include the percentage of correct answers that appear in our 10-best lists.

Set	DDN	Ours	10-best
DE-V	94.8	**97.5**	99.8
DE-N	88.3	**88.6**	98.6
ES-V	99.6	**99.8**	100
FI-V	97.2	**98.1**	99.9
FI-N	92.1	**93.0**	99.0
NL-V	90.5*	**96.1**	99.4
FR-V	98.8*	**99.2**	99.7

Table 3: Prediction accuracy of models trained and tested on individual inflections.

Our basic model achieves higher accuracy on all datasets, which shows that our refined transduction features are consistently more effective than the source-context features employed by the other system. Naturally, their system, as well as the system of Ahlberg et al., is intended for whole-table scenarios, which we test next.

4.3 Complete paradigms

In this experiment, we assume the access to complete inflection tables, as well as to raw corpora. We compare our reranking system to the Joint model of Durrett & DeNero (DDN), which is trained on complete tables, and the full model of Ahlberg et al. (AFH), which is trained on complete tables, and matches forms to rules with aid of corpus counts. Again, we calculated the numbers marked with an asterisk by running the respective implementations on our new datasets.

The results of the experiment are shown in Table 4. Our reranking model outperforms the Joint model of DDN on all sets, and the full model of AFH on most verb sets. Looking across tables to Table 3, we can see that reranking improves upon our independent model on 5 out of 7 sets, and is equivalent on the remaining two sets. However, accord-

Set	DDN	AFH	Ours
DE-V	96.2	**97.9**	**97.9**
DE-N	88.9	**91.8**	89.9

FI-V	96.4	96.6	**98.1**
FI-N	93.4	**93.8**	93.6
NL-V	94.4*	87.7*	**96.6**
FR-V	96.8*	98.1*	**99.2**

Table 4: Individual form accuracy of models trained on complete inflection tables.

Set	DDN	AFH	Ours
DE-V	85.0	76.5	**90.5**
DE-N	79.5	**82.0**	76.5
ES-V	95.0	98.0	**99.0**
FI-V	87.5	92.5	**94.5**
FI-N	83.5	**88.0**	82.0
NL-V	79.5*	37.7*	**82.1**
FR-V	92.1*	96.0*	**97.1**

Table 5: Complete table accuracy of models trained on complete inflection tables.

ing to single-form accuracy, neither our system nor DDN benefits too much from joint predictions. Table 5 shows the same results evaluated with respect to complete table accuracy.

4.4 Incomplete paradigms

In this experiment, we consider a scenario where, instead of complete tables, we have access to some but not all of the possible word-forms. This could occur for example if we extracted our training data from a morphologically annotated corpus. We simulate this by only including in our training tables the forms that are observed in the corresponding raw corpus. We then test our ability to predict the same test forms as in the previous experiments, regardless of whether or not they were observed in the corpus. We also allow a small held-out set of complete tables, which corresponds to the development set. For Durrett & DeNero's method, we include this held-out set in the training data, while for our system, we use it to train the reranker.

The Joint method of DDN and the methods of AFH are incapable of training on incomplete tables, and thus, we can only compare our results against the Factored model of DDN. However, unlike their Factored model, we can then still take advantage of paradigmatic and corpus information, by applying our reranker to the predictions made by our simple model.

The results are shown in Table 6, where we refer to our independent model as *Basic*, and to our reranked system as *Reranked*. The latter outperforms DDN on all sets. Furthermore, even with only partial tables available during training, reranking improves upon our independent model in every case.

4.5 Partial paradigms

We run a separate experiment for Czech, as the data is substantially less comprehensive than for the other languages. Although the number of 13.0% observed noun forms is comparable to the Finnish case, the percentages in Table 6 refer only to the training set: the test and held-out sets are complete. For Czech, the percentage includes the testing and held-out sets. Thus, the method of Durrett & DeNero and our reranker have access to less training data than in the experiment of Section 4.4.

The results of this experiment are shown in Table 7. Our Basic model outperforms DDN for both nouns and verbs, despite training on less data. However, reranking actually decreases the accuracy of our system on Czech nouns. It appears that the reranker is adversely affected by the lack of complete target paradigms. We leave the full investigation into the effectiveness of the reranker on incomplete data to future work.

4.6 Seed paradigms

Dreyer and Eisner (2011) are particularly concerned with situations involving limited training data, and approach inflection generation as a semi-supervised task. In our last experiment we follow their experimental setup, which simulates the situation where we obtain a small number of complete tables from an expert. We use the same training, development, and test splits to test our system. Due to the nature of our model, we need to set aside a hold-out set for reranking. Thus, rather than training on 50 and 100 tables, we train on 40 and 80, but compare the results

Set	% of Total	DDN	Ours	
			Basic	Reranked
DE-V	69.2	90.2	96.2	**97.9**
DE-N	92.7	88.3	88.4	**89.8**
ES-V	36.1	97.1	95.9	**99.6**
FI-V	15.6	73.8	78.7	**85.6**
FI-N	15.2	71.6	78.2	**80.4**
DU-V	50.5	89.8	94.9	**96.0**
FR-V	27.6	94.6	96.6	**98.9**

Table 6: Prediction accuracy of models trained on observed forms.

with the models trained on 50 and 100, respectively. For reranking, we use the same German corpus as in our previous experiments, but limited to the first 10M words.

The results are shown in Table 8. When trained on 50 seed tables, the accuracy of our models is comparable to both the basic model of Dreyer and Eisner (DE) and the Factored model of DDN, and matches the best system when we add reranking. When trained on 100 seed tables, our full reranking model outperforms the other models.

5 Error analysis

In this section, we analyze several types of errors made by the various systems. Non-word predictions are marked with an asterisk.

German and Dutch are closely-related languages that exhibit similar errors. Many errors involve the past participle, which is often created by circumfixation. For the German verb *verfilmen* "to film," we predict the correct *verfilmt*, while the other systems have *verfilmen**, and *geverfilmt**, respectively. DDN simply select an incorrect rule for the past participle. AFH choose paradigms through suffix analysis, which fails to account for the fact that verbs that begin with a small set of prefixes, such as *ver-*, do not take a *ge-* prefix. This type of error particularly affects the accuracy of AFH on Dutch because of a number of verbs in our test set that involve infixation for the past participle. Our system uses its source and target-side n-gram features to match these prefixes with their correct representation.

The second type of error is an over-correction by the corpus. The past participle of the verb *dimmen* is *gedimmt*, but AFH predict *dimmt**, and then change it to *dummen* with the corpus. *Dummen* is indeed a valid word in German, but unrelated to the verb *dimmen*. It is also far more common, with 181 occurrences in the corpus, compared with only 28 for *gedimmt*. Since AFH use corpus frequencies, mistakes like this can occur. Our system is trained to balance transducer confidence against a form's existence in a corpus (as opposed to log frequency), which helps it ignore the bias of common, but incorrect, forms.

Set	% of Total	DDN	Ours	
			Basic	Reranked
CZ-N	13.0	91.1	**97.7**	93.5
CZ-V	6.8	82.5	83.6	**85.8**

Table 7: Prediction accuracy of models trained on observed Czech forms.

The German verb *brennen* "to burn" has an irregular past participle: *gebrannt*. It involves both a stem vowel change and a circumfix, two processes that only rarely co-occur. AFH predict the form *brannt**, using the paradigm of the similar *bekennen*. The flexibility of DDN allows them to predict the correct form. Our basic model predicts *gebrennt**, which follows the regular pattern of applying a circumfix, while maintaining the stem vowel. The reranker is able to correct this mistake by relating it to the form *gebrannt* in the corpus, whose stem is identical to the stem of the preterite forms, which is a common paradigmatic pattern.

Our system can also over-correct, such as with the second person plural indicative preterite form for the verb *reisen*, which should be *reistet*, and which our basic model correctly predicts. The reranker, however, changes the prediction to *rist*. This is a nominal form that is observed in the corpus, while the verbal form is not.

An interesting example of a mistake made by the Factored model of DDN involves the Dutch verb *aandragen*. Their model learns that stem vowel *a* should be doubled, and that an *a* should be included as part of the suffix *-agt*, which results in an incorrect form *aandraaagt**. Thanks to the modelling of phonotactics, our model is able to correctly rule out the tripling of a vowel.

Seed Tables	DE		DDN		Ours	
	Basic	Full	Factored	Joint	Basic	Full
50	89.9	**90.9**	89.6	90.5	89.7	**90.9**
100	91.5	92.2	91.4	92.3	92.0	**92.6**

Table 8: Prediction accuracy on German verb forms after training on a small number of seed inflection tables.

Finnish errors tend to fall into one of three types. First, words that involve harmonically neutral vowels, such as "e" and "i" occasionally cause errors in vowel harmony. Second, all three systems have difficulty identifying syllable and compound boundaries, and make errors predicting vowels near boundaries. Finally, consonant gradation, which alternates consonants in open and closed syllables, causes a relatively large number of errors; for example, our system predicts **heltempien*, instead of the correct *hellempien* as the genitive singular of the comparative adjective *hellempi* "more affectionate".

6 Conclusion

We have proposed an alternative method of generating inflected word-forms which is based on discriminative string transduction and reranking. We have conducted a series of experiments on nine datasets involving six languages, including four new datasets that we created. The results demonstrate that our method is not only highly accurate, but also robust against incomplete or limited inflection data. In the future, we would like to apply our method to non-European languages, with different morphological systems. We also plan to investigate methods of extracting morphological tags from a corpus, including differentiating syncretic forms in context.

Penalized Expectation Propagation for Graphical Models over Strings*

Ryan Cotterell and **Jason Eisner**
Department of Computer Science, Johns Hopkins University
{ryan.cotterell,jason}@cs.jhu.edu

Abstract

We present penalized expectation propagation (PEP), a novel algorithm for approximate inference in graphical models. Expectation propagation is a variant of loopy belief propagation that keeps messages tractable by projecting them back into a given family of functions. Our extension, PEP, uses a structured-sparsity penalty to encourage simple messages, thus balancing speed and accuracy. We specifically show how to instantiate PEP in the case of string-valued random variables, where we adaptively approximate finite-state distributions by variable-order n-gram models. On phonological inference problems, we obtain substantial speedup over previous related algorithms with no significant loss in accuracy.

1 Introduction

Graphical models are well-suited to reasoning about linguistic structure in the presence of uncertainty. Such models typically use discrete random variables, where each variable ranges over a finite set of values such as words or tags. But a variable can also be allowed to range over an *infinite* space of discrete *structures*—in particular, the set of all strings, a case first explored by Bouchard-Côté et al. (2007).

This setting arises because human languages make use of many word forms. These strings are systematically related in their spellings due to linguistic processes such as morphology, phonology, abbreviation, copying error and historical change. To analyze or predict novel strings, we can model the joint distribution of many related strings at once. Under a graphical model, the joint probability of an assignment tuple is modeled as a product of potentials on sub-tuples, each of which is usually modeled in turn by a weighted finite-state machine.

In general, we wish to infer the values of unknown strings in the graphical model. Deterministic approaches to this problem have focused on belief propagation (BP), a message-passing algorithm that is exact on acyclic graphical models and approximate on cyclic ("loopy") ones (Murphy et al., 1999). But in both cases, further heuristic approximations of the BP messages are generally used for speed.

In this paper, we develop a more principled and flexible way to approximate the messages, using variable-order n-gram models.

We first develop a version of expectation propagation (EP) for string-valued variables. EP offers a principled way to approximate BP messages by distributions from a *fixed* family—e.g., by trigram models. Each message update is found by minimizing a certain KL-divergence (Minka, 2001a).

Second, we generalize to variable-order models. To do this, we augment EP's minimization problem with a novel penalty term that keeps the number of n-grams finite. In general, we advocate penalizing more "complex" messages (in our setting, large finite-state acceptors). Complex messages are slower to construct, and slower to use in later steps.

Our penalty term is formally similar to regularizers that encourage structured sparsity (Bach et al., 2011; Martins et al., 2011). Like a regularizer, it lets us use a more expressive family of distributions, secure in the knowledge that we will use only as many of the parameters as we really need for a "pretty good" fit. But *why* avoid using more parameters? Regularization seeks better *generalization* by not overfitting the model to the data. By contrast, we already have a model and are merely doing inference. We seek better *runtime* by not over-fussing about capturing the model's marginal distributions.

Our "penalized EP" (PEP) inference strategy is applicable to any graphical model with complex messages. In this paper, we focus on strings, and show how PEP speeds up inference on the computational phonology model of Cotterell et al. (2015).

We provide further details, tutorial material, and results in the appendices (supplementary material).

2 Background

Graphical models over strings are in fairly broad use. Linear-chain graphical models are equivalent to cascades of finite-state transducers, which have long been used to model stepwise derivational processes such as speech production (Pereira and Riley, 1997) and transliteration (Knight and Graehl, 1998). Tree-shaped graphical models have been used to model the evolution and speciation of word forms, in order to reconstruct ancient languages (Bouchard-Côté et al., 2007; Bouchard-Côté et al., 2008) and discover cognates in related languages (Hall and Klein, 2010; Hall and Klein, 2011). Cyclic graphical models have been used to model morphological paradigms (Dreyer and Eisner, 2009; Dreyer and Eisner, 2011) and to reconstruct phonological underlying forms (Cotterell et al., 2015). All of these graphical models, except Dreyer's, happen to be *directed* ones. And all of these papers, except Bouchard-Côté's, use *deterministic* inference methods—based on BP.

2.1 Graphical models over strings

A directed or undirected graphical model describes a joint probability distribution over a set of random variables. To perform inference *given* a setting of the model parameters *and* observations of some variables, it is convenient to construct a *factor graph* (Kschischang et al., 2001). A factor graph is a finite bipartite graph whose vertices are the random variables $\{V_1, V_2, \ldots\}$ and the factors $\{F_1, F_2, \ldots\}$. Each factor F is a function of the variables that it is connected to; it returns a non-negative real number that depends on the values of those variables. We define our factor graph so that the posterior probability $p(V_1 = v_1, V_2 = v_2, \ldots \mid \text{observations})$, as defined by the original graphical model, can be computed as proportional to the product of the numbers returned by all the factors when $V_1 = v_1, V_2 = v_2, \ldots$.

In a graphical model *over strings*, each random variable V is permitted to range over the strings Σ^* where Σ is a fixed alphabet. As in previous work, we will assume that each factor F connected to d variables is a d-way rational relation, i.e., a function that can be computed by a d-tape weighted finite-state acceptor (Elgot and Mezei, 1965; Mohri et al., 2002; Kempe et al., 2004). The weights fall in the semiring $(\mathbb{R}, +, \times)$: F's return value is the *total* weight of all paths that accept the d-tuple of strings, where a path's weight is the *product* of its arcs' weights. So our model marginalizes over possible paths in F.

2.2 Inference by (loopy) belief propagation

Inference seeks the posterior marginal probabilities $p(V_i = v \mid \text{observations})$, for each i. BP is an iterative procedure whose "normalized beliefs" converge to exactly these marginals if the factor graph is acyclic (Pearl, 1988). In the cyclic case, the normalized beliefs still typically converge and can be used as approximate marginals (Murphy et al., 1999).

A full presentation of BP for graphical models over strings can be found in Dreyer and Eisner (2009). We largely follow their notation. $\mathcal{N}(X)$ represents the set of neighbors of X in the factor graph.

For each edge in the factor graph, between a factor F and a variable V, BP maintains two *messages*, $\mu_{V \to F}$ and $\mu_{F \to V}$. Each of these is a function over the possible values v of variable V, mapping each v to a non-negative score. BP also maintains another such function, the *belief* b_V, for each variable V.

In general, each message or belief should be regarded as giving only *relative* scores for the different v. Rescaling it by a positive constant would only result in rescaling other messages and beliefs, which would not change the final normalized beliefs. The *normalized belief* is the probability distribution $\hat{b}_V$ such that each $\hat{b}_V(v)$ is proportional to $b_V(v)$.

The basic BP algorithm is just to repeatedly select and update a function until convergence. The rules for updating $\mu_{V \to F}$, $\mu_{F \to V}$, and b_V, given the set of "neighboring" messages in each case, can be found as equations (2)–(4) of Dreyer and Eisner (2009). (We will give the EP variants in section 4.)

Importantly, that paper shows that for graphical models over strings, each BP update can be implemented via standard finite-state operations of composition, projection, and intersection. Each message or belief is represented as a weighted finite-state acceptor (WFSA) that scores all strings $v \in \Sigma^*$.

2.3 The need for approximation

BP is generally only used directly for short cascades of finite-state transducers (Pereira and Riley, 1997; Knight and Graehl, 1998). Alas, in other graphical models over strings, the BP messages—which are acceptors—become too large to be practical.

In cyclic factor graphs, where exact inference for strings can be *undecidable*, the WFSAs can become *unboundedly* large as they are iteratively updated around a cycle (Dreyer and Eisner, 2009). Even in an acyclic graph (where BP is exact), the finite-state operations quickly lead to large WFSAs. Each intersection or composition is a Cartesian product construction, whose output's size (number of automaton states) may be as large as the *product* of its inputs' sizes. Combining many of these operations leads to exponential blowup.

3 Variational Approximation of WFSAs

To address this difficulty through EP (section 4), we will need the ability to approximate any probability distribution p that is given by a WFSA, by choosing a "simple" distribution from a family $\mathcal{Q}$.

Take $\mathcal{Q}$ to be a family of log-linear distributions

$$q_{\boldsymbol{\theta}}(v) \stackrel{\text{def}}{=} \exp(\boldsymbol{\theta} \cdot \boldsymbol{f}(v)) \,/\, Z_{\boldsymbol{\theta}} \quad (\forall v \in \Sigma^*) \qquad (1)$$

where $\boldsymbol{\theta}$ is a weight vector, $\boldsymbol{f}(v)$ is a feature vector that describes v, and $Z_{\boldsymbol{\theta}} \stackrel{\text{def}}{=} \sum_{v \in \Sigma^*} \exp(\boldsymbol{\theta} \cdot \boldsymbol{f}(v))$ so that $\sum_v q_{\boldsymbol{\theta}}(v) = 1$. Notice that the featurization function $\boldsymbol{f}$ specifies the family $\mathcal{Q}$, while the variational parameters $\boldsymbol{\theta}$ specify a particular $q \in \mathcal{Q}$.[1]

We project p into $\mathcal{Q}$ via inclusive KL divergence:

$$\boldsymbol{\theta} = \operatorname{argmin}_{\boldsymbol{\theta}} \mathrm{D}(p \,||\, q_{\boldsymbol{\theta}}) \qquad (2)$$

Now $q_{\boldsymbol{\theta}}$ approximates p, and has support everywhere that p does. We can get finer-grained approximations by expanding $\boldsymbol{f}$ to extract more features: however, $\boldsymbol{\theta}$ is then larger to store and slower to find.

3.1 Finding $\boldsymbol{\theta}$

Solving (2) reduces to maximizing $-H(p, q_{\boldsymbol{\theta}}) = \mathbb{E}_{v \sim p}[\log q_{\boldsymbol{\theta}}(v)]$, the log-likelihood of $q_{\boldsymbol{\theta}}$ on an "infinite sample" from p. This is similar to fitting a log-linear model to data (without any regularization: we want $q_{\boldsymbol{\theta}}$ to fit p as well as possible). This objective is concave and can be maximized by following its gradient $\mathbb{E}_{v \sim p}[\boldsymbol{f}(v)] - \mathbb{E}_{v \sim q_{\boldsymbol{\theta}}}[\boldsymbol{f}(v)]$. Often it is also possible to optimize $\boldsymbol{\theta}$ in closed form, as we will see later. Either way, the optimal $q_{\boldsymbol{\theta}}$ matches p's *expected* feature vector: $\mathbb{E}_{v \sim q_{\boldsymbol{\theta}}}[\boldsymbol{f}(v)] = \mathbb{E}_{v \sim p}[\boldsymbol{f}(v)]$. This inspired the name "expectation propagation."

3.2 Working with $\boldsymbol{\theta}$

Although p is defined by an arbitrary WFSA, we can represent $q_{\boldsymbol{\theta}}$ quite simply by just storing the parameter vector $\boldsymbol{\theta}$. We will later take sums of such vectors to construct product distributions: observe that under (1), $q_{\boldsymbol{\theta}_1 + \boldsymbol{\theta}_2}(v)$ is proportional to $q_{\boldsymbol{\theta}_1}(v) \cdot q_{\boldsymbol{\theta}_2}(v)$.

We will also need to construct WFSA versions of these distributions $q_{\boldsymbol{\theta}} \in \mathcal{Q}$, and of other log-linear functions (messages) that may not be normalizable into distributions. Let $\textsc{Encode}(\boldsymbol{\theta})$ denote a WFSA that accepts each $v \in \Sigma^*$ with weight $\exp(\boldsymbol{\theta} \cdot \boldsymbol{f}(v))$.

3.3 Substring features

To obtain our family $\mathcal{Q}$, we must design $\boldsymbol{f}$. Our strategy is to choose a set of "interesting" substrings $\mathcal{W}$. For each $w \in \mathcal{W}$, define a feature function "How many times does w appear as a substring of v?" Thus, $\boldsymbol{f}(v)$ is simply a vector of counts (nonnegative integers), indexed by the substrings in $\mathcal{W}$.

A natural choice of $\mathcal{W}$ is the set of all n-grams for fixed n. In this case, $\mathcal{Q}$ turns out to be equivalent to the family of n-gram language models.[2] Already in previous work ("variational decoding"), we used (2) with this family to approximate WFSAs or weighted hypergraphs that arose at runtime (Li et al., 2009).

Yet a fixed n is not ideal. If $\mathcal{W}$ is the set of bigrams, one might do well to add the trigram `the`—perhaps because `the` is "really" a bigram (counting the digraph `th` as a single consonant), or because the bigram model fails to capture how common `the` is under p. Adding `the` to $\mathcal{W}$ ensures that q_θ will now match p's expected count for this trigram. Doing this should not require adding all $|\Sigma|^3$ trigrams.

By including strings of mixed lengths in $\mathcal{W}$ we get *variable-order* Markov models (Ron et al., 1996).

3.4 Arbitrary FSA-based features

More generally, let $\mathcal{A}$ be any *unambiguous and complete* finite-state acceptor: that is, any $v \in \Sigma^*$ has exactly one accepting path in $\mathcal{A}$. For each arc or final state a in $\mathcal{A}$, we can define a feature function "How

[1] To be precise, we take $\mathcal{Q} = \{q_{\boldsymbol{\theta}} : Z_{\boldsymbol{\theta}} \text{ is finite}\}$. For example, $\boldsymbol{\theta} = \mathbf{0}$ is excluded because then $Z_{\boldsymbol{\theta}} = \sum_{v \in \Sigma^*} \exp 0 = \infty$. Aside from this restriction, $\boldsymbol{\theta}$ may be any vector over $\mathbb{R} \cup \{-\infty\}$. We allow $-\infty$ since it is a feature's optimal weight if $p(v) = 0$ for all v with that feature: then $q_{\boldsymbol{\theta}}(v) = 0$ for such strings as well. (Provided that $\boldsymbol{f}(v) \geq \mathbf{0}$, as we will ensure.)

[2] Provided that we include special n-grams that match at the boundaries of v. See Appendix B.2 for details.

many times is a used when $\mathcal{A}$ accepts v?" Thus, $\boldsymbol{f}(v)$ is again a vector of non-negative counts.

Section 6 gives algorithms for this general setting. We implement the previous section as a special case, constructing $\mathcal{A}$ so that its arcs essentially correspond to the substrings in $\mathcal{W}$. This encodes a variable-order Markov model as an FSA similarly to (Allauzen et al., 2003); see Appendix B.4 for details.

In this general setting, ENCODE($\boldsymbol{\theta}$) just returns a *weighted* version of $\mathcal{A}$ where each arc or final state a has weight $\exp \theta_a$ in the $(+, \times)$ semiring. Thus, this WFSA accepts each v with weight $\exp(\boldsymbol{\theta} \cdot \boldsymbol{f}(v))$.

3.5 Adaptive featurization

How do we choose $\mathcal{W}$ (or $\mathcal{A}$)? Expanding $\mathcal{W}$ will allow better approximations to p—but at greater computational cost. We would like $\mathcal{W}$ to include just the substrings needed to approximate a *given* p well. For instance, if p is concentrated on a few high-probability strings, then a good $\mathcal{W}$ might contain those full strings (with positive weights), plus some shorter substrings that help model the rest of p.

To select $\mathcal{W}$ at runtime in a way that adapts to p, let us say that $\boldsymbol{\theta}$ is actually an infinite vector with weights for *all possible* substrings, and define $\mathcal{W} = \{w \in \Sigma^* : \theta_w \neq 0\}$. Provided that $\mathcal{W}$ stays finite, we can store $\boldsymbol{\theta}$ as a map from substrings to *nonzero* weights. We keep $\mathcal{W}$ small by replacing (2) with

$$\boldsymbol{\theta} = \operatorname{argmin}_{\boldsymbol{\theta}} \mathrm{D}(p \mid\mid q_{\boldsymbol{\theta}}) + \lambda \cdot \Omega(\boldsymbol{\theta}) \qquad (3)$$

where $\Omega(\boldsymbol{\theta})$ measures the complexity of this $\mathcal{W}$ or the corresponding $\mathcal{A}$. Small WFSAs ensure fast finite-state operations, so ideally, $\Omega(\boldsymbol{\theta})$ should measure the size of ENCODE($\boldsymbol{\theta}$). Choosing $\lambda > 0$ to be large will then emphasize speed over accuracy.

Section 6.1 will extend section 6's algorithms to approximately minimize the new objective (3). Formally this objective resembles regularized log-likelihood. However, $\Omega(\boldsymbol{\theta})$ is not a regularizer—as section 1 noted, we have no statistical reason to avoid "overfitting" $\hat{p}$, only a computational one.

4 Expectation Propagation

Recall from section 2.2 that for each variable V, the BP algorithm maintains several nonnegative functions that score V's possible values v: the messages $\mu_{V \to F}$ and $\mu_{F \to V}$ ($\forall F \in \mathcal{N}(V)$), and the belief b_V.

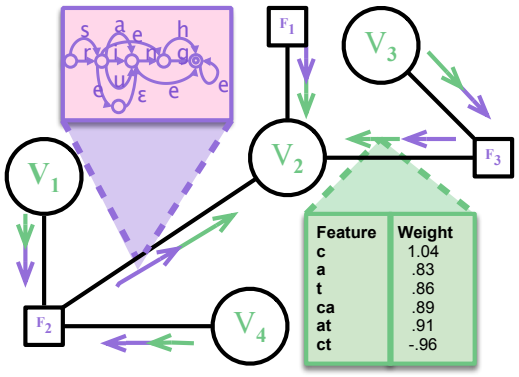

Figure 1: Information flowing toward V_2 in EP (reverse flow not shown). The factors work with purple μ messages represented by WFSAs, while the variables work with green $\boldsymbol{\theta}$ messages represented by log-linear weight vectors. The green table shows a $\boldsymbol{\theta}$ message: a sparse weight vector that puts high weight on the string `cat`.

EP is a variant in which all of these are forced to be log-linear functions from the same family, namely $\exp(\boldsymbol{\theta} \cdot \boldsymbol{f}_V(v))$. Here $\boldsymbol{f}_V$ is the featurization function we've chosen for variable V.[3] We can represent these functions by their parameter vectors—let us call those $\boldsymbol{\theta}_{V \to F}$, $\boldsymbol{\theta}_{F \to V}$, and $\boldsymbol{\theta}_V$ respectively.

4.1 Passing messages through variables

What happens to BP's update equations in this setting? According to BP, the belief b_V is the pointwise product of all "incoming" messages to V. But as we saw in section 3.2, pointwise products are *far easier* in EP's restricted setting! Instead of intersecting several WFSAs, we can simply add several vectors:

$$\boldsymbol{\theta}_V = \sum_{F' \in \mathcal{N}(V)} \boldsymbol{\theta}_{F' \to V} \qquad (4)$$

Similarly, the "outgoing" message from V to factor F is the pointwise product of all "incoming" messages *except* the one from F. This message $\boldsymbol{\theta}_{V \to F}$ can be computed as $\boldsymbol{\theta}_V - \boldsymbol{\theta}_{F \to V}$, which adjusts (4).[4] We never store this but just compute it on demand.

[3] A single graphical model might mix categorical variables, continuous variables, orthographic strings over (say) the Roman alphabet, and phonological strings over the International Phonetic Alphabet. These different data types certainly require different featurization functions. Moreover, even when two variables have the same type, we could choose to approximate their marginals differently, e.g., with bigram vs. trigram features.

[4] If features can have $-\infty$ weight (footnote 1), this trick might need to subtract $-\infty$ from $-\infty$ (the log-space version of $0/0$). That gives an undefined result, but it turns out that any result will do—it makes no difference to the subsequent beliefs.

4.2 Passing messages through factors

Our factors are weighted finite-state machines, so their messages still require finite-state computations, as shown by the purple material in Figure 1. These computations are just as in BP. Concretely, let F be a factor of degree d, given as a d-tape machine. We can compute a belief *at this factor* by joining F with d WFSAs that represent its d incoming messages, namely $\text{ENCODE}(\boldsymbol{\theta}_{V' \to F})$ for $V' \in \mathcal{N}(F)$. This gives a new d-tape machine, b_F. We then obtain each outgoing message $\mu_{F \to V}$ by projecting b_F onto its V tape, but removing (dividing out) the weights that were contributed (multiplied in) by $\boldsymbol{\theta}_{V \to F}$.[5]

4.3 Getting from factors back to variables

Finally, we reach the only tricky step. Each resulting $\mu_{F \to V}$ is a possibly large WFSA, so we must *force it back into our log-linear family* to get an updated approximation $\boldsymbol{\theta}_{F \to V}$. One cannot directly employ the methods of section 3, because KL divergence is only defined between probability distributions. ($\mu_{F \to V}$ might not be normalizable into a distribution, nor is its best approximation necessarily normalizable.)

The EP trick is to use section 3 to instead approximate the belief at V, which *is* a distribution, and *then* reconstruct the approximate message to V that would have produced this approximated belief. The "unapproximated belief" $\hat{p}_V$ resembles (4): it multiplies the unapproximated message $\mu_{F \to V}$ by the current values of all *other* messages $\boldsymbol{\theta}_{F' \to V}$. We know the product of those *other* messages, $\boldsymbol{\theta}_{V \to F}$, so

$$\hat{p}_V := \mu_{F \to V} \odot \mu_{V \to F} \tag{5}$$

where the pointwise product $\odot$ is carried out by WFSA intersection and $\mu_{V \to F} \stackrel{\text{def}}{=} \text{ENCODE}(\boldsymbol{\theta}_{V \to F})$.

We now apply section 3 to choose $\boldsymbol{\theta}_V$ such that $q_{\boldsymbol{\theta}_V}$ is a good approximation of the WFSA $\hat{p}_V$. Finally, to preserve (4) as an invariant, we reconstruct

$$\boldsymbol{\theta}_{F \to V} := \boldsymbol{\theta}_V - \boldsymbol{\theta}_{V \to F} \tag{6}$$

In short, EP combines $\mu_{F \to V}$ with $\boldsymbol{\theta}_{V \to F}$, then approximates the result $\hat{p}_V$ by $\boldsymbol{\theta}_V$ before removing $\boldsymbol{\theta}_{V \to F}$ again. Thus EP is approximating $\mu_{F \to V}$ by

$$\boldsymbol{\theta}_{F \to V} := \operatorname*{argmin}_{\boldsymbol{\theta}} \mathrm{D}(\underbrace{\mu_{F \to V} \odot \mu_{V \to F}}_{= \hat{p}_V} \,||\, \underbrace{q_{\boldsymbol{\theta}} \odot \mu_{V \to F}}_{= \boldsymbol{\theta}_V}) \tag{7}$$

in a way that updates not only $\boldsymbol{\theta}_{F \to V}$ but also $\boldsymbol{\theta}_V$.

Wisely, this objective focuses on approximating the message's scores for the *plausible* values v. Some values v may have $\hat{p}_V(v) \approx 0$, perhaps because *another* incoming message $\boldsymbol{\theta}_{F' \to V}$ rules them out. It does not much harm the objective (7) if these $\mu_{F \to V}(v)$ are poorly approximated by $q_{\boldsymbol{\theta}_{F \to V}}(v)$, since the overall belief is still roughly correct.

Our *penalized* EP simply adds $\lambda \cdot \Omega(\boldsymbol{\theta})$ into (7).

4.4 The EP algorithm: Putting it all together

To run EP (or PEP), initialize all $\boldsymbol{\theta}_V$ and $\boldsymbol{\theta}_{F \to V}$ to $\mathbf{0}$, and then loop repeatedly over the nodes of the factor graph. When visiting a factor F, ENCODE its incoming messages $\boldsymbol{\theta}_{V \to F}$ (computed on demand) as WFSAs, construct a belief b_F, and update the outgoing WFSA messages $\mu_{F \to V}$. When visiting a variable V, iterate $K \geq 1$ times over its incoming WFSA messages: for each incoming $\mu_{F \to V}$, compute the unapproximated belief $\hat{p}_V$ via (5), then update $\boldsymbol{\theta}_V$ to approximate $\hat{p}_V$, then update $\boldsymbol{\theta}_{F \to V}$ via (6).

For possibly faster convergence, one can alternate "forward" and "backward" sweeps. Visit the factor graph's nodes in a fixed order (given by an approximate topological sort). At a factor, update the outgoing WFSA messages to *later* variables only. At a variable, approximate only those incoming WFSA messages from *earlier* factors (all the outgoing messages $\boldsymbol{\theta}_{V \to F}$ will be recomputed on demand). Note that both cases examine all incoming messages. After each sweep, reverse the node ordering and repeat.

If gradient ascent is used to find the $\boldsymbol{\theta}_V$ that approximates $\hat{p}_V$, it is wasteful to optimize to convergence. After all, the optimization problem will keep changing as the messages change. Our implementation improves $\boldsymbol{\theta}_V$ by only a single gradient step on each visit to V, since V will be visited repeatedly.

See Appendix A for an alternative view of EP.

5 Related Approximation Methods

We have presented EP as a method for simplifying a variable's incoming messages during BP. The vari-

[5] This is equivalent to computing each $\mu_{F \to V}$ by "generalized composition" of F with the $d - 1$ messages to F from its *other* neighbors V'. The operations of join and generalized composition were defined by Kempe et al. (2004).

In the simple case $d = 2$, F is just a weighted finite-state transducer mapping V' to V, and computing $\mu_{F \to V}$ reduces to composing $\text{ENCODE}(\boldsymbol{\theta}_{V' \to F})$ with F and projecting the result onto the output tape. In fact, one can assume WLOG that $d \leq 2$, enabling the use of popular finite-state toolkits that handle at most 2-tape machines. See Appendix B.10 for the construction.

able's outgoing messages are pointwise products of the incoming ones, so they become simple too. Past work has used approximations with a similar flavor.

Hall and Klein (2011) heuristically predetermine a short, fixed list of plausible values for V that were observed elsewhere in their dataset. This list is analogous to our $\boldsymbol{\theta}_V$. After updating $\mu_{F\to V}$, they force $\mu_{F\to V}(v)$ to 0 for all v outside the list, yielding a *finite* message that is analogous to our $\boldsymbol{\theta}_{F\to V}$.

Our own past papers are similar, except they *adaptively* set the "plausible values" list to $\bigcup_{F'\in\mathcal{N}(V)} k\text{-BEST}(\mu_{F'\to V})$. These strings are favored by at least one of the *current* messages to V (Dreyer and Eisner, 2009; Dreyer and Eisner, 2011; Cotterell et al., 2015). Thus, simplifying one of V's incoming messages considers all of them, as in EP.

The above methods *prune* each message, so may prune correct values. Hall and Klein (2010) avoid this: they fit a full bigram model by inclusive KL divergence, which refuses to prune *any* values (see section 3). Specifically, they minimized $\mathrm{D}(\mu_{F\to V}\odot\tau \mid\mid q_{\boldsymbol{\theta}}\odot\tau)$, where τ was a simple fixed function (a 0-gram model) included so that they were working with distributions (see section 4.3). This is very similar to our (7). Indeed, Hall and Klein (2010) found their procedure "reminiscent of EP," hinting that τ was a surrogate for a real $\mu_{V\to F}$ term. Dreyer and Eisner (2009) had also suggested EP as future work.

EP has been applied only twice before in the NLP community. Daumé III and Marcu (2006) used EP for query summarization (following Minka and Lafferty (2003)'s application to an LDA model with fixed topics) and Hall and Klein (2012) used EP for rich parsing. However, these papers inferred a single structured variable connected to all factors (as in the traditional presentation of EP—see Appendix A), rather than inferring many structured variables connected in a sparse graphical model.

We regard EP as a generalization of loopy BP for just this setting: graphical models with large or unbounded variable domains. Of course, we are not the first to use such a scheme; e.g., Qi (2005, chapter 2) applies EP to linear-chain models with both continuous and discrete hidden states. We believe that EP should also be broadly useful in NLP, since it naturally handles joint distributions over the kinds of structured variables that arise in NLP.

6 Two Methods for Optimizing $\boldsymbol{\theta}$

We now fill in details. If the feature set is defined by an unambiguous FSA $\mathcal{A}$ (section 3.4), two methods exist to max $\mathbb{E}_{v\sim p}[\log q_{\boldsymbol{\theta}}(v)]$ as section 3.1 requires.

Closed-form. Determine how often $\mathcal{A}$ would traverse each of its arcs, in expectation, when reading a random string drawn from p. We would obtain an optimal $\text{ENCODE}(\boldsymbol{\theta})$ by, at each state of $\mathcal{A}$, setting the weights of the arcs from that state to be proportional to these counts while summing to 1.[6] Thus, the logs of these arc weights give an optimal $\boldsymbol{\theta}$.

For example, in a trigram model, the probability of the `c` arc from the `ab` state is the expected count of `abc` (according to p) divided by the expected count of `ab`. Such expected substring counts can be found by the method of Allauzen et al. (2003). For general $\mathcal{A}$, we can use the method sketched by Li et al. (2009, footnote 9): intersect the WFSA for p with the unweighted FSA $\mathcal{A}$, and then run the forward-backward algorithm to determine the posterior count of each arc in the result. This tells us the expected total number of traversals of each arc in $\mathcal{A}$, if we have kept track of which arcs in the intersection of p with $\mathcal{A}$ were derived from which arcs in $\mathcal{A}$. That bookkeeping can be handled with an expectation semiring (Eisner, 2002), or simply with backpointers.

Gradient ascent. For any given $\boldsymbol{\theta}$, we can use the WFSAs p and $\text{ENCODE}(\boldsymbol{\theta})$ to exactly compute $\mathbb{E}_{v\sim p}[\log q_{\boldsymbol{\theta}}(v)] = -H(p, q_{\boldsymbol{\theta}})$ (Cortes et al., 2006). We can tune $\boldsymbol{\theta}$ to globally maximize this objective.

The technique is to intersect p with $\text{ENCODE}(\boldsymbol{\theta})$, after lifting their weights into the expectation semiring via the mappings $k \mapsto \langle k, 0\rangle$ and $k \mapsto \langle 0, \log k\rangle$ respectively. Summing over all paths of this intersection via the forward algorithm yields $\langle Z, r\rangle$ where Z is the normalizing constant for p. We also sum over paths of $\text{ENCODE}(\boldsymbol{\theta})$ to get the normalizing constant $Z_{\boldsymbol{\theta}}$. Now the desired objective is $r/Z - \log Z_{\boldsymbol{\theta}}$. Its *gradient* with respect to $\boldsymbol{\theta}$ can be found by back-propagation, or equivalently by the forward-backward algorithm (Li and Eisner, 2009).

An overlarge gradient step can leave the feasible space (footnote 1) by driving $Z_{\boldsymbol{\theta}_V}$ to ∞ and thus driving (2) to ∞ (Dreyer, 2011, section 2.8.2). In this case, we try again with reduced stepsize.

[6] This method always yields a probabilistic FSA, i.e., the arc weights are locally normalized probabilities. This does not sacrifice any expressiveness; see Appendix B.7 for discussion.

6.1 Optimizing θ with a penalty

Now consider the penalized objective (3). Ideally, $\Omega(\boldsymbol{\theta})$ would count the number of nonzero weights in $\boldsymbol{\theta}$—or better, the number of arcs in $\textsc{Encode}(\boldsymbol{\theta})$. But it is not known how to efficiently minimize the resulting discontinuous function. We give two approximate methods, based on the two methods above.

Proximal gradient. Leaning on recent advances in sparse estimation, we replace this $\Omega(\boldsymbol{\theta})$ with a convex surrogate whose partial derivative with respect to each θ_w is undefined at $\theta_w = 0$ (Bach et al., 2011). Such a penalty tends to create sparse optima.

A popular surrogate is an ℓ_1 penalty, $\Omega(\boldsymbol{\theta}) \stackrel{\text{def}}{=} \sum_w |\boldsymbol{\theta}_w|$. However, ℓ_1 would not recognize that $\boldsymbol{\theta}$ is simpler with the features $\{\texttt{ab}, \texttt{abc}, \texttt{abd}\}$ than with the features $\{\texttt{ab}, \texttt{pqr}, \texttt{xyz}\}$. The former leads to a smaller WFSA encoding. In other words, it is cheaper to add `abd` once `abc` is already present, as a state already exists that represents the context `ab`.

We would thus like the penalty to be the number of distinct *prefixes* in the set of nonzero features,

$$|\{u \in \Sigma^* : (\exists x \in \Sigma^*)\, \theta_{ux} \neq 0\}|, \tag{8}$$

as this is the number of ordinary arcs in $\textsc{Encode}(\boldsymbol{\theta})$ (see Appendix B.4). Its convex surrogate is

$$\Omega(\boldsymbol{\theta}) \stackrel{\text{def}}{=} \sum_{u \in \Sigma^*} \sqrt{\sum_{x \in \Sigma^*} \theta_{ux}^2} \tag{9}$$

This *tree-structured group lasso* (Nelakanti et al., 2013) is an instance of group lasso (Yuan and Lin, 2006) where the string $w = \texttt{abd}$ belongs to four groups, corresponding to its prefixes $u = \epsilon, u = \texttt{a}, u = \texttt{ab}, u = \texttt{abd}$. Under group lasso, moving θ_w away from 0 increases $\Omega(\boldsymbol{\theta})$ by $\lambda|\theta_w|$ (just as in ℓ_1) *for each group in which w is the only nonzero feature*. This penalizes for the new WFSA arcs needed for these groups. There are also increases due to w's other groups, but these are smaller, especially for groups with many strongly weighted features.

Our objective (3) is now the sum of a differentiable convex function (2) and a *particular* non-differentiable convex function (9). We minimize it by proximal gradient (Parikh and Boyd, 2013). At each step, this algorithm first takes a gradient step as in section 6 to improve the differentiable term, and then applies a "proximal operator" to jump to a nearby point that improves the non-differentiable term. The proximal operator for tree-structured group lasso (9) can be implemented with an efficient recursive procedure (Jenatton et al., 2011).

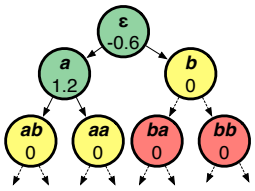

Figure 2: Active set method, showing the infinite tree of all features for the alphabet $\Sigma = \{a, b\}$. The green nodes currently have non-zero weights. The yellow nodes are on the frontier and are *allowed* to become non-zero, but the penalty function is still keeping them at 0. The red nodes are not yet considered, forcing them to remain at 0.

What if $\boldsymbol{\theta}$ is ∞-dimensional because we allow all n-grams as features? Paul and Eisner (2012) used just this feature set in a dual decomposition algorithm. Like them, we rely on an *active set* method (Schmidt and Murphy, 2010). We fix `abcd`'s weight at 0 until `abc`'s weight becomes nonzero (if ever);[7] only then does feature `abc` become "active." Thus, at a given step, we only have to compute the gradient with respect to the currently nonzero features (green nodes in Figure 2) and their immediate children (yellow nodes). This hierarchical inclusion technique ensures that we only consider a small, finite subset of all n-grams at any given iteration of optimization.

Closed-form with greedy growing. There are existing methods for estimating variable-order n-gram language models from data, based on either "shrinking" a high-order model (Stolcke, 1998) or "growing" a low-order one (Siivola et al., 2007).

We have designed a simple "growing" algorithm to estimate such a model from a WFSA p. It approximately minimizes the objective (3) where $\Omega(\boldsymbol{\theta})$ is given by (8). We enumerate all n-grams $w \in \Sigma^*$ in decreasing order of expected count (this can be done efficiently using a priority queue). We add w to $\mathcal{W}$ if we *estimate* that it will decrease the objective. Every so often, we measure the *actual* objective (just as in the gradient-based methods), and we stop if it is no longer improving. Algorithmic details are given in Appendices B.8–B.9.

[7] Paul and Eisner (2012) also required `bcd` to have nonzero weight, observing that `abcd` is a *conjunction* `abc`$\wedge$`bcd` (McCallum, 2003). This added test would be wise for us too.

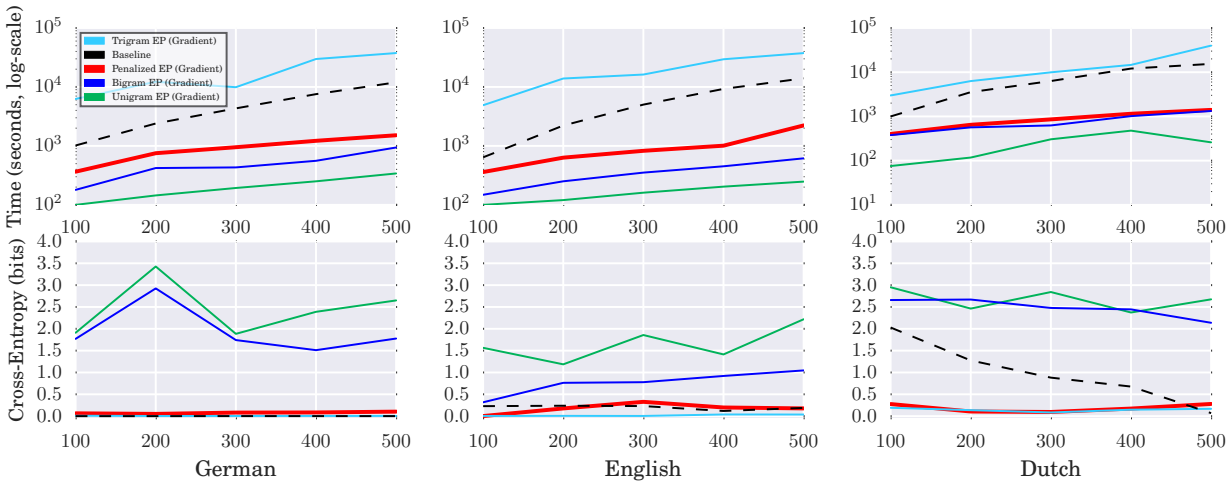

Figure 3: Inference on 15 factor graphs (3 languages $\times$ 5 datasets of different sizes). The first row shows the total runtime (logscale) of each inference method. The second row shows the accuracy, as measured by the negated log-probability that the inferred belief at a variable assigns to its gold-standard value, averaged over "underlying morpheme" variables. At this penalty level ($\lambda = 0.01$), PEP [thick line] is faster than the pruning baseline of Cotterell et al. (2015) [dashed line] and much faster than trigram EP, yet is about as accurate. (For Dutch with sparse observations, it is considerably more accurate than baseline.) Indeed, PEP is nearly as fast as bigram EP, which has terrible accuracy. An ideal implementation of PEP would be faster yet (see Appendix B.5). Further graphs are in Appendix C.

7 Experiments and Results

Our experimental design aims to answer three questions. (1) Is our algorithm able to beat a strong baseline (adaptive pruning) in a non-trivial model? (2) Is PEP actually better than ordinary EP, given that the structured sparsity penalty makes it more algorithmically complex? (3) Does the λ parameter successfully trade off between speed and accuracy?

All experiments took place using the graphical model over strings for the discovery of underlying phonological forms introduced in Cotterell et al. (2015). They write: "Comparing `cats` ([kæts]), `dogs` ([dɔgz]), and `quizzes` ([kwɪzɪz]), we see the English plural morpheme evidently has at least three pronunciations." Cotterell et al. (2015) sought a unifying account of such variation in terms of phonological underlying forms for the morphemes.

In their Bayes net, morpheme underlying forms are latent variables, while word surface forms are observed variables. The factors model underlying-to-surface phonological changes. They learn the factors by Expectation Maximization (EM). Their first E step presents the hardest inference problem because the factors initially contribute no knowledge of the language; so that is the setting we test on here.

Their data are surface phonological forms from the CELEX database (Baayen et al., 1995). For each of 3 languages, we run 5 experiments, by observing the surface forms of 100 to 500 words and running EP to infer the underlying forms of their morphemes. Each of the 15 factor graphs has $\approx$ 150–700 latent variables, joined by 500–2200 edges to 200–1200 factors of degree 1–3. Variables representing suffixes can have extremely high degree (> 100).

We compare PEP with other approximate inference methods. As our main baseline, we take the approximation scheme actually used by Cotterell et al. (2015), which restricts the domain of a belief to that of the union of 20-best strings of its incoming messages (section 5).We also compare to unpenalized EP with unigram, bigram, and trigram features.

We report both speed and accuracy for all methods. Speed is reported in seconds. Judging accuracy is a bit trickier. The best metric would to be to measure our beliefs' distance from the true marginals or even from the beliefs computed by vanilla loopy BP. Obtaining these quantities, however, would be extremely expensive—even Gibbs sampling is infeasible in our setting, let alone 100-way WFSA intersections. Luckily, Cotterell et al. (2015) provide gold-standard values for the latent variables (underlying

forms). Figure 3 shows the negated log-probabilities of these gold strings according to our beliefs, averaged over variables in a given factor graph. Our accuracy is weaker than Cotterell et al. (2015) because we are doing inference with their *initial* (untrained) parameters, a more challenging problem.

Each update to $\boldsymbol{\theta}_V$ consisted of a single step of (proximal) gradient descent: starting at the current value, improve (2) with a gradient step of size $\eta = 0.05$, then (in the adaptive case) apply the proximal operator of (9) with $\lambda = 0.01$. We chose these values by preliminary exploration, taking η small enough to avoid backtracking (section 6.1).

We repeatedly visit variables and factors (section 4.4) in the forward-backward order used by Cotterell et al. (2015). For the first few iterations, when we visit a variable we make $K = 20$ passes over its incoming messages, updating them iteratively to ensure that the high probability strings in the initial approximations are "in the ballpark". For subsequent iterations of message passing we take $K = 1$. For similar reasons, we constrained PEP to use only unigram features on the first iteration, when there are still many viable candidates for each morph.

7.1 Results

The results show that PEP is much faster than the baseline pruning method, as described in Figure 3 and its caption. It mainly achieves better cross-entropy on English and Dutch, and even though it loses on German, it still places almost all of its probability mass on the gold forms. While EP with unigram and bigram approximations are both faster than PEP, their accuracy is poor. Trigram EP is nearly as accurate but even slower than the baseline. The results support the claim that PEP has achieved a "Goldilocks number" of n-grams in its approximation—just enough n-grams to approximate the message well while retaining speed.

Figure 4 shows the effect of λ on the speed-accuracy tradeoff. To compare apples to apples, this experiment fixed the set of $\mu_{F \to V}$ messages for each variable. Thus, we held the set of beliefs fixed, but measured the size and accuracy of different approximations to these beliefs by varying λ.

These figures show only the results from gradient-based approximation. Closed-form approximation is faster and comparably accurate: see Appendix C.

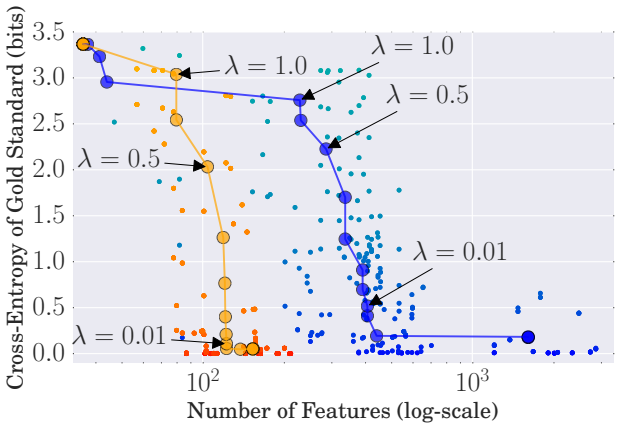

Figure 4: Increasing λ will greatly reduce the number of selected features in a belief—initially without harming accuracy, and then accuracy degrades gracefully. (Number of features has 0.72 correlation with runtime, and is shown on a *log scale* on the x axis.)

Each point shows the result of using PEP to approximate the belief at some latent variable V, using $\mu_{F \to V}$ messages from running the baseline method on German. Lighter points use larger λ. Orange points are affixes (shorter strings), blue are stems (longer strings). Large circles are averages over all points for a given λ.

8 Conclusion and Future Work

We have presented penalized expectation propagation (PEP), a novel approximate inference algorithm for graphical models, and developed specific techniques for string-valued random variables. Our method integrates structured sparsity directly into inference. Our experiments show large speedups over the strong baseline of Cotterell et al. (2015).

In future, instead of choosing λ, we plan to reduce λ as PEP runs. This serves to gradually refine the approximations, yielding an *anytime algorithm* whose beliefs approach the BP beliefs. Thanks to (7), the coarse messages from early iterations guide the choice of finer-grained messages at later iterations. In this regard, "Anytime PEP" resembles other coarse-to-fine architectures such as generalized A* search (Felzenszwalb and McAllester, 2007).

As NLP turns its attention to lower-resource languages and social media, it is important to model the rich phonological, morphological, and orthographic processes that interrelate words. We hope that the introduction of faster inference algorithms will increase the use of graphical models over strings. We are releasing our code package (see Appendix D).

Joint Generation of Transliterations from Multiple Representations

Lei Yao and **Grzegorz Kondrak**

Abstract

Machine transliteration is often referred to as phonetic translation. We show that transliterations incorporate information from both spelling and pronunciation, and propose an effective model for joint transliteration generation from both representations. We further generalize this model to include transliterations from other languages, and enhance it with reranking and lexicon features. We demonstrate significant improvements in transliteration accuracy on several datasets.

1 Introduction

Transliteration is the conversion of a text from one script to another. When a new name like *Eyjafjallajökull* appears in the news, it needs to be promptly transliterated into dozens of languages. Computer-generated transliterations can be more accurate than those created by humans (Sherif and Kondrak, 2007). When the names in question originate from languages that use the same writing script as the target language, they are likely to be copied verbatim; however, their pronunciation may still be ambiguous. Existing transliterations and transcriptions can help in establishing the correct pronunciation (Bhargava and Kondrak, 2012).

Transliteration is often defined as *phonetic translation* (Zhang et al., 2012). In the idealized model of Knight and Graehl (1997), a bilingual expert pronounces a name in the source language, modifies the pronunciation to fit the target language phonology, and writes it down using the orthographic rules of the target script. In practice, however, it may be difficult to guess the correct pronunciation of an unfamiliar name from the spelling.

Phonetic-based models of transliteration tend to achieve suboptimal performance. Al-Onaizan and Knight (2002) report that a spelling-based model outperforms a phonetic-based model even when pronunciations are extracted from a pronunciation dictionary. This can be attributed to the importance of the source orthography in the transliteration process. For example, the initial letters of the Russian transliterations of the names *Chicano* ([tʃɪkɑno]) and *Chicago* ([ʃɪkɑgo]) are identical, but different from *Shilo* ([ʃɪlo]). The contrast is likely due to the idiosyncratic spelling of *Chicago*.

Typical transliteration systems learn direct orthographic mapping between the source and the target languages from parallel training sets of word pairs (Zhang et al., 2012). Their accuracy is limited by the fact that the training data is likely to contain names originating from different languages that have different romanization rules. For example, the Russian transliterations of *Jedi*, *Juan*, *Jenins*, *Jeltoqsan*, and *Jecheon* all differ in their initial letters. In addition, because of inconsistent correspondences between letters and phonemes in some languages, the pronunciation of a word may be difficult to derive from its orthographic form.

We believe that transliteration is not simply phonetic translation, but rather a process that combines both phonetic and orthographic information. This observation prompted the development of several hybrid approaches that take advantage of both types of information, and improvements were reported on some test corpora (Al-Onaizan and Knight, 2002; Bilac and Tanaka, 2004; Oh and Choi, 2005). These models, which we discuss in more detail in Section 2.1, are well behind the current state of the art in machine transliteration.

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 943–952,
Denver, Colorado, May 31 – June 5, 2015.

In this paper, we conduct experiments that show the relative importance of spelling and pronunciation. We propose a new hybrid approach of joint transliteration generation from both orthography and pronunciation, which is based on a discriminative string transduction approach. We demonstrate that our approach results in significant improvements in transliteration accuracy. Because phonetic transcriptions are rarely available, we propose to capture the phonetic information from supplemental transliterations. We show that the most effective way of utilizing supplemental transliterations is to directly include their original orthographic representations. We show improvements of up to 30% in word accuracy when using supplemental transliterations from several languages.

The paper is organized as follows. We discuss related work in Section 2. Section 3 describes our hybrid model and a generalization of this model that leverages supplemental transliterations. Section 4 and 5 present our experiments of joint generation with supplemental transcriptions and transliterations, respectively. Section 6 presents our conclusions and future work.

2 Related work

In this section, we focus on hybrid transliteration models, and on methods of leveraging supplemental transliterations.

2.1 Hybrid models

Al-Onaizan and Knight (2002) present a hybrid model for Arabic-to-English transliteration, which is a linear combination of phoneme-based and grapheme-based models. The hybrid model is shown to be superior to the phoneme-based model, but inferior to the grapheme-based model.

Bilac and Tanaka (2004) propose a hybrid model for Japanese-to-English back-transliteration, which is also based on linear interpolation, but the interpolation is performed during the transliteration generation process, rather than after candidate target words have been generated. They report improvement over the two component models on some, but not all, of their test corpora.

Oh and Choi (2005) replace the fixed linear interpolation approach with a more flexible model that takes into account the correspondence between the phonemes and graphemes during the transliteration generation process. They report superior performance of their hybrid model over both component models. However, their model does not consider the coherence of the target word during the generation process, nor other important features that have been shown to significantly improve machine transliteration (Li et al., 2004; Jiampojamarn et al., 2010).

Oh et al. (2009) report that their hybrid models improve the accuracy of English-to-Chinese transliteration. However, since their focus is on investigating the influence of Chinese phonemes, their hybrid model is again a simple linear combination of basic models.

2.2 Leveraging supplemental transliterations

Previous work that explore the idea of taking advantage of data from additional languages tend to employ supplemental transliterations indirectly, rather than to incorporate them directly into the generation process.

Khapra et al. (2010) propose a bridge approach of transliterating low-resource language pair (X, Y) by pivoting on an high-resource language Z, with the assumption that the pairwise data between (X, Z) and (Y, Z) is relatively large. Their experiments show that pivoting on Z results in lower accuracy than directly transliterating X into Y. Zhang et al. (2010) and Kumaran et al. (2010) combine the pivot model with a grapheme-based model, which works better than either of the two approaches alone. However, their model is not able to incorporate more than two languages.

Bhargava and Kondrak (2011) propose a reranking approach that uses supplemental transliterations to improve grapheme-to-phoneme conversion of names. Bhargava and Kondrak (2012) generalize this idea to improve transliteration accuracy by utilizing either transliterations from other languages, or phonetic transcriptions in the source language. Specifically, they apply an SVM reranker to the top-n outputs of a base spelling-based model. However, the post-hoc property of reranking is a limiting factor; it can identify the correct transliteration only if the base model includes it in its output candidate list.

3 Joint Generation

In this section, we describe our approach of the joint transduction of a transliteration T from a source orthographic string S and a source phonemic string P (Figure 1). We implement our approach by modifying the DIRECTL+ system of Jiampojamarn et al. (2010), which we describe in Section 3.1. In the following sections, we discuss other components of our approach, namely alignment (3.2), scoring (3.3), and search (3.4). In Section 3.5 we generalize the joint model to accept multiple input strings.

3.1 DirecTL+

DIRECTL+ (Jiampojamarn et al., 2010) is a discriminative string transducer which learns to convert source strings into target strings from a set of parallel training data. It requires pairs of strings to be aligned at the character level prior to training. M2M-ALIGNER (Jiampojamarn et al., 2007), an unsupervised EM-based aligner, is often used to generate such alignments. The output is a ranked list of candidate target strings with their confidence scores. Below, we briefly describe the scoring model, the training process, and the search algorithm.

The scoring model assigns a score to an aligned pair of source and target strings (S, T). Assuming there are m aligned substrings, such that the ith source substring generates the ith target substring, the score is computed with the following formula:

$$\sum_{i}^{m} \alpha \cdot \Phi(i, S, T) \quad (1)$$

where α is the weight vector, and Φ is the feature vector.

There are four sets of features. *Context* features are character n-grams within the source word. *Transition* features are character n-grams within the target word. *Linear-chain* features combine context features and transition features. *Joint n-gram* features further capture the joint information on both sides.

The feature weights α are learned with the Maximum Infused Relaxed Algorithm (MIRA) of Crammer and Singer (2003). MIRA aims to find the smallest change in current weights so that the new weights separate the correct target strings from incorrect ones by a margin defined by a loss function. Given the training instance (S, T) and the current feature weights α_{k-1}, the update of the feature weights can be described as the following optimization problem:

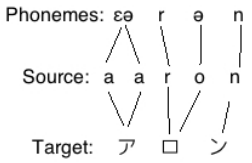

Figure 1: Triple alignment between the source phonemes, source graphemes, and the target graphemes ア ロ ン (A-RO-N).

$$\min_{\alpha_k} \|\alpha_k - \alpha_{k-1}\| \;\; s.t. \;\; \forall \hat{T} \in T_n :$$

$$\alpha_k \cdot (\Phi(S, T) - \Phi(S, \hat{T})) \geq loss(T, \hat{T})$$

where $\hat{T}$ is a candidate target in the n-best list T_n found under the current model parameterized by α_{k-1}. The loss function is the Levenshtein distance between T and $\hat{T}$.

Given an unsegmented source string, the search algorithm finds a target string that achieves the highest score according to the scoring model. It searches through all the possible segmentations of the source string and all possible target substrings using the following dynamic programming formulation:

$$Q(0, \$) = 0$$

$$Q(j, t) = \max_{t', t, j-N \leq j' < j} \alpha \cdot \phi(S^{j}_{j'+1}, t', t) + Q(j', t')$$

$$Q(J+1, \$) = \max_{t'} \alpha \cdot \phi(\$, t', \$) + Q(J, t')$$

$Q(j, t)$ is defined as the maximum score of the target sequence ending with target substring t, generated by the letter sequence $S_1 ... S_j$. ϕ describes the features extracted from the current generator substring $S^{j}_{j'+1}$ of target substring t, with t' to be the last generated target substring. N specifies the maximum length of the source substring. The \$ symbols are used to represent both the start and the end of a string. Assuming that the source string contains J characters, $Q(J+1, \$)$ gives the score of the highest scoring target string, which can be recovered through backtracking.

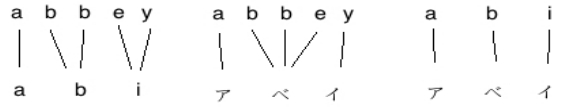

Figure 2: Three pairwise alignments between the English word *abbey*, its transcription [*abi*], and the Japanese transliteration アベイ (A-BE-I).

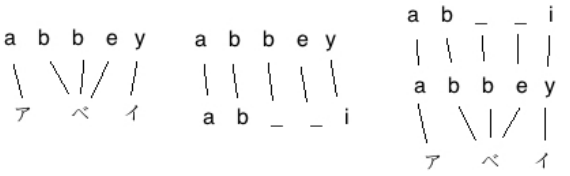

Figure 3: Obtaining a triple alignment by pivoting on the source word.

3.2 Multi-alignment

M2M-ALIGNER applies the EM algorithm to align sets of string pairs. For the purpose of joint generation, we need to align triples S, P and T prior to training. The alignment of multiple strings is a challenging problem (Bhargava and Kondrak, 2009). In general, there is no obvious way of merging three pairwise alignments. Figure 2 shows an example of three pairwise alignments that are mutually inconsistent: the English letter *e* is aligned to the phoneme [i] and to the grapheme ベ*(BE)*, which are not aligned to each other

Our solution is to select one of the input strings as the *pivot* for aligning the remaining two strings. Specifically, we align the pivot string to each of the other two strings through one-to-many alignments, where the maximum length of aligned substrings in the pivot string is set to one. Then we merge these two pairwise alignments according to the pivot string. Since the source phoneme string may or may not be available for a particular training instance, we use the source orthographic string as the pivot. The one-to-many pairwise alignments between the graphemes and phonemes, and between the graphemes and the transliterations are generated with M2M-ALIGNER. Figure 3 provides an example of this process.

An alternative approach is to pivot on the target string. However, because the target string is not available at test time, we need to search for the highest-scoring target string, given an unsegmented source string S and the corresponding unsegmented phoneme string P. We can generalize the original search algorithm by introducing another dimension into the dynamic-programming table for segmenting P, but it substantially increases the time complexity of the decoding process. Our development experiments indicated that pivoting on the target string not only requires more time, but also results in less accurate transliterations.

3.3 Scoring Model

The scoring formula (1) is extended to compute a linear combination of features of three aligned strings (S, P, T):

$$\sum_{i}^{m} \alpha \cdot [\Phi(i, S, T), \Phi(i, P, T)] \qquad (2)$$

The transition features on T are only computed once, because they are independent of the input strings. We observed no improvement by including features between S and P in our development experiments.

3.4 Search

Our search algorithm finds the highest-scoring target string, given a source string and a phoneme string. Since we pivot on the source string to achieve multiple alignment, the input to the search algorithm is actually one-to-many aligned pair of the source string and the phoneme string. The search space is therefore the same as that of DirecTL+, i.e. the product of all possible segmentations of the source string and all possible target substrings. However, since we apply one-to-many alignment, there is only one possible segmentation of the source string, which is obtained by treating every letter as a substring. We apply the same dynamic programming search as DirecTL+, except that we extend the feature extraction function $\phi(S^{j}_{j'+1}, t', t)$ in the original formulation to $[\phi(S^{j}_{j'+1}, t', t), \phi(P^{k}_{k'+1}, t', t)]$ so that features between the current phoneme substring $P^{k}_{k'+1}$ and the target substrings are taken into consideration. The time complexity of this search is only double of the complexity of DIRECTL+, and is independent of the length of the phoneme string.

3.5 Generalization

Since we may need to leverage information from other sources, e.g., phonemes of supplemental transliterations, each training instance can be composed of a source word, a target word, and a list of supplemental strings. The size of the list is not fixed because we may not have access to some of the supplemental strings for certain source words.

We first align all strings in each training instance by merging one-to-many pairwise alignments between the source word and every other string in the instance, as described in Section 3.2. The generalization of training is straightforward. For the scoring model, we extract the same set of features as before by pairing each supplemental string with the target word. Since the alignment is performed beforehand, the time complexity of the generalized search only increases linearly in the number of input strings with respect to the original complexity.

4 Leveraging transcriptions

In this section, we describe experiments that involve generating transliterations jointly from the source orthography and pronunciation. We test our method on the English-to-Hindi and English-to-Japanese transliteration data from the NEWS 2010 Machine Transliteration Shared Task (Li et al., 2010). We extract the corresponding English pronunciations from the Combilex Lexicon (Richmond et al., 2009). We split each transliteration dataset into 80% for training, 10% for development, 10% for testing. We limit the datasets to contain only transliterations that have phonetic transcriptions in Combilex, so that each entry is composed of a source English word, a source transcription, and a target Japanese or Hindi word. The final results are obtained by joining the training and development sets as the final training set. The final training/test sets contain 8,264/916 entries for English-to-Japanese, and 3,503/353 entries for English-to-Hindi.

4.1 Gold transcriptions

We compare three approaches that use different sources of information: (a) graphemes only; (b) phonemes only; and (c) both graphemes and phonemes. The first two approaches use DIRECTL+, while the last approach uses our joint model described in Section 3. We evaluate each approach by computing the word accuracy.

Model	En→Ja	En→Hi
Graphemes only	58.0	42.6
Phonemes only	52.4	39.4
Joint	**63.6**	**46.1**

Table 1: Transliteration word accuracy depending on the source information.

Table 1 presents the transliteration results. Even with gold-standard transcriptions, the phoneme-based model is worse than the grapheme-based model. This demonstrates that it is incorrect to refer to the process of transliteration as phonetic translation. On the other hand, our joint generation approach outperforms both single-source models on both test sets, which confirms that transliteration requires a joint consideration of orthography and pronunciation.

It is instructive to look at a couple of examples where outputs of the models differ. Consider the name *Marlon*, pronounced [mɑrlən], which is transliterated into Japanese as マロン *(MA-RO-N)* (correct), and マレン *(MA-RE-N)* (incorrect), by the orthographic and phonetic approaches, respectively. The letter bigram *lo* is always transliterated into ロ in the orthographic training data, while the phoneme bigram */lə/* has multiple correspondences in the phonetic training data. In this case, the unstressed vowel reduction process in English causes a loss of the orthographic information, which needs to be preserved in the transliteration.

In the joint model, the phonetic information sometimes helps disambiguate the pronunciation of the source word, thus benefiting the transliteration process. For example, the outputs of the three models for *haddock*, pronounced [hadək], are ハダク *(HA-DA-KU)* (phonetic), ハドドック *(HA-DO-DO-K-KU)* (orthographic), and ハドック *(HA-DO-K-KU)* (joint, correct). The phonetic model is again confused by the reduced vowel [ə], while the orthographic model mistakenly replicates the rendering of the consonant *d*, which is pronounced as a single phoneme.

Model	En→Ja	En→Hi
Graphemes only	63.1	43.5
Joint (gold phon.)	**67.4**	**48.0**
Joint (generated phon.)	65.8	46.1

Table 2: Transliteration accuracy improvement with gold and generated phonetic transcriptions.

Model	En→Ja	En→Hi
Graphemes only	53.3	46.4
Phonemes only	19.2	10.4
Joint (suppl. phonemes)	**54.8**	**50.0**

Table 3: Transliteration accuracy with transcriptions generated from third-language transliterations.

4.2 Generated Transcriptions

The training entries that have no corresponding transcriptions in our pronunciation lexicon were excluded from the experiment described above. When we add those entries back to the datasets, we can no longer apply the phonetic approach, but we can still compare the orthographic approach to our joint approach, which can handle the lack of a phonetic transcription in some of the training instances. The training sets are thus larger in the experiments described in this section: 30,190 entries for English-to-Japanese, and 12,070 for English-to-Hindi. The test sets are the same as in Section 4.1. The results in the first two rows in Table 2 show that the joint approach outperforms the orthographic approach even when most training entries lack the pronunciation information.[1]

Gold transcriptions are not always available, especially for names that originate from other languages. Next, we investigate whether we can replace the gold transcriptions with transcriptions that are automatically generated from the source orthography. We adopt DIRECTL+ as a grapheme-to-phoneme (G2P) converter, train it on the entire Combilex lexicon, and include the generated transcriptions instead of the gold transcriptions in the transliteration training and test sets for the joint model. The test sets are unchanged.

The third row in Table 2 shows the result of leveraging generated transcriptions. We still see improvement over the orthographic approach, albeit smaller than with the gold transcriptions. However, we need to be careful when interpreting these results. Since our G2P converter is trained on Combilex, the generated transcriptions of words in the test set are quite accurate. When we test the joint approach only on words that are *not* found in Combilex, the improvement over the orthographic approach largely disappears. We interpret this result as an indication that the generated transcriptions help mostly by capturing consistent grapheme-to-phoneme correspondences in the pronunciation lexicon.

[1]The improvement is statistically significant according to the McNemar test with $p < 0.05$. The differences in the baseline results between Table 1 and Table 2 are due to the differences in the training sets. The matching value of 46.1 across both tables is a coincidence. The comparison of results within any given table column is fair.

5 Leveraging transliterations

In the previous section, we have shown that phonetic transcriptions can improve the accuracy of the transliteration process by disambiguating the pronunciation of the source word. Unfortunately, phonetic transcriptions are rarely available, especially for words which originate from other languages, and generating them on the fly is less likely to help. However, transliterations from other languages constitute another potential source of information that could be used to approximate the pronunciation in the source language. In this section, we present experiments of leveraging such supplemental transliterations through our joint model.

5.1 Third-language transcriptions

An intuitive way of employing transliterations from another language is to convert them into phonetic transcriptions using a G2P model, which are then provided to our joint model together with the source orthography. We test this idea on the data from the NEWS 2010 shared task. We select Thai as the third language, because it has the largest number of the corresponding transliterations. We restrict the training and test sets to include only words for which Thai transliterations are available. The resulting English-to-Japanese and English-to-Hindi training/test sets contain 12,889/1,009, and 763/250 entries, respectively. We adopt DIRECTL+ as a G2P converter, and train it on 911 Thai spelling-pronunciation pairs extracted from Wiktionary. Be-

Language	Acc.	Data size
Thai	15.2	911
Hindi	25.9	819
Hebrew	21.3	475
Korean	40.9	3181

Table 4: Grapheme-to-phoneme word accuracy on the Wiktionary data.

Model	En→Ja	En→Hi
Graphemes only	54.5	46.1
Joint (suppl. phonemes)	**58.6**	**46.4**

Table 5: Transliteration accuracy with transcriptions generated from multiple transliterations.

cause of the small size of the training data, it can only achieve about 15% word accuracy in our G2P development experiment.

Table 3 shows the transliteration results. The accuracy of the model that uses only supplemental transcriptions (row 2) is very low, but the joint model obtains an improvement even with such inaccurate third-language transcriptions. Note that the Thai pronunciation is often quite different from English. For instance, the phoneme sequence [waj] obtained from the Thai transliteration of *Whyte*, helps the joint model correctly transliterate the English name into Japanese ホワイト*(HO-WA-I-TO)*, which is better than ホイト*(HO-I-TO)* produced by the orthographic model.

5.2 Multi-lingual transcriptions

Transcriptions obtained from a third language are not only noisy because of the imperfect G2P conversion, but often also lossy, in the sense of missing some phonetic information present in the source pronunciation. In addition, supplemental transliterations are not always available in a given third language. In this section, we investigate the idea of extracting phonetic information from multiple languages, with the goal of reducing the noise of generated transcriptions.

We first train G2P converters for several languages on the pronunciation data collected from Wiktionary. Table 4 shows the sizes of the G2P datasets, and the corresponding G2P word accuracy numbers, which are obtained by using 90% of the data for training, and the rest for testing.[2] For the highly-regular Japanese Katakana, we instead create a rule-based converter. Then we convert supplemental transliterations from those languages into noisy phonetic transcriptions. In order to obtain representative results, we also include transliteration pairs without supplemental transliterations, which results in different datasets than in the previous experiments. The sets for English-to-Japanese and English-to-Hindi now contain 30,190/17,557/1,886 and 12,070/3,777/380 entries, where the sizes refer to (1) the entire training set, (2) the subset of training entries that have at least one supplemental transcription, and (3) the test set (in which all entries have supplemental transcriptions).

An interlingual approach holds the promise of ultimately replacing n^2 pairwise grapheme-grapheme transliteration models involving n languages with $2n$ grapheme-phoneme and phoneme-grapheme models based on a unified phonetic representation. In our implementation, we merge different phonetic transcriptions of a given word into a single abstract vector representation. Specifically, we replace each phoneme with a phonetic feature vector according to a phonological feature chart, which includes features such as *labial, voiced*, and *tense*. After merging the vectors by averaging their weights, we incorporate them into the joint model described in Section 3.3 by modifying $\Phi(i, P, T)$. Unfortunately, the results are disappointing. It appears that the vector merging process compounds the information loss, which offsets the advantage of incorporating multiple transcriptions.

Another way of utilizing supplemental transcriptions is to provide them directly to our generalized joint model described in Section 3.5, which can handle multiple input strings. Table 5 presents the results on leveraging transcriptions generated from supplemental transliterations. We see that the joint generation from multiple transcriptions significantly boosts the accuracy on English-to-Japanese, but the improvement on English-to-Hindi is minimal.

[2]We use the entire datasets to train G2P converters for the transliteration experiments, but their accuracy is unlikely to improve much due to a small increase in the training data.

Model	En→Ja	Ja→En	En→Hi	Hi→En
DIRECTL+	51.5	19.7	43.4	42.6
Reranking	56.8	30.3	50.8	48.9
Joint	56.4	38.8	51.6	51.1
Joint + Reranking	**57.0**	44.6	**53.0**	57.2
+ Lexicon	-	**53.1**	-	**61.7**

Table 6: Transliteration accuracy with supplemental information.

5.3 Multi-lingual transliterations

The generated transcriptions of supplemental transliterations discussed in the previous section are quite inaccurate because of small and noisy G2P training data. In addition, we are prevented from taking advantage of supplemental transliterations from other languages by the lack of the G2P training data. In order to circumvent these limitations, we propose to directly incorporate supplemental transliterations into the generation process. Specifically, we train our generalized joint model on the graphemes of the source word, as well as on the graphemes of supplemental transliterations.

The experiments that we have conducted so far suggest two additional methods of improving the transliteration accuracy. We have observed that n-best lists produced by our joint model contain the correct transliteration more often than the baseline models. Therefore, we follow the joint generation with a reranking step, in order to boost the top-1 accuracy. We apply the reranking algorithm of Bhargava and Kondrak (2011), except that our joint model is the base system for reranking. In order to ensure fair comparison, the held-out sets for training the rerankers are subtracted from the original training sets.

Another observation that we aim to exploit is that a substantial number of the outputs generated by our joint model are very close to gold-standard transliterations. In fact, news writers often use slightly different transliterations of the same name, which makes the model's task more difficult. Therefore, we rerank the model outputs using a target-language lexicon, which is a list of words together with their frequencies collected from a raw corpus. We follow Cherry and Suzuki (2009) in extracting lexicon features for a given word according to coarse bins, i.e., $[< 2000]$, $[< 200]$, $[< 20]$, $[< 2]$, $[< 1]$. For example, a word with the frequency 194 will cause the features $[< 2000]$ and $[< 200]$ to fire.

We conduct our final experiment on forward and backward transliteration. We utilize supplemental transliterations from all eight languages in the NEWS 2010 dataset. The English-Japanese and English-Hindi datasets contain 33,540 and 13,483 entries, of which 23,613 and 12,131 have at least one supplemental transliteration, respectively. These sets are split into training/development/test sets. The entries that have no supplemental transliterations are removed from the test sets, which results in 2,321 and 1,226 test entries. In addition, we extract an English lexicon comprising 7.5M word types from the English gigaword monolingual corpus (LDC2012T21) for the back-transliteration experiments.

We evaluate the following models: (1) the baseline DIRECTL+ model trained on source graphemes; (2) the reranking model of Bhargava and Kondrak (2011)[3], with DIRECTL+ as the base system; (3) our joint model described in Section 3.5; (4) "combination", which is a reranking model with our joint model as the base system; and (5) a reranking model that uses the English target lexicon and model (4) as the base system.

Table 6 present the results. We see that our joint model performs much better by directly incorporating the supplemental transliterations than by using the corresponding phonetic transcriptions. This is consistent with our experiments in Section 4 that show the importance of the orthographic information. We also observe that our joint model achieves substantial improvements over the baseline on the back-transliteration tasks from Japanese and Hindi into English. This result suggests the orthographic information from the supplemental transliterations is

[3]Code from http://www.cs.toronto.edu/~aditya/g2p-tl-rr/

particularly effective in recovering the information about the pronunciation of the original word which is often obfuscated by the transliteration into a different language.

Our joint model is more effective in utilizing supplemental transliterations than the reranking approach of Bhargava and Kondrak (2011), except on English-to-Japanese. The combination of these two approaches works better than either of them, particularly on the back-transliteration tasks. Finally, the incorporation of a target-lexicon brings additional gains.

Back-transliteration from Japanese to English is more challenging than in the forward direction, which was already noted by Knight and Graehl (1997). Most of the names in the dataset originate from English, and Japanese phonotactics require introduction of extra vowels to separate consonant clusters. During back-transliteration, it is often unclear which vowels should be removed and which preserved. Our approach is able to dramatically improve the quality of the results by recovering the original information from multiple supplemental transliterations.

6 Conclusion

We have investigated the relative importance of the orthographic and phonetic information in the transliteration process. We have proposed a novel joint generation model that directly utilizes both sources of information. We have shown that a generalized joint model is able to achieve substantial improvements over the baseline represented by a state-of-the-art transliteration tool by directly incorporating multiple supplemental transliterations. In the future, we would like to further explore the idea of using interlingual representations for transliteration without parallel training data.

Abstract

It is well known that prosodic information is used by infants in early language acquisition. In particular, prosodic boundaries have been shown to help infants with sentence and word-level segmentation. In this study, we extend an unsupervised method for word segmentation to include information about prosodic boundaries. The boundary information used was either derived from oracle data (hand-annotated), or extracted automatically with a system that employs only acoustic cues for boundary detection. The approach was tested on two different languages, English and Japanese, and the results show that boundary information helps word segmentation in both cases. The performance gain obtained for two typologically distinct languages shows the robustness of prosodic information for word segmentation. Furthermore, the improvements are not limited to the use of oracle information, similar performances being obtained also with automatically extracted boundaries.

1 Introduction

Prosodic information is thought to play a fundamental role in early language acquisition, and provide infants with rich structural information about their language (Christophe et al., 1997). In particular, prosody has been claimed to help infants find word boundaries (Christophe and Dupoux, 1996). Newborns are able discriminate between disyllables that contains vs. does not contain a phonological phrase boundary (Christophe et al., 1994; Christophe et al., 2001), showing that they are able to encode the corresponding prosodic cues. Nine-month olds show evidence of parsing utterances into prosodic units, and show 'surprise' when a pause is inappropriately inserted inside as opposed to between these units (Jusczyk et al., 1992; Gerken et al., 1994). Ten to 13 month olds show evidence of using prosodic units to parse utterances into words, as they fail to recognize a familiar word if it appears to straddle a prosodic boundary (Gout et al., 2004).

Curiously enough, however, prosody is not used very much in unsupervised models of language acquisition, and in particular, in models of word segmentation. Most such models use text as input, and apply some form of lexical optimization. For instance, Brent and Cartwright (1996) used a Minimal Description Length Principle to optimize the size of the description of a corpus. State of the art systems use hierarchical Bayesian models (Goldwater et al., 2009) which parse a corpus into words or other linguistic units with a bias to reuse previously parsed elements. Adaptor Grammars is a generic framework which enables to formulate such Bayesian models within an overarching architecture based on probabilistic context free grammars (Johnson et al., 2007). Such models have been used to study the role of linguistic information such as syllabic structure (Johnson and Goldwater, 2009), morphology (Johnson, 2008), function words (Johnson et al., 2014), as well as the role of non-linguistic context (Synnaeve et al., 2014). To our knowledge, only one paper studied the role of prosodic information (Börschinger and Johnson, 2014). In this study, the authors used the role of word stress in constraining word segmentation (as in stress languages, there is only one main stress per word).

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 953–963,
Denver, Colorado, May 31 – June 5, 2015.

Here, we test whether prosodic boundaries could directly help symbolic word segmentation by providing some word boundaries 'for free', as this was already shown to be true in the case of signal-based term discovery systems (Ludusan et al., 2014). Being a feasibility study, we will use gold prosodic boundaries in order to quantify what is the maximum gain we can expect using this type of information. In addition to that, we test whether prosodic boundaries automatically derived from the speech signal (Ludusan and Dupoux, 2014) could also provide a performance gain. As this study relies on the existence of prosodic information (either gold, or derived from speech), we did not use the standard corpora used in these studies (the Bernstein-Ratner corpus), but introduced three new corpora, two in English and one in Japanese.

The paper is structured as follows: In the next sections we introduce the systems employed in this study - the prosodic boundary detection system in section 2 and the word segmentation procedure in section 3. Next, we present the datasets used in the experiments, with the results obtained being illustrated in section 5. The paper will conclude with a general discussion and some final remarks.

2 Prosodic annotation

There are numerous studies in the speech processing literature focusing on the detection of prosodic boundaries (e.g. Wightman and Ostendorf (1991), Ananthakrishnan and Narayanan (2008), Huang et al. (2008), Jeon and Liu (2009), just to name a few). While the approaches taken vary between these studies, they tend to use either supervised learning, thus needing large, prosodically annotated corpora, or higher level information (syntactic, lexical, etc) which would also require further annotations. Since unsupervised word segmentation is a process that requires low resources (only symbolic transcription), we have decided to use for the automatic detection of prosodic boundaries a previously proposed method which employs only acoustic cues that can be extracted from the speech signal (Ludusan and Dupoux, 2014).

The algorithm takes into consideration four acoustic cues which had been shown, in the language acquisition literature, to be used by young infants for the recognition of prosodic boundaries. The cues correspond to the following phenomena that occur next to prosodic breaks: silent pauses, final lengthening, initial strengthening and F0 reset. The acoustic cues were extracted at the syllable level and they include: the duration of the pause following the syllable (pause cue), the syllable nucleus duration (nucleus cue), the distance between the nucleus onset of the current syllable and that of the following one (onset cue) and the difference between the F0 end value of the current syllable and the F0 beginning value of the following syllable (F0 reset cue). The nucleus and onset cues are computed for all the syllables, the later being a combination of the nucleus cue, pause cue and the onset of the following syllable, which is the domain of the initial strengthening phenomenon. The pause cue is set to 0 for syllables not followed by a silence pause, while F0 reset is only computed for syllables which are at a local minimum for F0, otherwise it is set to 0. Then, for each individual cue function except pause, we considered only the values which were local maxima, the other values being set to 0.

Once a numerical value for each of the cues is obtained, they are standardized between 0 and 1 and combined in a detector function, by summing them up. The local maxima of the detector function are then obtained and the syllables corresponding to the maxima will be considered as prosodic boundary candidates. Next, a thresholding of these values is applied and all the right-hand boundaries of the syllables greater or equal to this threshold are marked as prosodic boundaries. This operation is followed by a second step in which prosodic boundaries are marked based on a different rule, rule that we would call conjunction of cues. This rule was inspired by the results of several studies in the infant literature (Seidl, 2007; Wellmann et al., 2012) showing that most prosodic boundaries tend to be marked by more than one acoustic cue. Taking these findings into account, we could also mark as prosodic boundaries all syllables which are signalled by at least two different cues, regardless of the value of these cues. Thus, by employing the conjunction of cues we can give a higher weight to a group of cues which, by appearing together, mark more reliably the presence of a boundary, in the hope that it would increase recall without decreasing too much the precision.

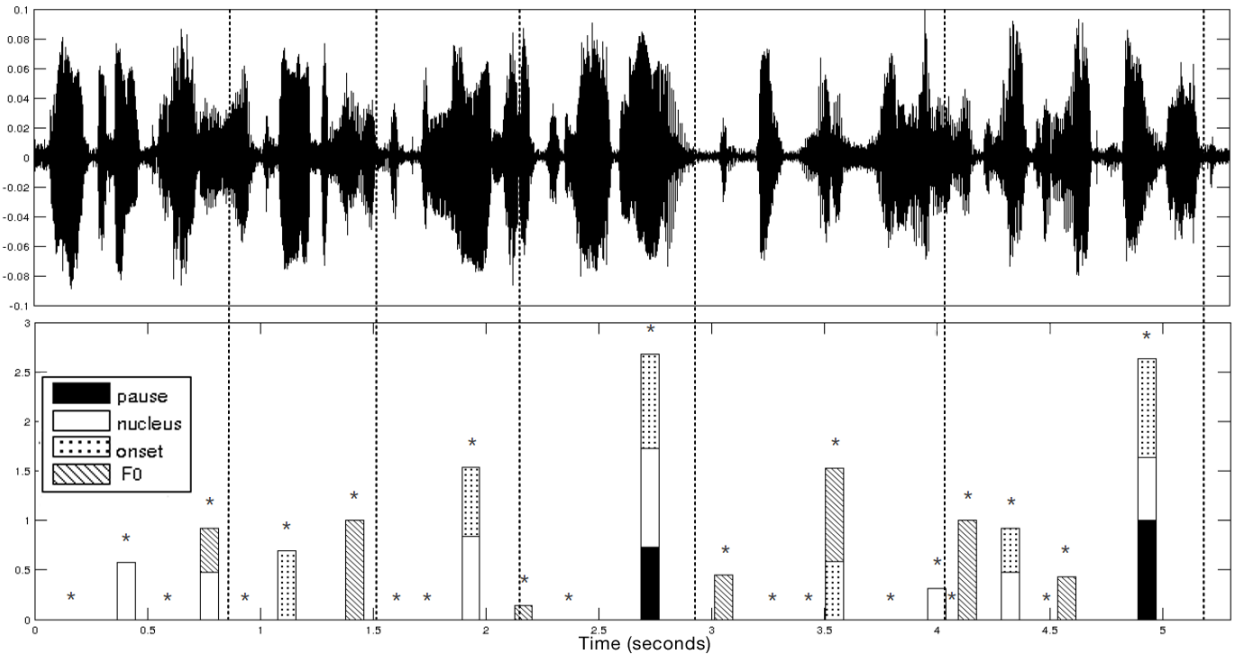

Figure 1: Speech waveform and corresponding detector function employed for prosodic boundary detection of the phrase: "My tape machine records well, but the knobs are too small, the buttons are flimsy and the counter misplaced" (for details, see (Ludusan and Dupoux, 2014)).

The parameters of the algorithm: the combination of cues, the cut-off threshold and the combination of conjunction of cues are obtained on a hold-out set, by aiming to maximize the performance of the system on that particular set.

The prosodic boundary detection procedure is illustrated in Figure 1 for the following utterance: "My tape machine records well, but the knobs are too small, the buttons are flimsy and the counter misplaced". The waveform of the speech signal is shown in the upper panel, with prosodic boundaries marked with dashed lines. In the lower panel are the values of the computed detector function, for each syllable, and the contribution of each of the cues towards the value of the function (the asterisk denotes the position of the syllable nucleus). The syllables corresponding to local maxima of the detector function (syllables 2, 4, 7, 10, 13, 17, 19, 21 and 25) would be considered as possible candidates for the position of a prosodic boundary. Provided that their value is higher than the decision threshold, they will be marked as actual boundaries. For example, if the threshold is set to the first percentile of the function, all the candidates will be kept, for the 50th percentile only syllables 10, 13, 17 and 25 will be considered, while a threshold equal to the value of the 100th percentile will leave only syllable 13 to be marked as a boundary. If we also use what we called conjunction of cues, and we set the cues to be the nucleus and the onset, syllables 10, 13, 22 and 25 will be marked as boundary placeholders, regardless of the fact they are or not a local maximum or they pass or not over the decision threshold.

3 Word segmentation models

3.1 Adaptor grammars

Adaptor Grammars (AGs) are an extension of probabilistic context-free grammars (PCFGs) that learn probability of entire subtrees as well as probabilities of rules (Johnson et al., 2007). A PCFG (N, W, R, S, θ) consists of a start symbol S, N and W disjoints sets of nonterminals and terminal symbols respectively. R is a set of rules producing elements of N or W. Finally, θ is a set of distributions over the rules $R_X, \forall X \in N$ (R_X are the rules that expand X). An AG $(N, W, R, S, \theta, A, C)$ extends the above PCFG with a subset ($A \subseteq N$) of adapted nonterminals, each of them ($X \in A$) having an associated adaptor ($C_X \in C$). An AG defines a dis-

tribution over trees $G_X, \forall X \in N \cup W$. If $X \notin A$, then G_X is defined exactly as for a PCFG:

$$G_X = \sum_{\substack{X \to Y_1 \ldots Y_n \\ \in R_X}} \theta_{X \to Y_1 \ldots Y_n} \mathrm{TD}_X(G_{Y_1} \ldots G_{Y_n})$$

With $\mathrm{TD}_X(G_1 \ldots G_n)$ the distribution over trees with root node X and each subtree $t_i \sim G_i$ i.i.d. If $X \in A$, then there is an additional indirection (composition) with the distribution H_X:

$$G_X = \sum_{\substack{X \to Y_1 \ldots Y_n \\ \in R_X}} \theta_{X \to Y_1 \ldots Y_n} \mathrm{TD}_X(H_{Y_1} \ldots H_{Y_n})$$

$$H_X \sim C_X(G_X)$$

We used C_X adaptors following the Pitman-Yor process (PYP) (Perman et al., 1992; Teh, 2006) with parameters a and b. The PYP generates (Zipfian) type frequencies that are similar to those that occur in natural language (Goldwater et al., 2011). Metaphorically, if there are n customers and m tables, the $n+1$th customer is assigned to table z_{n+1} according to (δ_k is the Kronecker delta function):

$$z_{n+1}|z_1 \ldots z_n \sim \frac{ma+b}{n+b}\delta_{m+1} + \sum_{k=1}^{m} \frac{n_k - a}{n+b}\delta_k$$

For an AG, this means that adapted non-terminals ($X \in A$) either expand to a previously generated subtree ($T(X)_k$) with probability proportional to how often it was visited (n_k), or to a new subtree ($T(X)_{m+1}$) generated through the PCFG with probability proportional to $ma + b$.

3.2 Grammars including prosodic information

The *baseline* that we are using is commonly called the "Colloc3-Syll" model (Johnson and Goldwater, 2009) and is reported at 87% token F-score on the standard Brent version of the Bernstein-Ratner corpus corpus. It posits that sentences are composed of 3 hierarchical levels of collocations, the lower level being collocations of words, and words are composed of syllables. Goldwater et al. (2009) showed how an assumption of independence between words (a unigram model) led to under-segmentation. So, above the $Word$ level, we take the collocations (co-occurring sequences) of words into account.

$$\begin{aligned}
Sentence &\to Colloc3^+ \\
\underline{Colloc3} &\to Colloc2^+ \\
\underline{Colloc2} &\to Colloc1^+ \\
\underline{Colloc1} &\to Word^+ \\
\underline{Word} &\to StructSyll
\end{aligned}$$

where the rule $\underline{Colloc2} \to Colloc1^+$ is implemented by:

$$\begin{aligned}
\underline{Colloc2} &\to Collocs1 \\
Collocs1 &\to Colloc1 \\
Collocs1 &\to Colloc1\ Collocs1
\end{aligned}$$

$Word$ splits into general syllables and initial- or final- specific syllables in $StructSyll$. In English, syllables consist of onsets or codas (producing consonants), and nuclei (vowels). Onsets, nuclei and codas are adapted, thus allowing this model to memorize sequences or consonants or sequences of vowels, dependent on their position in the word. Consonants and vowels are the pre-terminals, their derivation is specified in the grammar into phonemes of the language. In Japanese, syllables are adapted and are composed either of (Consonant-)Vowel(-Nasal) or Nasal. Phonemes are annotated either as consonant, vowel, or nasal (the moraic nasal /N/).

To allow for these grammars to use the prosodic information, we modify them so that prosodic boundaries are considered as breaks at a given level of collocations (or words). For instance we describe below how we change a Colloc3-Syll grammar to make use of the prosodic boundaries information at the lower level of collocations (Colloc1), by using the terminal symbols "|" (the rest is unchanged):

$$\begin{aligned}
\underline{Colloc2} &\to Collocs1 \\
Collocs1 &\to Colloc1 \\
Collocs1 &\to Colloc1 \mid Collocs1 \\
Collocs1 &\to Colloc1\ Collocs1 \\
\underline{Colloc1} &\to Word^+
\end{aligned}$$

We produced and tested grammars which incorporated these prosodic boundary annotations at different levels, from $Collocs3$ down to $Word$ level.

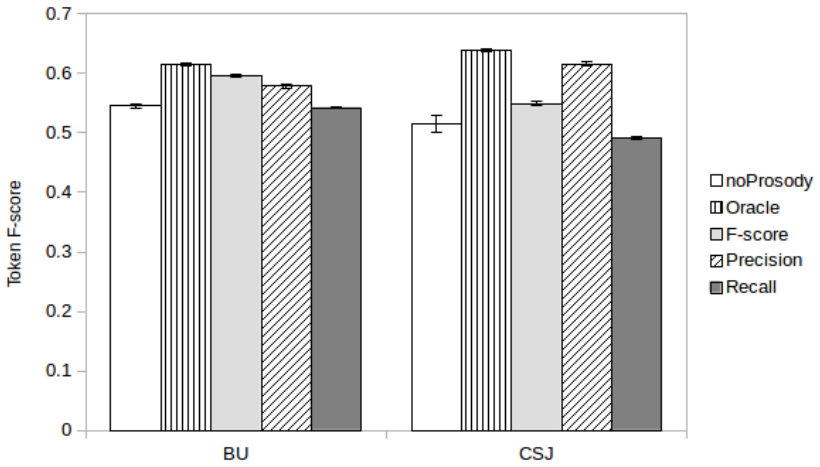

Figure 2: Colloc3-Syll based grammars scores on the BU and CSJ datasets. We show the best results without prosodic annotation, with hand-annotated prosody information (oracle), and with automatically derived annotations that maximize either F-score, precision, or recall of prosodic boundaries.

4 Materials

The experiments were performed on two distinct languages: English and Japanese. For English, we have chosen the Boston University radio news (BU) corpus (Ostendorf et al., 1995) and the LUCID corpus (Baker and Hazan, 2010). The first one, the BU corpus, consists of broadcast news recorded by professional speakers and is widely used in speech prosody research. Here, we only used the prosody annotated portion of the corpus, containing about 3 hours of recordings, labelled for accent tones and prosodic breaks following the ToBI standard for American English (Silverman et al., 1992). Level 3 and level 4 break indices, corresponding to intermediate and intonational phrase boundaries, were considered in this work. The recordings belonging to 6 speakers were used for the experiments, while those belonging to one speaker were employed as a development set, for setting the parameters of the automatic boundary detection algorithm. The evaluation set was divided into utterances, at pauses longer or equal to 200 ms, giving in total 2,273 utterances having 27,980 tokens.

While the BU corpus has the advantage of being annotated for prosodic boundaries, and thus being able to provide us with an upper bound of the performance increase that the prosodic information could bring, it is not large enough to give state-of-the-art results using AG. For this, we have taken a large corpus of spontaneous interactions, the LUCID corpus, and used it in connection to automatically detected prosodic boundaries. Due to the more spontaneous nature of these materials, we have defined utterances as being stretches of speech bounded by pauses at least 500 ms long. Since durational information is needed for the detection of the prosodic boundaries, the corpus was force aligned using the UPenn aligner (Yuan and Liberman, 2008). From the utterances obtained we have excluded all utterances containing hesitations or words not present in the dictionary of the aligner. Thus, a total of 21,649 utterances were eventually used in the experiments, corresponding to 118,640 tokens.

For Japanese, a subpart of the core of the Corpus of Spontaneous Japanese (CSJ) was used (Maekawa, 2003). It contains more than 18 hours of academic recordings from 70 speakers and it was annotated for prosodic boundaries using the X-JToBI standard (Maekawa et al., 2002). Oracle level 2 and level 3 prosodic breaks (accentual and intonational phrases) were used in this study as well as automatically obtained boundaries. The data set aside for the setting of parameters belongs to 5 speakers, with the recordings of the rest of the speakers used for the evaluation. We used the utterance markings provided with the corpus, the evaluation set containing 21,974 utterances and 195,744 tokens.

While previous studies on word segmentation have focused on infant-directed speech (IDS), we employ here corpora of adult-directed speech. The reason behind this choice is the fact that IDS corpora

Model	F-score	Precision	Recall
maxFscore	**.608**	.705	.535
maxPrecision	.391	**.986**	.244
maxRecall	.496	.377	**.724**

Table 1: Automatic prosodic boundary annotation performance on the BU corpus.

are not, generally, annotated for prosody. We would expect that experiments on ADS would improve less over the baseline, when compared to those run on IDS, due to its less exaggerated prosody and its reduced number of prosodic boundaries. Thus, any improvement found on ADS, would be found also on IDS.

The corpora used have all been transcribed phonetically, but, for the purpose of this paper, we have transformed this phonetic annotation into a phonemic one. For the English databases the mappings proposed by Lee and Hon (1989) were employed, with two notable exceptions: vowels /er/ and /axr/ were mapped to the phonemes /ah/ and /r/, while the syllabic consonants /el/, /em/ and /en/ were mapped to the label /ah/ and their corresponding consonant (/l/, /m/ or /n/). For Japanese, we employed the same mappings used by Boruta (2011).

5 Results

The prosodic boundary procedure on the BU and the CSJ used oracle segmental (phonetic) information, while phonemes were force-aligned from word-level annotation for the LUCID. The prosodic boundaries were evaluated with the classic measurements: precision, recall and F-score. The word segmentation token F-scores were obtained every 10 epochs (for less correlation due to the sampler) during the 100 epochs (BU corpus), or the 200 epochs (LUCID and CSJ corpora) centered around the point of convergence, and their mean and standard deviation computed. The convergence point was determined by smoothing the prior probability of the grammar with a sliding window and choosing the epoch where the negative log probability was the lowest.

5.1 English

The best parameters of the prosodic boundary detection system were searched for on the development set left aside for this purpose. The F-score of the system was maximized and the best combination of cues and conjunction of cues were $pause{+}onset$ and $pause + nucleus$, respectively. For these settings, we then determined the threshold values which gave the best F-score, precision and recall for boundary detection, which were further used to run the algorithm on the evaluation set. The results obtained on the evaluation set for the systems trying to maximize F-score ($maxFscore$), precision ($maxPrecision$) or recall ($maxRecall$) are presented in Table 1.

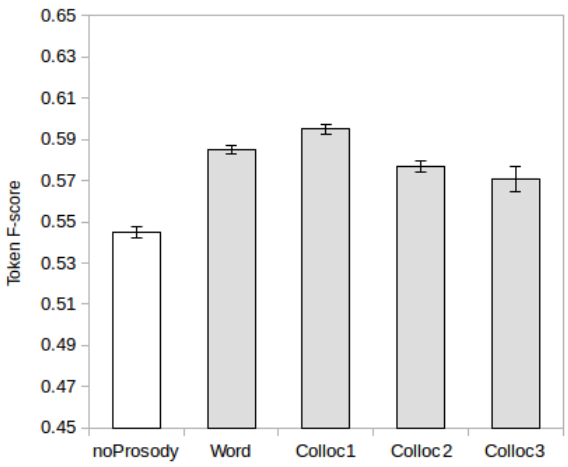

Figure 3: Colloc3-Syll based grammars scores on the BU dataset, comparing results without prosodic annotation, with those obtained by automatic prosodic boundaries that maximize F-score, added at different levels in the grammar.

The word segmentation method was then run with the grammars defined in section 3.2, with and without prosodic boundary information. For the prosody enhanced cases, both oracle and automatic boundaries were employed. The best results obtained on the BU corpus, for each of the five settings, are illustrated on the left side of Figure 2. It appears that all cases that employ prosodic information improve over the baseline, with oracle boundaries giving a 7% absolute performance gain.

Next, we looked in more detail at the behaviour of the best system that uses automatic boundaries ($maxFscore$). We present the token F-score obtained by this system for the different levels of the grammar where the prosodic information is added.

Although we obtained improvements on the BU corpus, for all cases when prosodic information was used, the overall results are far from state-of-the art

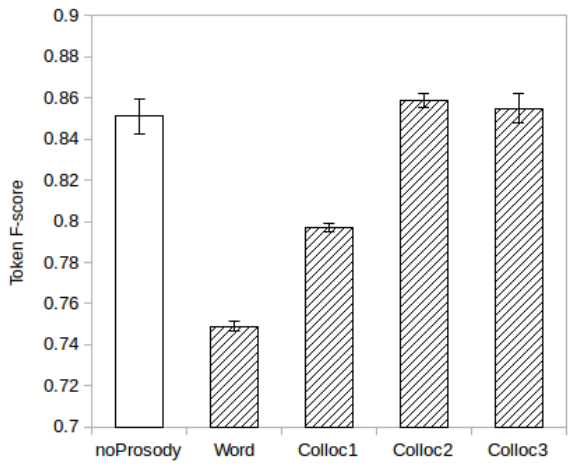

Figure 4: Colloc3-Syll based grammars scores on the LUCID dataset, comparing results without prosodic annotation, with those obtained by automatic prosodic boundaries that maximize precision, added at different levels in the grammar.

performance, due to the relatively small size of the corpus. For this reason, we chose to test on a bigger English corpus, LUCID. While this corpus is indeed larger, it has the disadvantage of not being prosodically annotated. Thus, we investigated only the cases when automatically determined prosodic boundaries are employed. The detection of prosodic boundaries used the same parameters obtained on the BU corpus but, since no prosodic annotation exists, we were not able to perform the same evaluation of the boundaries, as we did for BU.

The token F-scores for the best prosodic boundary setting ($maxPrecision$) are displayed in Figure 4. These results are closer to the state-of-the-art for English, which stand at 87% token F-score. Contrary to the results on the BU corpus, the prosody enhanced system improves over the baseline only when the boundary information is added at $Colloc2$ or $Colloc3$ level (best gain: 0.8% absolute value). While the improvements brought here tend to be quite small, compared to those obtained for BU, we are closer to ceiling value on LUCID and also the quality of the automatic boundaries might be lower, due to the different type of speech on which the parameters of the model were found.

With the Adaptor Grammar tending to slightly over-segment the results, the inclusion of prosody at $Word$ or $Colloc1$ has increased the precision slightly, at the expense of a significantly lower recall, and thus a lower overall F-score. This over-segmentation trait was instead much more pronounced for the BU corpus, where the increase in precision was accompanied only by a slight decrease in recall, brought the two measures closer together, and thus has maximized the F-score.

Model	F-score	Precision	Recall
maxFscore	**.469**	.533	.418
maxPrecision	.398	**.781**	.267
maxRecall	.431	.353	**.552**

Table 2: Automatic prosodic boundary annotation performance on the CSJ corpus.

5.2 Japanese

The same procedure for parameter detection as for the BU corpus was applied and the best cues obtained were $pause + onset$, while the best combination of conjunction of cues was $pause+f0Reset$. Table 2 illustrates the prosodic boundary results obtained on the CSJ evaluation set, for the systems maximizing F-score, precision and recall, respectively.

Since oracle prosodic information was available for this corpus, we were able to compare the performance of the baseline to that of the oracle and automatic boundaries enhanced system. This comparison is displayed in Figure 2, right hand side. Having a sizable corpus, the results are more similar to the state-of-the-art for Japanese, reported in (Fourtassi et al., 2013) (55%). Increases in performance can be observed when hand-labelled prosody is introduced (12.3% absolute value), and also when automatic boundaries ($maxPrecision$) are employed (10% absolute value).

Similarly to the previous experiments, we display in Figure 5 the comparison between the baseline and the best system employing automatic boundaries ($maxPrecision$), for the different levels where the information is added. It shows that prosody helps, regardless of the level where prosody is used, although it appears to favour the lower collocation levels.

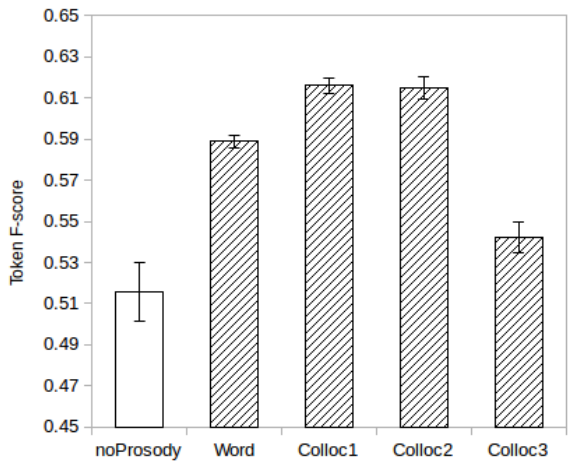

Figure 5: Colloc3-Syll based grammars scores on the CSJ dataset, comparing results without prosodic annotation, with those obtained by automatic prosodic boundaries that maximize precision, added at different levels in the grammar.

6 Discussion and Conclusions

We have investigated the use of prosodic boundary information for unsupervised word discovery in a multilingual setting. We showed that prosodic boundaries can improve word segmentation across both languages even when automatically determined boundaries are used. We also illustrated that the way in which to integrate prosody into word segmentation is not homogeneous across corpora, both in terms of the level of collocation where these boundaries are introduced, and in terms of the balance between precision and recall, when it comes to using automatic boundaries.

For the first issue, the results on BU suggest that $Word$ or $Colloc1$ would be the best level, those on LUCID show that either $Colloc2$ or $Colloc3$ would give the best performance, while the scores on CSJ favors $Colloc1$ or $Colloc2$. But, if we were to discard the results on BU, due to its heavy over-segmentation and its small size, and use the collocation level giving the most balanced scores on the other two datasets, it appears that $Colloc2$ would be the common denominator. Besides giving the most balanced token scores it also gives the most balanced boundary scores, striking a good compromise between the under-segmentation produced by adding the prosody at lower levels and the over-segmentation tendency for boundaries introduced at higher levels.

To investigate the second issue, a closer look to the tables presenting the evaluation of the automatic boundaries (Table 1 and Table 2) is needed. The best word segmentation scores on BU were obtained for the $maxFscore$ system, but we can observe that the condition also has a high precision (.705). At the same time, the best score on CSJ was obtained for the $maxPrecision$ system, the $maxFscore$ system (with a precision of .533) giving no improvement over the baseline (see Figure 2). Furthermore, $maxRecall$, which has very low precisions, seems to behave similar to, or below the baseline, for both datasets. Thus, it appears that a relatively high precision for the prosodic boundaries is needed to obtain improvements in word segmentation and, once this condition is fulfilled, any increase in recall would increase the gain over the baseline.

Further evidence supporting this can be found when performing a word-based evaluation of the automatic prosodic boundaries obtained. For the BU and CSJ corpora, we computed the percentage of word boundaries found, out of the total word boundaries in the corpora, and the proportion of incorrect word boundaries from the total number of boundaries found (see Table 3). It shows that the systems that bring improvements over the baseline ($maxFscore$ and $maxPrecision$ for BU, and $maxPrecision$ for CSJ) have a relatively low rate of false alarms (lower than 6%). At the same time, the increase in performance can be obtained even without a high coverage of the corpus, the $maxPrecision$ models achieving this with a coverage lower than 10%.

Since all the resuls reported in this paper were obtained using the state-of-the-art Adaptor Grammar model, $Colloc3-Syll$, we also verified that our results are generalizable across different models. We created several AG models, by varying the following settings in the grammar: using either one or three collocation levels, and having knowledge or not of the syllabic structure. This gave us, besides the already tested $Colloc3-Syll$ model, three new models: $Colloc3-noSyll$, $Colloc-Syll$ and $Colloc-noSyll$, which were all tested on the CSJ. When evaluating the token F-score obtained using these models, we can see improvements for all the models, regardless of the nature of the prosodic

Corpus	Model	% found	% incorr
BU	oracle	100	0
	maxPrecision	7.0	0.1
	maxFscore	20.3	5.7
	maxRecall	40.4	34.2
CSJ	oracle	100	0
	maxPrec	9.9	0.04
	maxFscore	21.0	23.5
	maxRecall	32.8	51.3

Table 3: Word boundary-based evaluation of the three systems used for prosodic boundary detection. We report the percentage of correct word boundaries found and the number of incorrect boundaries found, as a percentage of all boundaries found.

boundaries used.

Before closing, we note that prosody seem to helps differentially the segmentation of the two languages we tested. In Japanese we found improvements reaching 10 percentage points in F-score, whereas the improvements in English were more modest (5 points for the BU, 1 point for the LUCID), when automatic boundaries are used. This could be due to differences in the segmentation problem across these two languages. Indeed, words in Japanese are in their majority composed of several syllables, and many words contain embedded words, making the segmentation problem intrinsically more difficult than in English, for which the large majority of words are monosyllabic (Fourtassi et al., 2013). It is possible that prosody particularly helps those languages with a polysyllabic lexicon, by helping prevent over-segmentation.

While the current work examined the use of prosodic boundaries for word segmentation in two languages, we would like to extend the study to more languages. We would expect a similar behaviour also for other languages, but it would be interesting to investigate the interaction between boundary information and collocation level for other typologically distinct languages. Also, we have employed here oracle segmental information for the automatic detection of prosodic boundaries. In the future we plan to completely automatize the process, by employing segmental durations obtained with signal-based methods for speech segmentation. Finally, prosody was introduced here by way of a discrete symbol, forcing us to make a binary decision. A more integrated model would enable to associate prosodic break with a probability distribution, over acoustic features, thereby achieving the joint learning of segmentation and prosody.

So similar and yet incompatible: Toward automated identification of semantically compatible words

Germán Kruszewski and **Marco Baroni**
Center for Mind/Brain Sciences (University of Trento, Italy)
(german.kruszewski|marco.baroni)@unitn.it

Abstract

We introduce the challenge of detecting *semantically compatible* words, that is, words that can potentially refer to the same thing (*cat* and *hindrance* are compatible, *cat* and *dog* are not), arguing for its central role in many semantic tasks. We present a publicly available data-set of human compatibility ratings, and a neural-network model that takes distributional embeddings of words as input and learns alternative embeddings that perform the compatibility detection task quite well.

1 Introduction

Vectors encoding distributional information extracted from large text corpora provide very effective estimates of semantic similarity or, more generally, relatedness between words (Clark, 2015; Erk, 2012; Turney and Pantel, 2010). Semantic relatedness is undoubtedly a core property of word understanding, and indeed current vector-based *distributional semantic models* (DSMs) provide an impressive approximation to human judgments in many tasks (Baroni et al., 2014). However, relatedness alone is too general a notion to truly capture the nuances of human conceptual knowledge. The terms *animal*, *puppy*, and *cat* are all closely related to *dog*, but the nature of their relation is very different, each affording different inferences: If you tell me that Fido is a dog, I will also conclude that he's an animal, that he is not a cat, and that he might or might not be a puppy.

The previous examples hint at a fundamental semantic property that is only partially linked to relatedness, namely *compatibility*, that we define, for our current purposes, as follows: *Linguistic expressions w_1 and w_2 are compatible iff, in a reasonably normal state of affairs, they can both truthfully refer to the same thing. If they cannot, then they are incompatible*. We realize that the notion of a "reasonably normal sate of affairs" is dangerously vague, but we want to exclude science-fiction scenarios in which dogs mutate into cats. And we use *thing* as a catch-all term for anything words (or other linguistic expressions) can refer to (entities, events, collections, etc.).

The notions of compatibility and incompatibility have been introduced in theoretical semantics before (Cruse, 1986; Murphy, 2010). The definition that we give here for compatibility is related, but different from the one by Cruse. For example, subsuming pairs are out of the scope of compatibility under his definition, whereas we include them. Murphy defines incompatibility similarly to us, but she does not define compatibility. We are not aware, on the other hand, of any earlier systematic attempt to study the phenomenon empirically, nor to model it computationally.

In general, compatible terms will be semantically related (*dog* and *animal*). However, relatedness does not suffice: many semantically related, even very similar terms are not compatible (*dog* and *cat*). Relatedness is not even a necessary condition: A *husband* can be a *hindrance* in an all-too-normal state of affairs, but the concepts of husband and hindrance are not semantically close. Moreover, compatibility does not reduce to (a set of) more commonly studied semantic relations. While it relates to hy-

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 964–969,
Denver, Colorado, May 31 – June 5, 2015.

pernymy, synonymy and co-hyponymy, there are cases, such as *husband/hindrance*, that do not naturally map to any of these relations. Also, although many incompatibles among closely related pairs are co-hyponyms, this is not necessarily the case: You cannot be both a *dog* and a *cat*, but you can be a *violinist* and a *drummer*.

We argue that, since knowing what's compatible plays a central role in human semantic reasoning, algorithms that determine compatibility automatically will help in many domains that require human-like semantic knowledge. Most obviously, compatibility is a necessary (although not sufficient) prerequisite for coreference. *Dog* and *puppy* could belong to the same coreference chain, whereas *dog* and *cat* do not. We conjecture that the relatively disappointing performance of DSMs in support of coreference resolution (Poesio et al., 2010) is at least partially due to the inability of standard DSMs to distinguish compatible and incompatible terms. Compatibility is also central to recognizing entailment (and contradiction): Standard DSMs are of relatively little use in recognizing entailment as they treat antonymous, contradictory words such as *dead* and *alive* as highly related (Adel and Schütze, 2014; Mohammad et al., 2013), with catastrophic results for the inferences that can be drawn (antonyms are just the tip of the incompatibility iceberg: *dog* and *cat* are not antonyms, but one still contradicts the other). Knowing what's compatible might also help in tasks that require recognizing (distant) paraphrases, such as question answering, document summarization or even machine translation (*the violinist also played the drum* might corefer with *the drummer also played the violin*, whereas *the dog was killed* and *the cat was killed* must refer to different events). Other applications could include modeling semantic plausibility of a nominal phrase (Vecchi et al., 2011; Lynott and Connell, 2009), where the goal is to accept expressions like *coastal mosquito*, but reject *parlamentary tomato*. Finally, the notion of incompatibility relates to (certain kinds of) negation. Negation is notoriously difficult to model with DSMs (Hermann et al., 2013), and compatibility might offer a new angle into it.

In this paper, we introduce a new, large benchmark to evaluate computational models on compatibility detection. We then present a supervised neural-network based model that takes distributional semantic vectors as input and embeds them into a space that is optimized for compatibility detection. The model performs significantly better than direct DSM relatedness, and achieves high scores in absolute terms.

2 The compatibility benchmark

We started the benchmark construction by manually assembling a list of 299 words including mostly concrete, basic-level concepts picked from categories where taxonomically close terms tend to be incompatible (e.g., biological classes such as animals and vegetables), as well as from categories that are more compatibility-prone (kinship terms, professions), or somewhere in the middle (tools, places). The list also included category names at different levels of abstraction (*creature*, *animal*, *carnivore*...), as well as some terms that were expected to be of high general compatibility (*hindrance*, *expert*, *companion*...). By randomly coupling words from this list, we generated pairs that should reflect a wide range of compatibility patterns (compatible and incompatible coordinate terms, words in an entailment relation, dissimilar but compatible, dissimilar and incompatible, etc.).[1] We generated about 18K such random pairs.

We used a subset of about 3K pairs in a pilot study on the CrowdFlower[2] crowd-sourcing platforms, in which we asked participants to annotate them for compatibility either as a yes/no judgment accompanied by a confidence rating, or on a 7-point scale. Correlation between mean binary and ordinal ratings was extremely high ($>$0.95), so we decided to adopt the potentially more precise, albeit more noisy, 7-point scale. Confidence judgments (median: 6.6/7), participant agreement and sanity checks on obvious cases confirmed that the raters understood the task well and produced the expected judgments consistently.

We thus launched a larger CrowdFlower survey,

[1] We realize that the resulting pairs might not resemble the natural distribution of compatibility decisions that an average person might encounter in daily life. However, the fact that (as we show below) subjects were highly consistent in judging the items proves that the data reflect genuine shared semantic knowledge a computational model should be able to capture.

[2] http://www.crowdflower.com

asking participants to rate pairs on a 7-point scale by answering the following question: "How much do you agree with the statement that <*word1*> and <*word2*> can refer to the same thing, animal or person?" We asked the judges to consider real-life scenarios and fairly ordinary circumstances; in case of ambiguity, they were asked to choose the sense that would make the pair compatible, as long as it was sufficiently common. 20 control items with obvious choices (e.g. *drummer/ant* - *writer/father*) were inserted to exclude raters that did not perform the task seriously. We paid close attention to contributors' feedback, correcting dubious controls. For example, we removed *bucket/chair*, since one contributor pointed out that you could turn a bucket upside down and use it as a chair.[3] In this way, we obtained usable annotation for 17973 pairs, each rated by 10 participants[4]. The average standard deviation was as as low as 0.70, compared to the standard deviation of a uniformly distributed multinomial distribution, which amounts to 1.8. As expected, ratings were highly skewed as most random pairs are incompatible: the median is 1.10 (with a standard deviation of 1.81). Yet, the overall distribution is bimodal, peaking at the two ends of the scale.

In order to be able to phrase (in)compatibility detection not only in continuous terms, but also as dichotomous tasks, we further produced a list of unambiguously (in)compatible pairs from the ends of the rating scale. Specifically, we manually inspected a subset of the list (before any computational simulation was run), and picked a mean 3.7 rating (exclusive) as minimum value for compatible pairs, and 1.6 (inclusive) as maximum score for incompatible ones. The number of problematic cases above/below these thresholds was absolutely negligible. We thus coded the data set by classifying the 2,933 pairs above the first threshold as compatible (e.g., *expert/criminal*, *hill/obstacle*, *snake/vermin*), the 12,669 pairs below the second as incompatible (e.g., *bottle/plate*, *cheetah/queen*), and the remainder as neither.

[3]We also were surprised to learn that drummer ants actually exist. Yet, in that case we decided to keep the control item since, under the most common sense of *drummer*, and in ordinary circumstances, ants cannot be drummers.

[4]The guidlienes provided to the participants and the collected data set are available at: `http://clic.cimec.unitn.it/composes/`

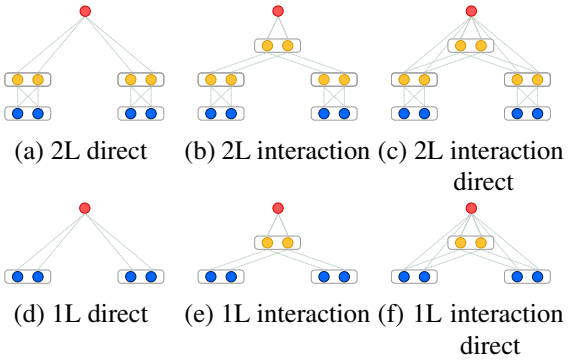

Figure 1: Schematic representation of the models

3 Models

We take DSM vectors as input, since they provide us with semantically rich word representations, and seek to induce a compatibility measure by learning the parameters of a model in a supervised manner. In particular, we used the word vectors publicly available at `http://clic.cimec.unitn.it/composes/semantic-vectors.html`. These vectors, extracted with the word2vec toolkit (Mikolov et al., 2013) from a 3B token corpus, were shown by Baroni et al. (2014) to produce near-state-of-the-art performance on a variety of semantic tasks.

We hypothesized that the interaction between a simple set of features (induced from the distributional ones) should account for a large portion of compatibility patterns. For example, human roles would typically be compatible (*classmate/friend*), whereas two animals would probably be incompatible (*iguana/zebra*). The model should thus be able to learn features associated to such classes, and compatibility rules associated to their interaction (e.g., if both w_1 and w_2 have large values for a *human* feature, compatibility is more likely). We incorporated this insight into the **2L interaction** neural network illustrated in Figure 1b. This network takes the distributional representations of the words in a pair, transforms them into new feature vectors by means of a mapping that is shared by both inputs, constructs the vector of pairwise interactions between the induced features, and finally uses the weighted combination of the latter to produce a real-number

score.

We considered then some variations of the 2L interaction model, to investigate the importance of each of its components. In **2L direct** (Figure 1a), we removed the interaction layer, making the model score a weighted combination of the mapped vectors. The **2L interaction direct** model (Figure 1c) computes the final score through a weighted combination of both the mapped representations and their interaction vector. The **1L** models (Figures 1d, 1e and 1f) are analogous to the corresponding 2L models, but removing the feature mapping layer, thus operating directly on the distributional vectors.

4 Experiments

Since compatibility is a symmetric relation, we first duplicated each pair in the benchmark by swapping the two words. We then split it into training, testing and development sections. To make the task more challenging, we enforced disjoint vocabularies in each of them. For example, *drummer* only occurs in the training set, while *ant*, only in the test set. We use about 1/10th of the vocabulary (29 words) on the development set and the rest was split equally between train and test (135 words each). The resulting partitions contain 7,228 (train), 7,336 (test) and 312 (development) pairs, respectively.

To train the models, we used the scores they generate in three sub-tasks: approximation of average ratings, classification of compatibles and classification of incompatibles. We used mean square error as cost function for the first sub-task, cross-entropy for the latter two.

We implemented the models in Torch7 (Collobert et al., 2011).[5] We trained them for 120 epochs with adagrad, with a batch size of 150 items and adopting an emphasizing scheme (LeCun et al., 2012), where compatibles, incompatibles and middle-ground items appear in equal proportions. We fixed hidden-layer size to 100 dimensions, while we tuned a coefficient for a L2-norm regularization term on the development data.

We evaluated the models ability to predict human compatibility ratings as well as to detect compatible and incompatible items.

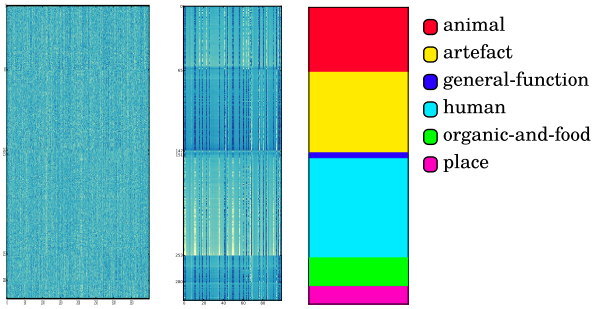
Table 1: Experimental results. Correlation with human ratings measured by Pearson r. (In)compatibility detection scored by the F1 measure.

We compared the supervised measures to the cosine of pairs directly represented by their DSM vectors (with thresholds tuned on the training set). We expected this baseline to fare relatively well on incompatibility detection, since many of our randomly generated pairs were both incompatible and dissimilar (e.g., *bag/bus*).

Also, we controlled for the portion of the data that can be accounted just by looking at one of the words of the relation (for example, the presence of a word might indicate that the relation is incompatible). To this end, we included two models that look at only one of the words in the pair. **1L mono** is a logistic regression model that only looks at the first word of the pair while **2L mono** is an analogous neural network with one hidden layer.

Results are reported in Table 1. As it can be seen, all the supervised models from Figure 1 strongly outperform the cosine (that, as expected, is nevertheless quite good at detecting incompatibles). Also, they outperform the mono models (with the only exception of 1L direct on incompatibility), showing that the data they account for cannot be reduced to properties of individual lexical items. Importantly, the 2L interaction model is way ahead of all other models, confirming our expectations.

To gain some insight into the features learned by the best model, we labeled the words of our input vocabulary with one of the following general category tags: *animal*, *artefact*, *general-function*, *human*, *organic-and-food* and *place*. The distribution



(a) Input vectors (b) Mapped vectors (c) Categories

Figure 2: Heatmap visualization of original DSM features and features learned by the mapping function of the 2L interaction model.

of the vocabulary across the labels is shown in Figure 2c. If we plot the input distributional vectors so that words tagged with the same category are adjacent to each other, and categories arranged as in Figure 2c, we obtain the heatmap in Figure 2a, where no obvious pattern emerges. If instead we plot the output vectors of 2L interaction mapping in the same way, we obtain the heatmap in Figure 2b. It is evident that the mapping produces vectors that are similar within most categories, and very different across them. Thus, the 2L interaction model clearly learned the relevance of general categories in capturing compatibility judgments. The fact that this model produced the best results hints at the importance of exploiting this source of information, confirming the intuition we used in designing it, that compatibility can be characterized by a combination of general relatedness and category-specific cues.

Finally, we explored to what extent the data can be accounted by co-hyponymy, an idea briefly introduced in the introductory discussion of Section 1. For simplicity purposes, we take the same category tags we just introduced as a word's hypernym. Classifying co-hyponyms as incompatibles and non-cohyponyms as compatibles performs very poorly (7 and 18 F1-scores for compatibility and incompatibility, respectively). On the other hand, the opposite strategy – co-hyponyms as compatibles and non-cohyponyms as incompatibles – works much better (62 and 84 F1), even outperforming many supervised models. Yet, this strategy does not suffice. For example, all animal pairs would be treated as compatibles, whereas 54% of them are actually incompatible. By contrast the L2 interaction model gets 78% of these incompatible pairs right.

5 Conclusion

We have introduced the challenge of modeling compatibility to the computational linguistics community. To this end, we collected a data set, and produced a model that satisfactorily captures a large portion of the data, that cannot be accounted for by simple semantic relatedness. Finally, we have explored the features learned by the model, confirming that high-order category information is relevant for producing compatibility judgements.

Computational models of compatibility could help in many semantic tasks, such as coreference resolution, question answering, modeling plausibility and negation. Future lines of research will explore the contributions that accounting for compatibility can make to these tasks.

Do Supervised Distributional Methods Really Learn Lexical Inference Relations?

Abstract

Distributional representations of words have been recently used in supervised settings for recognizing lexical inference relations between word pairs, such as hypernymy and entailment. We investigate a collection of these state-of-the-art methods, and show that they do not actually learn a relation between two words. Instead, they learn an independent property of a single word in the pair: whether that word is a "prototypical hypernym".

1 Introduction

Inference in language involves recognizing inference relations between two words (x and y), such as causality ($flu \rightarrow fever$), hypernymy ($cat \rightarrow animal$), and other notions of lexical entailment. The distributional approach to automatically recognize these relations relies on representing each word x as a vector $\vec{x}$ of *contextual features*: other words that tend to appear in its vicinity. Such features are typically used in word similarity tasks, where cosine similarity is a standard similarity measure between two word vectors: $sim(x, y) = cos(\vec{x}, \vec{y})$.

Many unsupervised distributional methods of recognizing lexical inference replace cosine similarity with an asymmetric similarity function (Weeds and Weir, 2003; Clarke, 2009; Kotlerman et al., 2010; Santus et al., 2014). Supervised methods, reported to perform better, try to learn the asymmetric operator from a training set. The various supervised methods differ by the way they represent each candidate pair of words (x, y): Baroni et al. (2012) use concatenation $\vec{x} \oplus \vec{y}$, others (Roller et al., 2014; Weeds et al., 2014; Fu et al., 2014) take the vectors' difference $\vec{y} - \vec{x}$, and more sophisticated representations, based on contextual features, have also been tested (Turney and Mohammad, 2014; Rimell, 2014).

In this paper, we argue that these supervised methods do not, in fact, learn to recognize lexical inference. Our experiments reveal that much of their previously perceived success stems from lexical memorizing. Further experiments show that these supervised methods learn whether y is a "prototypical hypernym" (i.e. a category), regardless of x, rather than learning a concrete relation between x and y.

Our mathematical analysis reveals that said methods ignore the interaction between x and y, explaining our empirical findings. We modify them accordingly by incorporating the similarity between x and y. Unfortunately, the improvement in performance is incremental. We suspect that methods based solely on contextual features of single words are not learning lexical inference relations because contextual features might lack the necessary information to deduce how one word relates to another.

2 Experiment Setup

Due to various differences (e.g. corpora, train/test splits), we do not list previously reported results, but apply a large space of state-of-the-art supervised methods and review them comparatively. We observe similar trends to previously published results, and make the dataset splits available for replication.[1]

Table 1: Datasets evaluated in this work.

2.1 Word Representations

We built 9 word representations over Wikipedia (1.5 billion tokens) using the cross-product of 3 types of contexts and 3 representation models.

2.1.1 Context Types

Bag-of-Words Uses 5 tokens to each side of the target word (10 context words in total). It also employs subsampling (Mikolov et al., 2013a) to increase the impact of content words.

Positional Uses only 2 tokens to each side of the target word, and decorates them with their position (relative to the target word); e.g. the_{-1} is a common positional context of cat (Schütze, 1993).

Dependency Takes all words that share a syntactic connection with the target word (Lin, 1998; Padó and Lapata, 2007; Baroni and Lenci, 2010). We used the same parsing apparatus as in (Levy and Goldberg, 2014).

2.1.2 Representation Models

PPMI A word-context positive pointwise mutual information matrix M (Niwa and Nitta, 1994).

SVD We reduced M's dimensionality to $k = 500$ using Singular Value Decomposition (SVD).[2]

SGNS Skip-grams with negative sampling (Mikolov et al., 2013b) with 500 dimensions and 5 negative samples. SGNS was trained using a modified version of `word2vec` that allows different context types (Levy and Goldberg, 2014).[3]

2.2 Labeled Datasets

We used 5 labeled datasets for evaluation. Each dataset entry contains two words (x, y) and a label whether x entails y. Note that each dataset was created with a slightly different goal in mind, affecting word-pair generation and annotation. For example, both of Baroni's datasets are designed to capture hypernyms, while other datasets try to capture broader notions of lexical inference (e.g. causality). Table 1 provides metadata on each dataset, and the description below explains how each one was created.

(Kotlerman et al., 2010) Manually annotated lexical entailment of distributionally similar nouns.

(Baroni and Lenci, 2011) a.k.a. BLESS. Created by selecting unambiguous word pairs and their semantic relations from WordNet. Following Roller et al. (2014), we labeled noun hypernyms as positive examples and used meronyms, noun cohyponyms, and random noun pairs as negative.

(Baroni et al., 2012) Created in a similar fashion to BLESS. Hypernym pairs were selected as positive examples from WordNet, and then permutated to generate negative examples.

(Turney and Mohammad, 2014) Based on a crowdsourced dataset of 79 semantic relations (Jurgens et al., 2012). Each semantic relation was linguistically annotated as entailing or not.

(Levy et al., 2014) Based on manually annotated entailment graphs of subject-verb-object tuples (propositions). Noun entailments were extracted from entailing tuples that were identical except for one of the arguments, thus propagating the existence/absence of proposition-level entailment to the noun level. This dataset is the most realistic dataset, since the original entailment annotations were made in the context of a complete proposition.

2.3 Supervised Methods

We tested 4 compositions for representing (x, y) as a feature vector: **concat** ($\vec{x} \oplus \vec{y}$) (Baroni et al., 2012), **diff** ($\vec{y} - \vec{x}$) (Roller et al., 2014; Weeds et al., 2014; Fu et al., 2014), **only x** ($\vec{x}$), and **only y** ($\vec{y}$). For each composition, we trained two types of classifiers, tuning hyperparameters with a validation set: logistic regression with L_1 or L_2 regularization, and SVM with a linear kernel or quadratic kernel.

3 Negative Results

Based on the above setup, we present three negative empirical results, which challenge the claim that the methods presented in §2.3 are learning a relation between x and y. In addition to our setup, these results were also reproduced in preliminary exper-

[2] Following Caron (2001), we used the square root of the eigenvalue matrix Σ_k for representing words: $M_k = U_k\sqrt{\Sigma_k}$.

iments by applying the JoBimText framework[4] for scalable distributional thesauri (Biemann and Riedl, 2013) using Google's syntactic N-grams (Goldberg and Orwant, 2013) as a corpus.

Lexical Memorization is the phenomenon in which the classifier learns that a specific word in a specific slot is a strong indicator of the label. For example, if a classifier sees many positive examples where $y = animal$, it may learn that anything that appears with $y = animal$ is likely to be positive, effectively *memorizing* the word $animal$.

The following experiment shows that supervised methods with contextual features are indeed memorizing words from the training set. We randomly split each dataset into 70% train, 5% validation, and 25% test, and train lexical-feature classifiers, using a one-hot vector representation of y as input features. By definition, these classifiers memorize words from the training set. We then add contextual-features (as described in §2.1), on top of the lexical features, and train classifiers analogously. Table 2 compares the best lexical- and contextual-feature classifiers on each dataset. The performance difference is under 10 points in the larger datasets, showing that much of the contextual-feature classifiers' success is due to lexical memorization. Similar findings were also reported by Roller et al. (2014) and Weeds et al. (2014), supporting our memorization argument.

To prevent lexical memorization in our following experiments, we split each dataset into train and test sets with zero lexical overlap. We do this by randomly splitting the vocabulary into "train" and "test" words, and extract train-only and test-only subsets of each dataset accordingly. About half of each original dataset contains "mixed" examples (one train-word and one test-word); these are discarded.

[4] http://jobimtext.org

Supervised vs Unsupervised While supervised methods were reported to perform better than unsupervised ones, this is not always the case. As a baseline, we measured the "vanilla" cosine similarity of x and y, tuning a threshold with the validation set. This unsupervised symmetric method outperforms all supervised methods in 2 out of 5 datasets (Table 3).

Ignoring x's Information We compared the performance of **only y** to that of the best configuration in each dataset (Table 3). In 4 out of 5 datasets, the difference in performance is less than 5 points. This means that the classifiers are *ignoring* most of the information in x. Furthermore, they might be overlooking the compatibility (or incompatibility) of x to y. Weeds et al. (2014) reported a similar result, but did not address the fundamental question it beckons: if the classifier *cannot* capture a relation between x and y, then what is it learning?

4 Prototypical Hypernyms

We hypothesize that the supervised methods examined in this paper are learning whether y is a likely "category" word – a *prototypical hypernym* – and, to a lesser extent, whether x is a likely "instance" word. This hypothesis is consistent with our previous observations (§3).

Though the terms "instance" and "category" pertain to hypernymy, we use them here in the broader sense of entailment, i.e. as "tends to entail" and "tends to be entailed", respectively. We later show (§4.2) that this phenomenon indeed extends to other inference relations, such as meronymy.

4.1 Testing the Hypothesis

To test our hypothesis, we measure the performance of a trained classifier on *mismatched* instance-

Dataset	Top Positional Contexts of y

Bless 2011	other$_{-1}$, resembling$_{+1}$, such$_{+1}$, assemblages$_{+1}$, magical$_{-1}$, species$_{+1}$, any$_{-2}$, invertebrate$_{-1}$
Baroni 2012	any$_{-1}$, any$_{-2}$, social$_{-1}$, every$_{-1}$, this$_{-1}$, kinds$_{-2}$, exotic$_{-1}$, magical$_{-1}$, institute$_{-2}$, important$_{-1}$
Turney 2014	of$_{+1}$, inner$_{-1}$, including$_{+1}$, such$_{+1}$, considerable$_{-1}$, their$_{-1}$, extra$_{-1}$, types$_{-2}$, different$_{-1}$, other$_{-1}$
Levy 2014	psychosomatic$_{-1}$, unidentified$_{-1}$, auto-immune$_{+2}$, specific$_{-1}$, unspecified$_{-1}$, treatable$_{-2}$, any$_{-1}$

Table 4: Top positional features learned with logistic regression over **concat**. Displaying positive features of y.

category pairs, e.g. $(banana, animal)$. For each dataset, we generate a set of such synthetic examples S, by taking the positive examples from the test portion T^+, and extracting all of its instance words T_x^+ and category words T_y^+.

$$T_x^+ = \{x|(x,y) \in T^+\} \quad T_y^+ = \{y|(x,y) \in T^+\}$$

We then define S as all the in-place combinations of instance-category word pairs that did not appear in T^+, and are therefore likely to be false.

$$S = \left(T_x^+ \times T_y^+\right) \setminus T^+$$

Finally, we test the classifier on a sample of S (due to its size). Since all examples are assumed to be false, we measure the false positive rate as *match error* – the error of classifying a mismatching instance-category pair as positive.

According to our hypothesis, the classifier cannot differentiate between matched and mismatched examples (T^+ and S, respectively). We therefore expect it to classify a similar proportion of T^+ and S as positive. We validate this by comparing *recall* (proportion of T^+ classified as positive) to *match error* (proportion of S classified as positive). Figure 1 plots these two measures across all configurations and datasets, and finds them to be extremely close (regression curve: $match\ error = 0.935 \cdot recall$), thus confirming our hypothesis.

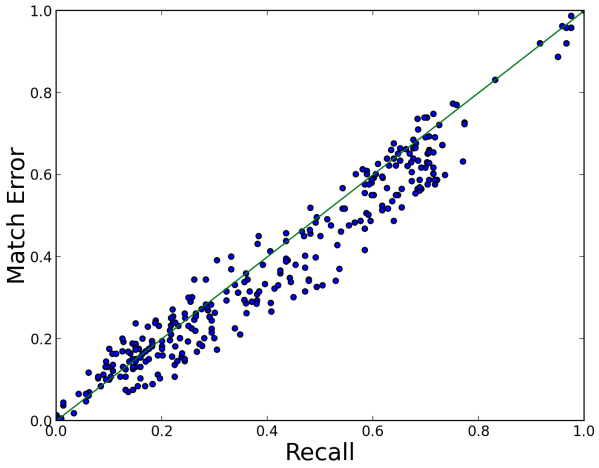

Figure 1: The correlation of recall (positive rate on T^+) with match error (positive rate on S) compared to perfect correlation (green line).

4.2 Prototypical Hypernym Features

A qualitative way of analyzing our hypothesis is to look at which features the classifiers tend to consider. Since SVD and SGNS features are not easily interpretable, we used PPMI with positional contexts as our representation, and trained a logistic regression model with L_1 regularization using **concat** over the entire dataset (no splits). We then observed the features with the highest weights (Table 4).

Many of these features describe dataset-specific category words. For example, in Levy's medical-domain dataset, many words entail "symptom", which is captured by the discriminative feature $psychosomatic_{-1}$. Other features are domain-independent indicators of category, e.g. any_{-1}, $every_{-1}$, and $kinds_{-2}$. The most striking features, though, are those that occur in Hearst (1992) patterns: $other_{-1}$, $such_{+1}$, $including_{+1}$, etc. These features appear in all datasets, and their analogues are often observed for x (e.g. $such_{-2}$). Even qualitatively, many of the dominant features capture prototypical or dataset-specific hypernyms.

As mentioned, the datasets examined in this work also contain inference relations other than hypernymy. In Turney's dataset, for example, 77 % of positive pairs are non-hypernyms, and y is often a quality ($coat \rightarrow warmth$) or a component ($chair \rightarrow legs$) of x. Qualities and components can often be detected via possessives, e.g. of_{+1} and $their_{-1}$. Other prominent features, such as $extra_{-1}$

and $exotic_{-1}$, may also indicate qualities. These examples suggest that our hypothesis extends beyond hypernymy to other inference relations as well.

5 Analysis of Vector Composition

Our empirical findings show that **concat** and **diff** are clearly ignoring the relation between x and y. To understand why, we analyze these compositions in the setting of a linear SVM. Given a test example, (x, y) and a training example that is part of the SVM's support (x_s, y_s), the linear kernel function yields Equations (1) for **concat** and (2) for **diff**.

$$K\left(\vec{x} \oplus \vec{y}, \vec{x_s} \oplus \vec{y_s}\right) = \vec{x} \cdot \vec{x_s} + \vec{y} \cdot \vec{y_s} \quad (1)$$

$$K\left(\vec{y} - \vec{x}, \vec{y_s} - \vec{x_s}\right) = \vec{x} \cdot \vec{x_s} + \vec{y} \cdot \vec{y_s} - \vec{x} \cdot \vec{y_s} - \vec{y} \cdot \vec{x_s} \quad (2)$$

Assuming all vectors are normalized (as in our experiments), the kernel function of **concat** is actually the similarity of the x-words plus the similarity of the y-words. Two dis-similarity terms are added to **diff**'s kernel, preventing the x of one pair from being too similar to the other pair's y (and vice versa).

Notice the absence of the term $\vec{x} \cdot \vec{y}$. This means that the classifier has no way of knowing if x and y are even related, let alone entailing. This flaw makes the classifier believe that any instance-category pair (x, y) is in an entailment relation, even if they are unrelated, as seen in §4. Polynomial kernels also lack $\vec{x} \cdot \vec{y}$, and thus suffer from the same flaw.

6 Adding Intra-Pair Similarity

Using an RBF kernel with **diff** slightly mitigates this issue, as it factors in $\vec{x} \cdot \vec{y}$, among other similarities:

$$K_{RBF}\left(\vec{y} - \vec{x}, \vec{y_s} - \vec{x_s}\right) = e^{-\frac{1}{\sigma^2}|(\vec{y}-\vec{x})-(\vec{y_s}-\vec{x_s})|^2}$$
$$= e^{-\frac{1}{\sigma^2}(\vec{x}\vec{y}+\vec{x_s}\vec{y_s}+\vec{x}\vec{x_s}+\vec{y}\vec{y_s}-\vec{x}\vec{y_s}-\vec{y}\vec{x_s}-2)} \quad (3)$$

A more direct approach of incorporating $\vec{x} \cdot \vec{y}$ is to create a new kernel, which balances intra-pair similarities with inter-pair ones:

$$K_{SIM}\left((\vec{x}, \vec{y}), (\vec{x_s}, \vec{y_s})\right) = \left(\vec{x}\vec{y} \cdot \vec{x_s}\vec{y_s}\right)^{\frac{\alpha}{2}} \left(\vec{x}\vec{x_s} \cdot \vec{y}\vec{y_s}\right)^{\frac{1-\alpha}{2}} \quad (4)$$

While these methods reduce match error – $match\ error = 0.618 \cdot recall$ versus the previous regression curve of $match\ error = 0.935 \cdot recall$ – their overall performance is only incrementally better than that of linear methods (Table 5). This improvement is also, partially, a result of the non-linearity introduced in these kernels.

Dataset	LIN(concat)	LIN(diff)	RBF(diff)	SIM
Kotlerman 2010	.367	.187	**.407**	.332
Bless 2011	.634	.665	.636	**.687**
Baroni 2012	.745	.769	.848	**.859**
Turney 2014	**.696**	.694	.691	.641
Levy 2014	.229	.219	**.252**	.244

Table 5: Performance (F_1) of SVM across kernels. **LIN** refers to the linear kernel (equations (1) and (2)), **RBF** to the Gaussian kernel (equation (3)), and **SIM** to our new kernel (equation (4)). Uses lexical train/test splits.

7 The Limitations of Contextual Features

In this work, we showed that state-of-the-art supervised methods for recognizing lexical inference appear to be learning whether y is a prototypical hypernym, regardless of its relation with x. We tried to factor in the similarity between x and y, yet observed only marginal improvements. While more sophisticated methods might be able to extract the necessary relational information from contextual features alone, it is also possible that this information simply *does not exist* in those features.

A (de)motivating example can be seen in §4.2. A typical y often has $such_{+1}$ as a dominant feature, whereas x tends to appear with $such_{-2}$. These features are relics of the Hearst (1992) pattern "y such as x". However, contextual features of single words cannot capture the *joint* occurrence of x and y in that pattern; instead, they record only this observation as two independent features of different words. In that sense, contextual features are inherently handicapped in capturing relational information, requiring supervised methods to harness complementary information from more sophisticated features, such as textual patterns that connect x with y (Snow et al., 2005; Turney, 2006).

Abstract

This paper presents the first attempt to use word embeddings to predict the compositionality of multiword expressions. We consider both single- and multi-prototype word embeddings. Experimental results show that, in combination with a back-off method based on string similarity, word embeddings outperform a method using count-based distributional similarity. Our best results are competitive with, or superior to, state-of-the-art methods over three standard compositionality datasets, which include two types of multiword expressions and two languages.

1 Introduction

Multiword expressions (MWEs) are word combinations that display some form of idiomaticity (Baldwin and Kim, 2009), including semantic idiomaticity, wherein the semantics of the MWE (e.g. *ivory tower*) cannot be predicted from the semantics of the component words (e.g. *ivory* and *tower*). Recent NLP work on semantic idiomaticity has focused on the task of "compositionality prediction", in the form of a regression task whereby a given MWE is mapped onto a continuous-valued compositionality score, either for the MWE as a whole or for each of its component words (Reddy et al., 2011; Schulte im Walde et al., 2013; Salehi et al., 2014b).

Separately in NLP, there has been a recent surge of interest in learning distributed representations of word meaning, in the form of "word embeddings" (Collobert and Weston, 2008; Mikolov et al., 2013a) and composition over distributed representations (Socher et al., 2012; Baroni et al., 2014).

This paper is the first attempt to bring together the work on word embedding-style distributional analysis with compositionality prediction of MWEs. In the context of compositionality prediction, our primary research questions here are:

RQ1: Are word embeddings superior to conventional count-based models of distributional similarity?
RQ2: How sensitive to parameter optimisation are different word embedding approaches?
RQ3: Are multi-prototype word embeddings empirically superior to single-prototype word embeddings?

We explore these questions relative to three compositionality prediction datasets spanning two MWE construction types (noun compounds and verb particle constructions) and two languages (English and German), and arrive at the following conclusions: (1) consistent with recent work over other NLP tasks, word embeddings are superior to count–based models of distributional similarity (and also translation-based string similarity); (2) the results are relatively stable under parameter optimisation for a given word embedding learning approach; and (3) based on two simple approaches to composition, single word embeddings are empirically slightly superior to multi-prototype word embeddings overall.

2 Related Work

Recent work on distributed approaches to distributional semantics has demonstrated their utility in a wide range of NLP tasks, including identifying various morphosyntactic and semantic relations (Mikolov et al., 2013a), dependency parsing (Bansal et al., 2014), sentiment analysis (Socher et al., 2013), named-entity recognition (Collobert and Weston, 2008; Passos et al., 2014), and machine translation (Zou et al., 2013; Devlin et al., 2014). Despite the wealth of research applying word embeddings within NLP, they have not yet been considered for predicting the compositionality of MWEs.

Much prior work on MWEs has been tailored to specific kinds of MWEs in particular languages (e.g. English verb–noun combinations (Fazly et al., 2009)). There has however been recent interest in approaches to MWEs that are more broadly applicable to a wider range of languages and MWE types (Brooke et al., 2014; Salehi et al., 2014b; Schneider et al., 2014). Word embeddings could form the basis for such an approach to predicting MWE compositionality.

3 Methodology

In this work, we estimate the compositionality of an MWE based on the similarity between the expression and its component words in vector space. We use three different vector-space models: (1) a simple count-based model of distributional similarity; (2) word embeddings based on WORD2VEC; and (3) a multi-sense skip-gram model that, unlike the previous two models, is able to learn multiple embeddings per target word (or MWE). For all three models, we first greedily pre-tokenise the corpus to represent each MWE as a single token, similarly to Baldwin et al. (2003). In this, we apply the constraint that no language-specific pre-processing can be applied to the training corpus, in order to make the method maximally language independent. As such, we cannot perform any form of lemmatisation, and MWE identification takes the form of simple string match for concatenated instances of the component words, naively assuming that all occurrences of that word combination are MWEs. We detail each of the distributional similarity methods below.

3.1 Count-Based Distributional Similarity

Our first method for building vectors is that of Salehi et al. (2014b): the top 50 most-frequent words in the training corpus are considered to be stopwords and discarded, and words with frequency rank 51–1051 are considered to be the content-bearing words, which form the dimensions for our vectors, in the manner of Schütze (1997). To measure the similarity of the MWE vector and the component word vectors, we considered two different approaches.

The first approach is based on Reddy et al. (2011) and Schulte im Walde et al. (2013). The similarity between the MWE and each of its components is measured, and the overall compositionality of the MWE is computed by combining the similarity scores for the two components as follows:

$$comp_1(\mathbf{MWE}) = \alpha sim(\mathbf{MWE}, \mathbf{C}_1) + (1-\alpha) sim(\mathbf{MWE}, \mathbf{C}_2)$$

where $\mathbf{MWE}$ is the vector associated with the MWE, $\mathbf{C}_i$ is the vector associated with the ith component word of the MWE, sim is a vector similarity function, and $\alpha \in [0, 1]$ is a weight parameter.

We also experimented with the approach from Mitchell and Lapata (2010), where $\mathbf{MWE}$ is compared directly with a composed vector of the component words, based on vector addition:[1]

$$comp_2(\mathbf{MWE}) = sim(\mathbf{MWE}, \mathbf{C}_1 + \mathbf{C}_2)$$

For both $comp_1$ and $comp_2$, we used cosine similarity as our similarity measure sim.

3.2 WORD2VEC

Our second method is based on the recurrent neural network language model (RNNLM) approach to learning word embeddings of Mikolov et al. (2013a) and Mikolov et al. (2013b), using the WORD2VEC package.[2] WORD2VEC uses a log-linear model inspired by the original RNNLM approach of Mikolov et al. (2010), in two forms: (1) a continuous bag-of-words ("CBOW") model, whereby all words in a context window are averaged in a single projection layer; and (2) a continuous skip-gram model

[1] We also experimented with vector multiplication, but found it to perform poorly compared to the other approaches.

[2] https://code.google.com/p/word2vec/

("C-SKIP"), whereby a given word in context is projected onto a projection layer, and used to predict its immediate context (preceding and following words). WORD2VEC generates a vector of fixed dimensionality d for each pre-tokenised word/MWE type with frequency above a certain threshold in the training corpus. We again use $comp_1$ and $comp_2$ to estimate compositionality from these vectors.

3.3 Multi-Sense Skip-gram Model

One potential shortcoming of WORD2VEC is that it generates a single word embedding for each word, irrespective of the relative polysemy of the word. Neelakantan et al. (2014) proposed a method motivated by WORD2VEC, which efficiently learns multiple embeddings per word/MWE. We refer to this approach as the multi-sense skip-gram (MSSG) model. We once again compose the resultant vectors with $comp_1$ and $comp_2$, but modify the formulation slightly to handle the variable number of vectors for each word/MWE, by searching over the cross-product of vectors in each sim calculation and taking the maximum in each case. We initially set the number of embeddings to 2 in our MSSG experiments — in keeping with the findings in Neelakantan et al. (2014) — but come back to examine the impact of the number of embeddings on compositionality prediction in Section 5.

4 Datasets

We evaluate our methods over three datasets:[3] (1) English noun compounds ("ENCs", e.g. *spelling bee* and *swimming pool*); (2) English verb particle constructions ("EVPCs", e.g. *stand up* and *give away*); and (3) German noun compounds ("GNCs", e.g. *ahornblatt* "maple leaf" and *eidechse* "lizard").

The ENC dataset consists of 90 binary English noun compounds, and is annotated on a continuous $[0, 5]$ scale for both overall compositionality and the component-wise compositionality of each of the modifier and head noun (Reddy et al., 2011). The state-of-the-art method for this dataset (Salehi et al., 2014b) is a supervised support vector regression model, trained over the distributional method from Section 3.1 as applied to both English and 51 target languages (under word and MWE translation).

The EVPC dataset consists of 160 English verb particle constructions, and is manually annotated for compositionality on a binary scale for each of the head verb and particle (Bannard, 2006). In order to translate the dataset into a regression task, we calculate the overall compositionality as the number of annotations of entailment for the verb, divided by the total number of verb annotations for that VPC. The state-of-the-art method for this dataset (Salehi et al., 2014b) is a linear combination of: (1) the distributional method from Section 3.1; (2) the same method applied to 10 target languages (under word and MWE translation, selecting the languages using supervised learning); and (3) the string similarity method of Salehi and Cook (2013).

The GNC dataset consists of 246 German noun compounds, and is annotated on a continuous $[1, 7]$ scale (von der Heide and Borgwaldt, 2009; Schulte im Walde et al., 2013). The state-of-the-art method for this dataset is a distributional similarity method applied to part-of-speech tagged and lemmatised data (Schulte im Walde et al., 2013).

5 Experiments

For all experiments, we train our models over raw text Wikipedia corpora for either English or German, depending on the language of the dataset. The raw English and German corpora were preprocessed using the WP2TXT toolbox[4] to eliminate XML and HTML tags and hyperlinks, and punctuation was removed. Finally, word-tokenisation was performed based on simple whitespace delimitation, after which we greedily identified all string occurrences of the MWEs in each of our datasets and combined them into a single token.[5]

The word embedding approaches are unable to generate vector representations for tokens which occur with frequency below a fixed cutoff.[6] In order to

[3] We also considered using the dataset from the DisCo shared task (Biemann and Giesbrecht, 2011), but ultimately excluded it because it includes different types of MWEs without indication of the syntactic type of a given MWE, preventing us from carrying out construction-specific parameter tuning.

[4] http://wp2txt.rubyforge.org/

[5] For English, a single model was trained over a corpus containing both ENC and EVPC tokens.

[6] For a frequency threshold of 15, the total numbers of ENCs, EVPCs and GNCs for which we were unable to generate word embeddings were 3, 0 and 25, respectively, in the latter case, largely as a result of our simple tokenisation strategy and

Table 1: Pearson's correlation (r) for the different methods over the three datasets; the state-of-the-art for each dataset is described in Section 4

generate a compositionality prediction back-off for the small numbers of MWEs in this category, we assign a default value, which is the mean of computed compositionality scores for other instances.[7]

As a baseline, we use the translation string similarity approach of Salehi and Cook (2013), including the cross-validation-based method for selecting the 10 best languages to use for each dataset. We further include a linear combination of the string similarity method with each of the various approaches based on word embeddings.

Table 1 shows the results for the various methods, over a range of hyper-parameter settings for each of WORD2VEC (vector dimensionality d; we also present results for CBOW vs. C-SKIP) and MSSG (vector dimensionality d and window size w), informed by the experimental results in the respective publications. Note that for EVPC, we don't use the vector for the particle, in keeping with Salehi et al. (2014b); as such, there are no results for $comp_2$. For $comp_1$, α is set to 1.0 for EVPC, and 0.7 for both ENC and GNC, also based on the findings of Salehi et al. (2014b).

The results indicate that the approaches using both WORD2VEC and MSSG outperform simple distributional and string similarity by a substantial margin. Further, over a variety of parameteriza-

lack of lemmatisation.

[7]We also experimented with using the string similarity approach as a back-off, which resulted in marginally lower results than what is reported in Table 1.

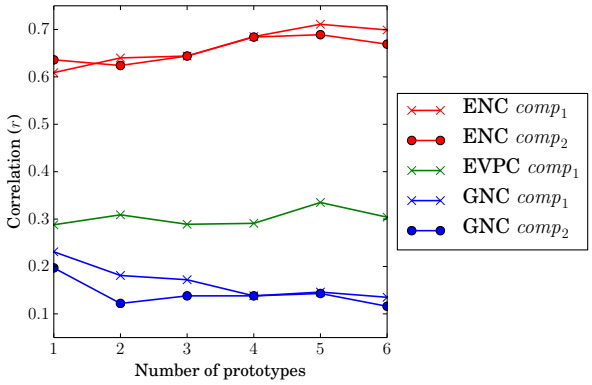

Figure 1: The effect of the number of prototypes on the results with MSSG

tions, they surpass the state-of-the-art methods for ENC and EVPC; in the case of GNC, the best-performing method (WORD2VEC with $d = 500$ and C-SKIP) roughly matches the state-of-the-art. Note that in each case, the state-of-the-art is achieved using varying levels of supervision over labelled data (ENC and EVPC) or language-specific pre-processing (GNC), whereas the word embedding methods use no labelled data. As such, the answer to RQ1 would appear to be a resounding yes.

Looking to RQ2, the models are remarkably insensitive to hyper-parameter optimisation for EVPC, but there are slight deviations in the results for ENC and GNC. Having said that, they are largely between the different word embedding approaches, and the results for a given approach under different parameter settings is relatively stable. A large part of the cause of the drop in results and greater parameter sensitivity over GNC is the lower token frequencies, through a combination of the Wikipedia corpus being markedly smaller and our naive tokenisation strategy having low recall over German due to the richer morphology. As such, the answer would appear to be a tentative "relatively insensitive, assuming high token frequencies".

Finally, looking to RQ3, there was little separating WORD2VEC and MSSG over ENC, but over the other two datasets, WORD2VEC had a clear advantage. Given the high levels of polysemy observed in high frequency English verb particle constructions (Salehi et al., 2014a), this result for EVPC was particularly surprising, and suggests that, at least under our two basic forms of composition, multi-prototype word embeddings are at best equal to, and in many cases, inferior to, single-prototype word embeddings.

According to the results, the string similarity approach complements all word-embedding approaches. We hypothesise that this is because it is not based on any corpus, and is thus not biased by the frequency of token instances in the corpus.

In Table 1, the number of embeddings for MSSG was set to 2 prototypes, based on the default recommendations of Neelakantan et al. (2014). To investigate the impact of this parameter on our results, we retrained MSSG over the range $[1, 6]$ and reran our experiments for each set of embeddings over the three datasets (without string similarity, to isolate the effect of the number of embeddings), as shown in Figure 1. For both English datasets (ENC and EVPC), setting the number of prototypes to a value higher than 2 boosts the results slightly, with 5 prototypes appearing to be the optimal value. For the German dataset (GNC), on the other hand, the best results are actually achieved for a single prototype. Further research is required to better understand this effect.

6 Conclusions

We presented the first approach to using word embeddings to predict the compositionality of MWEs. We showed that this approach, in combination with information from string similarity, surpassed, or was competitive with, the current state-of-the-art on three compositionality datasets. In future work we intend to explore the contribution of information from word embeddings of a target expression and its component words under translation into many languages, along the lines of Salehi et al. (2014b).
