Message from the Program Chairs

Hi, Welcome to the 2024 Annual Conference of the North American Association for Computational Linguistics! NAACL 2024 is a hybrid conference, and we are excited to have attendees and presenters join us both in person in Mexico City and online from all over the world. We are especially thrilled to hold the conference in Mexico City, which was originally planned for NAACL 2021 before COVID-19 required the transition to a virtual meeting. This will be the first NAACL conference in Latin America, and we hope this will contribute to a tradition of broadening access and participation in the greater region.

Special Theme: Languages of Latin America Languages are the heart and soul of cultural identity and communication, and nowhere is this more evident than in the vibrant tapestry of Latin America and the Caribbean. With a rich linguistic diversity that spans Spanish, Portuguese, and numerous indigenous languages, the region offers a unique challenge and opportunity for natural language processing researchers. For NAACL 2024, we invited submissions to the special theme track on "Languages of Latin America". This track was dedicated to taking stock of past research and developments in the field of natural language processing for languages of Latin America and the Caribbean while charting the course for future investigations. We received 19 submissions to the special theme, of which 10 have been accepted to appear at the conference.

Review Process NAACL 2024 implemented a two stage review process, where submissions were first sent to ACL Rolling Review (ARR) for reviews by reviewers and for meta-reviews by area chairs, and then sent to a separate NAACL 2024 commitment site for recommendations by senior area chairs and final acceptance decisions by program chairs.

For the ARR submission part of the process, NAACL program chairs coordinated with EACL 2024 and ACL 2024 program chairs to ensure a smooth revise-and-resubmit cycle across the three conferences. We also coordinated across conferences to recruit thousands of new reviewers and hundreds of new area chairs to ARR, resulting in 7344 reviewers and 870 ACs in the 2023 December ARR cycle to which most NAACL 2024 papers were submitted. Overall, the ARR process went mostly smoothly, successfully delivering three reviews and a meta-review for all 2604 papers submitted. Several of the suggestions that NAACL 2024 program chairs collected for improving the process (e.g., better OpenReview integration of the responsible NLP checklist) have already been adopted by ARR for future cycles.

For the NAACL commitment part of the process, NAACL program chairs recruited 73 senior area chairs for the 25 research areas defined by ARR. Senior area chairs made acceptance recommendations for 1140 committed papers based on the papers, reviews, and meta-reviews, and program chairs finalized the recommendations into acceptance decisions.

Acceptance Rate The acceptance rate calculation follows precedent set by previous conferences that also go through ARR, e.g. NAACL 2022, EACL 2024. The calculation takes into account the multi-stage process of ARR where a paper may get revised in ARR and then later committed to the conference. The denominator includes:

- Papers in the ARR December 2023 cycle that selected NAACL as a preferred venue.
- Papers in the ARR December 2023 cycle that did not select any conference as a preferred venue.
- Papers in the ARR December 2023 cycle that selected another conference, but then committed to NAACL 2024.
- Papers in the ARR cycles before December 2023 that committed to NAACL 2024.

In total, we had 2604 submissions in the ARR December 2023 cycle. Among these, 29 were withdrawn before reviews were released and 115 were desk-rejected. Of the remaining, 2328 had either an unspecified venue or included NAACL as the desired venue. Further, 17 out of the 132 submissions that selected other venues were committed to NAACL. Finally, an additional 89 papers from other cycles were committed. So in total, the denominator for acceptance rate calculation is 2328 + 17 + 89 = 2434. Among these, 1140 papers were officially committed to NAACL, and 565 were accepted. The acceptance rate for Main Conference papers is therefore: 565 / 2434 = 23.2

Findings papers are those which are not accepted at the Main Conference, but nevertheless have been judged worthy of publication as solid work with sufficient substance, quality and novelty. The next 304 / 2434 = 12.5

Presentation Format At NAACL 2024, we aimed to set all main conference papers on equal ground. All presenters were allowed the same 13 minute video recording on the virtual site, regardless of whether a paper was long or short, whether the presenter decided to attend in-person or virtually, and whether the paper was assigned an oral presentation or a poster presentation.

To ensure there was no prestige associated with getting to present in oral vs. poster format, we tried a new approach to presentation decisions: we assigned them randomly. Specifically, we calculated the counts of papers across research areas, took the square roots of the counts to slightly upweight smaller areas, converted the counts to a distribution, and then randomly sampled 130 orals from the research areas according to the distribution (sampling in blocks of 5 to match the duration of oral sessions at the conference).

Program Format At NAACL 2024, we aimed to improve both the in-person and virtual experiences. For this, we are implemented the following two actions:

- A pre-conference virtual poster session was scheduled for Thursday, June 13, 2024, avoiding conflicts with the conference's in-person sessions, and including different sessions to accommodate various time zones. The goal of this move was to encourage all attendees, both virtual and in-person, to join the virtual poster session.
- Oral presentations were given only to in-person attendees. (Oral presentations were still set to be live-streamed for all virtual attendees). The goal of this move was to avoid Zoom fatigue and encourage more in-person engagement with oral presenters.

The program includes live (and live-streamed) keynotes, plenaries, and panels, more than 100 live (and live-streamed) oral presentations, more than 400 live poster presentations, and more than 200 virtual poster presentations at the pre-conference event. The keynotes cover exciting topics including large language models and indigenous languages (Claudio Pinhanez, IBM Research Brazil) and large language models and neuroscience (Seana Coulson, UCSD), while the panel addresses the important issue of large language models and their impact on education (Victoria Yaneva, National Board of Medical Examiners; Swapna Somasundaran, Educational Testing Service; Karen Matías, Universidad Nacional Autónoma de México; and Ekaterina Kochmar, Mohamed Bin Zayed University of Artificial Intelligence). Other plenaries include the NAACL business meeting and the best paper awards session. The program is rounded out with dedicated sessions during the main conference for industry track, demonstrations track, student research workshop, NAACL Findings papers, and TACL/CL accepted papers.

Gratitude Conference organization is a team effort. We are very grateful for the support and contributions of many people, including:

- The General Chair, Katrin Erk

- The ARR Editors-in-Chief of the Dec 2023 cycle (Mausam, Vincent Ng) and the entire team (Viviane Moreira, Thamar Solorio, Lilja Øvrelid, Jun Suzuki, Jonathan Kummerfield)
- The OpenReview team, especially Harold Rubio
- The 73 Senior Area Chairs
- The 870 Area Chairs and 7344 Reviewers
- The best paper committee chairs, Isabelle Augenstein and Manuel Montes y Gómez
- The ethics chairs (Cecilia Alm, Diana Galvan Sosa, Anjalie Field, Ameeta Agrawal, Daniel Fried, Mark Yatskar, Maria Antoniak, Alane Suhr) and their team of reviewers
- The website chairs, Vered Shwartz and Xinya Du
- The publication chairs, Ryan Cotterell, Maarten Sap, and Lifu Huang, and their team of student helpers
- The publicity chairs, Ximena Gutierrez-Vasques, Samuel Gonzalez-Lopez, and Najoung Kim
- The local chair, Hiram Calvo
- The volunteers chairs, Lucy Lu Wang and Liang Huang
- The ACL Anthology Director, Matt Post, and his team
- The Program Chairs of EACL 2024 (Yvette Graham, Matthew Purver) and ACL 2024 (Lun-Wei Ku, Andre Martins, Vivek Srikumar)
- Damira Mršić and Underline Team
- Jenn Rachhford and entire conference support staff

Kevin Duh, Helena Gomez, and Steven Bethard
NAACL 2024 Program Committee Co-Chairs

Organizing Committee

General Chair

Katrin Erk, The University of Texas at Austin

Program Chairs

Kevin Duh, Johns Hopkins University
Helena Gomez, Universidad Nacional Autónoma de México
Steven Bethard, University of Arizona

Local Arrangements

Priscilla Rasmussen, ACL
Jennifer Rachford, ACL
Hiram Calvo, CIC-IPN

Industry Track Chairs

Avi Sil, IBM
Yi Yang, ASAPP
Anoop Kumar, Amazon
Aida Davani, Google

Tutorial Chairs

Rui Zhang, Penn State University
Nathan Schneider, Georgetown University
Snigdha Chaturvedi, UNC-Chapel Hill

Demo Chairs

Nazneen Rajani, Hugging Face
Kai-Wei Chang, UCLA
Annie Lee, University of Toronto

Workshops Chairs

Niranjan Balasubramanian, Stony Brook University
Malihe Alikhani, Northeastern University
Alexis Palmer, University of Colorado Boulder

Student Research Workshop Chairs

Yang (Trista) Cao, University of Maryland
Isabel Papadimitriou, Stanford University
Anaelia Ovalle, UCLA

Abstract

Large language models (LLMs) have demonstrated powerful capabilities in natural language processing, yet their vast number of parameters poses challenges for deployment and inference efficiency. Structured model pruning emerges as a viable approach to reduce model size and accelerate inference, without requiring specialized operators and libraries for deployment. However, structured pruning often severely weakens the model's capability. Despite repetitive fine-tuning can restore the capability to a certain extent, it impairs LLMs' utility as versatile problem solvers. To address this issue, we propose a novel structured pruning algorithm tailored for LLMs. It derives the importance of different components, namely rows and columns in parameter matrices, based on intermediate data dependencies. Then it removes coupled components across different layers simultaneously and preserves dependency relationships within remaining parameters, avoiding significant performance degradation. The pruned model requires only few epochs of fine-tuning to restore its performance, ensuring the model's ability to generalize. Empirical evaluations on LLaMA, Vicuna, and ChatGLM3 demonstrate our algorithm's efficacy, yielding 20% parameter reduction while retaining at least 94.4% of original performance metrics.

1 Introduction

Large language models (LLMs) have demonstrated powerful capabilities in solving a variety of general problems (OpenAI, 2023; Xue et al., 2020), particularly in language understanding and generating. However, the large number of parameters (Radford et al., 2018, 2019; Brown et al., 2020) in LLMs poses significant challenges for deployment and inference efficiency. Structured pruning (Wang et al., 2019; Xia et al., 2022; Zafrir et al., 2021) has been proved to be a viable approach to compress deep neural networks. It removes entire structural components of the neural network, without requiring specialized operators and libraries for executing the pruned model, so that it is convenient for deployment and acceleration.

Despite structured pruning algorithms have long been investigated (Lagunas et al., 2021; He et al., 2020; Kurtic et al., 2022), they face new challenges when tackling LLMs. Existing state-of-the-art pruning algorithms follow an iterative scheme (Han et al., 2015a; Louizos et al., 2017; Xia et al., 2022; Zafrir et al., 2021) for specific tasks. This scheme conducts iterative **evaluating, pruning and fine-tuning** on a large model for a single task, achieving low performance degradation. However, due to the repetitive fine-tuning on a single task, the pruned model has much less generalization ability on other tasks. This is a particularly serious issue for LLMs, since they are expected to be general-purpose models solving extensive problems. Simply extending the fine-tuning on more corpus and tasks to reserve the generalization ability is still challenging (Ma et al., 2023), because LLMs require huge volume of training corpus.

In this study, we propose a novel structured pruning algorithm tailored for LLMs. In contrast to existing iterative pruning works, our algorithm first conducts iterative **evaluating and pruning**, until the desired sparsity level is achieved. After completing all the iterations of evaluating and pruning, it then conducts one stage of **fine-tuning**, which involves few epochs of training on a small dataset. The intuition of our algorithm is to limit the fine-tuning operations as few as possible, so that the pruned model will not import too much bias towards specific tasks.

To ensure that the remaining parameters are consistently important and do not need repetitive fine-tuning to restore performance, we need to precisely evaluate the importance of structured components, namely rows and columns in parameter matrices.

Findings of the Association for Computational Linguistics: NAACL 2024, pages 1–12
June 16-21, 2024

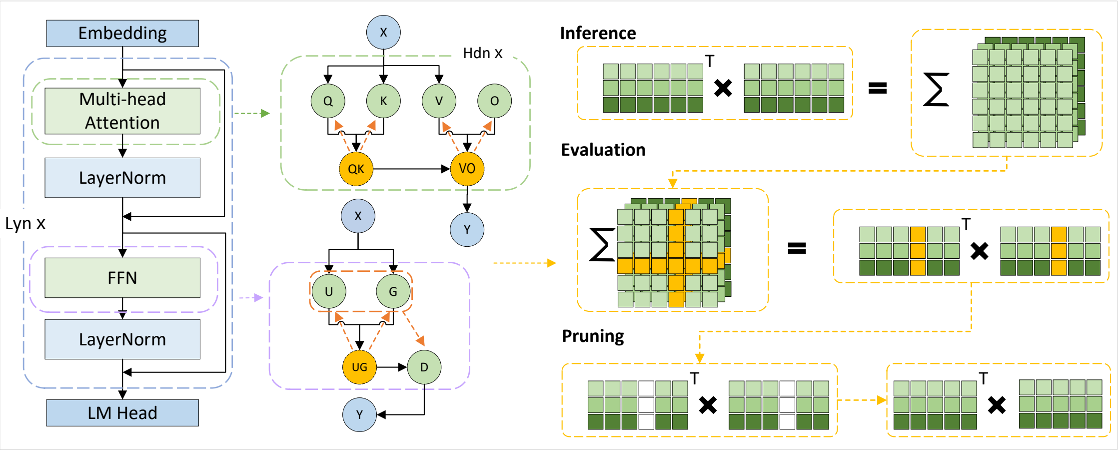

Figure 1: During the pruning process, we determine whether a component should be pruned according to the inference error caused by removing the component and its coupled components from intermediate results.

More concretely, our algorithm derives the importance and uncertainty of different components based on intermediate data dependencies, as shown in Figure (1). According to the Transformer-based model architecture, we can identify the coupled components that have data dependency on pruned components. These coupled components across different layers can be removed simultaneously, and the dependency relationships within remaining parameters can be still preserved, avoiding significant performance degradation. Moreover, we employ LoRA (Hu et al., 2022) fine-tuning to restore model performance, and use LoRA gradients (Zhang et al., 2023) instead of full-scale fine-tuning gradients to reduce the computational overhead during pruning. The model pruned by our algorithm preserves the original architecture with smaller parameter matrices, thus it is compatible to any other Transformer-specific optimization techniques, e.g, FlashAttention (Dao et al., 2022; Dao, 2023). We have validated our algorithm on LLaMA (Touvron et al., 2023), Vicuna (Chiang et al., 2023), and ChatGLM3 (Zeng et al., 2022; Du et al., 2022), achieving about 20% parameter reduction while retaining at least 94.4% of original performance metrics.

Contribution. In this paper, (i) we propose a new structured pruning algorithm for LLMs that uses minimal fine-tuning to recover model performance. The algorithm effectively reduces the number of parameters while maintaining model generalization. (ii) We propose a novel evaluation method that evaluates the impact of structured pruning on an LLM by evaluating coupled components instead of individual weights. (iii) We conduct our algorithm on representative LLMs, including LLaMA, Vicuna, and ChatGLM3. By reducing the parameter count by 20%, we maintain at least 94.4% of the model's performance while reducing MACs by 20%.

2 Related Work

2.1 Iterative Pruning

Iterative pruning is a type of algorithm that iteratively evaluates, prunes, and fine-tunes a neural network model. The process involves calculating scores for each weight in the model based on specific criteria, pruning weights with lower scores, and fine-tuning the pruned model on a dataset. PLATON (Zhang et al., 2022a) is a typical iterative pruning method for BERT (Devlin et al., 2019) and ViT (Dosovitskiy et al., 2020). It considers the sensitivity and uncertainty of different model components during evaluation, improving the accuracy of the evaluation process. Although iterative pruning has been proved to be effective for task-specific models, it faces difficulty for general-purpose LLMs due to the repeated fine-tuning.

2.2 LoRA

LoRA is an efficient fine-tuning algorithm for LLMs. Due to the large size of the parameter matrices in LLMs, the computational cost of full fine-tuning is often prohibitively high. In LoRA fine-tuning, a data bypass is created for the target parameter W_0: $W = W_0 + BA$, where $W_0 \in \mathbb{R}^{n \times m}$, $B \in \mathbb{R}^{n \times r}$, $A \in \mathbb{R}^{r \times m}$, and $r \ll \min(n, m)$. Typically, the parameters in A are initialized with a random Gaussian distribution, and the parameters in B are set to 0. During the subsequent fine-tuning process, the parameters in W_0 are frozen, and only the parameters in A and B are fine-tuned. LLM-Pruner (Ma et al., 2023) is a structured pruning algorithm for LLMs. It combines efficient LoRA fine-tuning to recover the performance of the pruned model with fewer fine-tuning epochs. LoRAPrune (Zhang et al., 2023) is a non-structured pruning algorithm for LLMs. Due to the high cost of obtaining gradients in LLM, LoRAPrune leverages LoRA gradients instead of full fine-tuning gradients to reduce computational overhead.

3 Method

Our pruning consists of three steps. (i) Partitioning the model into kernels and features, and grouping the coupled components formed by kernels. (ii) Iteratively evaluating and pruning coupled components and features until the desired sparsity level is achieved. (iii) After all evaluating and pruning finish, a fine-tuning stage is conducted to restore the model performance.

3.1 Partition of Kernels and Features

In our algorithm, the pruning granularity is rows or columns in the parameter matrices. The functionality of a row or a column varies in different parameter matrices. For example, in the Transformer architecture, each word in a sentence is transformed into a word vector with d_m features, the parameter matrix $V \in \mathbb{R}^{d_m \times d_k}$ of the Transformer, each row encounters all the weights in the word vectors during computation. However, each column encounters only one weight in the word vector (Fang et al., 2023). Therefore, we divide them into kernels and features based on their functionalities in the inference computation. If a row (or column) receives all the features of the word vector, we refer to that row (or column) as a **kernel**. For example, each row in the $Q \in \mathbb{R}^{d_k \times d_m}$ of a single head, as well as each column in $O \in \mathbb{R}^{d_m \times d_k}$. If a row (or column) receives a specific feature of the word vector, we refer to it as a **feature**. For example, each row in O, or each column in $Up \in \mathbb{R}^{im \times d_m}$ in LLaMA's intermediate layers.

3.2 Evaluation of Importance

Evaluating coupled components. In the multi-head attention mechanism of Transformer, the computation of a single head can be represented by the following equation Eq. (1):

$$Attn = \text{Softmax}\left(\frac{X^t Q^t K X}{\sqrt{d_k}}\right) X^t V^t O^t, \tag{1}$$

where $Q, K, V \in \mathbb{R}^{d_k \times d_m}$ represent the Query, Key, and Value of a single head in the multi-head attention mechanism, respectively, and $O \in \mathbb{R}^{d_m \times d_k}$ represents the projection matrix used to receive the output of that attention head. $X \in \mathbb{R}^{d_m \times \text{len}}$ represents the sequence of word vectors, where len is the length of the vector sequence. We can observe that Q and K are coupled together, and V and O are coupled together in the equation. The effective parameters in the multi-head attention mechanism are $Q^t K$ and $V^t O^t$. Hence, when evaluating the coupled components of the self-attention layer, we group Q, K for evaluation, and V, O for another evaluation. For the evaluation of coupled components, we take Q and K as an example. We consider Q and K as a sum of multiple kernels, i.e., $Q = [q_1^t, q_2^t, ..., q_{d_k}^t]^t$, $K = [k_1^t, k_2^t, ..., k_{d_k}^t]^t$, where $Q, K \in \mathbb{R}^{d_k \times d_m}$, and $q_i, k_i (i \in [1, d_k])$ are row vectors of dimension d_m. In this case, we expand $Q^t K$ in Eq.(2):

$$Q^t K = \sum_{i=1}^{d_k} q_i^t k_i. \tag{2}$$

If we prune one q_i, we can observe that the corresponding k_i will no longer be effective in the inference process and should be pruned simultaneously. We have found the coupled component $q_i^t k_i$ generated by Q and K. The same applies to the grouping of $V^t O^t$, where the coupled components become $v_i^t o_i^t$. In the intermediate layers of the model, we can also find a similar relationship. In previous models such as BERT (Devlin et al., 2019), GPT-Neo (Black et al., 2022) and OPT (Zhang et al., 2022b), a two-layer structure was commonly used, which can be represented by the equation Eq.(3):

$$Out = fc_2 F(fc_1 X). \tag{3}$$

Here, $fc_1 \in \mathbb{R}^{im \times d_m}$ and $fc_2 \in \mathbb{R}^{d_m \times im}$. F represents the activation function. The partitioning method at this stage is the same as the partitioning for $Q^t K$. In the LLaMA and ChatGLM3, a three-layer structure was used in the intermediate layers, which can be represented by the equation Eq.(4):

$$Out = Down(F(Gate X) \odot Up X). \tag{4}$$

Here, $Gate, Up \in \mathbb{R}^{im \times d_m}$, and $Down \in \mathbb{R}^{d_m \times im}$. In the LLaMA model, we cannot directly partition the kernels in the three parameter matrices through computation. However, we can observe that when any kernel in any of these three matrices is zero, the corresponding kernels in the remaining two matrices will no longer be effective. Therefore, we approximate the coupled component (d_i, g_i, u_i) as two sub-components: $d_i g_i^t$ and $d_i u_i^t$, where d_i, g_i, u_i correspond to the kernels in $Down, Gate, Up$, respectively. During the scoring process, we use the sum of scores of the sub-components $d_i g_i^t$ and $d_i u_i^t$ to represent the score of the coupled component (d_i, g_i, u_i).

After grouping the kernels, these coupled components can be represented as the multiplication of a column vector α and a row vector β. We denote such coupled components as $C = \alpha\beta$, where $C \in \mathbb{R}^{d_m \times d_m}$. During the evaluation process, we evaluate the importance of the coupled component C by measuring the error in neural network prediction when removing this group of coupled components. This is defined as the importance I_C (Ma et al., 2023) and can be calculated as Eq.(5):

$$\begin{aligned} I_C &= \left| \sum_{c \in C} \mathcal{L}(c) - \mathcal{L}(c=0) \right| \\ &= \left| \sum_{c \in C} \frac{\partial \mathcal{L}}{\partial c} c - \frac{1}{2}\left(\frac{\partial^2 \mathcal{L}}{\partial c^2} c^2 \right) + \mathcal{O}(c^3) \right| . \end{aligned} \tag{5}$$

For the second-order error term $\left(\frac{\partial^2 \mathcal{L}}{\partial c^2} c^2\right)$, we approximate it as $\left(\frac{\partial \mathcal{L}}{\partial c} c\right)^2$ based on (Ma et al., 2023; Yang et al., 2023). Therefore, we have Eq.(6):

$$I_C \approx \left| \sum_{c \in C} \frac{\partial \mathcal{L}}{\partial c} c - \frac{1}{2}\left(\frac{\partial \mathcal{L}}{\partial c} c \right)^2 \right| . \tag{6}$$

Additionally, we refer to the evaluation method proposed by PLATON (Zhang et al., 2022a), which combines the sensitivity of the network to determine the final score for the coupled components. The scoring process is as Eq.(7):

$$\begin{aligned} \bar{I}_C^{(t)} &= x_1 \bar{I}_C^{(t-1)} + (1 - x_1) I_C^{(t)}, \\ U_C^{(t)} &= |I_C^{(t)} - \bar{I}_C^{(t)}|, \\ \bar{U}_C^{(t)} &= x_2 \bar{U}_C^{(t-1)} + (1 - x_2) U_C^{(t)}, \\ S_C &= \sum_t \bar{I}_C^{(t)} \bar{U}_C^{(t)} . \end{aligned} \tag{7}$$

Here, t represents the current iteration of evaluation for the variable. $\bar{I}_C$ represents the smoothed treatment of importance changes during fine-tuning (Molchanov et al., 2019; Liang et al., 2021) . U_C represents the uncertainty of current importance for the coupled component (Zhang et al., 2022a). $\bar{U}_C$ represents the upper bound confidence for $\bar{I}_C$ (Zhang et al., 2022a). Finally, S_C is the final score for the coupled component. The hyperparameters x_1 and x_2 are chosen as 0.5 in our experiments.

Evaluating Features. According to the description in the (Fang et al., 2023), in structured pruning, if we want to prune a feature at a specific position, we need to prune the corresponding features at that position in all parameter matrices of the model. Therefore, we only need to group all corresponding features at the same position in the model. When we remove a feature from the model, the resulting error can be approximated as Eq.(8):

$$I_f \approx \sum_C \left| \sum_{c \in C[:,f] \cup C[f,:]} \frac{\partial \mathcal{L}}{\partial c} c - \frac{1}{2}\left(\frac{\partial \mathcal{L}}{\partial c} c \right)^2 \right| . \tag{8}$$

Here, C refers to the $Q^t K$ and $V^t O^t$ for each attention head in each layer. Taking the grouping of $Q^t K$ as an example, we consider Q and K in the multi-head attention mechanism as the superposition of multiple features, i.e., $Q = [q_1, q_2, ..., q_{d_m}]$ and $K = [k_1, k_2, ..., k_{d_m}]$, where q_i and k_i are column vectors of dimension d_k. If we set all the values at position j to zero, it is equivalent to setting all the values in the j-th row and j-th column of the matrix $Q^t K$ to zero.

In the evaluation of features, we do not consider the impact of intermediate layers. The importance of features is mainly determined by the self-attention process of the model, while the role of intermediate layers is to superimpose multiple self-attention processes (de Wynter and Perry, 2020). In our experiments with BERT and ViT (Dosovitskiy et al., 2020), we find that evaluating features using only self-attention layers already achieves good results. Additionally, because the partitioning of intermediate layers in LLaMA does not strictly consider the computation process, it may also affect the accuracy of the evaluation.

We also incorporate the scoring process from the PLATON algorithm into the feature evaluation, as shown in Equation Eq.(7). In this case, the coupled components C are replaced by features f.

3.3 Pruning

In pruning self-attention layers, we adopt a simple uniform strategy to remove unimportant components. Our pruning strategy for self-attention layers is to remove the lowest-scoring self-attention head for each self-attention layer in each iteration. The score of a self-attention head is the sum of the scores of its constituent Q, K, V, and O kernels.

For the pruning of intermediate layers, we also adopt a uniform pruning strategy. In each iteration, a fixed number of kernels are pruned for all parameter matrices in these layers. We have observed that

Pruning Ratio	tune	Method	WikiText2↓	PTB↓	BoolQ	PIQA	HellaSwag	WinoGrande	ARC-e	ARC-c	OBQA	Average
Ratio=0%	-	LLaMA-7B	12.62	22.14	73.18	78.35	72.99	67.01	67.45	41.38	42.40	63.25

		LP-Block	17.39	30.20	66.79	77.58	68.48	64.96	64.06	37.88	39.00	59.82
		Ours	22.00	42.58	72.26	75.13	68.87	66.53	63.29	38.73	41.40	60.88
Ratio=24%	w/o	Ours	34.55	72.14	63.36	69.96	55.92	60.37	53.19	33.70	35.40	53.12
Ratio=24%	w/	Ours	25.01	46.79	68.47	73.88	65.88	63.53	59.63	35.58	38.00	57.85

Table 1: LLaMA pruning experiments. The evaluation metric for WikiText2 and PTB tests is perplexity, which is the smaller the better. The evaluation metric for other tasks is accuracy, which is higher the better. In the experiments, "w/o" indicates that the model did not undergo fine-tuning after the pruning process, and "w/" indicates that the model underwent fine-tuning after the pruning process.

for most Transformer models, there is a constant ratio between the number of kernels im in each intermediate layer and the number of $head_{num} \times d_k$ in the self-attention layers (de Wynter and Perry, 2020). For example, this ratio is 4 for OPT models (Zhang et al., 2022b) and around 2.7 for LLaMA models. Therefore, in each iteration, we prune $r \times d_k$ kernels for each parameter matrix in the intermediate layers, where $r = im/(head_{num} \times d_k)$.

For features, we need to remove the features in the same positions of all parameter matrices of the model (Fang et al., 2023). We only need to score all features in each iteration and remove the lowest-scoring features. Since most parameter matrices in the self-attention layers of Transformer models are square matrices, for simplicity, we prune d_k features in each pruning operation, which ensures that the parameter matrices in the pruned self-attention layers are still square matrices.

Algorithm 1 LLMs Structure Pruning

```

    end    # end for
    $FinalModel$:= Finetune($model$)
return $FinalModel$    # end Main
```

3.4 Overall Process

This section summaries the overall process of our pruning algorithm, as shown in Alg.(1). It begins by partitioning the parameters using the approach outlined in section 3.1. Subsequently, we employ an iterative evaluation and pruning strategy, where the parameters are evaluated using the methods described in section 3.2, and the model is pruned using the approach detailed in section 3.3. Once the evaluation and pruning process is completed, we proceed with fine-tuning to restore the model's performance.

4 Experiments

4.1 LLaMA and Vicuna Pruning Experiments

We conduct experiments on the LLaMA-7B and Vicuna-7B which have identical architectures. We test the performance of these models at sparsity levels of 20% and 24%. The evaluation tasks we used are WikiText2 (Merity et al., 2016), PTB (Marcus et al., 1993), BoolQ (Clark et al., 2019), PIQA (Bisk et al., 2020), HellaSwag (Zellers et al., 2019), WinoGrande (Sakaguchi et al., 2021), ARC-e, ARC-c (Clark et al., 2018), and OBQA (Mihaylov et al., 2018). The evaluation metrics for WikiText2 and PTB tests are perplexity, which is the smaller the better. The evaluation metric (Gao et al., 2023) for other tasks is accuracy, which is higher the better. We compare the results with the structurally pruned LLM-Pruner. The experimental results are shown in Tables 1 and 2. All experiments are conducted on two Nvidia A100 GPUs.

Experimental Details. In every evaluation iteration of LLaMA and Vicuna, we randomly take 10 sentences of length 64 from the C4 (Dodge et al., 2021) dataset to obtain gradient and magnitude information. Our algorithm uses LoRA gradients instead of actual gradients. Since the parameters in the LoRA matrix are randomly initialized, we first train the LoRA parameter matrix for 5 iterations with the 10 sentences after concatenating the LoRA parameter matrices. After the pre-processing of the LoRA parameter matrix, we collect the gradient and magnitude information generated by inputting these 10 sentences into the model for evaluation.

In every prunning iteration, one self-attention head is pruned for all self-attention layers, and 320 kernels were removed for gate-proj, up-proj, and down-proj in each layer. Additionally, 128 features (model's $d_k = 128$) were removed from all parameter matrices.

To obtain the models with sparsity levels of 20%, we initially performed 3 iterations of evaluation and pruning. After the completion of the third iteration of evaluation-pruning, we obtained the 20% sparse model without fine-tuning. We can further increase the sparsity to 24% in the same way, just by changing the number of evaluation-pruning iterations from 3 to 4. Then we fine-tune this model for 4 epochs on the Alpaca (Taori et al., 2023) to restore its performance.

Experimental Analysis. In the LLaMA pruning experiments, we observe that our pruning algorithm performs well even at lower sparsity levels, even without fine-tuning. At sparsity levels of 20% and 24%, our algorithm surpasses LLM-Pruner's Channel mode at 20% sparsity. After pruning and fine-tuning, our algorithm achieves slightly higher perplexity in the WikiText2 and PTB tasks at a 20% sparsity level. Our algorithm outperforms LLM-Pruner's Channel and Block modes in average scores from BoolQ to OBQA, reaching 96% of the performance of the unpruned network. At a sparsity level of 24%, our algorithm, after fine-tuning, outperforms LLM-Pruner's Channel mode at 20% sparsity in average scores from BoolQ to OBQA, with an average score of 91% compared to the unpruned network.

In the Vicuna pruning experiments, our algorithm exhibits similar performance. At a sparsity level of 20%, our algorithm's perplexity performance in WikiText2 and PTB is comparable to LLM-Pruner's Block mode. Our algorithm outperforms LLM-Pruner's Block mode in average scores from BoolQ to OBQA, reaching 94% of the performance of the unpruned network. Additionally, at a sparsity level of 24%, our pruned network, after fine-tuning, shows no significant difference compared to LLM-Pruner's Block mode 20% sparsity model. The average score from BoolQ to OBQA only decreases by 0.17 points compared to LLM-Pruner, while achieving the performance of the original unpruned network 92%.

The inference performance and storage overhead of our pruned models are presented in Table 3. The evaluation is conducted following the methodology described in the (Ma et al., 2023). At sparsity levels of 20%, although our algorithm retains more remaining parameters, it doesn't exhibit a significant difference in memory consumption compared to LLM-Pruner. Our computational complexity falls between LLM-Pruner's Channel mode and Block mode. Therefore, our algorithm theoretically offers better acceleration performance than LLM-Pruner's Block mode.

4.2 ChatGLM3 Pruning Experiment

We conduct experiments on the ChatGLM3. We test the model on the datasets same to LLaMA and Vicuna to evaluate its performance at sparsity levels of 10% and 20%. We compare our pruning algorithm with random pruning and L2 (Han et al., 2015b; Li et al., 2016) weight pruning. All experiments are conducted on two Nvidia A100 GPUs.

Experimental Details. Differing from many Transformer-based models, like LlaMA, BERT, ViT, etc., ChatGLM3 has a unique structure in its self-attention layers. In ChatGLM3-6B, there are 32 Query heads and only 2 Key and Value heads in the multi-head self-attention mechanism. During inference, the model replicates the Key and Value heads 16 times to match the number of Query heads, and the subsequent computation follows the same process as other Transformer models. We make appropriate adjustments to our pruning algorithm to accommodate ChatGLM3's computation approach.

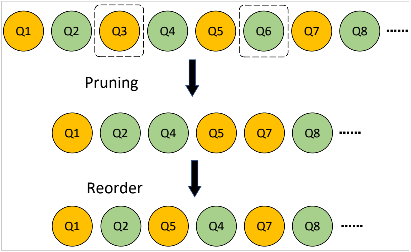

Figure 2: We reorder the remaining pruned Query heads. The processing of parameter matrix O follows the same approach.

We observe that in ChatGLM3, odd-numbered Query heads correspond to odd-numbered Key

Pruning Ratio	tune	Method	WikiText2↓	PTB↓	BoolQ	PIQA	HellaSwag	WinoGrande	ARC-e	ARC-c	OBQA	Average

Ours	24%	5.2B	328.7G	9998.0MiB

Table 3: Statistic for LLaMA and Vicuna.

and Value heads, and the same applies to even-numbered heads. Therefore, our previous pruning strategy becomes removing the Query head with the lowest score among all odd-numbered heads, the Query head with the lowest score among all even-numbered heads, and their corresponding parameter matrix O. The Key and Value heads remain unchanged. After pruning, as the order of Query heads may change from odd to even or vice versa, we rearrange the Query heads and the parameter matrix O according to their parity as Figure2.

The model evaluation and fine-tuning process are the same as in the LLaMA and Vicuna pruning. The 10% sparse model underwent one iteration of evaluation and pruning, while the 20% sparse model underwent two iterations of evaluation and pruning. After evaluation and pruning, all models are fine-tuned on the Alpaca dataset for 4 epochs.

For the random pruning and L2 weight pruning experiments, we also use the same grouping method. The only difference is that during the coupled components and feature evaluation, we don't consider the coupling relationship and only perform random pruning or evaluate based on the sum of L2 values of the kernels containing parameters.

Experimental Analysis. Our pruning algorithm achieves almost no decrease in average scores from BoolQ to OBQA at a sparsity level of 10%. At a sparsity level of 20%, our model retains 94% of the original model's performance. Furthermore, by comparing our algorithm with L2 weight pruning, we find that algorithms like L2 pruning, which are based on pruning based on the magnitude of model parameters, are almost ineffective in structured pruning tasks for LLMs. This evaluation method doesn't consider the dependencies between different coupled components, making it unsuitable for such coarse-grained structured pruning. Our algorithm, on the other hand, considers the coupling relationship between different components and the errors that may arise in the model's inference process after eliminating these components. Therefore, it performs better in structured pruning tasks for LLMs.

The inference performance and storage overhead of our pruned models are shown in Table 5. Our algorithm reduces MACs overhead by 30% at a sparsity level of 20%.

4.3 More Analysis

Global Pruning vs. Layer-wise Pruning. During coupled component elimination, we can employ layer-wise sorted pruning or global sorted pruning methods. However, during our initial experimentation with global ranking, we find that the global sorting approach was not effective. In our pruning experiments, we observe that most low-scoring coupled components are concentrated in the first two layers. However, removing these coupled components results in a significant performance degradation. Additionally, the pruning in LLM-Pruner excludes these layers, there is a need for prior knowledge (Ma et al., 2023) in determining the regions of the model that cannot be pruned. Therefore, we adopt a simpler strategy of uniform pruning (Sun et al., 2023) for every layer.

Kernel vs. Head. When pruning the self-attention layers, we have two options: removing the same number of kernels for each self-attention head or maintaining the same number of kernels per layer but removing one self-attention head in each layer. Based on our experiments with BERT and ViT in Figure3, the latter option performs better when the number of parameters keeps the same. This is because the distribution of importance in the model is not uniform, and low-importance ker-

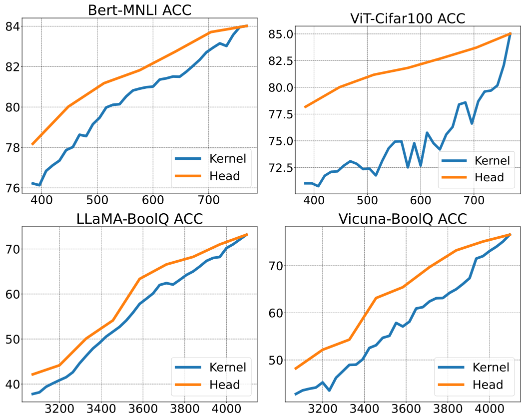

Figure 3: Pruning experiments on BERT, ViT, LLaMA and Vicuna, where the x-axis represents the parameter size of the self-attention layers and the y-axis represents the accuracy of the tasks.

nels are often concentrated within the same self-attention head. We observe this phenomenon in LLaMA and Vicuna as well. Therefore, our pruning strategy for self-attention layers is to remove the lowest-scoring head in each iteration.

Comparison to LLM-Pruner. Our algorithm shares similarities with LLM-Prnner's Channel mode in terms of pruning granularity. Our algorithm prunes features and removes one self-attention head per layer, reducing the size of parameter matrices and the number of self-attention computations, leading to a significant reduction in MACs. However, due to the negative impact from feature pruning, a more accurate evaluation is necessary. Our algorithm evaluates intermediate computation results during inference, offering a more accurate assessment of the impact of structured pruning on model inference performance, compared to LLM-Pruner's element-wise evaluation and summation.

LLM-Pruner's Block mode and our individual kernel-level pruning share similarities in terms of smaller pruning granularity. These operations have minimal impact on the model and enable more fine-grained optimization. However, LLM-Pruner's Block mode uses a global pruning strategy, excluding the first two layers and relying on prior knowledge. In contrast, our algorithm simplifies the process by evaluating multiple kernels as self-attention heads, eliminating the need for prior knowledge.

Furthermore, LLM-Prnner's Block mode alters the structure of certain layers in the model, thus it cannot adopt off-the-shelf libraries for convenient implementation and deployment. In contrast, our algorithm only modifies the size of parameter matrices and reduces the number of self-attention computations while preserving the model's structure. Therefore, our pruned model keeps compatible to existing deep learning programming frameworks, as well as all optimization techniques for Transformer-based models.

5 Conclusion

In this paper, we propose a structured pruning algorithm for LLMs. Our algorithm categorizes parameters into kernels and features based on their relationships between parameter matrices and word vectors in computations. We evaluated these components considering their coupling relationships and the computational characteristics of Transformer architecture. Experimental evaluations on LLaMA, Vicuna, and ChatGLM3 models demonstrated that our algorithm achieves compression to 20% of the original size with minor performance degradation. Our algorithm preserves the model structure, facilitating integration with other optimization techniques and practical deployment.

Limitations

Our algorithm employed a simple uniform pruning scheme across different layers of an LLM, which allows us to avoid acquiring prior knowledge and assumes equal importance for each layer in the model. However, most previous global pruning schemes imply an uneven distribution of importance across different layers of the model, which we did not further explore. In addition, we employed a more empirical approach for intermediate layer pruning, without further exploring the specific number of kernel pairs to be pruned in each layer. Our future work will focus on improving these aspects.

Appendix

A Runtime Analysis

We deployed the pruned model directly on GPUs to test the inference time, using a batch size of 1 to simulate real-world inference scenarios where typically only one sentence is inputted into the model at a time. We tested the time it takes to generate the next token for sequences of different lengths on NVIDIA RTX 3080 Ti and NVIDIA A100.

The runtime of LLaMA-7B and ChatGLM3-7B on NVIDIA RTX 3080 Ti is shown in Figure 4, where the missing parts indicate that it was not feasible to perform actual inference tasks at that sparsity level. This is mainly due to the fact that, during inference, besides saving the model parameters to the GPU memory, intermediate computation results also require GPU memory. This exceeds the 12 GB memory limit of NVIDIA RTX 3080 Ti. The experiments on NVIDIA A100, as shown in Figure 5, demonstrate that the longer the sequence length, the more noticeable the acceleration effect.

In this study, a cluster with GPU-like SIMT accelerators made in China is also tested. Each node in the cluster includes one CPU and four accelerators. The CPU has four NUMA nodes, where each NUMA node has eight X86 based processors. The accelerator adopts a GPU-like architecture with 16 GB HBM2 device memory. Accelerators connected to CPU with PCI-E, where the peak bandwidth of the data transcription between main memory and device memory is 16 GB/s. The evaluation result on this accelerator is shown in Figure 6. Similar to the experimental results on the NVIDIA A100, the acceleration effect becomes more pronounced as the sequence length increases.

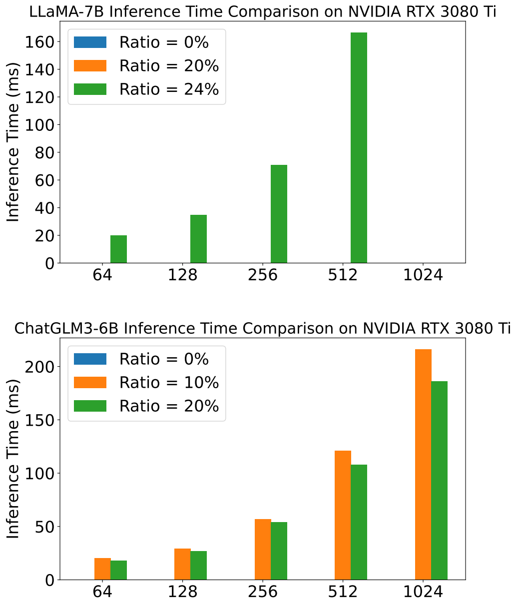

Figure 4: The performance of LLaMA-7B and ChatGLM3-6B in terms of inference time at different input sequence lengths on NVIDIA RTX 3080 Ti.

B Comparison to LoRAShear

We compared our approach with LoRAShear (Chen et al., 2023), as shown in Table 6. LoRAShear employs a more effective method during the model recovery stage, whereas our algorithm uses a simpler LoRA fine-tuning approach. Consequently, LoRAShear achieves more favorable results in this aspect, which we lack. We plan to conduct further research on the model recovery stage in our future work. Additionally, due to the large pruning granularity of our model, excessively high sparsity levels are not suitable, leading to poor performance at 50% sparsity. Our future work will also explore structured pruning methods at high sparsity levels.

Weight-Inherited Distillation for Task-Agnostic BERT Compression

Abstract

Knowledge Distillation (KD) is a predominant approach for BERT compression. Previous KD-based methods focus on designing extra alignment losses for the student model to mimic the behavior of the teacher model. These methods transfer the knowledge in an indirect way. In this paper, we propose a novel Weight-Inherited Distillation (WID), which directly transfers knowledge from the teacher. WID does not require any additional alignment loss and trains a compact student by inheriting the weights, showing a new perspective of knowledge distillation. Specifically, we design the row compactors and column compactors as mappings and then compress the weights via structural re-parameterization. Experimental results on the GLUE and SQuAD benchmarks show that WID outperforms previous state-of-the-art KD-based baselines. Further analysis indicates that WID can also learn the attention patterns from the teacher model without any alignment loss on attention distributions. The code is available at GitHub.

1 Introduction

Transformer-based Pre-trained Language Models (PLMs), such as BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), XLNET (Yang et al., 2019), have achieved great success in many Natural Language Process (NLP) tasks. These models are pre-trained on massive corpus via self-supervised tasks to learn contextualized text representations. However, PLMs have high costs in terms of storage, memory, and computation time, which brings challenges to online services in real-life applications. Therefore, it is crucial and feasible to compress PLMs while maintaining their performance.

Approach	**Alignment Loss**		**Hard Loss**	**Task-Agnostic**
	Logit	**Feature**		
DistilBERT	✓	✓	✓	✓
TinyBERT (GD)	✓	✓	✗	✓
PKD	✓	✓	✓	✗
MiniLM	✗	✓	✗	✓
MobileBERT	✓	✓	✓	✓
WID (ours)	✗	✗	✓	✓

Table 1: Comparison with previous state-of-the-art distillation methods. **Logit** and **Feature** denote whether logit-based loss and feature-based loss are used for distillation. To the best of our knowledge, WID is the first distillation method without any alignment loss and directly transfers the knowledge by weight inheritance.

Knowledge Distillation (KD), which trains a compact student model by mimicking the behavior of a teacher model, is a predominant method for PLM compression. There are two settings for KD in BERT compression: 1) task-specific, which first fine-tunes the teacher PLMs on specific tasks and then performs distillation, and 2) task-agnostic, which distills PLMs in the pre-training stage. For task-agnostic distillation, the student model can be directly and generically fine-tuned on various downstream tasks (Wang et al., 2020; Sun et al., 2020). Hence, we evaluate the proposed weight-inherited distillation (WID) under a task-agnostic setting.

Previous KD-based methods mainly focus on designing alignment losses to minimize the distance between the teacher model and the student model. We can further categorize these alignment losses into 1) logit-based, which measures the distance of logit distributions, and 2) feature-based, which aims to align the intermediate features including token embeddings, hidden states, and self-attention distributions. However, selecting various loss functions and balancing the weights of each loss are laborious (Sun et al., 2019; Jiao et al., 2020). Meanwhile, the knowledge is embedded in the weights. This gives rise to an intuitive thought: *can we distill the knowledge by directly inheriting the weights, rather than aligning the logit distributions or intermediate features*?

Findings of the Association for Computational Linguistics: NAACL 2024, pages 13–28
June 16-21, 2024

In this work, we propose Weight-Inherited Distillation (WID), which does not require any additional alignment loss and trains the student by directly inheriting the weights from the teacher. In WID, we factorize the KD process into the compression of each weight matrix. Inspired by structural re-parameterization in CNN compression (Ding et al., 2021), we design row compactors and column compactors, and then view them as mappings to compress the weights by row and column, respectively. For the matrices to compress the row only, such as the output layer for MLM task (the column is always the size of vocabulary), we employ the row compactors exclusively to compress them. Moreover, during training, we design a novel alignment strategy to align the compactors due to the residual connection in Transformer (Vaswani et al., 2017). As shown in Table 1, WID is the only method for task-agnostic distillation without any alignment loss.

We conduct extensive experiments on downstream NLP tasks, including the GLUE and SQuAD benchmarks. Experimental results demonstrate that WID outperforms traditional KD-based baselines. Further analysis shows that WID can also learn high-level semantic knowledge such as self-attention patterns via inheriting weights.

Our contributions can be summarized as follows:

- We propose Weight-Inherited Distillation (WID), revealing a new pathway to KD by directly inheriting the weights via structural re-parameterization.
- We design the compactor alignment strategy and conduct WID for task-agnostic BERT compression. Experiments on the GLUE and SQuAD benchmark datasets demonstrate the effectiveness of WID for model compression.
- We perform further analyses on how to get better performance in BERT compression. Even more, we find that WID is able to learn attention patterns from the teacher.

2 Preliminaries

2.1 Embedding Layer

In BERT (Devlin et al., 2019), the input texts are tokenized to tokens by WordPiece (Wu et al., 2016). The representations ($\{\mathbf{x}_i\}_{i=1}^{|x|}$) of the input sequence are constructed by summing the corresponding token embedding, segment embedding, and position embedding. For the token embedding layer in BERT, the weight is $W_T \in \mathbb{R}^{|V| \times d}$, where $|V|$ and d denote the sizes of the vocabulary and the hidden state vector, respectively.

2.2 Transformer Layer

Transformer layers are adapted to encode the contextual information of input texts. The input vector ($\{\mathbf{x}_i\}_{i=1}^{|x|}$) are packed to $\mathbf{H}^0 = [\mathbf{x}_1, \cdots, \mathbf{x}_{|x|}]$. After that, the L-layer transformer computes the encoding vectors following:

$$\mathbf{H}^l = \text{Transformer}_l(\mathbf{H}^{l-1}),\ l \in [1, L]. \quad (1)$$

The final output $\mathbf{H}^L = [h_1^L, \cdots, h_{|x|}^L] \in \mathbb{R}^{|x| \times d}$ is employed as the contextualized representation of $\{\mathbf{x}_i\}_{i=1}^{|x|}$. Each transformer layer consists of a multi-head self-attention (MHA) sub-layer and a feed-forward (FFN) sub-layer. In these two sub-layers, the residual connection (He et al., 2016) is employed, followed by Layer Normalization (LN) (Ba et al., 2016).

MHA For the l-th transformer layer with A attention heads, the output $\mathbf{O}_{l,a}$ of the attention head $a \in [1, A]$ is calculated as:

$$\begin{aligned} \mathbf{Q}_{l,a} &= \mathbf{H}^{l-1}\mathbf{W}_{l,a}^Q \\ \mathbf{K}_{l,a} &= \mathbf{H}^{l-1}\mathbf{W}_{l,a}^K \\ \mathbf{V}_{l,a} &= \mathbf{H}^{l-1}\mathbf{W}_{l,a}^V \end{aligned} \quad (2)$$

$$\mathbf{O}_{l,a} = \mathbf{A}_{l,a}\mathbf{V}_{l,a}, \mathbf{A}_{l,a} = \text{softmax}(\frac{\mathbf{Q}_{l,a}\mathbf{K}_{l,a}^T}{\sqrt{d_k}}) \quad (3)$$

where linear projection $\mathbf{W}_{l,a}^Q, \mathbf{W}_{l,a}^K, \mathbf{W}_{l,a}^V \in \mathbb{R}^{d \times d_k}$ and $d_k = \frac{d}{A}$ is the dimension of each head. The final output of MHA sub-layer is as follows:

$$\mathbf{O}_l = \text{LN}(\mathbf{H}^{l-1} + (||_{a=1}^A \mathbf{O}_{l,a})\mathbf{W}_l^O) \quad (4)$$

where $\mathbf{W}_l^O \in \mathbb{R}^{d \times d}$, LN is layer normalization and $||$ denotes the concatenation operation.

FFN The l-th FFN sub-layer consists of an up projection and a down projection, parameterized by $\mathbf{W}_l^U \in \mathbb{R}^{d \times d_f}$, $\mathbf{W}_l^D \in \mathbb{R}^{d_f \times d}$, and corresponding bias $\mathbf{b}_l^U \in \mathbb{R}^{d_f}$, $\mathbf{b}_l^D \in \mathbb{R}^d$:

$$\text{FFN}(\mathbf{O}_l) = \text{gelu}(\mathbf{O}_l\mathbf{W}_l^U + \mathbf{b}_l^u)\mathbf{W}_l^D + \mathbf{b}_l^d. \quad (5)$$

Typically, $d_f = 4d$. Finally, we obtain the output of layer l by:

$$\mathbf{H}^l = \text{LN}(\mathbf{O}_l + \text{FFN}(\mathbf{O}_l)). \quad (6)$$

2.3 Knowledge Distillation

Knowledge Distillation (KD) trains a compact student model S by mimicking the behaviors of the teacher model T. The losses can be categorized into logit-based and feature-based.

For logit-based loss, the target is to minimize the distance between logit distribution $\mathbf{p}_s$ from the student and $\mathbf{p}_t$ from the teacher, which can be formalized as:

$$\mathcal{L}_{logit} = \mathcal{H}_1(\mathbf{p}_s/\tau, \mathbf{p}_t/\tau), \tag{7}$$

where τ is the temperature and $\mathcal{H}_1$ is the cross-entropy loss or KL-divergence.

Feature-based loss aims to align the intermediate features between the teacher and the student by:

$$\mathcal{L}_{feature} = \mathcal{H}_2(f^S(x), f^T(x)), \tag{8}$$

where $\mathcal{H}_2$ is the loss function such as Mean Square Error (MSE) and $f(x)$ denotes for the intermediate output including hidden state vector $\mathbf{H}$ and attention distribution $\mathbf{A}$.

As shown in Table 1, logit-based and feature-based loss can be jointly employed for better distillation. However, balancing the weights of each loss is laborious. For example, the overall loss of PKD (Sun et al., 2019) is:

$$\mathcal{L} = (1-\alpha)\mathcal{L}_{hard} + \alpha\mathcal{L}_{logit} + \beta\mathcal{L}_{feature}, \tag{9}$$

where $\mathcal{L}_{hard}$ is the loss on target tasks and α and β are the hyper-parameters. PKD performs grid search over α and τ, where $\alpha \in \{0.2, 0.5, 0.7\}$ and $\tau \in \{5, 10, 20\}$. After that, the best α and τ are fixed, followed by a search of $\beta \in \{10, 100, 500, 1000\}$.

Meanwhile, selecting various loss functions is also laborious. In PKD, $\mathcal{L}_{feature}$ is defined as the mean square loss between the normalized hidden states for each layer. DistilBERT (Sanh et al., 2019) adopts the cosine embedding loss for hidden states. TinyBERT (Jiao et al., 2020) employs the mean square loss for self-attention distributions, embedding layer outputs, and hidden states.

3 Weight-Inherited Distillation

3.1 Structural Re-parameterization

As mentioned in Section 2, the PLMs (e.g., BERT) consist of embedding layers and transformer layers. To compress the BERT, we have to learn a mapping from the larger weight in the teacher model to the compact one. In terms of matrices, these mappings can be categorized as:

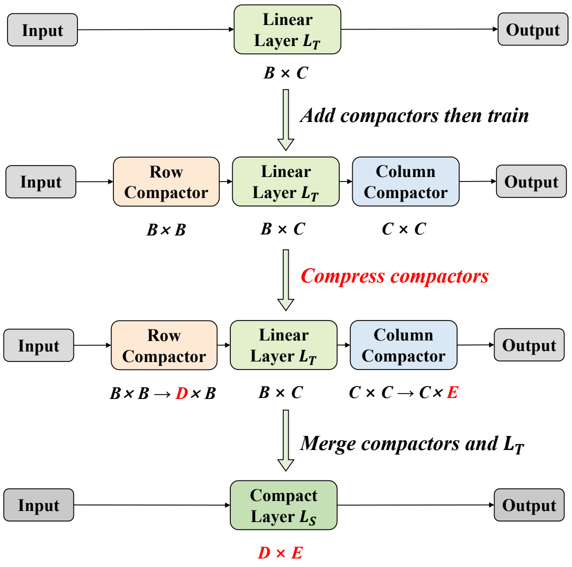

Figure 1: Overview of compressing linear layer L_T with weight $\mathbf{W}^{L_T} \in \mathbb{R}^{B \times C}$ to compact linear layer L_S with weight $\mathbf{W}^{L_S} \in \mathbb{R}^{D \times E}$ via WID. Both row compactor and column compactor are initialized as **identity matrices**. After training, we compress the compactors and merge them with the original layer. All the linear layers in the teacher model are compressed **simultaneously**.

- column mapping only, such as the token embedding matrix $W_T \in \mathbb{R}^{|V| \times d}$,
- row mapping only, such as the weight of output layer for MLM task with size $\mathbb{R}^{d \times |V|}$,
- column and row mapping, such as up projection $\mathbf{W}_{l,u} \in \mathbb{R}^{d \times d_f}$ in FFN.

In WID, we adopt the re-parameterization trick and design the row compactor for row mapping and column compactor for column mapping, respectively.

Figure 1 gives an example showing the process of compressing the original weight $\mathbf{W}^{L_T} \in \mathbb{R}^{B \times C}$ to a compact weight $\mathbf{W}^{L_S} \in \mathbb{R}^{D \times E}$ adopting both row compactor and column compactor. First, we insert the row compactor with weight $\mathbf{W}^{rc} \in \mathbb{R}^{B \times B}$ and the column compactor with weight $\mathbf{W}^{cc} \in \mathbb{R}^{C \times C}$ before and after the linear layer L_T from the teacher model. All compactors are linear layers without bias and their weights are initialized as identity matrices. For an arbitrary input X, the re-parameterized teacher model produces identical outputs as the original, since

$$X\mathbf{W}^{L_T} = X\mathbf{W}^{rc}\mathbf{W}^{L_T}\mathbf{W}^{cc}. \tag{10}$$

Second, we train the re-parameterized teacher model on the pre-training task. After training,

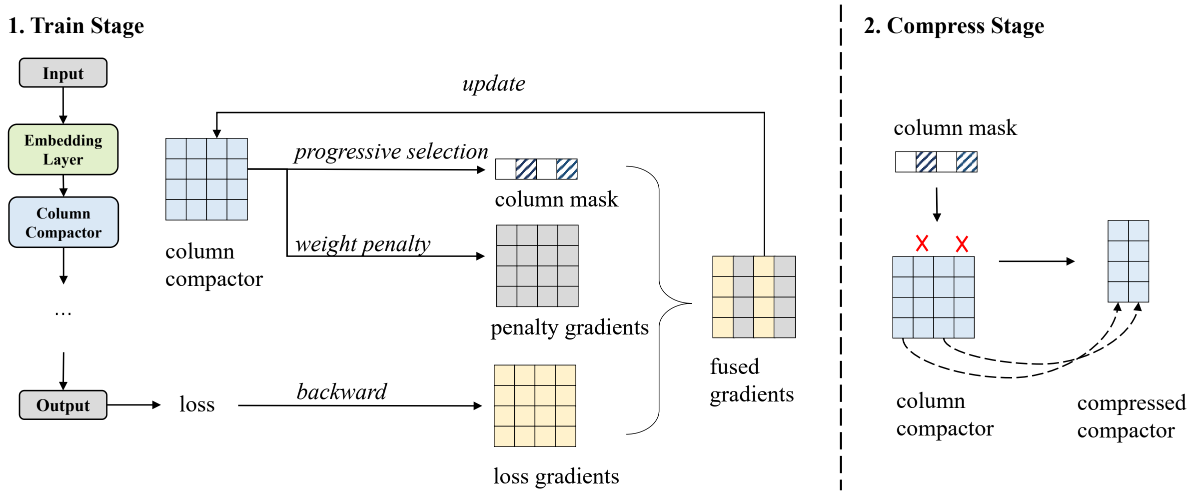

Figure 2: Training and compression for column compactor. During the training process, we add weight penalty gradients by columns and progressively select the mask to fuse the penalty gradients and original loss gradients. After training, we compress the column compactor following the column mask.

the row compactor is compressed by reducing the $B-D$ rows, and the column compactor is compressed by reducing $C-E$ columns. The objects are as follows:

$$\begin{aligned} \mathbf{W}^{rc} \in \mathbb{R}^{B\times B} \rightarrow \mathbf{W}^{rc'} \in \mathbb{R}^{D\times B} \\ \mathbf{W}^{cc} \in \mathbb{R}^{C\times C} \rightarrow \mathbf{W}^{cc'} \in \mathbb{R}^{C\times E}. \end{aligned} \tag{11}$$

More details can be found in Section 3.2. Finally, we merge the compressed compactors $\mathbf{W}^{rc'}, \mathbf{W}^{cc'}$ and the original teacher layer $\mathbf{W}^{L_T}$ to obtain the compact layer for the student following:

$$\mathbf{W}^{L_S} = \mathbf{W}^{rc'}\mathbf{W}^{L_T}\mathbf{W}^{cc'} \in \mathbb{R}^{D\times E} \tag{12}$$

For the weights to compress the rows only, we adopt the row compactor exclusively. Similarly, we employ the column compactor exclusively for the weights to compress the columns only.

3.2 Compactor Compression

The goal is to maintain the performance of the teacher model as much as possible and compress the compactors simultaneously.

Figure 2 presents the training and compression process for the column compactor. To compress the compactors, we add extra penalty loss to minimize the norms of some columns. Given the column compactor $\mathbf{W}^{cc} \in \mathbb{R}^{C\times C}$ and original gradients $g^{cc}_{ori} \in \mathbb{R}^{C\times C}$ from training tasks, the penalty gradients $g^{cc}_{pen} \in \mathbb{R}^{C\times C}$ are calculated as follows:

$$g^{cc}_{pen} = \frac{\mathbf{W}^{cc}}{||\mathbf{W}^{cc}||_2} \tag{13}$$

where $||\mathbf{W}^{cc}||_2$ denotes the Euclidean norm across each column.

However, applying the g^{cc}_{ori} and penalty gradients g^{cc}_{pen} to the same row/column leads to the gradient competition (Ding et al., 2021). Therefore, we choose some columns to reduce and apply the penalty gradients g^{cc}_{pen}, while the rest columns are adopted to keep performance and updated with g^{cc}_{ori}. Specifically, we pick top-k columns with lower norm value based on the $||\mathbf{W}^{cc}||_2$ and set the corresponding value in our column mask $M = \{0,1\}^C$ to be 1. Later, the original gradients g^{cc}_{ori} and the penalty gradients g^{cc}_{pen} are fused as follows:

$$g^{cc}_{fused}[:,i] = \begin{cases} g^{cc}_{pen}[:,i], & \text{if } M[i]=1 \\ g^{cc}_{ori}[:,i], & \text{if } M[i]=0 \end{cases} \tag{14}$$

where $0 \le i \le C$. We employ the fused gradients g^{cc}_{fused} to update the corresponding column compactor. After training, we compress the column compactor by column mask:

$$\mathbf{W}^{cc'} = \mathbf{W}^{cc}[:,i], \text{ where } M[i]=0. \tag{15}$$

Moreover, the process is similar for row compactors. We calculate $||\mathbf{W}^{rc}||_2$ for each row and select the top-k rows with the lower norm value.

For stability and better performance, we choose the rows/columns of the compactors progressively. Concretely, we increase k by d for N steps until reaching the desired size during the training stage. Moreover, we also try the dynamic selection (Ding et al., 2021) for mask and it makes no effect.

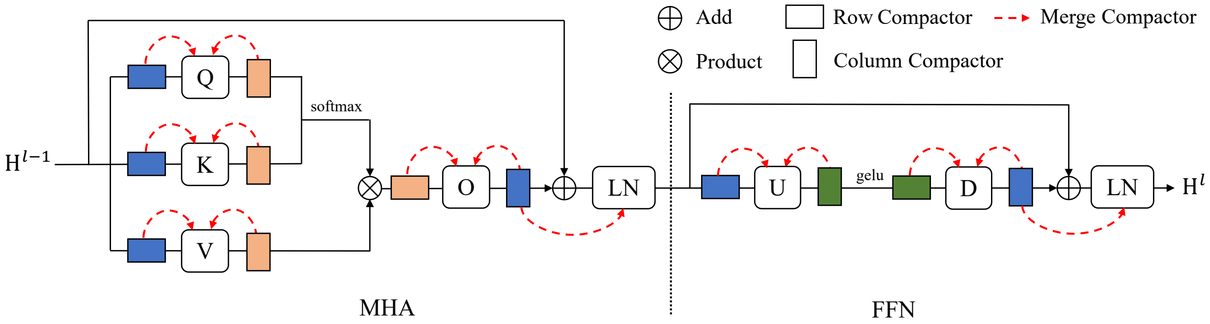

Figure 3: Compactor merging process for a Transformer block. For the bias terms, we merge them with corresponding column compactors. For beta and gamma in Layer Norm (LN), we adopt the previous column compactors to update them. During training, the compactors in the **same color** are aligned. For each group of the aligned compactors, we learn one of them and duplicate (or, flip) it for the rest compactors.

3.3 Compactor Alignment Strategy

To apply WID for BERT compression, we design a novel compactor alignment strategy. Since each dimension in a hidden representation h_1 is connected to the same dimension in another hidden representation h_2 through a residual connection, the compactors before and after the h_1 and h_2 need to be aligned. As shown in Figure 3, the compactors in a transformer block are divided into three groups (same color, same group). The first compactor before the $\mathbf{H}^{l-1}$ and the first compactor after the $\mathbf{H}^{l}$ are also aligned with groups in blue. Therefore, the column compactor for the embedding layer, the row compactor for the output layer, and compactors in blue from each layer are all aligned. Meanwhile, the groups in orange/green can be different across layers since they are not adjacent. For each group of the aligned compactors, we learn one of them and duplicate (or, flip) it for the rest. Please refer to Appendix B.2 for more details.

4 Experiments

4.1 Task-Agnostic Distillation

We employ the uncased version of $\text{BERT}_{\text{base}}$ as our teacher model [1] and implement WID based on TencentPretrain framework(Zhao et al., 2023). $\text{BERT}_{\text{base}}$ (Devlin et al., 2019) is a 12-layer transformer model (d=768, A=12, L=12), which contains 110M parameters. For student models, we compress the teacher model to various model sizes for comparison, including WID_{55} (d=516, A=12, L=12) with 55M parameters and WID_{11} (d=192, A=12, L=12) with 11M parameters. We use the documents of English Wikipedia and BookCorpus (Zhu et al., 2015) for pre-training following Devlin et al. (2019). We use AdamW (Loshchilov and Hutter, 2019) with $\beta_1 = 0.9$, $\beta_2 = 0.99$. The compactors are trained with peak learning rate 5e-5 and the original linear layers with peak learning rate 1e-6. For WID, we adopt the 2-norm and set N=500, d=$\lfloor (d_t - d_s)/16 \rfloor$. It costs about 64 hours to train for 400,000 steps with a batch size of 960 on 8 A100 GPUs.

4.2 Downstream Tasks

Following previous PLM-based KD methods (Sanh et al., 2019; Wang et al., 2020), we evaluate our WID on the SQuAD v1.1 (Rajpurkar et al., 2016) and GLUE benchmark (Wang et al., 2019). The GLUE benchmark consists of CoLA (Warstadt et al., 2019), SST-2(Socher et al., 2013), MRPC (Dolan and Brockett, 2005), STS-B (Cer et al., 2017), QQP (Chen et al., 2018), MNLI (Williams et al., 2018), QNLI(Rajpurkar et al., 2016) and RTE (Bentivogli et al., 2009). After task-agnostic distillation, we fine-tune our compressed BERT WID_{55} and WID_{11} on these benchmarks adopting the grid search and report the results on the development sets. The result of MNLI is the score of MNLI-m. More details about these datasets including dataset sizes and metrics and the hyperparameters for fine-tuning can be found in the Appendix A.

4.3 Baselines

For a fair comparison, we compare our WID with the **task-agnostic distillation** baselines. These baselines include: 1) DistilBERT (Sanh et al., 2019), which distills the student by the combination of the original MLM loss, the cosine distance for features, and the KL divergence for output logits. 2) TinyBERT (GD) (Jiao et al., 2020), which aligns the attention distributions and hidden states

Table 2: Comparison between our WID and various task-agnostic distillation methods. We compare the task-agnostic distilled models without both data augmentation and task-specific distillation. † means that we fine-tune the official weights. ‡ means that we reproduce the methods following the official code. Other results are taken from corresponding papers. For MiniLM and MiniLM v2, the average reported scores are 81.0 and 81.7, and both are lower than the 82.3 of WID.

for general distillation. 3) MiniLM (Wang et al., 2020) and MiniLM v2 (Wang et al., 2021), which align the attention matrix and values-values scaled dot-product. We also reproduce the TinyBERT in the same architecture as WID, following the official code. For fair comparison, we employ the same corpus and follow the official hyperparameters. We do not compare with MobileBERT (Sun et al., 2020) since its teacher is IB-BERT$_{\text{large}}$ (much higher accuracy than BERT$_{\text{base}}$) and its computations (4096 batch size, 740,000 steps) is much higher. Moreover, we also compare WID with task-specific methods in Appendix C.1.

4.4 Main Results

We compare WID with other task-agnostic distillation methods in **various** model sizes. All the methods utilize the BERT$_{\text{base}}$ as the teacher model. As shown in Table 2, WID retains 98.9% and 90.9% performance of BERT$_{\text{base}}$ using only 49.2% and 10.2% parameters, respectively. In particular, in the CoLA task, WID$_{55}$ gets a higher score than BERT$_{\text{base}}$. Compared to the baselines with 67.5M parameters, WID$_{55}$ gets comparable performance with MiniLM and higher performance than DistilBERT with fewer parameters. Meanwhile, WID outperforms the TinyBERT under the same architecture on GLUE benchmarks and SQuAD, showing its superiority over the traditional KD methods with logit-based loss and feature-based loss. Without CoLA, WID$_{55}$ gets an average score of 85.8 and still outperforms the TinyBERT (GD) with an average score of 85.0.

Meanwhile, we apply WID for generative PLM. Please refer to C.4 for more details.

Larger Performance Gap Since the performance gap between teacher and student has always been a crucial point and difficulty in KD, we conduct experiments for smaller student models (11.3M parameters). We reproduce the task-agnostic TinyBERT under the General Distillation (GD) as the baseline. As shown in Table 2, we find that WID (average score: 76.7) still outperforms TinyBERT (average score: 75.6) when the student model is about 10x smaller.

5 Analysis and Discussion

5.1 WID vs Pruning

Pruning (LeCun et al., 1989) aims to remove redundant weights from a neural network to achieve parameter-efficiency while preserving model performance, including unstructured pruning which sets weights to 0, and structured pruning which removes components such as attention heads. Unstructured pruning methods do not reduce the model size. However, WID is very likely to be confused with structured pruning methods.

Structured pruning methods aim to remove the redundant units and then usually get sub-networks without a pre-defined structure. However, WID **does not** remove any parts of the original weights from the teacher models but learns a student model with a pre-defined structure. Meanwhile, the goal of KD is to transfer the knowledge from teacher models to student models. In WID, we design the compactors as mappings to inherit knowledge from teacher models, rather than to find sub-networks. Hence, we consider WID as a KD method though the compression process of compactors is similar to pruning. More comparison between WID and pruning methods can be found in C.2.

Method	**SST-2**	**CoLA**	**MRPC**	**QNLI**	**QQP**	**RTE**	**STS-B**	**MNLI**	**SQuAD**	**AVG**

Table 4: Comparison between different teacher models after they are compressed to WID_{11}^{head}. BERT_{55} means the BERT model with same architecture as WID_{55}^{head}.

5.2 MHA: Dropping Heads or Reducing Dimension

Multi-Head Attention (MHA) allows the model to jointly attend to the information from different representation subspaces (Vaswani et al., 2017). When compressing the weights in MHA, there are two options, including 1) dropping heads, which reduces the number of heads A, and 2) reducing dimension, which reduces the size of each head d_k. For TinyBERT (Jiao et al., 2020) and MiniLM (Wang et al., 2020), they keep A=12 and reduce d_k due to the constraint of attention-based loss. Our proposed WID is more flexible since we do not employ any alignment loss. Moreover, we can easily achieve these two strategies by constraining the column mask in MHA. For WID_{55} and WID_{11} reported in Table 2, we reduce the size of each attention head following TinyBERT for a fair comparison.

To further explore these two strategies, we conduct WID under these two settings and report the scores on downstream tasks. In $\text{BERT}_{\text{base}}$, we have A=12 and d_k=64. The student models are selected as: WID_{55}^{dim} (A=12, d_k=43), WID_{55}^{head} (A=8, d_k=64), WID_{11}^{dim} (A=12, d_k=16), and WID_{11}^{head} (A=3, d_k=64). As shown in Table 3, the dropping head strategy performs slightly worse under 55M parameters and much better under 11M parameters. For attention heads in WID_{55}, both 43 and 64 are large enough to encode the textual information in the representation subspace. Thus, the WID_{55}^{dim} with more attention heads gets slightly better results. Similarly, the attention heads with size 16 perform worse due to the limited representation subspace, leading to the poor performance of WID_{11}^{dim}.

5.3 Impact of Teacher Models

To study the impact of teacher models, we compare the results of three teachers, including 1) $\text{BERT}_{\text{base}}$, 2) WID_{55}^{head}, which is compressed by $\text{BERT}_{\text{base}}$ adopting the dropping head strategy, 3) BERT_{55}, which shares the same architecture as WID_{55}^{head}. Both $\text{BERT}_{\text{base}}$ and BERT_{55} are downloaded from the official repository [2]. We compress these three teachers to WID_{11}^{head} employing the dropping head strategy. Table 4 shows the results of three teachers. Some findings are summarized as follows:

(1) A smaller teacher can also teach a smart student. Both $\text{BERT}_{\text{base}}$ and BERT_{55} are pre-trained on the MLM tasks. But the student from BERT_{55} gets an average score of 77.5, which is comparable to 77.6 from the student of $\text{BERT}_{\text{base}}$. A similar conclusion is also observed in Zhang et al. (2023).

(2) An educated teacher teaches better. The WID_{55}^{head} is compressed by $\text{BERT}_{\text{base}}$ adopting the dropping head strategy. Compared to BERT_{55} under the same architecture, WID_{55}^{head} can teach a better student on both GLUE benchmarks and the SQuAD task.

5.4 Looking into WID

We visualize the attention distributions between the teacher $\text{BERT}_{\text{base}}$ and the student WID_{11}^{dim} with the same input tokens. For more comparison, we also pre-train BERT_{11} from scratch which shares the same architecture as WID_{11}^{dim}. As shown in Figure

---

[2] https://github.com/google-research/bert

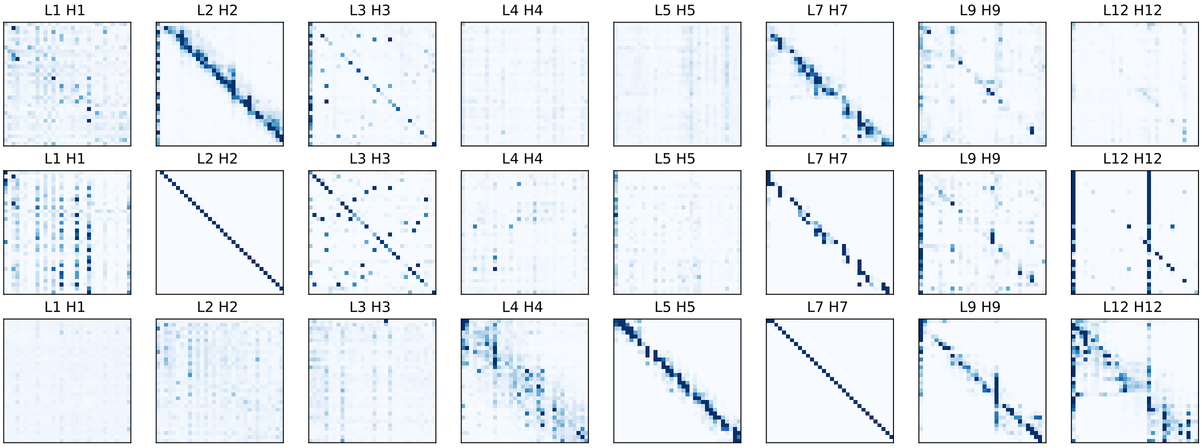

Figure 4: Attention distributions under same input tokens for $\text{BERT}_{\text{base}}$ (upper), WID_{11}^{dim} (middle), and BERT_{11} (bottom). Our WID can learn the knowledge about attention distributions from the teacher without any alignment loss.

4, WID can learn the attention patterns in various layers of the teacher model $\text{BERT}_{\text{base}}$, while BERT_{11} can not. The results of more attention heads can be found in Appendix C.5.

In WID, we do not use any alignment loss between the teacher and the student. However, the compressed student model can still learn attention patterns. This indicates that inheriting the weights can also inherit high-level semantic knowledge.

6 Related Work

6.1 BERT Compression

Transformer-based Pre-trained Language Models (PLMs) can be compressed via Quantization (Stock et al., 2021; Tao et al., 2022), Matrix Decomposition (Mao et al., 2020), Pruning (Xia et al., 2022; Lagunas et al., 2021), and Knowledge Distillation (Jiao et al., 2020; Wang et al., 2020). We refer the readers to Ganesh et al. (2021) for a comprehensive survey. In this paper, we focus on KD for BERT compression.

6.2 Knowledge Distillation

KD aims to transfer the knowledge from the teacher model to the student model (Hinton et al., 2015; Wang et al., 2023; Wu et al., 2023). The distillation methods can be directly divided into three main categories: offline distillation, online distillation, and self-distillation (Gou et al., 2021). For PLMs, the majority of methods follow the offline distillation pattern where the teacher model is pre-trained before distillation. Meanwhile, distillation methods for PLMs can be divided into task-agnostic, which distills the PLM in pre-training stage, and task-specific, which fine-tunes the teacher model on specific tasks and then distills.

In this work, we focus on the task-agnostic distillation. Previous methods mainly focus on designing extra matching losses for the student model to mimic the teacher model. These losses mainly include feature-based loss for features in intermediate layers and logit-based loss for output logits. DistilBERT (Sanh et al., 2019) adopts the output logit and embedding outputs of the teacher to train the student. TinyBERT (Jiao et al., 2020) and MobileBERT (Sun et al., 2020) further employ the self-attention distributions and hidden states for alignment loss. Such layer-to-layer distillation restricts the number of student layers or requires an extra mapping function. To address this issue, MiniLM (Wang et al., 2020) proposes a new loss based on the attention matrix and values-values scaled dot-product. WD (Lin et al., 2021) employs a similar idea to inherit the knowledge in parameters. However, WD initializes the weights of student models randomly and still requires alignment losses.

Different from existing methods, WID does not require additional alignment losses, thus avoiding laborious selection for both loss functions and loss weights.

7 Conclusion

This work proposes a novel Weight-Inherited Distillation (WID) method for task-agnostic BERT compression. In WID, we factorize the compression process as weight mappings, and then design the row compactors and column compactors for row mappings and column mappings, respectively. Empirical results on various student model sizes demonstrate the effectiveness of WID. Further analysis indicates that inheriting the weights can also inherit high-level semantic knowledge such as attention patterns. In future work, we would consider reducing the extra memory cost by compactor layers, such as compactor sharing. Moreover, employing WID on the large language model (LLM) would be another interesting topic.

Limitations

Our proposed WID inserts row/column compactors to learn the mappings from the teacher model to the student model. Thus, WID requires additional computational time and memory. However, WID still outperforms TinyBERT with fewer time costs. As shown in Table 7, WID$_{55}^{dim}$ trained with 100k steps achieves a higher score and saves more than 50% time costs compared to TinyBERT. However, we believe that such a trade-off is valuable since a faster and better compact student would save more time on downstream tasks.

A GLUE and SQuAD

A.1 Data Statistics

Table 5 shows the sizes of the train/development set and the metrics for downstream tasks.

Task	#Train	#Dev	Metric
SST-2	67k	872	Accuracy
QNLI	105k	5.5k	Accuracy
MNLI	393k	20k	Accuracy
QQP	364k	40k	Accuracy
CoLA	8.5k	1k	Matthews corr.
RTE	2.5k	276	Accuracy
STS-B	7k	1.5k	Spearman corr.
MRPC	3.7k	408	Accuracy
SQuAD	87.6k	34.7k	F1 & EM

Table 5: Data statistics of GLUE and SQuAD datasets.

A.2 Hyperparameters

We employ the grid search to fine-tune the GLUE benchmarks and SQuAD.

GLUE The learning rate is searched in {1e-5, 2e-5, 3e-5}. We set the search space for the training batch size based on the size of the training set. For large datasets including QNLI, MNLI, and QQP, the batch size is searched in {32, 48}. For small datasets including MRPC, RTE, CoLA, and STS-B, the batch size is searched in {4, 6}. For SST-2, the batch size is searched in {8, 16}. All tasks are trained for 10 epochs.

SQuAD The learning rate is searched in {1e-5, 2e-5, 3e-5} and batch size is searched in {4,6,8}. The training epochs are set to 3.

B Method Details

B.1 Algorithm

More details about the proposed WID can be found in Algorithm 1.

B.2 Groups of Aligned Compactors

Specifically, we can divide all the compactors in BERT into the following aligned groups:

- One group in blue: {CC for embedding layer, blue compactors in each Transformer layer, RC for output layer},
- L groups in orange: {orange compactors in layer 1}; {orange compactors in layer 2}; ... {orange compactors in layer L},
- L groups in green: {green compactors in layer 1}; {green compactors in layer 2}; ... {green compactors in layer L},

Where RC/CC denotes the row/column compactor and $\{\cdot\}$ denotes a group. For the only one group in blue, we calculate the column compactor for the embedding layer and duplicate (or, flip) it for the other compactors. For each group in orange, we calculate the column compactor for the Value projection and duplicate (or, flip) it for the rest three compactors. For each group in green, we calculate the column compactor for the Up-project and flip it for the other one.

Algorithm 1 Weight-Inherited Distillation

```
Input: teacher model $\mathcal{T}$ with width $d_t$
Params: $k$: number of rows/columns to compress, $N$: steps to increase $k$, $d$: increment for $k$ each time
Output: student model $\mathcal{S}$ with width $d_s$
Add compactors for $\mathcal{T}$ to construct the re-parameterized teacher model $\hat{\mathcal{T}}$. Initialize the weights for compactors as identity matrices.
$k \leftarrow 0$ ; $M \leftarrow [\,]$
for $i = 0$ to max training steps do
    Forward a batch through $\hat{\mathcal{T}}$, derive the gradients $g_{ori}$ for compactors to update
    if $i\%N == 0$ & $k < d_t - d_s$ then
        Calculate p-norm values
        Select the top-$k$ row/column with the lower norm to get $M$
        Get penalty gradients $g_{pen}$ following Eq. 13
        $g_{fused} \leftarrow f(g_{ori}, g_{pen}, M)$ following Eq. 14
        $k \leftarrow k + d$
    end if
    Update the compactors with corresponding $g_{fused}$ and original layers with $g_{ori}$
    Apply the compactor aligning strategy
end for
Compress the compactors following Eq. 15
Merge the compactors and original layers following Eq. 12 to get compact layers for $\mathcal{S}$
return $\mathcal{S}$
```

C Extensive Analysis

C.1 Comparison with Task-Specific Distillation

We also compare WID with task-specific distillation methods where the teacher model in task-specific distillation methods is fine-tuned for the task before distillation. For baselines, we select BERT-of-Theseus (Xu et al., 2020), DynaBERT (Hou et al., 2020) and MetaDistill(Zhou et al., 2022). As shown in Table 6, WID also outperforms these task-specific methods on the GLUE benchmarks.

Method	Type	Params	SST-2	CoLA	MRPC	QNLI	QQP	RTE	STS-B	MNLI	AVG
$\text{BERT}_{\text{base}}$	Teacher	110.1M	92.7	59.1	90.4	91.7	91.4	70.8	90.1	84.5	83.8
DynaBERT	TS-KD	67.5M	92.7	54.6	85.0	90.6	91.1	66.1	88.6	83.7	81.6
MetaDistill	TS-KD	67.5M	92.3	58.6	86.8	90.4	91.0	69.4	89.1	83.8	82.7
TinyBERT*	TS-KD	67.5M	91.9	52.4	86.5	89.8	90.6	67.7	88.7	83.8	81.4
BlockPruning	Pruning	77.0M	89.3	52.6	88.3	88.2	90.7	63.9	84.6	82.9	80.1
WID_{55} (ours)	TA-KD	54.9M	92.4	61.7	88.2	90.1	91.0	70.4	87.9	82.9	83.4
CoFi	Pruning	28.4M	90.6	35.6	82.6	86.1	90.1	64.7	83.1	80.6	76.6
WID_{11} (ours)	TA-KD	11.3M	88.8	44.2	81.9	85.4	89.5	60.3	84.5	78.4	76.6

Table 6: Comparison among WID, task-specific distillation methods, and pruning methods on GLUE benchmarks without data augmentation. TS-KD and TA-KD denote task-specific knowledge distillation and task-agnostic knowledge distillation, respectively. * means the results are taken from Zhou et al. (2022). Other results are taken from the corresponding papers.

C.2 Comparison with Pruning

We try to compare WID with pruning methods for BERT compression, including task-specific CoFi (Coarse- and Fine-grained Pruning,(Xia et al., 2022)) and BlockPruning(Li et al., 2020). As mentioned in Appendix C.1, the task-agnostic setting is more difficult than the task-specific setting. However, as shown in Table 6, WID still achieves comparable results with less than 50% parameters compared to CoFi, and achieves better performance than BlockPruning with 28.7% fewer parameters.

C.3 Less Training Steps

In Table 2, we report the results of WID_{55}^{dim} trained for 400k steps. We re-implement TinyBERT and train 3 epochs following the setting in Jiao et al. (2020). We reduce the training steps for WID_{55}^{dim} to 50k and 100k. All experiments are carried out with 8 A100 GPUs. As shown in Table 7, WID_{55}^{dim} trained with 100k steps can still outperform TinyBERT and save more than 50% training time.

Model	Steps	Time	Score
TinyBERT (GD)	450k	33h	81.27
WID_{55}^{dim}	50k	8h	80.78
WID_{55}^{dim}	100k	16h	81.65
WID_{55}^{dim}	400k	64h	83.08

Table 7: Comparison between TinyBERT and WID trained with less steps on GLUE benchmarks.

C.4 WID for GPT Compression

To evaluate the performance of WID on the generative pre-trained language model, we train a GPT model and compress it via vanilla KD and WID. Due to the limited GPU memory, we train a GPT teacher (12 layers and hidden size as 768) for 100k steps. After that, we train a student model (12 layers and hidden size as 512) and compress the teacher model into such a setting via vanilla KD and WID. During distillation, we employ BookCorpus as training datasets and report the training accuracy. For hyperparameters, the batch size is 64 and the learning rate is 1e-4. Figure 5 shows the training process. We can conclude that WID still works for generative pre-trained language models, and can get better performance than vanilla KD.

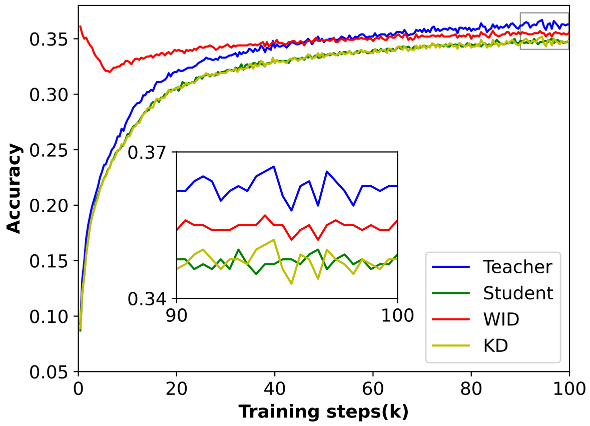

Figure 5: The training process for teacher GPT, vanilla student GPT, and students via KD and WID.

C.5 Attention Distributions

We visualize the attention distributions for the teacher $\text{BERT}_{\text{base}}$, pre-trained BERT_{55} and the student WID_{11}^{head} under the same input tokens (input sentence: "if the world harassed me, it will harass you too.") in Figure 6, Figure 7 and Figure 8, respectively. WID can effectively learn the attention patterns from the teacher model while BERT_{11} is much more different.

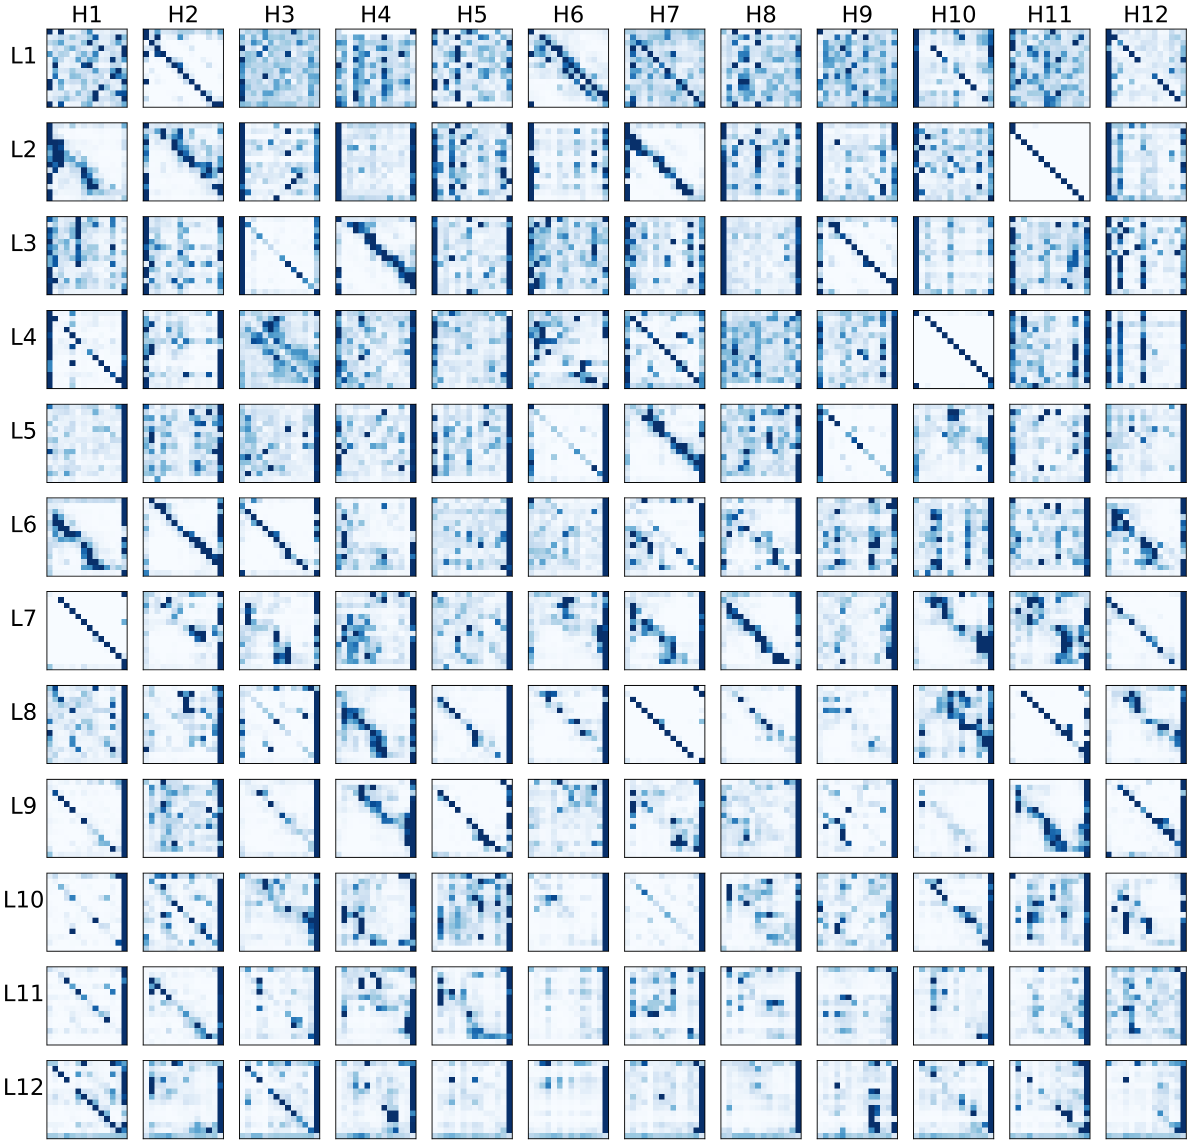

Figure 6: The self-attention distributions for teacher model $\mathrm{BERT}_{\mathrm{base}}$.

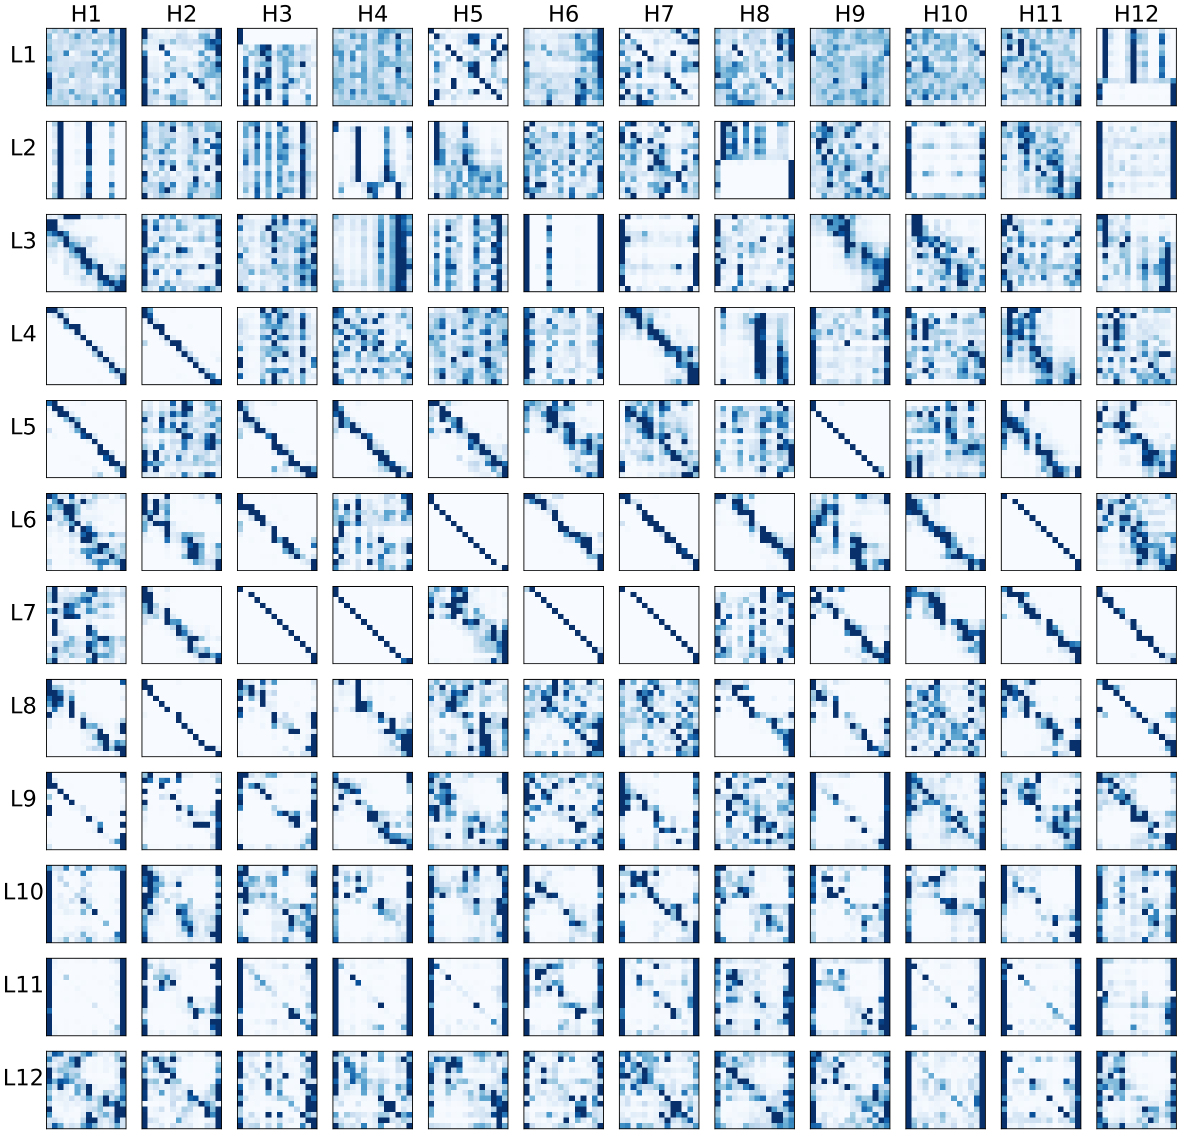

Figure 7: The self-attention distributions for BERT_{11}.

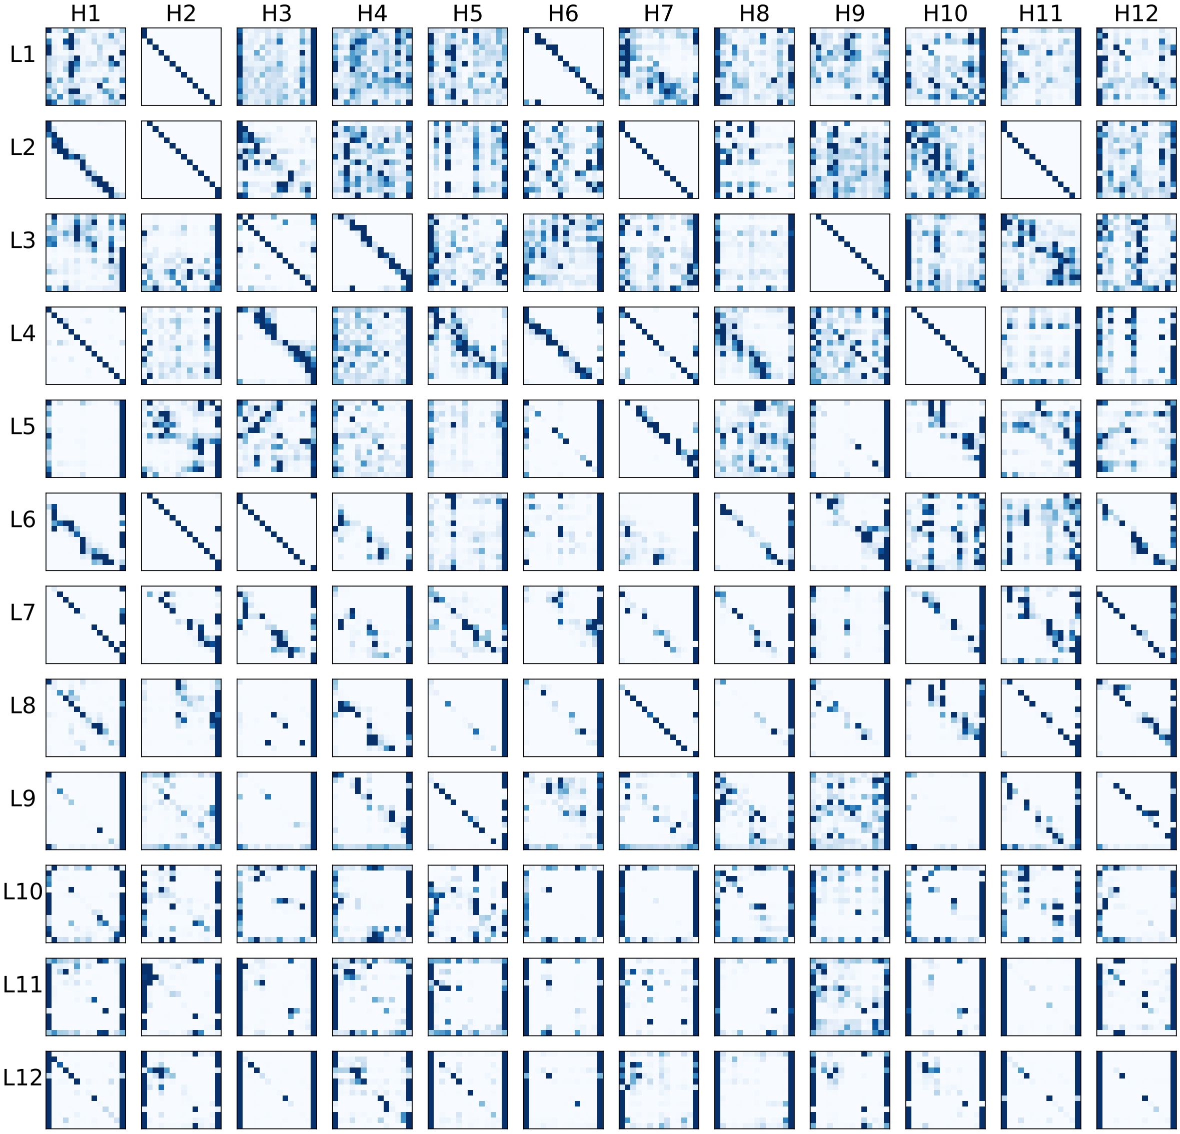

Figure 8: The self-attention distributions for our proposed WID_{11}^{dim}.

Ignore Me But Don't Replace Me: Utilizing Non-Linguistic Elements for Pretraining on the Cybersecurity Domain

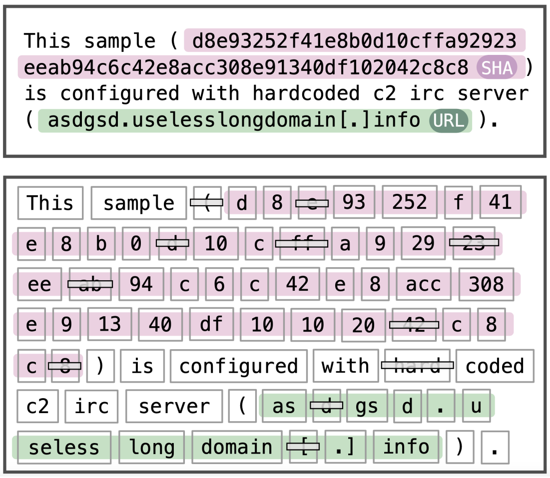
Abstract

Cybersecurity information is often technically complex and relayed through unstructured text, making automation of cyber threat intelligence highly challenging. For such text domains that involve high levels of expertise, pretraining on in-domain corpora has been a popular method for language models to obtain domain expertise. However, cybersecurity texts often contain non-linguistic elements (such as URLs and hash values) that could be unsuitable with the established pretraining methodologies. Previous work in other domains have removed or filtered such text as noise, but the effectiveness of this approach has not been investigated, especially in the cybersecurity domain. We experiment with different pretraining methodologies to account for non-linguistic elements (NLEs) and evaluate their effectiveness through downstream tasks and probing tasks. Our proposed strategy, a combination of selective MLM and jointly training NLE token classification, outperforms the commonly taken approach of replacing NLEs. We use our domain-customized methodology to train CyBERTuned, a cybersecurity domain language model that outperforms other cybersecurity PLMs on most tasks.

1 Introduction

Cybersecurity is a critical concern as the world continues to grow reliant on technology. Modern cybersecurity practice emphasizes the need for preemptive defense utilizing Cyber Threat Intelligence (CTI) — actionable information on possible cyber-threats (Farnham and Leune, 2013). However, due to the unstructured and complex nature of such information, leveraging CTI requires extensive manual inspection by human experts (Husari et al., 2017). Although automating cyber threat intelligence has been regarded as important (Fernández Vázquez et al., 2012; Kampanakis, 2014), it has been considered highly challenging (Wagner et al., 2019).



This sample (d8e93252f41e8b0d10cffa92923 eeab94c6c42e8acc308e91340df102042c8c8 SHA) is configured with hardcoded c2 irc server (asdgsd.uselesslongdomain[.]info URL).

Figure 1: A threat report excerpt after tokenization and masking with 15% probability. The tokens inside the SHA hash and URL are highlighted. Masked tokens are indicated by a gray bar.

Meanwhile, pretrained language models (PLMs) have shown great potential for text comprehension (He et al., 2020). However, PLMs are unlikely to have developed the necessary expertise for domains that require significant domain knowledge, such as the cybersecurity domain. This could be somewhat addressed by extremely large models (Sergeev, 2023), but this option is costly to train and run. A more common approach to teach domain expertise to PLMs has been to pretrain on a domain-specific corpus. The effectiveness of such domain-pretrained PLMs has been demonstrated in the biomedical (Lee et al., 2019), scientific (Beltagy et al., 2019), and legal (Chalkidis et al., 2020) domains to name a few. Several cybersecurity domain PLMs (Ranade et al., 2021; Aghaei et al., 2022; Bayer et al., 2022) were also trained in a similar manner.

However, cybersecurity texts often incorporate non-linguistic elements (NLEs) that could be inappropriate for self-supervised pretraining. Self-supervised objectives like masked language mod-

Findings of the Association for Computational Linguistics: NAACL 2024, pages 29–42
June 16-21, 2024

eling (MLM) (Devlin et al., 2019) or de-noising objectives (Lewis et al., 2020) learn by recovering original texts from a masked or modified state. While this is mostly beneficial for natural language, such tasks might not be effective when trying to recover tokens in non-linguistic parts of text. Figure 1 shows an excerpt from a malware threat report containing a SHA hash and a URL. The SHA hash tokens are linguistically random, and therefore training a model to correctly recover these tokens may not be beneficial. Similarly, the URL tokens are less predictable compared to the natural language text surrounding it, and therefore potentially unsuitable for pretraining.

Outside of the cybersecurity domain, previous works addressed such NLEs through replacement (e.g. replace all URLs with "*[URL]*") (Dai et al., 2020; Caselli et al., 2021; Jin et al., 2023) or filtering (Le et al., 2020; Raffel et al., 2020; Hung et al., 2022). However, no attempt has been made to verify whether these approaches actually benefit pretraining. It is also unclear whether such practices would have similar benefits in the cybersecurity domain, where it is more common for NLEs to be used alongside natural language. Conversely, pretraining with NLEs could be beneficial to utilize the informational value of NLEs. For instance, a model may learn to identify suspicious domains in URLs or recognize familiar hash values in the way human cybersecurity experts can.

We investigate different strategies of pretraining on the cybersecurity domain. We first identify commonly occurring NLE types that can be extracted using regular expressions. We then pretrain models using different MLM strategies, testing the effectiveness of selective masking and NLE token classification and comparing to the vanilla MLM and replacement strategy. Our experiments suggest that replacement benefits on downstream tasks but harms performance on probing tasks, especially near NLEs. Instead, we find that a strategy of selective masking while jointly training with NLE token classification generally outperforms the replacement strategy. Using this strategy, we train CyBERTuned (Cybersecurity BERT-like Utilizing Non-linguistic Elements of the Domain), a cybersecurity domain PLM trained with the domain-customized pretraining methodology. We show CyBERTuned outperforms comparable cybersecurity domain PLMs in most tasks. CyBERTuned model weights, training resources, and code are publicly available at `https://github.com/genesith/CyBERTuned`.

Our contributions are as follows:

- We propose and test multiple strategies to deal with NLEs when pretraining on a cybersecurity corpus.
- Through experiments on a variety of domain tasks, we find a strategy that is preferable to the common practice of replacing NLEs.
- We use our methodology to train CyBERTuned, a cybersecurity domain encoder model that outperforms other cybersecurity models.
- We provide our model weights, training resources, and code.

2 Related Work

Cybersecurity NLP Automating cyber threat intelligence has been often discussed in literature (Kampanakis, 2014; Wagner et al., 2019; Jo et al., 2021). Classical off-the-shelf NLP methods, such as regex processing and dependency parsing, have been used to extract attack patterns (Husari et al., 2017) or malware behaviors (Zhu and Dumitraş, 2016) from cybersecurity texts. Recent works explore the potential of using BERT (Devlin et al., 2019) for more complex tasks such as exploitability prediction (Yin et al., 2020), malware detection (Rahali and Akhloufi, 2021), and dark web analysis (Jin et al., 2023).

Domain PLMs PLMs train with large text corpora using self-supervision tasks (Devlin et al., 2019; Lewis et al., 2020; He et al., 2020). Many domain PLMs (Lee et al., 2019; Chalkidis et al., 2020; Beltagy et al., 2019) were able to outperform general PLMs on domain-specific tasks by simply replicating existing pretraining procedures on domain corpora. PLMs for the cybersecurity domain using this approach have been suggested by several works (Ranade et al., 2021; Aghaei et al., 2022; Bayer et al., 2022). Our work differs in that we use a domain-customized methodology after investigating the effectiveness of various strategies.

Pretraining Strategies Self-supervised tasks for pretraining have been investigated by many works (Lewis et al., 2020; Aroca-Ouellette and Rudzicz, 2020; Yamaguchi et al., 2021). Some works find improvements by modifying the masking procedure of the MLM task. Changing mask-

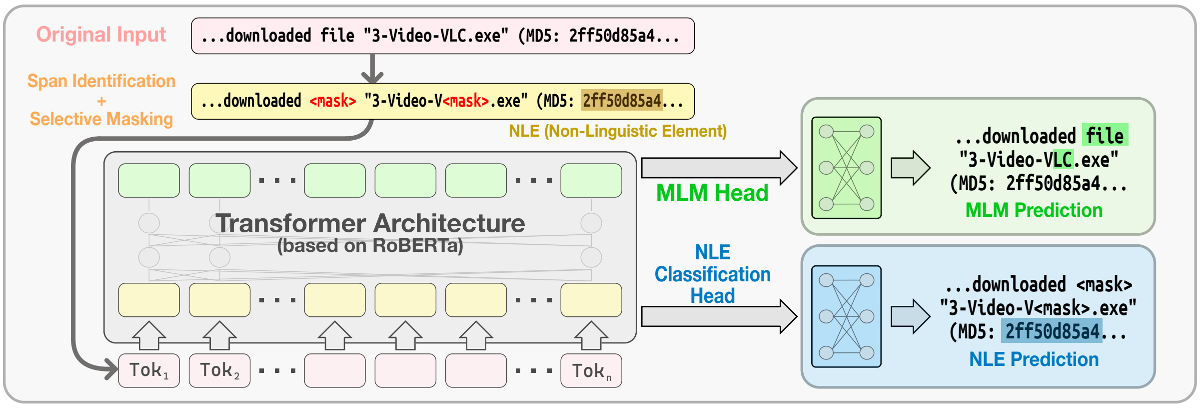

Figure 2: The overall architecture of CyBERTuned. NLE spans from the original input is used in the masking step and for NLE classification.

ing from token-level to word-level significantly improved BERT pretraining for Chinese (Cui et al., 2021). Works on selective masking suggested that masking tokens important to tasks (Gu et al., 2020), entities (Lin et al., 2021), or reasoning (Sanyal et al., 2023) more frequently was effective. Conversely, our selective masking method skips masking tokens that are ineffective for MLM training. Previously, dropping less important tokens mid-training was suggested as a way to increase training efficiency (Hou et al., 2022), but at the cost of losing semantic sensitivity (Zhong et al., 2023). In our work, ineffective tokens are identified beforehand via NLE spans, and are skipped during masking rather than dropped during training.

3 Method

In this section, we first discuss the types of NLEs in cybersecurity texts and how to extract NLE instances. We then propose some methods to utilize the extracted NLE spans in pretraining with cybersecurity texts.

3.1 Non-linguistic Elements

Cybersecurity texts often feature non-linguistic text alongside natural language. Among non-linguistic texts, certain types of are extractable with regular expressions (Husari et al., 2017). We narrow our scope to non-linguistic elements that can be identified by regular expressions, since our aim is to apply them into self-supervised tasks. After manual inspection of cyber threat reports, we select the NLE types that are both frequent and identifiable with regular expressions. The following 7 types were selected: *URLs*, *email addresses*, *IP addresses*, *MD5 hashes*, *SHA hashes*, *Bitcoin addresses*, and *CVE IDs*[1]. Note that we do not consider NLE types that require significant effort to extract precisely, such as filepaths or code blocks. We also extend detection to defanged NLEs (e.g., *hxxp*://example.com, 192.168*[.]*1.192) by utilizing the iocide Python library[2].

3.2 Leveraging NLE Spans in Pretraining

We study two methods to leverage extracted NLE spans to guide the pretraining. Figure 2 shows a model utilizing both methods.

NLE Classification: The model is explicitly instructed to predict which tokens belong to NLEs in the pretraining text. This can be modeled as a simple token classification task and can be trained alongside the MLM task. Each token is labeled with its NLE type (0 if outside of NLE span), which is predicted by a token classification head (linear layer).

Since this task is a more semantically shallow task compared to the original MLM task, it should not dominate the total loss function (Aroca-Ouellette and Rudzicz, 2020). Therefore, we apply a scaling factor (0.1) before adding with the MLM loss to produce the total loss.

Selective MLM: In the masking stage, the NLE spans are used to avoid masking tokens that are inside NLEs. However, since informational content varies between NLE types it must be investigated whether all NLE types should be avoided.

---

Table 1: Comparisons between how each text types are processed in different strategies. In the MLM examples, highlighted sections indicate text that are considered for masking. In the NLE Classification examples, each token is predicted for its NLE type (indicated by color).

We note that NLEs that involve human generated text (URLs and emails), unlike protocol-generated values (IP addresses, hash values, etc.), can contain linguistically meaningful information. For instance, a human expert may identify the URL *github[.]url-mini[.]com/msg.zip* as a malicious file download link from a fake domain masquerading as the legitimate GitHub domain.

To make a simple distinction between NLE types, we group the NLEs based on whether they are generated by humans or protocol. Specifically, we group *URLs* and *emails* as **semi-linguistic elements** (SLEs) and *IP addresses*, *MD5 hashes*, *SHA hashes*, *Bitcoin addresses*, and *CVE IDs* as **fully non-linguistic elements** (FNLEs). We then test two settings of selective masking: **Mask-None**: all NLE types are avoided during masking. **Mask-Semis**: fully non-linguistic elements are avoided but semi-linguistic NLEs are allowed to be masked.

4 Pretraining the Models

To evaluate our pretraining methodology on the cybersecurity domain, we pretrain models on a cybersecurity text corpus using a number of strategies. We first describe the tested pretraining strategies, including the vanilla MLM and ablation settings. We also describe our cybersecurity corpus and show statistics that suggest NLEs are more frequent in cybersecurity texts.

4.1 Pretraining Strategies

We compare a total of 6 pretraining strategies. First we include two commonly used strategies as baselines. As ablation studies, we also test two strategies using only one method. Then two strategies that utilize both NLE classification and selective MLM are described. Examples of these strategies can be seen in Table 1.

Vanilla MLM: The original masking strategy (Devlin et al., 2019). After tokenization, 15% of the input tokens are selected for prediction. Following the original implementation, 80% are converted into the mask token, 10% are converted into a random token, and 10% are unchanged.

Replace All: A commonly used strategy to reduce the impact of NLEs in pretraining (Caselli et al.,

2021; Jin et al., 2023). The MLM method is unchanged, but the NLEs in the input corpus is converted to an identifier of the NLE type (e.g., all CVE IDs are replaced with "<CVE>"). However, comes with a risk of reducing informational content in the pretraining corpus.

Vanilla + NLEC: The MLM method is unchanged, but the joint task of token-level NLE classification (NLEC) is also performed. While MLM is still done on NLE tokens, NLEC could instruct the model to understand the different role the tokens have.

Mask-Semis: A selective MLM method that avoids masking of FNLEs (hash values, IP addresses, etc.) while allowing masking of SLEs (URLs and emails).

Mask-Semis + NLEC: A strategy using both the selective masking and NLEC. In this setting, tokens in SNLEs are allowed to be masked and tokens in FNLEs are avoided.

Mask-None + NLEC: A strategy using both the selective masking and NLEC. In this setting, tokens in all NLEs are avoided during masking.

4.2 Cybersecurity Corpus

We collect and curate a large amount of text from publicly available online sources. Like other cybersecurity PLMs, we construct our corpus with data from a variety of sources: Online Security Articles, Security Paper Abstracts, Wikipedia Articles, and CVE Descriptions. A detailed description of the components and collection of the corpus can be found in Appendix A and D.

Pretraining subset. We further identify a subset of the corpus focused on threat reports to pretrain on. This is because the full corpus covers a variety of styles, including news articles written for non-expert audiences. Such articles contain little technical information and few NLEs. Since our goal is to compare pretraining strategies of teaching technical expertise of analysts to models, we filter to find sources that publish for expert audiences. From 60 total online source sites, we select 30 sites that more often feature technical information to make up the pretraining subset. The data size of our sources used for constructing the corpus and the pretraining subset is listed in Table 2.

NLE Statistics. To demonstrate the frequency of non-linguistic elements in our cybersecurity text corpus, we compare our corpus with two general domain text corpora: the Wikipedia corpus and the C4 corpus (Raffel et al., 2020). The Wikipedia corpus, used in pretraining BERT and other models, consists of text content from Wikipedia articles. The C4 corpus, first used for pretraining T5 (Raffel et al., 2020), is a collection of crawled web pages. Unlike our corpus, the C4 corpus aims to include only natural language text and use heuristics to filter text with non-natural language. Due to the large size of this dataset, we sample 0.1% of the total size (365,234 documents) for our analysis.

To compare between corpora, we calculate the frequency of NLEs. We first count the number of instances of each NLE type, using our detection methodology (discussed in Section 3.1) on each corpus. We use the NLTK (Bird and Loper, 2004) tokenizer to count the number of words in each corpus. Table 3 shows the frequencies of each non-linguistic element per million words. We observe that the frequency of NLEs in our corpus is significantly higher compared to the two general domain corpora.

Strategies	Downstream Tasks			Probing Tasks	
	CyNER	CySecED	MTDB	All	Near-FNLEs
RoBERTa	0.637	0.504	0.802	0.278	0.270
Vanilla MLM	0.648	0.510	0.822†	0.382	0.460
Replace All	0.664$^{\dagger *}$	0.544	0.827†	0.381	0.438
Vanilla + NLEC	0.652	0.526	0.820	0.380	0.455
Mask-Semis	0.638	0.538	0.817	**0.386**	0.463
Mask-Semis + NLEC	**0.667**$^{\dagger *}$	**0.544**†	0.825†	0.383	**0.464**
Mask-None + NLEC	0.643	0.533†	**0.829**†	0.382	0.452

Table 4: Experimental results on multiple pretraining strategies. Downstream tasks show median values over 10 runs. **Boldface** represents the best score and underlined values represents the second best score. The † symbols indicates statistically significant distributions from the RoBERTa-base baseline. The * symbols indicates statistically significant distributions from the Vanilla MLM baseline.

4.3 Pretraining Setup

For our experiments, we pretrain further on the pretrained RoBERTa-base model (Liu et al., 2019). We choose the RoBERTa model as the base architecture because its minimal pre-tokenization scheme and coverage is suitable to our corpus[3]. For efficiency, we choose to pretrain further on the pretrained model, following findings that suggest that this method is as effective as training a model from scratch (Chalkidis et al., 2020; El Boukkouri et al., 2022). We mostly follow RoBERTa's training hyperparameters, with few modifications to account for our smaller corpus size (details can be found in Appendix C). Note that the *Replace All* strategy modifies the pretraining corpus size. For fair comparison, all models were trained for 500 steps (∼12 epochs for the *Replace All* model, ∼10 epochs for other models).

5 Experiments

We evaluate the models trained by each pretrained strategy with both downstream tasks and probing tasks. For comparison, we also experiment with the base RoBERTa model.

5.1 Downstream Tasks

We compare the ability of each model to fine-tune onto downstream tasks using challenging cybersecurity datasets.

CyNER (Alam et al., 2022): A named entity recognition dataset of annotated malware threat reports. The reports are annotated for five entity types: Malware, System, Organization, Indicator, and Vulnerability.

CySecED (Man Duc Trong et al., 2020): An event detection dataset of annotated articles from The Hacker News. The articles are annotated for 30 fine-grained events types describing cyber-attacks or vulnerabilities.

MalwareTextDB (MTDB) (Lim et al., 2017; Phandi et al., 2018): A dataset of malware reports annotated for four types of attributes ActionName, Capability, StrategicObjectives and TacticalObjectives. The labels are cast into a multiple choice question format, where the objective is to identify the correct attribute given a passage, attribute type, and answer choices.

5.2 Probing Tasks

A disadvantage of comparing performance with downstream tasks is that fine-tuning modifies the model weights learned from pretraining. In order to evaluate the model weights themselves, we probe the model's ability to produce correct MLM answers for relevant tokens similar to the LAMA (Petroni et al., 2019) framework. We follow the domain-specific version by Chalkidis et al. (2023), in which a list of legal terminology was used to find instances of the terms from a target corpus. Models are then evaluated by its ability to recover the correct terminology after it is masked.

Our implementation tests model ability to cor-

---

[3] The BERT pretokenizer assumes there are spaces between the ':', '/', '.' characters common in URLs. The corpus also contains obscure characters that aren't considered by other tokenizers(the T5 tokenizer does not have the '\' character in its vocabulary.

rectly identify cybersecurity terminology in text context. We first construct a list of relevant terminology by taking words used in MITRE's database of enterprise attack techniques[4]. After processing and filtering, we identify 226 tokens to be used for probing (see Appendix B). To probe the ability of each model, we evaluate the MLM performance on the validation split of the full corpus after masking all target tokens. A total of 77,983 tokens were masked. We also mark tokens in the vicinity (within 20 tokens away) of FNLEs, to see if the presence of FNLEs affects the probing performance. A total of 4,906 tokens were near FNLEs.

5.3 Results

The results of the experiments are presented in Table 4. For downstream tasks, we report the median values over 10 seeds. We mark statistical significance of $p < 0.05$ compared with the base RoBERTa and *Vanilla MLM* baselines. F1 scores are shown for the CyNER and CySecED tasks and accuracy is shown for the MTDB task and probing tasks.

NLEC. Comparing the *Vanilla MLM* with the *Vanilla + NLEC model* suggests that the classification task, on its own, does not provide meaningful benefits. However, when comparing the *Mask-Semis* and *Mask-Semis + NLEC* settings, the addition of the NLEC task provides a noticeable benefit in downstream tasks. In both comparisons, NLEC caused a slight decrease in the probing tasks.

Selective Masking. Comparing the *Vanilla MLM* with the *Mask-Semis* model suggest that selective masking does not produce consistent gains in downstream tasks, although it benefits probing tasks. Comparing *Mask-Semis + NLEC* and *Mask-None + NLEC* settings, the strategy of masking SLEs seems to benefit more consistently across downstream tasks and the probing tasks. This results suggests that there is value in performing masking on URLs and emails.

Best performers. While different pretraining methods suit different tasks (Lewis et al., 2020), the *Mask-Semis + NLEC* model performed consistently well across all tasks. The *Replace All* model was also very capable in downstreaming tasks, but was weaker in probing tasks. Especially, the model probing performance was worst of all the pretrained models when the probed token was near an FNLE. This is an undesirable characteristic of the model, since the model is expected to encounter multiple FNLEs in the domain. We argue *Mask-Semis + NLEC* is the best strategy because it allows the model to utilize NLEs while achieving high downstream performance.

6 CyBERTuned Experiments

6.1 Pretraining CyBERTuned

With our findings, we train our final model CyBERTuned. We train on a larger scale with the *Mask-Semis + NLEC* strategy. We compare our model with other language models on a larger array of downstream tasks in the cybersecurity domain. The CyBERTuned model is trained on our full cybersecurity corpus using a similar setup. Compared to the previous experiments, we train longer for a total of 200 epochs on a larger corpus.

6.2 Downstream Tasks

We conduct downstream tasks[5] on a wider variety of cybersecurity tasks. The new tasks are described below.

CASIE (Satyapanich et al., 2020): An event detection dataset of annotated news articles for non-expert audiences. The articles are annotated for five event types: data breach, phishing, ransom, discover, and patch.

TwitterThreats (TT) (Zong et al., 2019): A binary sequence classification dataset of annotated tweets that mention threat keywords. Each tweet is annotated on whether the tweet describes a threat to the mentioned entity.

CYDEC (Yagcioglu et al., 2019): A binary sequence classification dataset of annotated tweets that mention cybersecurity keywords. Each tweet annotated on whether the tweet describes a cybersecurity-related event.

6.3 Baselines

We compare CyBERTuned with the base RoBERTa model and other cybersecurity domain PLMs. All models follow the 12-layer Transformer encoder architecture.

RoBERTa-base (Liu et al., 2019): The RoBERTa-base model that was used to initialize CyBERTuned.

---

[4] `https://attack.mitre.org/techniques/enterprise/`

[5] Note that we do not do the probing tasks, since only our model was trained on the same sources of text with the validation corpora.

	Token Class.			Sequence Class.		MCQA
	CASIE	CyNER	CySecED	CYDEC	TT	MTDB
RoBERTa-base	0.748	0.637	0.504	0.829	0.831	0.802
CyBERT	0.711†	0.462†	0.361†	0.798	0.832	0.731†
CySecBERT	0.734	0.572†	0.491	0.814	0.845†	0.808
SecureBERT	**0.753**	0.638	0.529†	0.816	0.828	0.825
CyBERTuned (Ours)	0.750	**0.654**	**0.585**†	**0.844**	**0.857**†	**0.861**†

Table 5: Experimental results of CyBERTuned and baselines on downstream cybersecurity tasks, showing median F1 scores across 10 seeds. **Boldface** values represents the best score and underlined values represents the second best score. The symbols † (positive) and † (negative) indicates statistically significant distributions from the baseline (RoBERTa-base).

CyBERT (Ranade et al., 2021): A cybersecurity BERT-based model, further pretrained on the base BERT model. The BERT vocabulary is extended by 1,000 tokens from the training corpus identified by TF-IDF.

CySecBERT (Bayer et al., 2022): A cybersecurity BERT-based model, further pretrained on the base BERT model. The model uses the BERT vocabulary.

SecureBERT (Aghaei et al., 2022): A cybersecurity RoBERTa-based model, further pretrained on the base RoBERTa model. The model uses a custom vocabulary with adjusted token weights.

6.4 Results

The experiment results are presented in the Table 5. As before, we conduct each experiment over 10 seed values and report median values.

The base RoBERTa model, despite being pretrained on the general domain, performed better than some domain PLMs in several tasks. Of the two BERT-based models, CyBERT performed poorly on most tasks while CySecBERT generally showed competitive performance. However, even CySecBERT performed poorly in the CyNER task. This is possibly due to its usage of the uncased BERT tokenizer, which not only distorts texts with special characters but is case-insensitive (possibly important for NER).

SecureBERT was the only model that beat CyBERTuned in a task. It showed high performance in the token-level tasks, suggesting some benefit of their custom tokenizer. On the other hand, CyBERTuned performed consistently, achieving best or second-best performance in all tasks.

7 Discussion

RoBERTa's performance. The base RoBERTa model achieved good performance on certain tasks after fine-tuning, often outperforming domain-pretrained models. A possible interpretation is that previously challenging cybersecurity tasks, such as binary sequence classification of threat tweets, do not require extensive domain knowledge to achieve high performance. It should be noted that the CYDEC dataset reports a human F1-score of 0.59 and the TwitterThreats dataset reports a Cohen's κ of 0.66, suggesting these models have possibly already exceeded human and annotator performance on these tasks. This underscores the need for more challenging datasets for benchmarking models in the cybersecurity domain.

NLE Classification as auxiliary task. Although MLM loss takes long to plateau, NLE classification loss plateaus quite early during pretraining. We note that the NLE classification overhead is not large, training with and without NLE classifications only had a 0.6% difference in training time. One possible method to increase training efficiency might be to drop NLE classification task after the loss plateaus. Whether this would achieve comparable performance could be investigated in further work.

NLEs of other domains. While it is common practice to remove NLEs in other domains, our investigation suggests proper modifications to training may be preferable. However, our experiments were conducted in the cybersecurity domain, where certain NLE types can contain informative content. The optimal pretraining strategy is likely different across text domains, and dependent on informational content of NLEs.

8 Conclusion

We investigate methods to modify pretraining to suit the cybersecurity domain. We find that a strategy of selective MLM that allows for masking of semi-linguistic elements but not fully-linguistic elements with an auxiliary NLE classification task showed best performance. With these findings, we present CyBERTuned, a cybersecurity PLM with our modified pretraining methodology. The final CyBERTuned model shows strong performance across all cybersecurity downstream tasks. Our findings support the importance of adapting pretraining methodologies to suit target domains.

Limitations

Non-linguistic Element Types. The types of non-linguistic element discussed in this work represent a subset of a large set of textual data that are atypical to natural language. While there are more text types that fall under this category, our scope was limited to types that are easily identifiable to be practical for self-supervision. We note the existence of more complex types of text that are relevant to understanding cybersecurity text such as code blocks, filepaths, or log entries. We leave the detection and effective utilization of such text types for future work.

Another limitation is that the strategies tested utilized broad distinctions between SLEs and FNLEs. Due to computational restraints, it was not possible to pretrain while treating each NLE type uniquely. Therefore, even with our method that utilizes masking SLEs to improve performance, it is difficult to attribute the performance gains to specific individual NLE types. For now we focus discussions on our empirical results, and leave fine-grained analysis to future work.

Downstream tasks. There are many factors to consider when fine-tuning downstream tasks across multiple models. We attempt to find stable settings that allow all runs to be successful, but there are inconsistent runs. To mitigate this, we report median values of 10 seed values and suggest the probing task as an alternative. Since our experiments are run across multiple models, multiple tasks, and multiple hyperparameters, there may be cases of novel untested hyperparameter combinations on model-task combinations that have not been explored.

NLEs in different domains. As stated in Section 7, the findings in this work were investigated only in the cybersecurity domain. For example, the URL NLE type also occurs frequently in other domains, but might not have the similar information value of performing MLM as the cybersecurity domain. Therefore, the decision to do MLM on URL tokens could depend on the domain. An example of a domain where MLM of URL tokens might be inappropriate is in the Twitter text domain, where links are randomized by the Twitter URL shortener.

A Corpus

We construct our corpus with data from the following sources:

- **Online Security Articles**: Following work in CTI (Zhao et al., 2020) we identify news outlets, corporate blogs, and personal blogs that discuss cybersecurity content. We find a total of 60 online sources (see Appendix D). We extract text using Scrapy[6] and Selenium[7].
- **Security Paper Abstracts**: We identify security conferences that make the abstracts of accepted papers publicly available. In total, we collect 7,301 abstracts from 8 different security conferences.
- **Wikipedia Articles**: We start with the cybercrime category[8], recursively visiting its subcategories one by one and collecting all the pages under each category while discarding irrelevant pages through manual inspection. We collect a total of 3,411 pages.
- **CVE Descriptions**: The CVE database[9] is a database of publicly disclosed vulnerabilities. Each vulnerability is assigned an ID and given a short description. We process the database to remove duplicate descriptions, incomplete (reserved or unused CVEs) descriptions, and descriptions that are too short (less than 10 words). We retain a total of 184,956 CVE entries of unique and informative descriptions.

B Tokens for Probing Task

We collect a total of 556 phrases from the attack techniques and subtechniques listed in the MITRE database. For simplification, we only select single-token target words. From the phrases, we seperate into words and check if the word is in the RoBERTa tokenizer. This way we find a total of 871 target tokens. Since many common tokens such as “ and" or “ to" are selected in this way, we apply a simple filter by token IDs to remove common tokens (ID < 25,000). This results in a target token list of 226 tokens including “ Unix" and “ runtime".

C Experiment settings

C.1 Pretraining

To pretrain the models for Section 4, we train on 2 NVIDIA A100 80GB GPUs. We use a slightly lowered effective batch size of 2024 to accomodate the smaller corpus size, and a warmup ratio of 0.048 following RoBERTa (which uses fixed steps). Other hyperparameters regarding including learning weights, weight decay, and adam hyperparameters are kept the same as RoBERTa’s.

To pretrain the full CyBERTuned model described in Section 6.1, we train on 4 NVIDIA A100 80GB GPUs on our full corpus. The hyperparameter settings are kept the same as above with the exception of the maximum epochs, which is set to 200.

C.2 Fine-tuning

For all tasks, fine-tuning is done with 20 max epochs, warmup ratio of 0.06, and an early stopping patience of 4 based on evaluation loss on the dev set. For the token classification tasks, evaluation is done every epoch. For sequence classification tasks, evaluation is done every 200 steps. For the multi-choice QA task, evaluation is done every 200 steps.

To best compare the models themselves, we keep implementations simple for downstream tasks. We use the Hugging Face (Wolf et al., 2020) implementations of each task. For token classification, sequence classification, and multichoice QA tasks, we use the AutoModelForTokenClassification, AutoModelForSequenceClassification, and AutoModelForMultipleChoice, respectively.

To simplify hyperparameter selection, we select a batch size for each task following observations that input types varied heavily on the task (such as sentences and documents). First we conducted a grid search of learning rates $\in \{2e5, 3e5, 5e5, 1e\text{-}4\}$ and batch sizes $\in \{1, 2, 4, 8, 32\}$ for the CyNER task. We identified learning rate of 5e-5 and batch size 32 worked best. This combination worked well with all tasks involving single-sentence inputs. CYDEC and TwitterThreats use this setting. For CySecED (document), we did grid search of batch sizes $\in \{1, 2, 4, 8, 32\}$ and find that batch size of 1 works best. CASIE also uses this setting. For MTDB (QA), we did grid search of batch sizes $\in \{1, 2, 4, 8, 32\}$ and find that batch size of 8 works best.

We use the train/eval/test given in the datasets

---

[7] https://www.selenium.dev

[8] https://en.wikipedia.org/wiki/Category:Cybercrime

[9] https://cve.mitre.org/

if possible (CyNER, CySecED, MTDB). If the dataset does not have splits (CASIE, TwitterThreats, CyDEC), we split randomly at a 8:1:1 ratio. Since CyNER deals with identifying exact spans while CySecED and CASIE deals with identifying event triggers, we use a stricter matching for CyNER (with seqeval[10]) but use a loose matching scheme for CySecED and CASIE.

Extremely efficient online query encoding for dense retrieval

Nachshon Cohen

guyk@amazon.com

Abstract

Existing dense retrieval systems utilize the same model architecture for encoding both the passages and the queries, even though queries are much shorter and simpler than passages. This leads to high latency of the query encoding, which is performed online and therefore might impact user experience. We show that combining a standard large passage encoder with a small efficient query encoder can provide significant latency drops with only a small decrease in quality. We offer a pretraining and training solution for multiple small query encoder architectures. Using a small transformer architecture we are able to decrease latency by up to $\sim 12\times$, while $MRR@10$ on the MS MARCO dev set only decreases from 38.2 to 36.2. If this solution does not reach the desired latency requirements, we propose an efficient RNN as the query encoder, which processes the query prefix incrementally and only infers the last word after the query is issued. This shortens latency by $\sim 38\times$ with only a minor drop in quality, reaching 35.5 $MRR@10$ score.[1]

1 Introduction

Information retrieval was revolutionized by semantic matching models (Karpukhin et al., 2020; Xiong et al., 2021; Gao and Callan, 2021, 2022). Such models encode the corpus of passages[2] and the query in a shared embedding space, where retrieval is performed using an (approximated) nearest neighbors search (Johnson et al., 2021). These models increase the quality of search results dramatically (Zhao et al., 2022), but suffer from a large computational overhead (Chen et al., 2021). While training a large model and encoding the corpus is costly, this can usually be done offline once (or every couple of days/weeks) and cost is bounded by the size of the corpus. On the other hand, encoding queries is a major part of the retrieval system that is performed frequently and online, making latency an important consideration.[3] Hence, cutting the latency of this component directly leads to a cut in the online-latency of the whole system.[4]

Today, practically all semantic retrieval models use the same architecture to embed both the corpus (passages) and the queries. Knowledge distillation (Hinton et al., 2015) has been used to improve efficiency by creating smaller models. However, mainly transformer-based architectures (Vaswani et al., 2017) of medium size were considered (Gao et al., 2020; Chen et al., 2021), putting a bound on the achievable latency of the query encoding.

Balancing between the latency and cost requirements is challenging; while sophisticated GPU implementations can run BERT inference in just a few milliseconds, this hardware is very costly. This is especially problematic in an over-provisioning setting, where utilization is kept low to handle burst of traffic. Further, as query encoding is run online, it is often necessary to use a batch size of 1, which also limits the GPU utilization. Therefore, it is often necessary to use a CPU for query encoding, which in-turn increases the latency overhead. This challenge calls for a query-embedding solution that can balance cost and latency, while still providing quality embeddings for retrieval.

The simple, yet crucial observation we make in this paper is that queries are usually very short; often just 3-5 words, and rarely exceeding 15 words. This is in contrast to passages (or documents),

---

[1] Code can be found at https://github.com/amzn/extremely-efficient-query-encoder

[2] In this paper we consider the passage retrieval task. Retrieving documents or other textual units is similar in concept.

[3] The other significant part typically run online is an approximate KNN-search. We experiment with ScaNN (Guo et al., 2020), a popular KNN solution. We use it with standard parameters to retrieve from MS-MARCO's corpus and find that query embedding takes $\sim \times 4$ more time than the KNN search. Hence, we can determine that the significant portion of online latency is spent on embedding the query.

[4] Additional avenues for reducing latency are presented in (Seo et al., 2019; Fang et al., 2020; Lewis et al., 2021; Formal et al., 2021).

Findings of the Association for Computational Linguistics: NAACL 2024, pages 43–50
June 16-21, 2024

which consist of dozens of words or more in some settings. Therefore, we argue that while large, complex models and a vast amount of training data are crucial for quality passage embedding[5], for query embedding it is sufficient to use smaller, simpler models. With this observation, we propose a method to trade-off latency and quality of online query encoding for dense retrieval, reaching low latency while preserving reasonable quality.

Specifically, we propose training two different variations of small models for query encoding. The first straightforward option is a small, efficient transformer. This leads to impressive results, barely hurting the retrieval quality, but the decrease in online-latency is limited to $12\times$, reaching 2.1 milliseconds. To extend our solution and also deal with cases where a more significant decrease in online latency is needed, we propose using an RNN-based model. As mentioned above, queries tend to be short, making RNNs a viable option.

Apart from being efficient, the RNN architecture offers another benefit for online latency. Since an RNN processes tokens sequentially, the system can feed the model with the prefix of the query as it is typed by the user. When the user issues the query, the model only needs to process its last word. This method is denoted as *incremental inference* in this paper, and is able to further reduce online-latency. Our smallest proposed model reaches a $38\times$ drop in latency compared to the baseline, with an online latency of only 0.7 milliseconds running on a CPU, while also achieving competitive quality results. Finally, for cases where online-latency is of utmost importance, we suggest a method to practically nullify the contribution of query-encoding to the online-latency at the cost of $\sim 4\times$ rise in compute.

2 Design

We want to train a dual encoder system composed of a small and efficient query encoder and a standard larger transformer passage encoder. We are not interested in the training procedure of the large encoder, which was already studied thoroughly. Therefore, we assume one is available.

We denote by T_{enc} the large Transformer encoder, and S_q as the small query encoder (either a smaller transformer, or an RNN). Even though the passage and query encoders cannot share all their weights due to their different sizes and architectures, we opt to keep the token embeddings of both models tied. This ensures that a token has the same "meaning" in both models (Dong et al., 2022). This decision is further discussed in Appendix A. To train the efficient query encoder we operate in stages, as detailed in this section.

2.1 Pretraining via Distillation

A large encoder T_{enc}, trained for passage and query encoding, is available. Thus, we use it as a teacher to the smaller S_q. We train S_q to imitate the embeddings T_{enc} generates for all queries in the train set. We use a standard cosine similarity loss, pushing the embeddings generated by S_q towards the embeddings generated by T_{enc}. We pretrain for 10 epochs, as discussed in Section 4.4.1.

2.2 Training on Labeled Data

The large passage encoder T_{enc} and the small query encoder, starting from the pretrained S_q, are trained for dense retrieval. We use the standard training procedure of (Gao and Callan, 2022), including the selection of negative samples and other hyper-parameters. Further details appear in Appendix B.

2.3 Small Model Architectures

RNN. In this work we use a GRU (Cho et al., 2014) as the architecture of S_q. In order to increase the capability of the network, we consider models with different capacities by stacking multiple recurrent networks together and adding a feed-forward (FF) layer on top of the embedding generated for the last token of the query. This, of course, comes with a latency cost. The FF network is defined as:

$$FF(x) = LayerNorm(x + W_2(Gelu(W_1 \cdot x + b_1) + b_2)$$

Small Transformer (ST). When using a transformer based model to implement S_q, we use a BERT-like architecture with different number of layers. We initialize the model from the first layers of the pretrained encoder T_{enc}.

3 Incremental Inference with RNNs

When using an RNN to encode a token-sequence, the encoding of the prefix of tokens is independent of the rest of the tokens:

$$\mathrm{RNN}(\mathrm{pref} + \mathrm{suff}) = \mathrm{RNN}(\mathrm{RNN}(\mathrm{pref}), \mathrm{suff})$$

This property enables incremental encoding of user queries before they are fully composed. Upon

---

[5] Gao et al. (2020) show that in order to properly distil an encoder for retrieval a vast amount of data is needed.

query completion, encoding only the remaining part accelerates encoding and minimizes latency.

However, while the model can encode tokens incrementally, the tokenization process is not independent of the prefix. For example, while `hell` is a prefix of `hello`, their token representations are not. Luckily, word boundaries (e.g., a space) are not crossed by the tokenizer, so prefix encoding can immediately be applied when coming across such a boundary. When the user issues the query, only the last word has to be encoded.

A single word can span multiple tokens (e.g., 'cephalosporin' consists of 5 tokens), necessitating multiple inference steps. Still, in the MS MARCO dev set queries, the last word's token count percentiles (p50, p90, p95, and p99) are 1, 2, 3, and 4 (respectively). In complete queries the same percentiles correspond to 9, 12, 14, and 18 tokens. This suggests that by only processing the last word of a query on the critical path of inference, we can significantly reduce the latency. Note, the current Guinness record for fast typing is 212 words per minute[6], or 283ms per average word. As our computation speed per word is significantly smaller, computations of the query prefix are done before the last word is issued. While this approach could increase overall computation time[7], in most cases the latency of the critical path is more important than overall latency. Section 4.1 shows that incremental encoding can vastly reduce this measure.

3.1 Extreme Incremental Encoding

There are cases where reducing latency is drastically more important than computation cost. Assuming that the user has to hit the Enter key to initiate the search, we show that by encoding each intermediate string, each requiring a single RNN computation step, the query encoding can be computed before the user hits Enter, practically translating to an online latency of 0.

We start by stating a property of tokenizers:

Property 1 *For every string S and non-space character c, the tokenization of $S + c$ consists of a sequence of tokens T such that $T[:-1]$ corresponds to the tokenization of a prefix of S.*

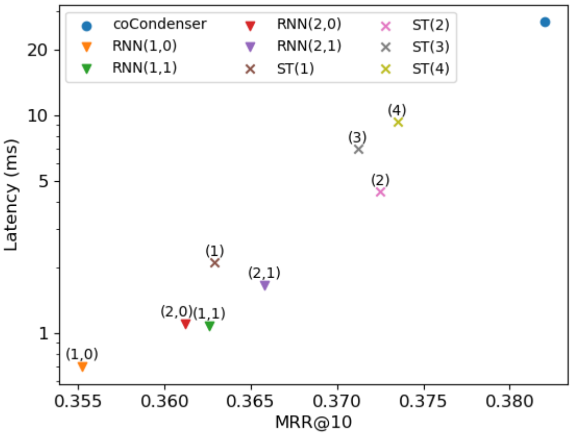

Figure 1: Illustrating the quality (MRR@10) - latency (in milli-seconds) tradeoff. **x** represents the small transformers architecture, $\triangledown$ represents the RNN architecture.

Thus, adding a single character to a string corresponds to adding just a single token to a prefix of the computed tokens. Assuming we store the embeddings of all token prefixes, the embeddings of the tokens of the new string can be computed with a single RNN step. We note that the encodings generated by this process are equivalent to those generated by the vanilla RNN approach. Therefore, result presented in Section 4.1 for the RNN models are reached by this method as well, with an online latency of 0. However, this incurs a computational cost, as we encode every possible prefix of the string. The number of steps grows by a factor equal to the number of non-space characters divided by the number of tokens in the query. In MS MARCO, this is equal to $\sim 4\times$ compared to the vanilla RNN approach.

4 Experiments

Our models are based on the Tevatron framework (Gao et al., 2022) and therefore coCondenser is the main baseline we compare to. For completeness we also include the results of BM25, DPR (Karpukhin et al., 2020) and ANCE (Xiong et al., 2021). We follow many previous works and train and test our methods on the MS MARCO dataset (Nguyen et al., 2016) using $MRR@10$ as the main metric and $R@50/1000$ as complementary metrics, and on the NQ dataset (Kwiatkowski et al., 2019) using $R@5/20/100$ as metrics. For T_{enc} we use the pretrained version of coCondenser, trained on the MLM task in a retrieval-friendly way. S_q is implemented both using an RNN model and a ST model as described in Section 2. We denote by RNN(ℓ, f) an RNN model with ℓ layers and f feed-forward layers. ST(ℓ) is an ST model with ℓ layers.

Table 1: Online latency vs quality of different query encoder models. Number of parameters is reported in millions. Online latency is measured in milliseconds and the p95 percentile is reported.

4.1 Main Results

Main results are provided in Table 1.[8] Using a small query encoder can indeed be very rewarding. For example, on the MS-MARCO dataset reducing the query-encoder from the standard 12-layer transformer to a 2-layer transformer drops latency by $\sim 6\times$ for only a modest drop in the $MRR@10$ score (from 38.2 to 37.2) and barely any change in the $Recall@1000$ measure. On a different note, in Figure 1 it can be seen that the RNN methods are highly effective in extending the latency/quality trade-off curve. While the smallest transformer can reduce $\sim 12\times$ in latency compared to the baseline with a drop from 38.2 to 36.2 in $MRR@10$ score, the smallest RNN model extends the drop in latency to $\sim 38\times$ reaching 35.5 $MRR@10$ score. A similar trend can be seen in the results for NQ, with a slight difference in behavior at the top and bottom of the lists metrics. We further elaborate on this topic in Section 4.2.

4.2 Fine-grained Topical Understanding

R@k	MS-MARCO	NQ
1	92%	88%
5	93%	89%
10	94%	93%
20	95%	95%
50	96%	96%
100	96%	98%

Table 2: Performance of RNN(1,0) measured in percentage w.r.t. the performance of coCondenser.

Table 2 compares the fine-grained topical understanding of our smallest architecture, RNN(1,0), with that of coCondenser. As expected, the smaller models are less capable in capturing more complex nuances, affecting its R@k scores for small k-s. Yet, it is interesting to note that its performance is almost on-par with that of coCondenser for large k-s, showing impressive coarse-grained understanding. Another observation is that the performance of the small models follow a similar trend on both datasets, with some advantage in MS-MARCO at small k-s and a slight advantage in NQ at large k-s.

4.3 RNNs Dependence on Query Length

A concern one might have regarding using RNN models as query encoders, due to the recursive inference process of RNNs, is that the encoding quality will drop significantly for longer queries.

To measure whether quality drops (more than the baseline) when the query becomes longer, we computed the quality drop for each query by subtracting the $MRR@10$ score of an RNN model from the score of the coCondenser baseline, computed on the MS-MARCO dataset. We then compute Pearson correlation between the score drop and the query length. We found that the correlation is only 0.018 and 0.045 for the RNN(1,0) and RNN(2,0) models respectively. These results suggest that the RNN architecture is capable of computing quality embeddings even for the longer queries in the dataset.

---

[8] For brevity, we report only the 95^{th} percentile as the latency measure in this table. Extended latency results and measurements can be found in Appendix C, where it can be seen that trends are kept across all percentiles.

Epochs	MRR@10	
	ST(2)	RNN(2,1)
0	34.1	31.5
5	37.2	36.5
10	37.3	36.6
15	37.3	36.7

Table 3: Pretraining effect.

model type	passage embeder	MRR@10
RNN	pretrained_coco	0.362
RNN	fine-tuned_coco	0.353
transformer	pretrained_coco	0.372
transformer	fine-tuned_coco	0.362

Table 4: Starting the retrieval training from a trained/pre-trained passage encoder model.

4.4 Ablation Study

We study some of the design decisions made when training the models. Specifically, we discuss the pretraining procedure and the teacher model used.

4.4.1 Pretraining

Table 3 shows that the pretraining procedure described in Section 2.1 improves the MRR@10 scores. For the RNN-based models, pretraining is especially important. This makes sense as pretrained RNN weights are not available for initialization, as opposed to the transformer which is initialized from the first layers of a pretrained model.

4.4.2 Teacher Selection

Training S_q relies on a teacher model. The main results uses a pre-trained version of coCondenser as the teacher T_{enc}, which utilizes a self-supervised MLM training. An alternative option would be to utilize the fine-tuned coCondenser model, trained on ground truth labels. On one hand, starting from a well trained model may result in converging to a better model, but on the other hand, it might result in overfitting the training data. We report results both on the RNN architecture (with 2 RNN layers and without feed-forward layers) and the transformer architecture (2 layers) in Table 4. It can be seen that the encoders benefit from learning the retrieval task simultaneously, as opposed to starting the training from a well-trained passage encoder and an untrained query encoder.

5 Conclusions

In this paper, we point out that queries are significantly shorter and simpler than passages, suggesting that using similar architectures for both passage and query encoders might be wasteful. Indeed, we show that small transformer-based query encoders improve latency with only a minor hurt to quality. We also introduce incremental inference with RNN-based encoders, and show they produce an even lower latency, better suited for cases where latency is highly constrained. Again, we show this improvement in latency comes with only a small drop in the quality of the generated embeddings.

6 Limitations

While incremental inference with RNNs drops latency significantly when running on CPUs this is not the case when using GPUs. The overhead of calling the GPU is high compared to the embedding time; in addition, GPUs are not well optimized for the RNN architecture. This means that the benefit of the proposed method is limited. CPUs are often used for retrieval as discussed in Section 1, but there are cases where GPUs are used in which RNN-based architectures are expected to give a lesser gain.

Another limitation of our method is that it requires running two training procedures. First, training a large encoder, and only after it is trained we can start the pretraining and training procedure of the smaller query encoder. Furthermore, since training the query encoder involves inferencing passages (using a larger passage encoder) the training time of a small model is very similar ($\sim$ 10 hours) to the training time of the large transformer. Nevertheless, since online query encoding can run a vast amount of time and the query encoder is trained once, in most cases we believe this is a price worth paying.

A Tying the Passage and Query Encoders Embeddings

In this section we provide justification for our decision to tie the token embeddings of the passage and query encoders. This decision can be split into two; For the transformer based models, that are loaded from the first layers of some pretrained model, it is not very significant. Experiments show that tying the embeddings has very small effect on these models (e.g. for a 2-layer transformer $MRR@10$ results increase from 37.25 to 37.28). On the other hand, we do not have available pretrained models to initialize GRU-based models. Tying the embeddings allows us to transfer some of the knowledge acquired during the pretraining of the transformers to the GRU models. Further, if a dev query contains a token that does not appear at all in the train set, during testing on the dev set the token embedding will be totally random, and the model will not be able to correctly encode the query. Indeed, experiments show that for the GRU-models tying the embeddings is extremely important as without doing so they have a hard time to converge.

B Training Procedure

This work does not focus on the training procedure of the model. Thus, we chose to utilize the popular training procedure of (Gao and Callan, 2022). For completeness we provide the technical details of their procedure in this section.

We assume we have at hand a pre-trained model. The procedure starts by retrieving hard negative examples using a model denote by S_1 (described below). Then, our model is trained for three epochs and a batch size of 64 using a contrastive loss. We used the AdamW optimizer with a $5e-6$ learning rate and a linear learning rate schedule.

The model S_1 is trained using the same training procedure. It only differs in the set of negative samples used. Specifically, when training S_1 the negative samples are retrieved by BM25.

C Complete Latency Report

In Table 5 we give a full latency report. For each model we report latency in milliseconds of 50, 90, 95 and 99 percentiles. We report both online-latency (marked as pX) and full latency (marked as pXf). Online and full latency differ only For RNN-based models where online latency is considered as latency when applying incremental inference as described in Section 3. We measure latency on a c6i.2xlarge EC2 machine featuring Ice Lake processor with 8 hyperthreads. Each evaluation is repeated 1020 times, and we discard the first 20 to allow the model to warm up. We report the average of the remaining runs. We note that utilizing a GPU typically requires provisioning a separate machine with a GPU. Since network latency is above 5ms, this does not decrease the total inference cost, so we avoid measuring it here.

Abstract

Large Language Models (LLMs) excel in generating text but struggle with hallucinations, particularly for uncommon queries, due to reliance on internal knowledge. Retrieval-augmented models address this by integrating external knowledge, enhancing accuracy. Nonetheless, recent approaches have primarily emphasized retrieval from unstructured text corpora, owing to its seamless integration into prompts. When using structured data such as knowledge graphs, most methods simplify it into natural text, neglecting the underlying structures. Moreover, a significant gap in the current landscape is the absence of a realistic benchmark for evaluating the effectiveness of grounding LLMs on heterogeneous knowledge sources (e.g., knowledge base and text). To fill this gap, we have curated a comprehensive dataset that poses two unique challenges: (1) **Two-hop multi-source questions** that require retrieving information from both open-domain structured and unstructured knowledge sources; retrieving information from structured knowledge sources is a critical component in correctly answering the questions. (2) **Generation of symbolic queries** (e.g., SPARQL for Wikidata) is a key requirement, which adds another layer of challenge. Our dataset is created using a combination of automatic generation through predefined reasoning chains and human annotation. We also introduce a novel approach that leverages multiple retrieval tools, including text passage retrieval and symbolic language-assisted retrieval. Our model outperforms previous approaches by a significant margin, demonstrating its effectiveness in addressing the above-mentioned reasoning challenges.

1 Introduction

LLMs have shown exceptional performance in multi-hop question-answering (QA) tasks over text (TextQA) (Rajpurkar et al., 2018; Kwiatkowski et al., 2019; Joshi et al., 2017; Trivedi et al., 2022a; Yang et al., 2018; Ho et al., 2020), tables (TableQA) (Yu et al., 2018; Zhong et al., 2017; Pasupat and Liang, 2015; Chen et al., 2019), and knowledge-bases (KBQA) (Gu et al., 2021; Yih et al., 2015; Talmor and Berant, 2018; Bao et al., 2016), where the supporting fact is contained in a single knowledge source – structured or unstructured. However, in many real-world scenarios, a QA system may need to retrieve information from both unstructured and structured knowledge sources; failing to do so results in insufficient information to address user queries.

aspects: *(1) Closed-book QA:* Closed-book questions do not accurately reflect the real-world setting where individuals generally have access to diverse knowledge sources on the Internet; *(2) Automatically generated data:* The lack of human verification results in erroneous data; *(3) Imbalanced emphasis across different knowledge sources:* Current benchmarks feature knowledge sources with varying levels of importance. Answers may be found in multiple sources, leading models to prioritize textual sources while underutilizing structured knowledge sources; *(4) Suboptimal use of structured knowledge:* Structured knowledge sources are typically treated as textual sources by linearizing triplets from the knowledge base or rows/columns from tables, missing the opportunity to fully realize the benefit of highly-precise structured knowledge by probing them via symbolic queries.

Despite the inherent challenges, being able to generate structured queries effectively can offer a number of benefits. First, unlike a query to retrieve text passages, the structured query itself can share the responsibility of reasoning (Liu et al., 2022). For example, for the question "`How many awards has Neil Armstrong received?`", to get an answer from a knowledge base such as Wikidata (Vrandečić and Krötzsch, 2014), a SPARQL query (Pérez et al., 2006) can use an aggregation function to return the numerical number as the final result as shown in Figure 1. In contrast, a text retriever needs to locate all the relevant passages and rely on a reader module to get the final result. The commonly used readers often come with an input length constraint. The number of returned passages could be too many to fit into the reader's context, causing a wrong answer. Even when the context length is not an issue, even the best LLMs have difficulties in locating the answer (Liu et al., 2023a). Besides, there is less room for ambiguity in structured queries. For example, a dense retriever cannot easily distinguish between similar song titles such as "`I'll be good to you`" and "`I have been good to you`" by different singers. On the other hand, given the right identifier of the entity, the structured knowledge search engine can return the relevant information for the exact entity.

In this work, we propose DivKnowQA, a novel fact-centric multi-hop QA benchmark that requires models to utilize heterogeneous knowledge sources equitably in order to answer a question. We perform the first study to assess the reasoning ability of LLMs, via jointly exploiting open-domain QA over heterogeneous knowledge sources. In particular, we have chosen Knowledge Base (KB) as our primary case study for the structured source, and we have created a dataset comprising 940 human-annotated examples. Additionally, each entry in our dataset includes a corresponding symbolic SPARQL query to facilitate the retrieval of information from the KB. To generate the questions, we construct a question collection pipeline comprising three key steps: text-based QA sampling, KB question generation, and question composition, all while minimizing the need for human annotation efforts.

To set up a baseline, in addition to benchmarking on standard and tool-augmented LLMs, we propose a Diverse rEtrieval Tool Augmented LLM (DetLLM) to address the challenges posed by DivKnowQA. DetLLM decomposes a multi-hop question into multiple single-hop questions, and adopts two novel strategies: (1) *symbolic query generation* to retrieve supportive text from a KB by transforming a single-hop natural question into a SPARQL query, and (2) *retrieval tool design*, which includes a textual retriever and a symbolic query generation tool to recall relevant evidence from heterogeneous knowledge sources. Our method shows improvements of up to 4.2% when compared to existing methods.

2 The DivKnowQA Dataset

2.1 Dataset Collection

Our goal is to create a method for generating complex questions from diverse knowledge sources, making each source indispensable; and we aim to do so with a minimal human annotation effort. Additionally, we wish to provide Wikidata entity and relation IDs to support structured query-based

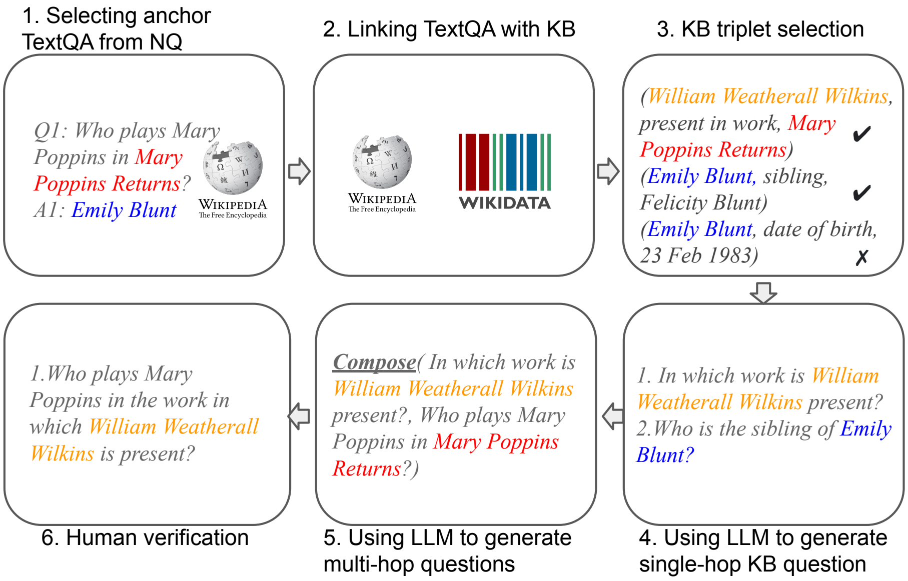

Figure 2: An overview of DIVKNOWQA data generation process.

knowledge retrieval. Figure 2 depicts our proposed method. We first sample a single-hop text question from the Natural Question dataset (Kwiatkowski et al., 2019) as an anchor, to which we link to a relevant Wikidata triplet. Then single-hop KB questions are generated based on the sampled triplets thereby using the anchor question to automatically compose a *heterogeneous* multi-hop question. Human annotators finally verify the quality of the machine-generated question and rewrite the question that needs revision. In the following, we elaborate on the steps.

Natural Questions as Anchors The Natural Question (NQ) dataset is a question-answering dataset containing tuples of `(question, answer, title, passage)`, where `title` and `passage` are respectively the title of the Wikipedia page and the passage containing the answer. The questions in NQ were collected from real-world user queries issued to the Google search engine, and it contains 307K training examples. We concentrate on constructing a multi-hop dataset linked through the initial step's single-hop answer. To achieve this, we extract question-answer pairs where the question contains a succinct answer of up to 5 words to ensure the quality of the resulting composed question.

Linking Natural Questions to Wikidata We adopt the notion of *bridge entity* from Yang et al. (2018) to describe the single-hop answer in the initial step when breaking down a multi-hop question. We explore two linking options, each involving a unique choice of bridging an entity to connect the natural question to Wikidata. We explain the options using the example question "`Who plays Mary Poppins in Mary Poppins Returns?`" with the answer "`Emily Blunt`". (a) Text → KB Approach: We treat the answer "`Emily Blunt`" as the bridge entity, and search for a Wikidata triplet where "`Emily Blunt`" is the *subject*, for example, `(Emily Blunt, sibling, Felicity Blunt)`. (b) KB → Text Approach: In this alternative method, we recognize the question entity that exists in Wikidata, in this case, "`Mary Poppins Returns`", as the bridge entity. For simplicity, we only consider the entity mentioned in the Wikipedia title. We then link to the Wikidata triplet using it as the *object*, leading to triplets such as "`(William Weatherall Wilkins, present in work, Mary Poppins Returns)`".

Selection of KB Triplets To maintain an equal emphasis on both structured and unstructured knowledge sources, we implement a meticulous selection process for KB triplets to ensure that the associated knowledge cannot be easily obtained by merely retrieving information from the textual source (Wikipedia passages). We retain triplets $(sub, relation, obj)$, where either the subject sub is not linked to a Wikipedia page or the object obj does not exist within the Wikipedia page associated with the subject. This ensures that simply retrieving the Wikipedia passage for the sub is unlikely to yield an answer to a question involving sub and

obj, thereby requiring the model to utilize the KB. Furthermore, when generating questions in the KB → Text linking option, we selectively retain triplets where only one object is associated with the given relation and subject This approach ensures the completeness and uniqueness of the reasoning chain. For example, given a composed question, "Who plays Mary Poppins in Lin-Manuel Miranda's notable work?", "Mary Poppins Returns" is one of the notable works from "Lin-Manuel Miranda". By querying KB given the subject "Mary Poppins Returns" and the relation "notable work", we will locate multiple answers rather than the single bridge entity "Mary Poppins Returns", posing a challenge to infer the second sing-hop question "Who plays Mary Poppins in Mary Poppins Returns?".

Generating Single-Hop KB Questions We then create single-hop questions from the selected $(sub, relation, obj)$ triplets. These questions are designed to emphasize the relationship between sub and obj, with obj being the expected answer. For instance, for the KB triplet "`(Emily Blunt, sibling, Felicity Blunt)`", we expect to generate a question like "`Who is the sibling of Emily Blunt?`". For this, we employ the `gpt-turbo-3.5` LLM from OpenAI; the prompt can be found in Appendix A.1.

Generating Heterogeneous Multi-Hop Questions In this stage, we wish to create a multi-hop question by composing a textual question and a KB question. We generate such *heterogeneous* questions by carefully chaining two single-hop questions together. DIVKNOWQA supports three question types: short entity, yes/no, and aggregate questions, and two question composition orders: Text → KB and KB → Text. This combination results in a total of five question types, as we construct aggregate questions following only the Text → KB order. We employ `gpt-turbo-3.5` as a question composer to connect two single-hop questions. This is achieved by substituting the entity mentioned in the outer question with a rephrased version of the first question. The prompt for generating the multi-hop questions is given in Appendix A.2. Our generation method for different question types is discussed as follows.

Short Entity Question We use a factoid entity as the final answer. The final answer can be the object from Wikidata or the factoid answer from NQ.

Yes/No Question In contrast to Short Entity questions, Yes/No questions involve an additional step. Initially, the original question is reformulated into a verification-style question typically starting with phrases like "`Is/Was/Were/Does/Do/Did`". This new question includes a candidate answer for verification purposes. For instance, let's consider the original question "`What grade were they in High School Musical 1?`" with a known answer of "`juniors`". To create a verification question, we might rephrase it as "`Were they seniors in High School Musical 1?`" and include the verifying answer "`seniors`" within the question. Generating the candidate answer for verification can be a complex task as it requires choosing a verifying answer that aligns well with the context of the question. Sampling incorrect distractors as verifying answers is also a part of the process. These distractors should be incorrect but closely related to the answer, and they are generated by prompting `gpt-turbo-3.5`. This approach ensures that the verification process is robust and accurate, preventing situations where the verifying answer deviates from the question's context and potentially leads to a simplistic answer "`no`" during evaluation.

Aggregate Question We formulate aggregating questions in the "`Text → KB`" composition order, where the outermost question pertains to counting the number of associated triplets based on the given subject and relation. For instance, the outermost question "`How many awards does Milton Friedman receive?`" arises from the KB triplets of the form `(Milton Friedman, award received, award name)`" with 10 such `award name` objects. In such cases, we leverage the aggregate feature offered by the structural query (i.e., SPARQL).

2.2 Human Annotation

We recruited five individuals, three undergraduate and two graduate students with experience in the field of NLP for data verification and annotation. Each question underwent a verification and rewriting process involving two annotators. To mitigate any potential annotation bias, we presented each question to both annotators, with the order of examples shown to annotators randomized. Annotators were tasked with assessing the quality of KB question generation, and they had three options to choose from: "Accept", "Revise", or "Reject". When a question required revision, annotators were instructed to make modifications while preserving the focus on the subject and relation and keeping the answer unchanged. Additionally, they were responsible for evaluating the quality of complex questions and providing necessary revisions. The instruction provided to human annotators is shown in Appendix A.4. Annotators were duly compensated for their valuable contributions to our study. Out of 1,000 examples that were annotated, 757 examples received unanimous approval, 183 underwent revisions, and 60 were rejected. Both unanimously accepted and revised examples were included in the dataset.

2.3 Dataset Statistics and Analysis

In this section, we analyze the question types and KB single-hop relation types in DIVKNOWQA.

Question Central Word Taking inspiration from (Yang et al., 2018), we designate the first three words of a question as the Center Question Words (CQW). We adopt this approach because our questions typically do not contain comparison queries, and a majority of question words are found at the beginning of the question. Due to the page limit, Figure 4(a) in Appendix A.6 provides a visual representation of CQW in DIVKNOWQA.

KB Relation Types We also analyze the distribution of relations by counting the frequency of different relations that appear in the KB triplets used to construct the single-hop KB questions. Due to the page limit, Figure 4(b) in Appendix A.6 features the distribution of diverse relations.

Anecdotal Examples for Representative Types Due to the length limit, in Appendix A.7, Table 7 presents illustrative examples drawn from the DIVKNOWQA benchmark for each of our five question composition types. These examples serve to showcase how our dataset necessitates information retrieval from diverse sources in varying orders. Additionally, they highlight that the answer types require models to perform tasks such as answer span extraction, candidate answer verification, and information aggregation based on relevance.

3 DETLLM: Diverse Retrieval Tool Augmented LLM

We now introduce our diverse retrieval tool augmented LLM (DETLLM) and show its promising capability on the proposed DIVKNOWQA benchmark by unifying the retrieval ability from the structured and unstructured knowledge sources.

To tackle a complex question, we follow the chain-of-thought (CoT) framework (Wei et al., 2022) to decompose a complex question into single-hop questions where each single-hop question is knowledge-intensive, requiring supportive fact retrieval from a knowledge source.

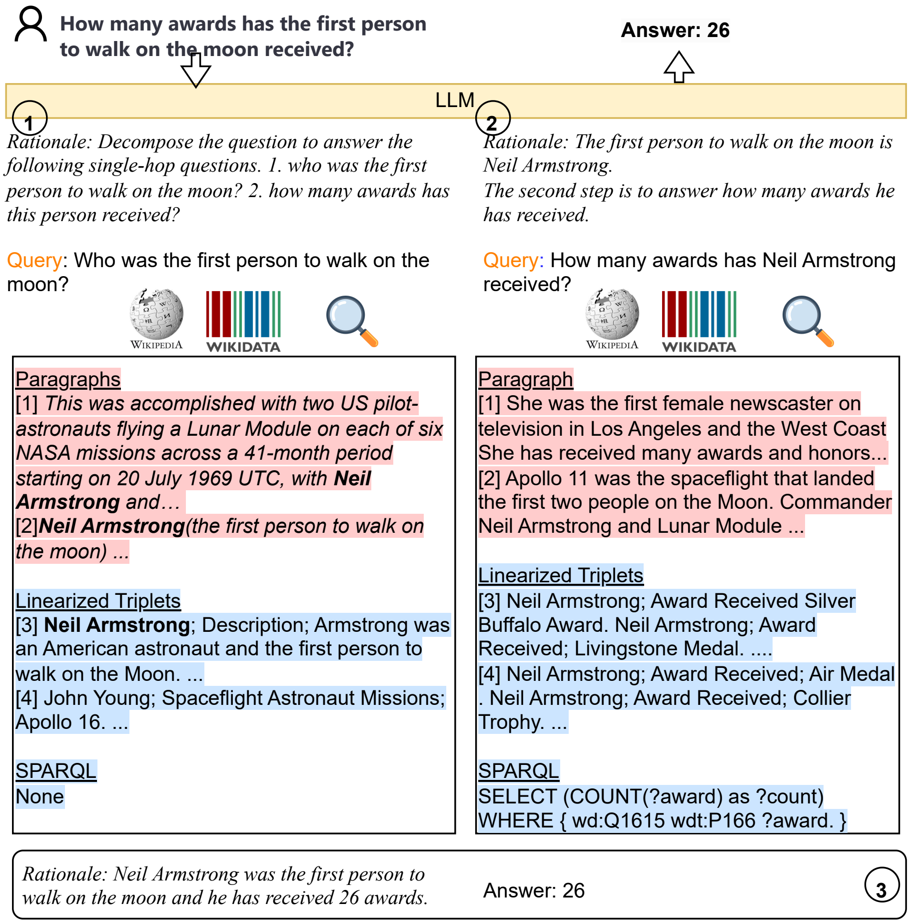
We design a retrieval tool capable of retrieving from heterogeneous knowledge sources. For unstructured text knowledge, a dense passage retriever (Izacard et al., 2022) is employed to retrieve relevant passages. For structured knowledge, we consider two modalities of structured knowledge to maximize the relevant information coverage. First, we transform the structured data into text passages by linearizing the relation triplets into passages in which case a sparse text retriever can be used to detect similar sources. Second, we propose a symbolic query generation module to map a natural language query to a structured query (e.g., SPARQL) to directly query against the KB (e.g., Wikidata). The benefits are twofold: (1) pinpointing precise knowledge, and (2) leveraging the compositionality of the query language and reducing the mere reliance on the language model's reasoning responsibility. Figure 3 shows the DETLLM flow for querying an LLM.

3.1 Question Decomposition and Planning

Our approach to answering a complex multi-hop question is inspired by the conceptual framework of DSP (Khattab et al., 2022). When dealing with a question that involves n hops, we query the LLM n times to generate retrieval queries and retrieve information from a knowledge source. The final query is used to ultimately arrive at the final answer, utilizing the retrieved passage to answer the last single-hop question. This process results in a total of $n + 1$ interactions with the LLM. At the j-th LLM prompting, the LLM's task is to utilize the previously retrieved information to answer the $j - 1$ single-hop question. It then dissects the original question Q into the j-th subsequent single-hop questions q_j, which serve as a retriever query to gather information from a knowledge source.

3.2 Multi-Source Knowledge Retrieval

In addressing the single-hop questions, our approach entails searching across diverse knowledge sources to gather supporting facts. To an-



Rationale: Decompose the question to answer the following single-hop questions. 1. who was the first person to walk on the moon? 2. how many awards has this person received?

Query: Who was the first person to walk on the moon?

Paragraphs

[1] *This was accomplished with two US pilot-astronauts flying a Lunar Module on each of six NASA missions across a 41-month period starting on 20 July 1969 UTC, with* ***Neil Armstrong*** *and…*

[2]***Neil Armstrong****(the first person to walk on the moon) ...*

Linearized Triplets

[3] **Neil Armstrong**; Description; Armstrong was an American astronaut and the first person to walk on the Moon. ...

[4] John Young; Spaceflight Astronaut Missions; Apollo 16. ...

SPARQL

None

Rationale: The first person to walk on the moon is Neil Armstrong.

The second step is to answer how many awards he has received.

Query: How many awards has Neil Armstrong received?

Paragraph

[1] She was the first female newscaster on television in Los Angeles and the West Coast She has received many awards and honors...

[2] Apollo 11 was the spaceflight that landed the first two people on the Moon. Commander Neil Armstrong and Lunar Module ...

Linearized Triplets

[3] Neil Armstrong; Award Received Silver Buffalo Award. Neil Armstrong; Award Received; Livingstone Medal. ....

[4] Neil Armstrong; Award Received; Air Medal . Neil Armstrong; Award Received; Collier Trophy. ...

SPARQL

SELECT (COUNT(?award) as ?count)
WHERE { wd:Q1615 wdt:P166 ?award. }

Rationale: Neil Armstrong was the first person to walk on the moon and he has received 26 awards.

Answer: 26

Figure 3: The illustration of DETLLM to instruct LLMs for addressing multi-source multi-hop questions.

swer the subsequent single-hop question q_j, we begin by having the LLM generate semantically diverse queries, denoted as $Query_j = \{query_1^j, \ldots, query_t^j\}$. We set the LLM decoding temperature to 0.7 to sample diverse queries.

In our approach, we treat unstructured and structured knowledge separately and retrieve relevant information from both knowledge sources. As mentioned, for unstructured knowledge, we use a dense retriever Contriever (Izacard et al., 2022) to retrieve relevant passages, while for structured knowledge, we retrieve relevant information from both textual and structured formats. The preparation of the textual knowledge base involves linearizing KB triplets $(sub, relation, obj)$ into a string format "`sub relation obj`" after which we create a retrieval index for efficient passage retrieval using a sparse text retriever BM25 (Robertson et al., 2009). The Contriever, trained on natural language corpus, is adaptable to unstructured knowledge but struggles when faced with linearized structured knowledge because it lacks natural language formatting. In contrast, the sparse retriever BM25 performs better with structured knowledge by using a keyword-based search methodology. We show the ablation study in Section 4.3.

Table 2: Answer and Sub-Step Retrieval Accuracy on DIVKNOWQA.

	EM	F1	Recall	H1-R	H2-R
Vanilla Prompt	26.0	28.3	26.8	42.2	-
ReAct	16.1	18.4	19.0	-	-
DSP	27.9	31.0	31.2	57.6	41.2
DETLLM (our)	**32.1**	**35.7**	**35.6**	**70.1**	**47.1**

In addition, we generate SPARQL queries to execute against the Wikidata engine to retrieve further relevant information. Our retrieval tool thus comprises three components: a sparse retriever, a dense retriever, and a symbolic query language generation module. These elements collectively enable the comprehensive retrieval of information from heterogeneous knowledge sources.

3.3 Multi-Source Knowledge Ranking

To consolidate the retrieved information obtained from the tool, we perform a ranking of information from various knowledge sources. The goal is to select the top-k most relevant pieces of information. This selection is necessary because of the inherent length constraint of the language model, which prevents us from incorporating all the retrieved information into the prompt. To achieve this ranking, our approach leverages the off-of-shelf cross-encoder model (Reimers and Gurevych, 2019) to assess the relevance of each piece of retrieved information in the context of a single-hop question. We use the `sentence-transformers` package implementation with the model checkpoint `cross-encoder/ms-marco-MiniLM-L-6-v2`.[1]

4 Benchmarking

4.1 Experimental Setup

Baselines (1) ChatGPT (OpenAI, 2023): We employ OpenAI's ChatGPT model (`gpt-3.5-turbo`) by single-step query inputting the question and retrieved-context and obtaining its response as the final answer. (2) DSP (Khattab et al., 2022): We apply the demonstrate-search-predict framework to iteratively address complex QA tasks with the assistance of retrieved context. (3) ReAct (Yao et al., 2023): It leverages a synergistic approach, combining reasoning with tool usage. It involves verbally generating a reasoning trace and issuing the necessary commands to invoke a tool, which then takes action accordingly. We use `gpt-3.5-turbo` as the backbone model.

Evaluation Metrics To assess the accuracy and relevance of various models for factoid questions, we rely on established metrics. We report the exact match and F1 score for final answer quality, following the methodology of (Yang et al., 2018). Besides, we report the Recall score indicating whether the ground-truth answer is a substring in prediction since LLM may generate extra information. In addition, we report the retrieval accuracy for each decomposed single-hop question denoted as H1-R and H2-R for the two-hop question.

Implementation Details To ensure a comprehensive and equitable comparison, we offer baseline model access to both structured knowledge and unstructured knowledge as retrieval sources. In the case of the baseline model, the KB is converted into linearized passages, which are then combined with the unstructured knowledge, creating a unified source for retrieval. We use BM25 (Robertson et al., 2009) and Contriever (Izacard et al., 2022) as sparse and dense retrieval tools respectively. Unless specified otherwise, we experiment with a few-shot prompt that includes three human-annotated demonstrations along with task instructions to guide the model generation process.

Table 3: Ablation study on the retrieval strategy.

	EM	F1	Recall	H1-R	H2-R
w/o SPARQL					
Text-KB(Sparse)	27.9	31.0	31.2	57.6	41.2
Text-KB(Dense)	22.7	26.1	26.9	54.9	32.0
Text(Sparse)-KB(Sparse)	26.4	29.8	30.2	60.0	41.2
Text(Dense)-KB(Sparse)	30.7	35.0	35.5	68.9	46.8
w/ SPARQL					
Text-KB(Sparse)	28.8	31.9	32.9	58.0	42.9
Text-KB(Dense)	31.2	34.7	35.9	64.3	42.6
Text(Sparse)-KB(Sparse)	28.5	31.8	32.0	61.5	42.1
DETLLM (our)	**32.1**	**35.7**	**35.6**	**70.1**	**47.1**

4.2 Main Results

Comparing with State-of-the-Art LLMs Table 2 presents the model performance results on the DIVKNOWQA. ReAct exhibits lower performance compared to the Vanilla prompt. The retrieval tool created for ReAct is specialized for querying unstructured knowledge. As the presence of irrelevant passages distracts the LLM (Chen et al., 2023; Mallen et al., 2023), the iterative reasoning accumulates errors, leading to less accurate answers. Conversely, DSP outperforms both Vanilla Prompt and ReAct, thanks to its robust search module designed to engage with frozen retrievers. DSP enhances a single retrieval query into multiple queries, employing a fusion function to rank candidate passages and identify the most relevant one. However, the search module cannot effectively retrieve structured knowledge. Our model stands out as the top-performing model, demonstrating its capability to generate symbolic language for retrieval from structured knowledge.

Retrieval Performance Table 2 also presents the single-step retrieval accuracy. Among the baseline methods, comparing single-step generation e.g. Vanilla Prompt with the multi-step generation e.g. ReAct and DSP, the retrieval accuracy increases due to the decomposed query from the multi-step generation process. On the other hand, the DETLLM shows stronger retrieval performance compared to DSP due to the careful retrieval tool

---

Table 4: Comparison between the closed book setting and open domain retrieval.

	EM	F1	Recall	H1-R	H2-R
Closed Book	30.2	33.8	31.2	-	-
DETLLM	32.1	35.7	35.6	70.1	47.1

Table 5: Breakdown Analysis on SPARQL generation.

	QID	QID+REL	QID*
Text-KB(Sparse)	26.5	22.4	6.91
Text-KB(Dense)	31.8	27.6	7.87
Text(Sparse)-KB(Sparse)	26.3	22.6	7.34
Text(Dense)-KB(Sparse)	29.7	26.5	7.66

design, the unstructured and structured knowledge is treated separately. This finding underscores the importance of having a robust retrieval strategy to provide reliable and focused information, grounding the LLM on relevant supportive facts.

4.3 Discussion

Ablation Study Table 3 presents the results of an ablation study involving three key factors: a) the integration of heterogeneous knowledge sources, b) the choice between dense and sparse retrievers, and c) the incorporation of SPARQL. Our findings indicate that optimal performance is achieved when handling heterogeneous knowledge sources separately, combined with careful retriever tool selection. The unsupervised dense retriever (i.e., Contriever), trained on natural language corpus, demonstrates adaptability to unstructured knowledge but loses its advantage when dealing with linearized structured knowledge due to the absence of natural language formatting. Conversely, the sparse retriever BM25 performs better on structured knowledge, relying on keyword-based search methodologies. Furthermore, the SPARQL tool consistently outperforms its counterparts in all settings, showcasing improvements regardless of the integration of knowledge sources and the choice of retriever.

Comparing with Closed-book LLM Table 4 presents a comparison between DETLLM and LLM performance in the closed-book setting, where no external knowledge is accessible. We demonstrate that DETLLM exhibits improvements in scenarios distinct from the closed-book setting. We observe that only 50.8% of examples answered correctly by our DETLLM are also present in the closed-book setting, highlighting the orthogonal performance of DETLLM compared to the closed-book setting. The combination of correctly answered examples accounts for 45.4% of the entire dataset. One plausible hypothesis is that the closed book setting enables the LLM to access knowledge stored in its memory, reducing the impact of retriever errors. We also suggest a potential research direction, which involves designing a strategy to switch between the closed book setting and open domain retrieval to achieve optimal performance.

SPARQL Generation Analysis Symbolic language generation is an essential tool, which is executed against the Wikidata engine to assist with structured knowledge retrieval. We provide a detailed breakdown analysis of SPARQL generation in Table 5. "QID" represents the percentage of examples with entity IDs correctly linked to Wikidata. Additionally, we present the percentage of examples linked to the Wikidata in terms of both entity IDs and relation IDs denoted as "QID+REL". The last column, labeled "QID*", showcases the percentage of examples with great potential for accurate identification through entity disambiguation. In our experimental process, we first identify the entity name from the decomposed question as a retriever query and then link the entity from the query to Wikidata. The returned results provide a list of candidate Wikidata entities, from which we select the most semantically similar one by computing the similarity between the query and the entity's description. The displayed number reveals that this heuristic entity disambiguation process fails to recognize those examples that actually contain the correct entity ID within the candidate list. This highlights a potential avenue for further improving model performance.

Establishing Oracle Performance In Table 6, we present the experimental results obtained using Oracle information. In these experiments, we grant the model access to ground-truth passages from the Oracle Text and linearized KB triplets from the KB Oracle. A notable observation is the comparison between Text Oracle and KB Oracle. We find that KB Oracle exerts a more significant influence on the final results. This is because structured knowledge contains long-tail knowledge, showing the necessity to effectively explore structured knowledge. Furthermore, when both Text and KB Oracle sources are provided, the model's performance reaches an Exact Match (EM) rate of 48.7%, highlighting the necessity of each knowledge source. In comparison to our current established results

Table 6: Experiment results using Oracle knowledge source retrieval in each sub-step.

	EM	F1	Recall	H1-R	H2-R
Oracle_Text	26.8	31.3	33.4	96.4	51.7
Oracle_KB	38.1	40.0	42.2	100.0	62.1
Oracle_All	48.7	52.2	52.8	100.0	96.7

from DETLLM, this benchmark reveals substantial room for the research community to further explore and improve upon.

5 Related Work

5.1 Assessing the Reasoning Ability of LLMs

LLMs (Brown et al., 2020; Touvron et al., 2023; Nijkamp et al., 2023) have exhibited notable advancements in their capabilities, particularly in the domain of reasoning skills. These skills encompass various categories, including inductive reasoning (Wang et al., 2023; Yang et al., 2022), deductive reasoning (Creswell et al., 2023; Han et al., 2022), and abductive reasoning (Wiegreffe et al., 2022; Lampinen et al., 2022), depending on the type of reasoning involved. Current research efforts have predominantly focused on evaluating LLMs in the context of open-ended multi-hop deductive reasoning. These scenarios involve complex question-answering tasks (Yang et al., 2018; Gu et al., 2021; Trivedi et al., 2022b; Liu et al., 2023c) and fact-checking (Jiang et al., 2020). Notably, our work contributes to this landscape by introducing an additional layer of complexity: the integration of multi-hop and multi-source reasoning. In our approach, we retrieve supporting facts from heterogeneous knowledge sources, further enhancing the challenges posed to LLMs in this deductive reasoning context.

5.2 Retrieval-Augmented LLMs

Retrieval-Augmented Large Language Models (RALLMs) are semi-parametric models that integrate both model parameters and a non-parametric datastore to make predictions. RALLMs enhance LLMs by updating their knowledge (Izacard et al., 2023; Khandelwal et al., 2020; Yavuz et al., 2022; Mallen et al., 2023), providing citations to support trustworthy conclusions (Menick et al., 2022; Gao et al., 2023). RALLMs can retrieve information in an end-to-end fashion within a latent space (Khandelwal et al., 2020, 2021; Min et al., 2023), or they can follow the retrieve-then-read paradigm, leveraging an external retriever to extract information from textual sources (Ram et al., 2023; Khattab et al., 2022). Recent work (Zhao et al., 2023, 2021; Liu et al., 2022, 2023b) have explored methods for anchoring language models to essential knowledge sources, aiming to enhance the language models' capacity to utilize and incorporate relevant information effectively. Our approach adheres to the retrieve-then-read paradigm, with a specific emphasis on multi-source retrieval, advocating for structured knowledge retrieval through symbolic generation.

6 Conclusion

We introduce the DIVKNOWQA, designed to evaluate the proficiency of question-answering systems, especially those enhanced by retrieval tools, in addressing knowledge-intensive questions with a strong emphasis on multi-hop multi-source retrieval. This dataset is constructed through automated data generation and subsequent human verification, minimizing manual effort. Our evaluation encompasses both standard LLMs and LLMs augmented with retrieval tools. Notably, we identify that this task presents a new challenge for state-of-the-art models due to the demand for structured knowledge retrieval and the inherent lack of prior knowledge in this context. To tackle this challenge, we propose the DETLLM, which incorporates diverse retrieval tools including innovative symbolic query generation for retrieving information from the structured knowledge source. In the future, we are keen on enhancing LLMs' capabilities in understanding and generating symbolic language, as well as exploring methods to improve performance on knowledge-intensive and complex question-answering tasks.

Limitations

One limitation of our proposed DETLLM is that the retrieval tool is used in each decomposed single-hop question-answering step. A further step involves investigating when the large language model truly requires retrieval knowledge, rather than invoking the tool at every step. Recent research (Mallen et al., 2023) has indicated that LLMs derive substantial benefits from general domain knowledge but may encounter challenges when dealing with long-tail knowledge because LLMs' memorization is often limited to popular knowledge. Future work can address the issue of uncertainty in LLMs' reliance on retrieval tools, aiming to optimize tool usage efficiently and establish trustworthiness in the process.

Another limitation is the need to explore the impact of extended prompts on retrieval-augmented language models. Recent research has revealed that LLMs can be susceptible to recency bias (Liu et al., 2023a). Furthermore, a study (Peysakhovich and Lerer, 2023) indicates that documents containing the ground truth answer tend to receive higher attention, suggesting that reordering documents by placing the highest-attention document at the forefront can enhance performance. Thus, an avenue for further investigation of whether document reordering strategies, based on attention mechanisms, can be employed to improve retrieval-augmented LM performance on multi-source multi-hop QA task.

A Appendix

A.1 Single-Hop Knowledge Base Question Generation Prompt

Prompt 1: Single-Hop Knowledge Base Question Generation

```
Instruction: Question generation given
    the following information:
1) Answer
2) Short relation between the question
    entity and the answer
3) Question entity.

IMPORTANT: The answer must be avoided
    in the question.

Answer: Jacques Boigelot;
Relation: director;
Question Entity: Peace in the Fields;
Question: Who directs Peace in the
    Fields?

Answer: Academy Award for Best Sound
    Mixing;
Relation: award received;
Question Entity: Douglas Shearer;
Question: Which award does Douglas
    Shearer receive?

Answer: Rio de Janeiro;
Relation: place of birth;
Question Entity: David Resnick;
Question: Where was David Resnick born?
```

A.2 Multi-Hop Complex Question Generation Prompt

Prompt 2: Multi-Hop Complex Question Generation

```
Instruction: Compose 2 single-hop
    questions into a 2-hop question
    given:
1) Hop1 question
2) Hop1 answer
3) Hop2 question.

Hop1 question: Who said a rose by any
    other name would smell just as
    sweet?
Hop1 answer: Juliet
Hop2 question: What is the cause of
    death of Juliet?
Composed question: What is the cause of
    death of the person who said a rose
    by any other name would smell just
    as sweet?

Hop1 question: Who hosted The Price Is
    Right before Bob Barker?
Hop1 answer: Bill Cullen
Hop2 question: What is the medical
    condition of Bill Cullen?
Composed question: What is the medical
    condition of the person who hosted
    The Price Is Right before Bob
    Barker?
```

```
Hop1 question: Who wrote If You Go Away
     on a Summer's Day?
Hop1 answer: Rod McKuen
Hop2 question: Which record company
     does Rod McKuen own?
Composed question: Which record company
     does the person who wrote If You Go
     Away on a Summer's Day own?
```

A.3 Benchmark Prompt

To use the DETLLM method and generate the final answer, three steps are followed: (1) First-hop prompting, (2) Second-hop prompting, and (3) Final answer generation. The prompt for each stage is provided below. For simplicity, we denote the k retrieved passages as "*Context: [[1] ... [k]]*".

Prompt 3: First Hop

```
Write a search query, query entity, and
     SPARQL that will help answer a
     complex question.
Follow the following format.
Context: ${sources that may contain
     relevant content}
Question: ${the question to be answered}
Rationale: Let's think step by step.
     Based on the context, we have
     learned the following.
     ${information from the context that
     provides useful clues}
Search Query: ${a simple question for
     seeking the missing information}
Query Entity: ${query entity name from
     search query}
SPARQL: ${SPARQL query used to query
     against Wikidata}

Example 1
Context:
Question: What are the occupations of
     the person who holds the most
     women's Wimbledon titles?
Rationale: Let's think step by step.
     Based on the context, we have
     learned the following. Decompose
     the question to answer the
     following single-hop questions. 1.
     Who holds the most women's
     Wimbledon titles? 2. What are the
     occupations of this person
Search Query: Who holds the most
     women's Wimbledon titles?
Query Entity: women's Wimbledon titles
SPARQL: None

Example 2
Context:
Question: Which bay is the name of
     David Resnick's place of birth?
Rationale: Let's think step by step.
     Based on the context, we have
     learned the following. Decompose
     the question to answer the
     following single-hop questions. 1.
     Where was David Resnick born? 2.
     Which bay is the name of this place
Search Query: Where was David Resnick
     born?
Query Entity: David Resnick
SPARQL: SELECT ?place WHERE {wd:Q962183
     wdt:P19 ?place.}

Example 3
Context:
Question: Is the person who directed
     the film The Shape of Water a
     member of the Writers Guild of
     America, West?
Rationale: Let's think step by step.
     Based on the context, we have
     learned the following. Decompose
     the question to answer the
     following single-hop questions. 1.
     Who directed the film the shape of
     water? 2. Is the person the person
     a member of the Writers Guild of
     America, West?
Search Query: The director of the film
     The Shape of Water
Query Entity: The Shape of Water
SPARQL: SELECT ?name WHERE
     {wd:Q26698156 wdt:P57 ?name.}

Target Question
Context:
Question: How many organizations is the
     26th president of the United States
     a member of?
Rationale: Let's think step by step.
     Based on the context, we have
     learned the following. Decompose
     the question to answer the
     following single-hop questions. 1.
     who is the 26th president of the
     United States? 2. How many
     organizations is this person a
     member of?
Search Query: 26th president of the
     United States
Query Entity: None
SPARQL: None
```

Prompt 4: Second Hop

```
Write a search query, query entity, and
     SPARQL that will help answer a
     complex question.
Follow the following format.
Context:${sources that may contain
     relevant content}
Question: ${the question to be answered}
Rationale: Let's think step by step.
     Based on the context, we have
     learned the following.
     ${information from the context that
     provides useful clues}
Search Query: ${a simple question for
     seeking the missing information}
Query Entity: ${query entity name from
     search query}
SPARQL: ${SPARQL query used to query
     against Wikidata}
```

```
Example 1
Context:[[1] ... [k]]
Question: What are the occupations of
    the person who holds the most
    women's Wimbledon titles?
Rationale: Let's think step by step.
    Based on the context, we have
    learned the following. Wimbledon is
    a tennis tournament, and tennis
    player Martina Navratilova holds
    the most women's Wimbledon titles.
    The second step is to answer what
    are the occupations of this person.
Search Query: What are the occupations
    of Martina Navratilova?
Query Entity: Martina Navratilova
SPARQL: SELECT ?name WHERE {wd:Q54545
    wdt:P106 ?name.}

Example 2
Context:[[1] ... [k]]
Question: Which bay is the name of
    David Resnick's place of birth?
Rationale: Let's think step by step.
    Based on the context, we have
    learned the following. David
    Resnick was born in Rio de Janeiro.
    The second step is to answer which
    bay is the name of Rio de Janeiro?
Search Query: which bay is the name of
    Rio de Janeiro?
Query Entity: Rio de Janeiro
SPARQL: None

Example 3
Context:[[1] ... [k]]
Question: Is the person who directed
    the film The Shape of Water a
    member of the Writers Guild of
    America, West?
Rationale: Let's think step by step.
    Based on the context, we have
    learned the following. The Shape of
    Water is directed by Guillermo del
    Toro. The second step is to answer
    is the person a member of the
    Writers Guild of America, West
Search Query: the organization
    Guillermo del Toro is in
Query Entity: Guillermo del Toro
SPARQL: SELECT ?name WHERE {wd:Q219124
    wdt:P463 ?name.}

Target Question
Context:[[1] ... [k]]
Question: How many organizations is the
    26th president of the United States
    a member of?
Rationale: Let's think step by step.
    Based on the context, we have
    learned the following. The 26th
    president of the United States is
    Theodore Roosevelt. The second step
    is to answer how many organizations
    he is a member of.
Search Query: How many organizations is
    Theodore Roosevelt a member of?
Query Entity: Theodore Roosevelt
SPARQL : SELECT (COUNT(?organization)
    as ?count) WHERE { wd:Q33866
    wdt:P463 ?organization. }
```

Prompt 5: Final QA Step

```
Answer questions with short factoid
    answers.
Follow the following format.
Context:${sources that may contain
    relevant content}
Question: ${the question to be answered}
Rationale: Let's think step by step.
    ${a step-by-step deduction that
    identifies the correct response,
    which will be provided below}
Answer: ${a short factoid answer, often
    between 1 and 5 words}

Example 1
Context: [[1] ... [k]]
Question: What are the occupations of
    the person who holds the most
    women's Wimbledon titles?
Rationale: Let's think step by step.
    Martina Navratilova is a tennis
    player, writer, novelist, and
    autobiographer.
Answer: tennis player, writer,
    novelist, and autobiographer

Example 2
Context: [[1] ... [k]]
Question: Which bay is the name of
    David Resnick's place of birth?
Rationale: Let's think step by step.
    David Resnick was born in Rio de
    Janeiro, and "Rio de Janeiro" was
    the name of Guanabara Bay.
Answer: Guanabara Bay

Example 3
Context:[[1] ... [k]]
Question: Is the person who directed
    the film The Shape of Water a
    member of the Writers Guild of
    America, West?
Rationale: Let's think step by step.
    Guillermo del Toro Gomez is a
    filmmaker, he is a member of the
    Writers Guild of America, West.
Answer: yes

Target
Context:[[1] ... [k]]
Question: How many organizations is the
    26th president of the United States
    a member of?
Rationale: The 26th president of the
    United States was Theodore
    Roosevelt. He is a member of 5
    organizations.
Answer: 5
```

A.4 Human Annotation Instruction

We show the instructions and annotating examples provided to human annotators to annotate the dataset as below.

Overall Instruction The goal of the annotation is to judge and revise the complex question chained by two single-hop questions. To complete this goal, you need to do the following two tasks:

- Judge and revise the single-hop question generated from the knowledge base triplet.
- Judge and revise the composed complex question.

Task 1 Given a triplet (subject, relation, object) and a machine-generated question as shown below, you need to judge the quality of the generated question and whether it is acceptable, needs revision, or is rejected. If the question can be revised, please revise the question rather than reject it. If the question is too poor to revise, reject the question.

```
Triplet: (LeBron James; child; [Bryce
    James, Zhuri James, Bronny James])
Question: How many children does LeBron
    James have?
```

An accepted triplet question should satisfy the following criteria:

- The question focuses on the subject w.r.t relation.
- The question should sound natural and fluent.
- The answer to the generated question should be the object, thus the object cannot be shown in the question.

Task 2 Judge and revise the composed complex question given the following information. If the question can be revised, please revise the question rather than reject it. If the question is too poor to revise, reject the question and choose the reason for rejection.

Below is a list of provided information:

- Two single-hop question-answer pairs: “(Question 1, Answer 1)” and “(Question 2, Answer 2)”.
- The bridging entity “Bridge Entity” that chains two single-hop questions together.
- Machine generated composed question “Composed Question”.

```
Question 1: Who is the highest-paid
    athlete in the NBA
Answer 1: LeBron James
Question 2: How many children does
    LeBron James have?
Answer 2: [3, three]
Bridge Entity: LeBron James
Composed Question: How many children
    does the highest-paid athlete in
    the NBA have?
```

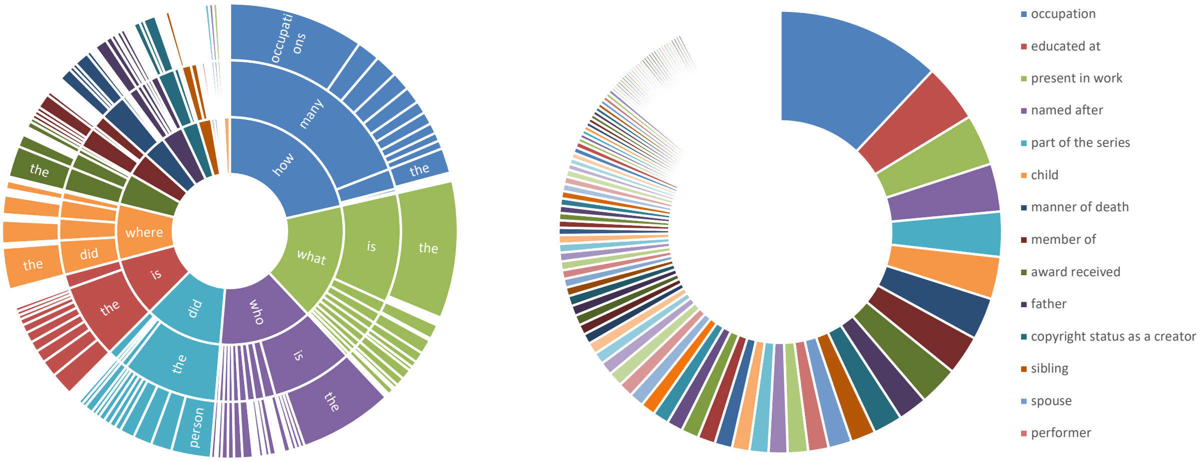
An accepted question should meet the following criteria:

- The composed question must be constructed using two single-hop questions, with the answer to the first question becoming the subject of the second question.
- Ensure that the composed question does not reveal the answer itself.
- Use ‘Answer 2’ as the answer to the composed question.

If you choose to reject the question, please select one of the following reasons. If your reason is not listed, choose ’Other’ and include a comment.

- Circular question: Two single-hop questions are the same question.
- Bridge entity answer leaking.
- Final answer leaking.
- Change in the original meaning of single-hop questions.
- Other.

A.5 An overview of DETLLM data generation process



(a) Types of questions.

(b) Types of KB relations.

Figure 4: Types of (a) questions, and (b) KB relations, covered in DIVKNOWQA.

A.6 Dataset Analysis

The stats of the dataset are shown in Figure 4.

A.7 Anecdotal Examples for Representative Types

Anecdotal Examples for Representative Types are shown in Table 7.

Table 7: Types of multi-hop reasoning required to answer questions in DIVKNOWQA. Two single-hop questions are shown: TextQA is sampled from NQ, and KBQA is generated using the sampled KB-Triplet. The question from **DIVKNOWQA** is based on those two single-hop questions.

Order	Type	%	Example
Text → KB	short entity	20.3	TextQA: Who is Rafael Nadal married to? Answer: María Francisca Perelló KB-Triplet: (Rafael Nadal, spouse, María Francisca Perelló) KBQA: Who won the Men's US Open 2017? Answer: Rafael Nadal **DIVKNOWQA**: Who is the person married to the winner of the Men's US Open 2017? **Answer**: María Francisca Perelló
	yes/no	17.9	TextQA: Who sang When the Lights Went Out in Georgia? Answer: Vicki Lawrence KB-Triplet: (Vicki Lawrence, hair color, red hair) KBQA: What is Vicki Lawrence's hair color? Answer: red hair **DIVKNOWQA**: Is the hair color of the singer of "When the Lights Went Out in Georgia" gray? **Answer**: no
	aggregate	21.1	TextQA: who does Meg 's voice on Family Guy? Answer: Vicki Lawrence KB-Triplet: (Mila Kunis, child, [Wyatt Kutcher, Dimitri Kutcher]) KBQA: How many children does Mila Kunis have? Answer: Two **DIVKNOWQA**: How many children does the person who does Meg's voice on Family Guy have? **Answer**: Two
KB → Text	short entity	20.7	KB-Triplet: (William Weatherall Wilkins, present in work, Mary Poppins Returns) KBQA: In which work is William Weatherall Wilkins present? Answer: Mary Poppins Returns TextQA: Who play Mary Poppins in Mary Poppins Returns? Answer: Emily Blunt **DIVKNOWQA**: Who plays Mary Poppins in the work in which William Weatherall Wilkins is present? **Answer**: Emily Blunt
	yes/no	20.0	KB-Triplet: (Girl #2, present in work, High School Musical) KBQA: In which work is Girl #2 present? Answer: High School Musical TextQA: What grade were they in in high school musical 1? Answer: juniors **DIVKNOWQA**: Were they seniors in the work in which Girl #2 is present? **Answer**: no

SpeedE: Euclidean Geometric Knowledge Graph Embedding Strikes Back

Aleksandar Pavlović and **Emanuel Sallinger**
Research Unit of Databases and Artificial Intelligence
TU Wien
Vienna, Austria
aleksandar.pavlovic@tuwien.ac.at, emanuel.sallinger@tuwien.ac.at

Abstract

Geometric knowledge graph embedding models (gKGEs) have shown great potential for knowledge graph completion (KGC), i.e., automatically predicting missing triples. However, contemporary gKGEs require *high embedding dimensionalities* or *complex embedding spaces* for good KGC performance, drastically limiting their space and time efficiency. Facing these challenges, we propose SpeedE, a lightweight Euclidean gKGE that (1) provides strong inference capabilities, (2) is competitive with state-of-the-art gKGEs, even significantly outperforming them on YAGO3-10 and WN18RR, and (3) dramatically increases their efficiency, in particular, needing solely a fifth of the training time and a fourth of the parameters of the state-of-the-art ExpressivE model on WN18RR to reach the same KGC performance.

1 Introduction

Geometric knowledge graph embedding models (gKGEs) represent entities and relations of a *knowledge graph* (KG) as geometric shapes in the semantic vector space. gKGEs achieved promising performance on *knowledge graph completion* (KGC) and knowledge-driven applications (Wang et al., 2017; Broscheit et al., 2020); while allowing for an intuitive *geometric interpretation* of their captured patterns (Pavlović and Sallinger, 2023a,b).

Efficiency Problem. Recently, increasingly *more complex* embedding spaces were explored to boost the KGC performance of gKGEs (Sun et al., 2019; Zhang et al., 2019; Cao et al., 2021). However, more complex embedding spaces typically require more costly operations or more parameters, lowering their time and space efficiency compared to Euclidean gKGEs (Wang et al., 2021). Even more, most gKGEs require *high-dimensional embeddings* to reach good KGC performance, increasing their time and space requirements (Chami et al., 2020; Wang et al., 2021). Thus, the need for (1) complex embedding spaces and (2) high-dimensional embeddings lowers the efficiency of gKGEs, hindering their application in resource-constrained environments, especially in mobile smart devices (Sun et al., 2019; Zhang et al., 2019; Wang et al., 2021).

Table 1: Dimensionality, MRR, convergence time, and number of parameters of SotA gKGE's on WN18RR.

Model	Dim.	MRR	Conv. Time	#Parameters
SpeedE	**50**	**.500**	**6min**	**2M**
ExpressivE	200	**.500**	31min	8M
HAKE	500	.497	50min	41M
ConE	500	.496	1.5h	20M
RotH	500	.496	2h	21M

Challenge and Methodology. Although there has been much work on scalable gKGEs, any such work has focused exclusively on either reducing the embedding dimensionality (Balazevic et al., 2019a; Chami et al., 2020; Bai et al., 2021) or using simpler embedding spaces (Kazemi and Poole, 2018; Zhang et al., 2020; Pavlović and Sallinger, 2023b), thus addressing only one side of the efficiency problem. Facing these challenges, this work aims to design a *Euclidean* gKGE that performs well on KGC under *low-dimensional* conditions, reducing its storage space, inference, and training times. To reach this goal, we analyze ExpressivE (Pavlović and Sallinger, 2023b), a Euclidean gKGE that has shown promising performance on KGC under high-dimensional conditions.

Contribution. Based on ExpressivE, we propose the lightweight SpeedE model that (1) halves ExpressivE's inference time and (2) enhances ExpressivE's distance function, significantly improving its KGC performance. We evaluate SpeedE on the three standard KGC benchmarks, WN18RR, FB15k-237, and YAGO3-10, finding that it (3) is competitive with SotA gKGEs on FB15k-237 and even outperforms them significantly on WN18RR

Findings of the Association for Computational Linguistics: NAACL 2024, pages 69–92
June 16-21, 2024 ©2024 Association for Computational Linguistics

and the large YAGO3-10 benchmark. Furthermore, we find that (4) SpeedE preserves ExpressivE's KGC performance on WN18RR with much fewer parameters, in particular, requiring solely a fourth of the number of parameters of ExpressivE and solely a fifth of its training time to reach the same KGC performance (Table 1, also c.f. Section 6.3). In total, we propose the SpeedE model, which reaches strong KGC performance using low-dimensional embeddings while maintaining the low space and time requirements of Euclidean gKGEs.

Organization. Our paper is organized as follows: Section 2 introduces the KGC problem. Section 3 reviews related work. Section 4 discusses the ExpressivE model. Section 5 disassembles ExpressivE's components to find a simpler model that still supports the core inference patterns (c.f. Section 2) and continues by building on these results to introduce the lightweight SpeedE model. Section 6 empirically evaluates SpeedE's KGC performance and studies its space and time efficiency. Finally, Section 7 summarizes our results, and the appendix lists proofs, further experiments, and setup details.

2 Knowledge Graph Completion

This section discusses the KGC problem and its empirical evaluation (Abboud et al., 2020). First, we introduce the *triple vocabulary*, consisting of a finite set of *relations* $\boldsymbol{R}$ and *entities* $\boldsymbol{E}$. We use this vocabulary to define triples, i.e., expressions of the form $r_j(e_h, e_t)$, where $r_j \in \boldsymbol{R}$, $e_h, e_t \in \boldsymbol{E}$, and where we call e_h the triple's *head* and e_t its *tail*. A finite set of triples over the triple vocabulary is called a knowledge graph G. KGC describes the problem of predicting missing triples of G.

Empirical Evaluation. To experimentally evaluate gKGEs, a set of true and corrupted triples is required. True triples $r_i(e_h, e_t) \in G$ are corrupted by substituting either e_h or e_t with any $e_c \in \boldsymbol{E}$ such that the corrupted triple does not occur in G. To estimate a given triple's truth, gKGEs define scores over triples and are optimized to score true triples higher than false ones. The KGC performance of a gKGE is measured with the *mean reciprocal rank* (MRR), the average of inverse ranks ($1/rank$), and H@k, the proportion of true triples within the predicted ones whose rank is at maximum k.

Theoretical Evaluation. A gKGE's theoretical capabilities are commonly evaluated by studying the *inference patterns* it captures. An inference pattern is a logical rule $\phi \Rightarrow \psi$, where ϕ is called its body and ψ its head. A rule $\phi \Rightarrow \psi$ is satisfied over a graph G iff if ϕ is satisfied in G, then ψ must be satisfied in G. A rule of the form $\phi \Rightarrow \bot$ states that the pattern ϕ is never satisfied in G. For instance, $r_1(X,Y) \wedge r_1(Y,X) \Rightarrow \bot$ represents that there is no pair of entities $X, Y \in \boldsymbol{E}$, such that both $r_1(X,Y) \in G$ and $r_1(Y,X) \in G$.

Intuition of Capturing. Following (Sun et al., 2019; Abboud et al., 2020; Pavlović and Sallinger, 2023b), a gKGE *captures* an inference pattern if there is an embedding instance such that the pattern is captured (1) exactly and (2) exclusively as formalized in the appendix. Capturing a pattern means, at an intuitive level, that there is an embedding instance such that (1) if the instance satisfies the pattern's body, then it also satisfies its head, and (2) the instance does not capture any unwanted inference pattern.

Core Inference Patterns. Next, we briefly list important inference patterns that are commonly studied in the gKGE literature (Sun et al., 2019; Abboud et al., 2020; Pavlović and Sallinger, 2023b): (1) symmetry $r_1(X,Y) \Rightarrow r_1(Y,X)$, (2) anti-symmetry $r_1(X,Y) \wedge r_1(Y,X) \Rightarrow \bot$, (3) inversion $r_1(X,Y) \Leftrightarrow r_2(Y,X)$, (4) composition $r_1(X,Y) \wedge r_2(Y,Z) \Rightarrow r_3(X,Z)$, (5) hierarchy $r_1(X,Y) \Rightarrow r_2(X,Y)$, (6) intersection $r_1(X,Y) \wedge r_2(X,Y) \Rightarrow r_3(X,Y)$, and (7) mutual exclusion $r_1(X,Y) \wedge r_2(X,Y) \Rightarrow \bot$. We shall call these seven types of patterns *core inference patterns* henceforth.

3 Related Work

The main focus of our work lies on *gKGEs*, i.e., knowledge graph embedding models (KGEs) that allow for a geometric interpretation of their captured inference patterns. Thus, we have excluded neural KGEs as they are typically less interpretable (Dettmers et al., 2018; Socher et al., 2013; Nathani et al., 2019; Wang et al., 2021). gKGEs are commonly classified by how they embed relations:

Bilinear gKGEs embed relations as matrices, allowing them to factorize a graph's adjacency matrix by computing the bilinear product of entity and relation embeddings. The pioneering bilinear model is RESCAL (Nickel et al., 2011), embedding relations with full-rank $d \times d$ matrices and entities with d-dimensional vectors. However, its parameter size grows quadratically with its dimensionality d, limiting RESCAL's scalability (Kazemi and Poole, 2018). Thus, more scalable bilinear gKGEs were proposed, such as DistMult (Yang et al., 2015), ComplEx (Trouillon et al., 2016), TuckER (Balazevic et al., 2019b), SimplE (Kazemi and Poole, 2018), QuatE (Zhang et al., 2019), and DualQuatE (Cao et al., 2021). Although these enhanced models could capture increasingly more inference patterns, none of them can capture composition patterns.

Spatial gKGEs embed relations as semantic regions within the embedding space. BoxE (Abboud et al., 2020) is the pioneering spatial gKGE, embedding relations with two bounded hyper-rectangles. This allows BoxE to capture most of the core inference patterns. However, purely spatial models cannot capture composition patterns.

Functional gKGEs embed relations as functions $f_{r_i} : \mathbb{K}^d \to \mathbb{K}^d$ and entities as high-dimensional points $e_j \in \mathbb{K}^d$ over some field $\mathbb{K}$. The pioneering functional model is TransE (Bordes et al., 2013), which embeds relations as translations from head to tail entity embeddings. However, representing relations as translations limits TransE from capturing inference patterns, such as symmetry or hierarchy. Thus, many extensions were proposed, solving some of these limitations, such as RotatE (Sun et al., 2019), MuRP (Balazevic et al., 2019a), RotH (Chami et al., 2020), HAKE (Zhang et al., 2020) and ConE (Bai et al., 2021). However, none of these models can capture hierarchy patterns.

Spatio-Functional gKGEs. Recently, Pavlović and Sallinger (2023b) proposed ExpressivE, a *spatio-functional gKGE* that combines the advantages of both spatial and functional models by embedding relations as hyper-parallelograms. Thereby, it can capture all core inference patterns simultaneously.

Embedding Space Problem. Although these model families are vastly different, many contemporary gKGEs overcome the limitations of former ones by exploring increasingly *more complex* spaces. For example, while (a) RESCAL and DistMult use the Euclidean space $\mathbb{R}$, (b) ComplEx uses the complex space, extending $\mathbb{R}$ by one imaginary unit, (c) QuatE uses the quaternion space, extending $\mathbb{R}$ by three imaginary units, and (d) DualQuatE uses the dual-quaternion space, extending $\mathbb{R}$ by seven imaginary units. Thus, a d-dimensional entity embedding of (a) RESCAL and DISTMULT requires d, (b) ComplEx requires $2d$, (c) QuatE requires $4d$, and (d) DualQuatE requires even $8d$ real-valued parameters. Therefore, gKGEs based in more complex embedding spaces typically require more parameters, lowering their efficiency compared to Euclidean gKGEs (Wang et al., 2021).

High-Dimensionality Problem. Even more, most gKGEs require *high-dimensional* embeddings to reach good KGC performance (Chami et al., 2020; Wang et al., 2021). Yet, high embedding dimensionalities of 200, 500, or 1000 (Sun et al., 2019; Zhang et al., 2019) increase the time and space requirements of gKGEs, limiting their efficiency and application to resource-constrained environments, especially mobile smart devices (Wang et al., 2021).

Hyperbolic gKGEs such as RotH and AttH (Chami et al., 2020) embed entities and relations in the hyperbolic space, which allows for high-fidelity and parsimonious representations of *hierarchical relations* (Balazevic et al., 2019a; Chami et al., 2020), i.e., relations that describe hierarchies between entities, such as *part_of*. This allowed them to reach promising KGC performance using low-dimensional embeddings, addressing the high-dimensionality problem (Chami et al., 2020). Yet, most hyperbolic gKGEs were limited to expressing a single global entity hierarchy per relation. ConE (Bai et al., 2021) solves this problem by embedding entities as hyperbolic cones and relations as transformations between these cones. However, hyperbolic gKGEs typically cannot directly employ Euclidean addition and scalar multiplication but require far more costly hyperbolic versions of these operations, termed Möbius Addition and Multiplication. Thus, they fail to address the embedding space problem, which results in high time requirements for hyperbolic gKGEs (Wang et al., 2021).

Euclidean gKGEs have recently shown strong representation, inference, and KGC capabilities under high-dimensional conditions. On the one hand, HAKE (Zhang et al., 2020) achieved promising results for representing hierarchical relations on which hyperbolic gKGEs are typically most effective. On the other hand, ExpressivE (Pavlović and Sallinger, 2023b) managed to capture all core inference patterns. Although Euclidean gKGEs address the embedding space problem, their reported KGC results under low dimensionalities are dramatically lower than those of hyperbolic gKGEs (Chami et al., 2020). Thus, they currently fail to address the high-dimensionality problem.

Our work is inspired by (1) the gap of gKGEs addressing both sides of the efficiency problem, i.e., the use of (a) complex embedding spaces and (b) high-dimensional embeddings (Wang et al., 2021), and (2) the promising results of Euclidean gKGEs under high embedding dimensionalities (Pavlović and Sallinger, 2023b). In contrast to prior work, our paper *jointly* focuses on both sides of the efficiency problem to design a highly resource-efficient gKGE.

4 The ExpressivE Model

This section reviews ExpressivE (Pavlović and Sallinger, 2023b), a Euclidean gKGE with strong KGC performance under high dimensionalities.

Representation. ExpressivE embeds entities $e_h \in \boldsymbol{E}$ via vectors $\boldsymbol{e_h} \in \mathbb{R}^d$ and relations $r_j \in \boldsymbol{R}$ via hyper-parallelograms in $\mathbb{R}^{2d}$. The hyper-parallelogram of a relation r_j is parameterized via the following three vectors: (1) a *slope vector* $\boldsymbol{s_j} \in \mathbb{R}^{2d}$ representing the slopes of its boundaries, (2) a *center vector* $\boldsymbol{c_j} \in \mathbb{R}^{2d}$ representing its center, and (3) a *width vector* $\boldsymbol{w_j} \in (\mathbb{R}_{\geq 0})^{2d}$ representing its width. At an intuitive level, a triple $r_j(e_h, e_t)$ is captured to be *true* by an ExpressivE embedding if the concatenation of its head and tail embedding is within r_j's hyper-parallelogram. Formally, this means that a triple $r_j(e_h, e_t)$ is true if the following inequality is satisfied:

$$(\boldsymbol{e_{ht}} - \boldsymbol{c_j} - \boldsymbol{s_j} \odot \boldsymbol{e_{th}})^{|.|} \preceq \boldsymbol{w_j} \tag{1}$$

Where $\boldsymbol{e_{xy}} := (\boldsymbol{e_x} || \boldsymbol{e_y}) \in \mathbb{R}^{2d}$ with $||$ representing concatenation and $e_x, e_y \in \boldsymbol{E}$. Furthermore, the inequality uses the following operators: the element-wise less or equal operator $\preceq$, the element-wise absolute value $\boldsymbol{x}^{|.|}$ of a vector $\boldsymbol{x}$, and the element-wise (i.e., Hadamard) product $\odot$.

Scoring. ExpressivE employs the typical distance function $D : \boldsymbol{E} \times \boldsymbol{R} \times \boldsymbol{E} \rightarrow \mathbb{R}^{2d}$ of spatial gKGEs (Abboud et al., 2020; Pavlović and Sallinger, 2023b), which is defined as follows:

$$D(h, r_j, t) = \begin{cases} \boldsymbol{\tau_{r_j(h,t)}} \oslash \boldsymbol{m_j}, & \text{if } \boldsymbol{\tau_{r_j(h,t)}} \preceq \boldsymbol{w_j} \\ \boldsymbol{\tau_{r_j(h,t)}} \odot \boldsymbol{m_j} - \boldsymbol{k_j}, & \text{otherwise} \end{cases} \tag{2}$$

Where $\oslash$ denotes the element-wise division operator, $\boldsymbol{\tau_{r_j(h,t)}} := (\boldsymbol{e_{ht}} - \boldsymbol{c_j} - \boldsymbol{s_j} \odot \boldsymbol{e_{th}})^{|.|}$ denotes the triple embedding, $\boldsymbol{m_j} := \boldsymbol{2} \odot \boldsymbol{w_j} + \boldsymbol{1}$ represents the distance function's slopes, and $\boldsymbol{k_j} := \boldsymbol{0.5} \odot (\boldsymbol{m_j} - \boldsymbol{1}) \odot (\boldsymbol{m_j} - \boldsymbol{1} \oslash \boldsymbol{m_j})$.

Based on this distance function $D(h, r_j, t)$, we define ExpressivE's scoring function for quantifying the plausibility of a given triple $r_j(h, t)$ as follows:

$$s(h, r_j, t) = -||D(h, r_j, t)||_2 \tag{3}$$

5 The Methodology

Our goal is to design a gKGE that addresses the efficiency problems raised by the use of (1) complex embedding spaces and (2) high-dimensional embeddings while (3) allowing for a geometric interpretation of its embeddings (Abboud et al., 2020; Pavlović and Sallinger, 2023b). We reach this goal by designing a KGC model that (1) is based in the Euclidean space, (2) reaches high KGC performance under low-dimensional conditions while at the same time supports the *core inference patterns* (Section 2), and (3) is a gKGE.

Toward our goal, Section 5.1 analyzes the SotA ExpressivE model, finding that it uses redundant parameters that negatively affect its inference time. By redundant parameters, we mean parameters that can be removed while preserving the support of the core inference patterns (Section 2). Facing this problem, we propose the lightweight Min_SpeedE model that removes these redundancies, halving ExpressivE's inference time (Section 5.1).

However, Min_SpeedE loses the ability to adjust its distance function, which is essential for representing hierarchical relations (as empirically verified in Section 6). Thus, Section 5.2 introduces SpeedE, a model that enhances Min_SpeedE by adding carefully designed parameters for flexibly adjusting the distance function while preserving Min_SpeedE's low inference times.

5.1 Min_SpeedE

To design Min_SpeedE, let us first analyze ExpressivE's parameters, particularly its width vector. Adjusting ExpressivE's width vector $\boldsymbol{w_j}$ has two competing effects: (1) it alters the distance function's slopes (by $\boldsymbol{m_j}$ in Inequality 2), and (2) it changes which entity pairs are inside the relation hyper-parallelogram (by $\boldsymbol{w_j}$ in Inequality 1). To increase ExpressivE's time efficiency substantially, we introduce Min_SpeedE, a constrained version of ExpressivE that replaces the relation-wise width vectors $\boldsymbol{w_j} \in (\mathbb{R}_{\geq 0})^{2d}$ by a constant value $w \in \mathbb{R}_{>0}$ - that is shared across all relations $r_j \in \boldsymbol{R}$. The following paragraphs theoretically analyze Min_SpeedE's inference capabilities and time efficiency.

Inference Capabilities. We find that Min_SpeedE surprisingly still captures the core inference patterns (given in Section 2) and prove this in Theorem 5.1. We give the full proof in the appendix and discuss one of the most interesting parts here, namely, hierarchy patterns.

Theorem 5.1. *Min_SpeedE captures the core inference patterns, i.e., symmetry, anti-symmetry, inversion, composition, hierarchy, intersection, and mutual exclusion.*

Hierarchy Patterns. According to Pavlović and Sallinger (2023b), an ExpressivE model captures a hierarchy pattern $r_1(X, Y) \Rightarrow r_2(X, Y)$ iff r_1's hyper-parallelogram is a proper subset of r_2's. Thus, one would expect that ExpressivE's ability to capture hierarchy patterns is lost in Min_SpeedE, as the width parameter $w \in \mathbb{R}_{>0}$ (responsible for adjusting a hyper-parallelogram's size) is shared across all hyper-parallelograms. However, the actual size of a hyper-parallelogram does not solely depend on its width but also on its slope parameter $\boldsymbol{s_j} \in \mathbb{R}^{2d}$, allowing one hyper-parallelogram $\boldsymbol{H_1}$ to properly subsume another $\boldsymbol{H_2}$ even when they share the same width parameter w. We have visualized two hyper-parallelograms $\boldsymbol{H_2} \subset \boldsymbol{H_1}$ with the same width parameter w in Figure 1.

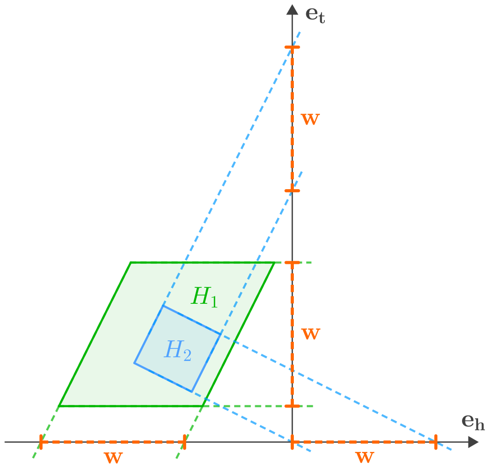


Figure 1: Representation of the two-dimensional relation hyper-parallelograms $\boldsymbol{H_1}$ and $\boldsymbol{H_2}$, such that $\boldsymbol{H_1}$ subsumes $\boldsymbol{H_2}$ and such that they share the same width parameter w in each dimension.

Intuition. Min_SpeedE can capture $\boldsymbol{H_2} \subset \boldsymbol{H_1}$ as w (depicted with orange dotted lines) represents the intersection of the bands (depicted with blue and green dotted lines), expanded from the hyper-parallelogram, and the axis of the band's corresponding dimension. Thus, a hyper-parallelogram's actual size can be adapted by solely changing its slopes, removing the need for a learnable width parameter per dimension and relation.

Inference Time. The most costly operations during inference are operations on vectors. Thus, we can estimate ExpressivE's and Min_SpeedE's inference time by counting the number of vector operations necessary for computing a triple's score: By reducing the width vector to a scalar, many operations reduce from a vector to a scalar operation. In particular, the calculation of m_j and k_j uses solely scalars in Min_SpeedE instead of vectors. Thus, ExpressivE needs 15, whereas Min_SpeedE needs solely 8 vector operations to compute a triple's score. This corresponds to Min_SpeedE using approximately half the number of vector operations of ExpressivE for computing a triple's score, thus roughly halving ExpressivE's inference time, which aligns with Section 6.3's empirical results.

Key Insights. Fixing the width to a constant value w stops Min_SpeedE from adjusting the distance function's slopes. As we will empirically see in Section 6, the effect of this is a severely degraded KGC performance on hierarchical relations. Introducing independent parameters for adjusting the distance function's slopes solves this problem. However, these parameters must be designed carefully to (1) preserve ExpressivE's geometric interpretation and (2) retain the reduced inference time provided by Min_SpeedE. Each of these aspects will be covered in detail in the next section.

5.2 SpeedE

SpeedE further enhances Min_SpeedE by adding the following two carefully designed scalar parameters to each relation embedding: (1) the inside distance slope $s^i_j \in [0, 1]$ and (2) the outside distance slope s^o_j with $s^i_j \preceq s^o_j$. Let $m^i_j := 2s^i_j w + 1$, $m^o_j := 2s^o_j w + 1$, and $k_j := m^o_j(m^o_j - 1)/2 - (m^i_j - 1)/(2m^i_j)$, then SpeedE defines the following distance function:

$$D(h, r_j, t) = \begin{cases} \boldsymbol{\tau}_{\boldsymbol{r_j(h,t)}} \oslash m^i_j, & \text{if } \boldsymbol{\tau}_{\boldsymbol{r_j(h,t)}} \preceq w \\ \boldsymbol{\tau}_{\boldsymbol{r_j(h,t)}} \odot m^o_j - k_j, & \text{otherwise} \end{cases} \quad (4)$$

Again, the distance function is separated into two piece-wise linear functions: (1) the inside distance $D_i(h, r_j, t) = \boldsymbol{\tau}_{\boldsymbol{r_j(h,t)}} \oslash m^i_j$ for triples that are captured to be true (i.e., $\boldsymbol{\tau}_{\boldsymbol{r_j(h,t)}} \preceq w$) and (2) the outside distance $D_o(h, r_j, t) = \boldsymbol{\tau}_{\boldsymbol{r_j(h,t)}} \odot m^o_j - k_j$

for triples that are captured to be false (i.e., $\tau_{r_j(h,t)} \succ w$). Based on this function, SpeedE defines the score as $s(h, r_j, t) = -||D(h, r_j, t)||_2$.

Geometric Interpretation. The intuition of s_j^i and s_j^o is that they control the slopes of the respective linear inside and outside distance functions. However, without any constraints on s_j^i and s_j^o, SpeedE would lose ExpressivE's intuitive geometric interpretation (Pavlović and Sallinger, 2023b) as s_j^i and s_j^o could be chosen in such a way that distances of embeddings within the hyper-parallelogram are larger than those outside. By constraining these parameters to $s_j^i \in [0, 1]$ and $s_j^i \leq s_j^o$, we preserve lower distances within hyper-parallelograms than outside and, thereby, the intuitive geometric interpretation of our embeddings.

Inference Time. The additional introduction of two scalar distance slope parameters $s_j^i, s_j^o \in \mathbb{R}$ per relation r_j does not change the number of vector operations necessary for computing a triple's score and, thus, does not significantly affect SpeedE's inference time. Thus, we expect that SpeedE retains the time efficiency of Min_SpeedE, as empirically validated in Section 6.3.

With this, we have finished our introduction and theoretical analysis of SpeedE. What remains to be shown is its empirical performance, which we shall evaluate next.

6 Experiments

This section empirically evaluates SpeedE: Section 6.1 describes the experimental setup. Section 6.2 studies SpeedE's KGC performance, finding that it is competitive with SotA gKGEs on FB15k-237 and even significantly outperforms them on YAGO3-10 and WN18RR. Section 6.3 studies SpeedE's space and time efficiency, finding that on WN18RR, SpeedE needs a quarter of ExpressivE's parameters to reach the same KGC performance while training five times faster than it.

6.1 Experimental Setup

Datasets. We empirically evaluate SpeedE on the three standard KGC benchmarks, WN18RR (Bordes et al., 2013; Dettmers et al., 2018), FB15k-237 (Bordes et al., 2013; Toutanova and Chen, 2015), and YAGO3-10 (Mahdisoltani et al., 2015). We provide detailed information about these benchmarks, including their languages, licenses, and number of triples in Appendix I.2.

Characteristics. Table 2 displays the following characteristics of the benchmarks: their number of entities $|\boldsymbol{E}|$ and relations $|\boldsymbol{R}|$, their curvature C_G (taken from Chami et al. (2020)), and the Krackhardt scores κ (taken from Bai et al. (2021)), consisting of the four metrics: (*connectedness*, *hierarchy*, *efficiency*, *LUBedness*). Both C_G and κ state how tree-like a benchmark is and, thus, how hierarchical its relations are. Following the procedure of Chami et al. (2020), we employ the standard augmentation protocol (Lacroix et al., 2018), adding inverse relations to the benchmarks.

Table 2: Benchmark dataset characteristics. Curvature C_G is from (Chami et al., 2020); the lower, the more hierarchical the data. Krackhardt scores κ are from (Bai et al., 2021); the higher, the more hierarchical the data.

Dataset	$\|\boldsymbol{E}\|$	$\|\boldsymbol{R}\|$	C_G	κ
FB15k-237	14,541	237	-0.65	(1.00, 0.18, 0.36, 0.06)
WN18RR	40,943	11	-2.54	(1.00, 0.61, 0.99, 0.50)
YAGO3-10	123,143	37	-0.54	-

Setup. We compare our SpeedE model to (1) the Euclidean gKGEs ExpressivE (Pavlović and Sallinger, 2023b), HAKE (Zhang et al., 2020), TuckER (Balazevic et al., 2019b), MuRE (Balazevic et al., 2019a), and RefE, RotE, and AttE (Chami et al., 2020), (2) the complex gKGEs ComplEx-N3 (Lacroix et al., 2018) and RotatE (Sun et al., 2019), and (3) the hyperbolic gKGEs ConE (Bai et al., 2021), MuRP (Balazevic et al., 2019a), and RefH, RotH, and AttH (Chami et al., 2020). Following Pavlović and Sallinger (2023b), we train SpeedE and ExpressivE for up to 1000 epochs using gradient descent and the Adam optimizer (Kingma and Ba, 2015) and stop the training if the validation H@10 score does not increase by minimally 0.5% for WN18RR, YAGO3-10, and 1% for FB15k-237 after 100 epochs. We average the experimental results over three runs on each benchmark to handle marginal performance fluctuations. Furthermore, as in (Chami et al., 2020), we evaluate SpeedE and ExpressivE in the low-dimensional setting using an embedding dimensionality of 32.

Reproducibility. We list further details on our experimental setup, hardware, hyperparameters, libraries (Ali et al., 2021), and definitions of metrics in the appendix. To facilitate the reproducibility of our results, we provide SpeedE's source code in a public GitHub repository[1].

---

6.2 Knowledge Graph Completion

This section evaluates the KGC performance of SpeedE and SotA gKGEs. Furthermore, we study how well these models represent hierarchical relations, on which hyperbolic gKGEs are typically most effective (Balazevic et al., 2019a; Chami et al., 2020). Finally, we analyze the effect of embedding dimensionality on SpeedE's KGC performance.

Low-Dimensional KGC. Following the evaluation protocol of Chami et al. (2020), we evaluate each gKGE's performance under $d = 32$. We report the MRR and H@1 in Table 3 and provide the complete results in the appendix. Table 3 reveals that on YAGO3-10 — the largest benchmark, containing over a million triples — SpeedE outperforms any SotA gKGE by a relative difference of 7% on H@1, providing strong evidence for SpeedE's scalability to large KGs. Furthermore, it shows that our enhanced SpeedE model is competitive with SotA gKGEs on FB15k-237 and even outperforms any competing gKGE on WN18RR by a large margin. Furthermore, SpeedE's performance gain over Min_SpeedE on the highly hierarchical dataset WN18RR (see Table 2) provides strong empirical evidence for the effectiveness of the distance slope parameters for representing hierarchical relations under low-dimensional conditions. SpeedE's performance on the more hierarchical WN18RR already questions the necessity of hyperbolic gKGEs for representing hierarchical relations, which will be further investigated in the following.

Hierarchical Relations (Chami et al., 2020; Zhang et al., 2020) describe hierarchies between entities, such as *part_of*. Hyperbolic gKGEs have shown great potential for representing hierarchical relations, outperforming Euclidean gKGEs under low-dimensional conditions and thereby justifying the increased model complexity added by the hyperbolic space (Chami et al., 2020). To study SpeedE's performance on hierarchical relations, we evaluate SpeedE on the triples of any hierarchical relation of WN18RR following the methodology of Bai et al. (2021). Table 4 presents the results of this study. It reveals that SpeedE significantly improves over ExpressivE on most relations and outperforms RotH on five out of the seven hierarchical ones. Most notably, SpeedE improves over RotH by a relative difference of 23% on H@10 on the hierarchical relation *_member_of_domain_usage*, providing empirical evidence for SpeedE's promising potential for representing hierarchical relations even under low-dimensional settings. The performance gain on hierarchical relations is likely due to the added distance slope parameters, which allow for independently adjusting the distance function's slopes.

Table 4: H@10 of ExpressivE, RotH, and SpeedE on hierarchical relations (Bai et al., 2021) of WN18RR.

Relation	ExpressivE	RotH	SpeedE
_member_meronym	0.362	**0.399**	0.379
_hypernym	0.276	0.276	**0.301**
_has_part	0.308	**0.346**	0.330
_instance_hypernym	0.509	0.520	**0.543**
_member_of_domain_region	0.365	0.365	**0.397**
_member_of_domain_usage	**0.545**	0.438	0.538
_synset_domain_topic_of	0.468	0.447	**0.502**

Dimensionality Study. To analyze the effect of the embedding dimensionality on the KGC performance, we evaluate state-of-the-art gKGEs on WN18RR under varied dimensionalities. Figure 2 visualizes the results of this study, displaying error bars for our SpeedE model with average MRR and standard deviation computed over three runs. The figure reveals that, surprisingly, ExpressivE significantly outperforms RotH, especially under low-dimensional conditions, and that the enhanced SpeedE model achieves an additional performance improvement over ExpressivE. This result provides further evidence for the great potential of Euclidean gKGEs under low-dimensional conditions.

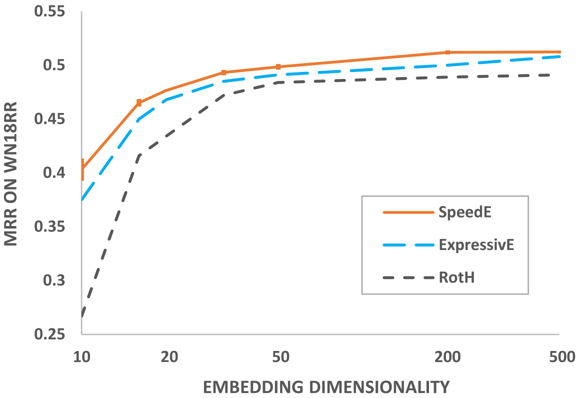

Figure 2: MRR of SotA gKGEs on WN18RR using $d \in \{10, 16, 20, 32, 50, 200, 500\}$.

High-Dimensional KGC. The KGC performance of SotA gKGEs under high-dimensional conditions (i.e., $d \geq 200$) is listed in the appendix. It reveals that on FB15k-237, SpeedE achieves highly competitive KGC performance compared to gKGEs of its own family while dramatically outperforming any competing gKGE on WN18RR.

6.3 Space and Time Efficiency

This section empirically analyzes SpeedE's space and time efficiency compared to SotA gKGEs.

Time per Epoch. Following the methodology of Wang et al. (2021), Table 5 displays the training time per epoch of SpeedE and SotA gKGEs for WN18RR, FB15k-237, and YAGO3-10 with embedding dimensionality $d = 32$, negative sampling size $n = 500$, and batch size $b = 500$. The times per epoch were recorded on a GeForce RTX 2080 Ti GPU of our internal cluster. The empirical results of the table align with the theoretical results of Sections 5.1 and 5.2, stating that SpeedE approximately halves ExpressivE's inference time and, thus, also its time per epoch. Furthermore, the results emphasize SpeedE's efficiency benefits over SotA gKGEs, as they reveal that under the same configurations, SpeedE solely requires about a sixth of RotH's and AttH's time per epoch.

Next, to provide a fair comparison of each gKGE's space and time efficiency, we measure the convergence time of gKGEs with approximately equal KGC performance. Specifically, we observe that SpeedE with dimensionality $d = 50$ achieves comparable or slightly better KGC performance on WN18RR to ExpressivE with $d = 200$ and the best-published results of RotH, HAKE, and ConE with $d = 500$. In particular, the results are summarized in Table 1 (provided in Section 1).

Table 5: Time per epoch of SpeedE, ExpressivE, RotH, and AttH.

Model	Time per Epoch		
	WN18RR	FB15k-237	YAGO3-10
SpeedE	7s	22s	88s
ExpressivE	15s	46s	185s
RotH	42s	112s	520s
AttH	43s	113s	533s

Hypotheses. Since (1) the dimensionality of SpeedE embeddings is much smaller in comparison to RotH's, HAKE's, ConE's, and ExpressivE's dimensionality, while (2) SpeedE achieves comparable or even slightly better KGC performance, we expect a considerable improvement in SpeedE's space and time efficiency at comparable KGC performance. Next, based on Table 1's results, we analyze how strongly SpeedE reduces the model size and convergence time of competing gKGEs.

Model Size Analysis. Since $|\boldsymbol{R}| << |\boldsymbol{E}|$ in most graphs, (WN18RR: $|\boldsymbol{R}|/|\boldsymbol{E}| = 0.00012$) and since SpeedE, ExpressivE, ConE, and RotH embed each entity with a single real-valued vector, SpeedE ($d = 50$) needs solely a quarter of ExpressivE's ($d = 200$) and a tenth of ConE's and RotH's ($d = 500$) number of parameters, while preserving their KGC performance on WN18RR (Table 1). As HAKE requires two real-valued vectors per entity, SpeedE ($d = 50$) solely needs a twentieth of HAKE's ($d = 500$) parameters to achieve a slightly better KGC performance. Table 1 lists the number of parameters of a trained SpeedE model and SotA gKGEs, empirically confirming that SpeedE significantly reduces the size of competing gKGEs.

Convergence Time Analysis. To quantify the convergence time, we measure for each gKGE the time to reach a validation MRR score of 0.490, i.e., approximately 1% less than the worst reported MRR score of Table 1. As outlined in the table, SpeedE converges already after $6min$. Thus, while keeping strong KGC performance on WN18RR, SpeedE speeds up ExpressivE's convergence time by a factor of 5, HAKE's by a factor of 9, ConE's by a factor of 15, and RotH's by a factor of 20.

Discussion. These results show that SpeedE is not only competitive with SotA gKGEs on FB15k-237 and significantly outperforms them on YAGO3-10 and WN18RR but even preserves their KGC performance on WN18RR with much fewer parameters and a dramatically shorter convergence time, in particular speeding up the convergence time of the SotA ExpressivE model by a factor of 5, while using solely a fourth of its number of parameters.

7 Conclusion

Although there has been much work on resource-efficient gKGEs, any such work has focused exclusively on reducing the embedding dimensionality (Balazevic et al., 2019a; Chami et al., 2020; Bai et al., 2021) or using simpler embedding spaces (Kazemi and Poole, 2018; Zhang et al., 2020; Pavlović and Sallinger, 2023b), thus addressing only one side of the efficiency problem.

In this work, we address the embedding space and dimensionality side jointly by introducing SpeedE, a lightweight gKGE that (1) provides strong inference capabilities, (2) is competitive with SotA gKGEs, even significantly outperforming them on YAGO3-10 and WN18RR, and (3) dramatically increases the efficiency of current gKGEs, needing solely a fifth of the training time and a fourth of the number of parameters of the SotA ExpressivE model on WN18RR to reach the same KGC performance.

8 Limitations and Future Work

SpeedE and ExpressivE use one d-dimensional vector to embed entities and four, respectively, six d-dimensional vectors to embed relations. Thus, ExpressivE and SpeedE have the same space complexity, which is linear in the number of relations and entities (i.e., $O(d|E| + d|R|)$. A critical limitation of both models is that they use the same dimensionality d for relations and entities. Being able to decouple the relation and entity embedding dimensionalities might be crucial for further raising their efficiency as (1) at an intuitive level, entities are less complex objects than relations (which represent sets of pairs of entities) and therefore (2) entity embeddings might solely require a lower embedding dimensionality than relation embeddings. Since in real-world KGs, the number of entities is typically much higher than the number of relations, a lower entity dimensionality might further raise the model's efficiency.

Since gKGEs naturally provide a geometric interpretation of their learned patterns, how to automatically and efficiently mine these learned patterns from the embeddings — to make the implicitly learned knowledge explicit and further raise the model's transparency — remains an open challenge and forms an exciting branch for future work. Finally, another interesting direction for future work points at how to integrate knowledge graph embeddings in novel practical applications, such as aligning their learned knowledge with the latent representations of large language models.

9 Ethical Impact

We designed SpeedE with the goal of finding a highly resource-efficient model for KGC that, at the same time, provides a geometric interpretation of its captured patterns. Therefore, our work aligns with two pressing challenges of the machine learning community in general and the KGC community in particular, namely, (1) raising the resource efficiency of KGC models while (2) offering some degree of explainability via the geometric interpretation of captured patterns. Specifically, SpeedE reduces the training time — and thus the total compute — of the SotA ExpressivE model on WN18RR to one-fourth while sustaining ExpressivE's KGC performance and geometric interpretation. Therefore, we do not foresee any negative impact, but even expect a potential positive *environmental* (see 1) and *social impact* (see 2) of our work by introducing a highly resource-efficient model that allows for some degree of explainability.

A Organization

This appendix includes complete proofs, experimental setup details, and additional results. In particular, Section B lists the complete low-dimensional benchmark results. Section C provides an overview of SpeedE's modifications and their impact on SpeedE's efficiency and prediction performance. Section D studies the relevance of the distance slope parameters by performing an ablation study. Section E reports the KGC performance of SpeedE and SotA gKGEs under high-dimensional conditions. Section F briefly summarizes the notation that is used throughout this paper. Section G formally defines vital concepts for SpeedE that we will use in our proofs. Based on the introduced concepts, Section H proves Theorem 5.1. Finally, Section I lists details on reproducing our results and on our implementation, training setup, evaluation protocol, and estimated CO2 emissions.

B Complete Low-Dimensional KGC Results

This section reports the complete KGC performance of SotA gKGEs under low-dimensional conditions (i.e., $d = 32$). Table 6 displays these results, where the results for SpeedE, Min_SpeedE, and ExpressivE were obtained by us; for ConE are from (Bai et al., 2021), for HAKE are from (Zheng et al., 2022), for TuckER are from (Wang et al., 2021), and for any other gKGE are from (Chami et al., 2020). Table 6 reveals that on YAGO3-10 — the largest benchmark, containing over a million triples (see Appendix I.2, Table 11) — SpeedE outperforms any considered gKGE by a relative difference of 7% on H@1, providing strong evidence for SpeedE's scalability to large KGs. Furthermore, it shows that our enhanced SpeedE model is competitive with SotA gKGEs on FB15k-237 and even outperforms any competing gKGE on WN18RR by a large margin. Furthermore, SpeedE's performance gain over Min_SpeedE on the highly hierarchical dataset WN18RR provides strong empirical evidence for the effectiveness of the distance slope parameters for representing hierarchical relations under low-dimensional conditions.

Table 6: KGC performance under low dimensionalities ($d = 32$) of SpeedE, Min_SpeedE, ExpressivE, and SotA gKGEs on WN18RR, FB15k-237, and YAGO3-10 split by embedding space.

C SpeedE's Advancements

When we theoretically analyzed ExpressivE, we noticed that (1) its space and time efficiency and (2) its prediction performance could significantly be increased by (a) replacing its width vector with a scalar and (b) adding flexibility to its distance function by enhancing it with learnable parameters that (c) are constrained in such a way that the intuitive geometric interpretation of its embeddings is preserved. The advancements of Points (a), (b), and (c) (discussed in Section 5) are highly non-trivial and need significant theoretical and empirical effort to show that they do not have a negative impact but even a significant positive impact on SpeedE's prediction performance and resource efficiency. The following paragraphs briefly discuss each reported evidence for SpeedE's advancements over SotA gKGEs.

Min_SpeedE's Inference Capabilities. Surprisingly, there is no theoretical downside to replacing ExpressivE's relation-wise width parameters $\mathbf{w_j}$ with a constant width w, as shown in Theorem 5.1 (proven in Appendix H). Specifically, it shows that Min_SpeedE, a model that replaces ExpressivE's width vector with a scalar, still captures all core inference patterns and, thus, does not lose any of its inference capabilities.

Min_SpeedE's Prediction Performance. Furthermore, Min_SpeedE has no empirical downside compared to ExpressivE, as verified in Table 3. Specifically, Table 3 shows that Min_SpeedE performs similarly or slightly better than ExpressivE on KGC under low embedding dimensionalities, although Min_SpeedE replaces ExpressivE's width vector with a scalar.

SpeedE's Performance Boost Analysis. Recall, as explained in Section 3, hyperbolic gKGEs were proposed to capture hierarchical relations more effectively with low embedding dimensionalities, which was the key reason for their strong KGC performance under low-dimensional conditions (Chami et al., 2020). To test how well SpeedE performs on hierarchical relations, we evaluated SpeedE's KGC performance on hierarchical relations of the highly hierarchical benchmark WN18RR and compared them to the KGC performance of SotA gKGES. Table 4 presents the results of this analysis, showing that our SpeedE model outperforms the best-performing gKGEs on most hierarchical relations. Thus, SpeedE's performance boost under low-dimensional conditions is likely due to SpeedE's strong performance on hierarchical relations (see Table 4). Furthermore, Table 3 shows that SpeedE even outperforms Min_SpeedE by a large margin on WN18RR, which gives strong empirical evidence for the hypothesis that the added learnable parameters in SpeedE's distance function boost SpeedE's KGC performance in low-dimensional conditions. Even more, Table 3 reveals that SpeedE outperformed any competing gKGE by a large margin on the highly hierarchical benchmark WN18RR.

SpeedE's Scalability and Efficiency Results. To test whether SpeedE's prediction performance scales to larger KGs, we benchmarked SpeedE on the YAGO3-10 benchmark (which contains over one million triples) and reported the results in Table 3. We found that SpeedE outperforms any of the considered gKGEs on YAGO3-10 by a large margin, even outperforming the best-performing hyperbolic gKGE, namely AttH, on most metrics. These results provide strong empirical evidence for SpeedE's scalability to large KGs with millions of triples. Moreover, we did not solely show that SpeedE reaches SotA KGC performance but that it even dramatically boosts the resource efficiency of any considered gKGE. Specifically, Table 1 shows that SpeedE preserves ExpressivE's KGC performance on WN18RR with fewer parameters and a much smaller training time. In particular, SpeedE requires solely a fourth of ExpressivE's number of parameters and only a fifth of its training time to reach the same KGC performance. Table 5 further emphasizes SpeedE's efficiency benefits over SotA gKGEs, revealing that under the same configurations, SpeedE requires half of ExpressivE's and about a sixth of RotH's and AttH's time per epoch on all benchmarks.

Conclusion. In this section, we have very comprehensively shown that SpeedE's modifications did not solely lead to significant KGC performance boosts as verified in Theorem 5.1, Figure 2, and Tables 3 and 4, but also that SpeedE dramatically boosts the space and time efficiency of SotA gKGEs as shown in Tables 1 and 5.

D Ablation Study

To study the necessity of s^i_j and s^o_j in SpeedE, we introduce two versions of SpeedE: (1) Eq_SpeedE that forces $s^i_j = s^o_j$ and (2) Diff_SpeedE, where s^i_j and s^o_j can be different. We hypothesize that the flexibility of different s^i_j and s^o_j might be beneficial under lower dimensionalities, while under higher dimensionalities, reducing the number of parameters and thus setting $s^i_j = s^o_j$ might be beneficial. Figure 3 visualizes the result of this analysis, empirically supporting our hypothesis, as Diff_SpeedE outperforms Eq_SpeedE under low dimensionalities and vice-versa in high ones.

E High-Dimensional KGC Results

This section reports the KGC performance of SotA gKGEs under high-dimensional conditions (i.e., $d \geq 200$). Table 7 displays these results, where the results for SpeedE were obtained by us, for ExpressivE are from (Pavlović and Sallinger, 2023b), for HAKE are from (Zhang et al., 2020), for ConE are from (Bai et al., 2021), for BoxE are from (Abboud et al., 2020), for MuRE and MuRP are from (Balazevic et al., 2019a; Chami et al., 2020), for DistMult are from (Dettmers et al., 2018), for RotatE are from (Sun et al., 2019), for TuckER are from (Balazevic et al., 2019b), and for any other gKGE are from (Chami et al., 2020). Table 7 reveals that on FB15k-237, SpeedE achieves highly competitive KGC performance compared to gKGEs of its own family while dramatically outperforming any competing gKGE on WN18RR.

Table 7: KGC performance under high dimensionalities of SpeedE and SotA gKGEs on WN18RR and FB15k-237 split by model family.

F Notation

In this section, we give a brief overview of the most important notations we use. Note that, for ease of readability and comparability, we use exactly the same language as ExpressivE (Pavlović and Sallinger, 2023b).

v . . . non-bold symbols represent scalars
$\boldsymbol{v}$ . . . bold symbols represent vectors, sets or tuples
$\mathbf{0}$ . . . represents a vector of zeros (the same semantics apply to $\mathbf{0.5}$, $\mathbf{1}$, and $\mathbf{2}$)
$\oslash$ . . . represents the element-wise division operator
$\odot$ . . . represents the element-wise (Hadamard) product operator
$\succeq$ . . . represents the element-wise greater or equal operator
$\succ$ . . . represents the element-wise greater operator
$\preceq$ . . . represents the element-wise less or equal operator
$\prec$ . . . represents the element-wise less operator
$\boldsymbol{x}^{|.|}$ . . . represents the element-wise absolute value
$||$ . . . represents the concatenation operator

G Definition of Capturing

In this section, we introduce the formal semantics of SpeedE models. Note that, for ease of readability and comparability, we use exactly the same language as ExpressivE (Pavlović and Sallinger, 2023b). In places where SpeedE significantly differs from ExpressivE, we will explicitly note this and compare the two. Specifically, this section introduces the notions of capturing a pattern in a SpeedE model that we informally discussed in Section 2. Furthermore, it introduces some additional notations, which will help us simplify the upcoming proofs and present them intuitively.

Knowledge Graph. A tuple $(\boldsymbol{G}, \boldsymbol{E}, \boldsymbol{R})$ is called a knowledge graph, where $\boldsymbol{R}$ is a finite set of relations, $\boldsymbol{E}$ is a finite set of entities, and $\boldsymbol{G} \subseteq \boldsymbol{E} \times \boldsymbol{R} \times \boldsymbol{E}$ is a finite set of triples. W.l.o.g., we assume that any relation is non-empty since removing any virtual entity pair embedding from a hyper-parallelogram would be trivial, just adding unnecessary complexity to the proofs.

SpeedE Model. We define a SpeedE model as a tuple $\boldsymbol{M}^+ = (\boldsymbol{\epsilon}, \boldsymbol{\sigma}, w, \boldsymbol{\rho})$, where $\boldsymbol{\epsilon} \subset 2^{\mathbb{R}^d}$ is the set of entity embeddings, $\boldsymbol{\sigma} \subset 2^{\mathbb{R}^d}$ is the set of center embeddings, $w \in \mathbb{R}_{>0}$ represents the width constant, and $\boldsymbol{\rho} \subset 2^{\mathbb{R}^d}$ is the set of slope vectors. Note that this definition is slightly different from an ExpressivE model $\boldsymbol{M} = (\boldsymbol{\epsilon}, \boldsymbol{\sigma}, \boldsymbol{\delta}, \boldsymbol{\rho})$, where instead of the width constant w, we have $\boldsymbol{\delta} \subset 2^{\mathbb{R}^d}$ that represents the set of width embeddings.

Linking Embeddings to KGs. A SpeedE model $\boldsymbol{M}^+ = (\boldsymbol{\epsilon}, \boldsymbol{\sigma}, w, \boldsymbol{\rho})$ and a KG $(\boldsymbol{G}, \boldsymbol{E}, \boldsymbol{R})$ are linked via the following assignment functions: The entity assignment function $\boldsymbol{f_e} : \boldsymbol{E} \to \boldsymbol{\epsilon}$ assigns to each entity $e_h \in \boldsymbol{E}$ an entity embedding $\boldsymbol{e_h} \in \boldsymbol{\epsilon}$. Based on $\boldsymbol{f_e}$, the virtual assignment function $\boldsymbol{f_v} : \boldsymbol{E} \times \boldsymbol{E} \to \mathbb{R}^{2d}$ defines for any pair of entities $(e_h, e_t) \in \boldsymbol{E}$ a virtual entity pair embedding $\boldsymbol{f_v}(e_h, e_t) = (\boldsymbol{f_e}(e_h)||\boldsymbol{f_e}(e_t))$, where $||$ represents the concatenation operator. Furthermore, we define SpeedE's relation assignment function $\boldsymbol{f_h^+}(r_j) : \boldsymbol{R} \to \mathbb{R}^{2d} \times \mathbb{R} \times \mathbb{R}^{2d}$ as $\boldsymbol{f_h^+}(r_j) = (\boldsymbol{c_j^{ht}}, w, \boldsymbol{s_j^{th}})$, where $\boldsymbol{c_j^{ht}} = (\boldsymbol{c_j^h}||\boldsymbol{c_j^t})$ with $\boldsymbol{c_j^h}, \boldsymbol{c_j^t} \in \boldsymbol{\sigma}$ and where $\boldsymbol{s_j^{th}} = (\boldsymbol{s_j^t}||\boldsymbol{s_j^h})$ with $\boldsymbol{s_j^t}, \boldsymbol{s_j^h} \in \boldsymbol{\rho}$. Note that this is different from ExpressivE's relation assignment function $\boldsymbol{f_h}(r_j) : \boldsymbol{R} \to \mathbb{R}^{2d} \times \mathbb{R}^{2d} \times \mathbb{R}^{2d}$, where $\boldsymbol{f_h}(r_j) = (\boldsymbol{c_j^{ht}}, \boldsymbol{w_j^{ht}}, \boldsymbol{s_j^{th}})$ with $\boldsymbol{w_j^{ht}} = (\boldsymbol{w_j^h}||\boldsymbol{w_j^t})$ being two concatenated width embeddings.

Virtual Triple Space. To be able to assign a geometric interpretation to $\boldsymbol{f_h^+}(r_j)$, we briefly recap the definition of the virtual triple space $\mathbb{R}^{2d}$ introduced by Pavlović and Sallinger (2023b). Specifically, the virtual triple space is constructed by concatenating the head and tail entity embeddings. In detail, this means that any pair of entities $(e_h, e_t) \in \boldsymbol{E} \times \boldsymbol{E}$ defines a point in the virtual triple space by concatenating their entity embeddings $\boldsymbol{e_h}, \boldsymbol{e_t} \in \mathbb{R}^d$, i.e., $(\boldsymbol{e_h}||\boldsymbol{e_t}) \in \mathbb{R}^{2d}$. We will henceforth call the first d dimensions of the virtual triple space the *head dimensions* and the second d dimensions the *tail dimensions*. A set of important sub-spaces of the virtual triple space are the 2-dimensional spaces created from the k-th dimension of the head and tail dimensions — i.e., the k-th and $(d+k)$-th virtual triple space dimensions. We call them *correlation subspaces* as they visualize the captured relation-specific dependencies of head and tail entity embeddings. Moreover, we call the correlation subspace spanned by the k-th and $(d+k)$-th virtual triple space dimension the k-th correlation subspace. Now, the geometric interpretation of $\boldsymbol{f_h^+}(r_j)$ within the virtual triple space is a hyper-parallelogram whose edges are solely crooked in each correlation subspace, representing the relationship between head and tail entity embeddings.

Model Configuration. We call a SpeedE model $\boldsymbol{M^+}$ together with a concrete relation assignment function $\boldsymbol{f_h^+}$ a relation configuration $\boldsymbol{m_h^+} = (\boldsymbol{M^+}, \boldsymbol{f_h^+})$. If $\boldsymbol{m_h^+}$ additionally has a virtual assignment function $\boldsymbol{f_v}$, we call it a complete model configuration $\boldsymbol{m^+} = (\boldsymbol{M^+}, \boldsymbol{f_h^+}, \boldsymbol{f_v})$. Note that an ExpressivE relation configuration $\boldsymbol{m_h} = (\boldsymbol{M}, \boldsymbol{f_h})$ and a complete ExpressivE model configuration $\boldsymbol{m} = (\boldsymbol{M}, \boldsymbol{f_h}, \boldsymbol{f_v})$ are defined differently by replacing $\boldsymbol{M^+}$ and $\boldsymbol{f_h^+}$ with their ExpressivE equivalents, i.e., $\boldsymbol{M}$ and $\boldsymbol{f_h}$.

Definition of Truth. A triple $r_j(e_h, e_t)$ is captured to be true in some $\boldsymbol{m^+}$, with $r_j \in \boldsymbol{R}$ and $e_h, e_t \in \boldsymbol{E}$ iff Inequality 5 holds for the assigned embeddings of h, t, and r. This means more precisely that Inequality 5 needs to hold for $\boldsymbol{f_v}(e_h, e_t) = (\boldsymbol{f_e}(e_h) || \boldsymbol{f_e}(e_t)) = (\boldsymbol{e_h}, \boldsymbol{e_t})$ and $\boldsymbol{f_h^+}(r_j) = (\boldsymbol{c_j^{ht}}, w, \boldsymbol{s_j^{th}})$. Note that, for ExpressivE, the definition of a triple's truth is slightly different, as w in Inequality 5 would be exchanged by the respective width embedding $\boldsymbol{w_j^{ht}}$.

$$(\boldsymbol{e_{ht}} - \boldsymbol{c_j^{ht}} - \boldsymbol{s_j^{th}} \odot \boldsymbol{e_{th}})^{|.|} \preceq w, \tag{5}$$

Intuition. At an intuitive level, a triple $r_j(e_h, e_t)$ is captured to be true by some complete SpeedE model configuration $\boldsymbol{m^+}$ iff the virtual pair embedding $\boldsymbol{f_v}(e_h, e_t)$ of entities e_h and e_t lies within the hyper-parallelogram of relation r_j defined by $\boldsymbol{f_h^+}(r_j)$.

Simplifying Notations. Therefore, to simplify the upcoming proofs, we denote with $\boldsymbol{f_v}(e_h, e_t) \in \boldsymbol{f_h^+}(r_j)$ that the virtual pair embedding $\boldsymbol{f_v}(e_h, e_t)$ of an entity pair $(e_h, e_t) \in \boldsymbol{E} \times \boldsymbol{E}$ lies within the hyper-parallelogram $\boldsymbol{f_h^+}(r_j)$ of some relation $r_j \in \boldsymbol{R}$ in the virtual triple space. Accordingly, for sets of virtual pair embeddings $\boldsymbol{P} := \{\boldsymbol{f_v}(e_{h_1}, e_{t_1}), \dots, \boldsymbol{f_v}(e_{h_n}, e_{t_n})\}$, we denote with $\boldsymbol{P} \subseteq \boldsymbol{f_h^+}(r_j)$ that all virtual pair embeddings of $\boldsymbol{P}$ lie within the hyper-parallelogram of the relation r_j. Furthermore, we denote with $\boldsymbol{f_v}(e_h, e_t) \notin \boldsymbol{f_h^+}(r_j)$ that a virtual pair embedding $\boldsymbol{f_v}(e_h, e_t)$ does not lie within the hyper-parallelogram of a relation r_j and with $\boldsymbol{P} \not\subseteq \boldsymbol{f_h^+}(r_j)$ we denote that an entire set of virtual pair embeddings $\boldsymbol{P}$ does not lie within the hyper-parallelogram of a relation r_j.

Capturing Inference Patterns. Based on the previous definitions, we define capturing patterns formally: A relation configuration $\boldsymbol{m_h^+}$ captures a pattern ψ *exactly* if for any ground pattern $\phi_{B_1} \wedge \dots \wedge \phi_{B_m} \Rightarrow \phi_H$ within the deductive closure of ψ and for any instantiation of $\boldsymbol{f_e}$ and $\boldsymbol{f_v}$ the following conditions hold:

- if ϕ_H is a triple and if $\boldsymbol{m_h^+}$ captures the body triples to be true — i.e., $\boldsymbol{f_v}(args(\phi_{B_1})) \in \boldsymbol{f_h^+}(rel(\phi_{B_1})), \dots, \boldsymbol{f_v}(args(\phi_{B_m})) \in \boldsymbol{f_h^+}(rel(\phi_{B_m}))$ — then $\boldsymbol{m_h^+}$ also captures the head triple to be true — i.e., $\boldsymbol{f_v}(args(\phi_H)) \in \boldsymbol{f_h^+}(rel(\phi_H))$.
- if $\phi_H = \bot$, then $\boldsymbol{m_h^+}$ captures at least one of the body triples to be false — i.e., there is some $j \in \{1, \dots, m\}$ such that $\boldsymbol{f_v}(args(\phi_{B_j})) \notin \boldsymbol{f_h^+}(rel(\phi_{B_j}))$.

where $args()$ is the function that returns the arguments of a triple, and $rel()$ is the function that returns the relation of the triple. Furthermore, a relation configuration $\boldsymbol{m_h^+}$ captures a pattern ψ *exactly* and *exclusively* if (1) $\boldsymbol{m_h^+}$ exactly captures ψ and (2) $\boldsymbol{m_h^+}$ does not capture any *positive* pattern ϕ (i.e., $\phi \in \{symmetry,\ inversion,\ hierarchy,\ intersection,\ composition\}$) such that $\psi \not\models \phi$ except where the body of ϕ is not satisfied over $\boldsymbol{m_h^+}$.

Discussion. The next paragraphs provide some intuition of the above definition of capturing a pattern.

Capturing a pattern *exactly* is defined straightforwardly by adhering to the semantics of logical implication $\phi := \phi_B \Rightarrow \phi_H$, i.e., a relation configuration $\boldsymbol{m_h^+}$ needs to be found such that for any complete model configuration $\boldsymbol{m^+}$ over $\boldsymbol{m_h^+}$ if the body ϕ_B of the pattern is satisfied, then its head ϕ_H can be inferred.

Capturing a pattern *exactly* and *exclusively* imposes additional constraints. Here, the aim is not solely to capture a pattern but additionally to showcase that a pattern can be captured independently from any other pattern. Therefore, some notion of minimality/exclusiveness of a pattern is needed. As in Abboud et al. (2020); Pavlović and Sallinger (2023b), we define minimality by means of *solely* capturing those positive patterns ϕ that directly follow from the deductive closure of the pattern ψ, except for those ϕ that are captured trivially, i.e., except for those ϕ where their body is not satisfied over the constructed $\boldsymbol{m_h^+}$.

The authors of (Pavlović and Sallinger, 2023b) have shown that any core inference patterns (given in Section 2) can be expressed by means of spatial relations of the corresponding relation hyper-parallelograms in the virtual triple space. Therefore, *exclusiveness* is formulated intuitively as the ability to limit the intersection of hyper-parallelograms to only those intersections that directly follow from the captured pattern ψ for any known relation $r_j \in \boldsymbol{R}$, which is in accordance with the notion of exclusiveness of the literature (Abboud et al., 2020; Pavlović and Sallinger, 2023b).

Note that the definition of capturing patterns solely depends on relation configurations. This is vital for SpeedE to capture patterns in a *lifted* manner, i.e., SpeedE shall be able to capture patterns without grounding them first. Furthermore, being able to capture patterns in a lifted way is not only efficient but also natural, as the aim is to capture patterns between relations. Thus, it would be unnatural if constraints on entity embeddings were necessary to capture such relation-specific patterns.

As outlined in the previous paragraphs, the definition of capturing patterns is in accordance with the literature (Abboud et al., 2020; Pavlović and Sallinger, 2023b), focuses on efficiently capturing patterns, and gives us a formal foundation for the upcoming proofs, which will show that SpeedE can capture the core inference patterns.

H Proof of Theorem 5.1

In Section 2, we have already briefly introduced inference patterns. To prove that SpeedE captures the core inference patterns exactly and exclusively (Theorem 5.1), let us now first recall the full, formal definition of these patterns.

Definition H.1. *(Abboud et al., 2020; Pavlović and Sallinger, 2023b) Let the inference patterns be defined as follows:*

- *Patterns of the form* $r_1(X,Y) \Rightarrow r_1(Y,X)$ *with* $r_1 \in \boldsymbol{R}$ *are called* symmetry patterns.
- *Patterns of the form* $r_1(X,Y) \land r_1(Y,X) \Rightarrow \bot$ *with* $r_1 \in \boldsymbol{R}$ *are called* anti-symmetry patterns.
- *Patterns of the form* $r_1(X,Y) \Leftrightarrow r_2(Y,X)$ *with* $r_1, r_2 \in \boldsymbol{R}$ *and* $r_1 \neq r_2$ *are called* inversion patterns.
- *Patterns of the form* $r_1(X,Y) \land r_2(Y,Z) \Rightarrow r_3(X,Z)$ *with* $r_1, r_2, r_3 \in \boldsymbol{R}$ *and* $r_1 \neq r_2 \neq r_3$ *are called (general)* composition patterns.
- *Patterns of the form* $r_1(X,Y) \Rightarrow r_2(X,Y)$ *with* $r_1, r_2 \in \boldsymbol{R}$ *and* $r_1 \neq r_2$ *are called* hierarchy patterns.
- *Patterns of the form* $r_1(X,Y) \land r_2(X,Y) \Rightarrow r_3(X,Y)$ *with* $r_1, r_2, r_3 \in \boldsymbol{R}$ *and* $r_1 \neq r_2 \neq r_3$ *are called* intersection patterns.
- *Patterns of the form* $r_1(X,Y) \land r_2(X,Y) \Rightarrow \bot$ *with* $r_1, r_2 \in \boldsymbol{R}$ *and* $r_1 \neq r_2$ *are called* mutual exclusion patterns.

Based on these definitions, we will prove that SpeedE captures the core inference patterns exactly and exclusively, thereby proving Theorem 5.1. To prove Theorem 5.1, we give the relevant propositions obtained from and proved by Pavlović and Sallinger (2023b) and adapt them to SpeedE. For each of them, we give proofs, which in some situations follow from the ones in Pavlović and Sallinger (2023b), and in other situations are entirely new constructions.

The key change of SpeedE that will be of our concern in the following proofs is fixing the width to a constant value, as this will require new proofs for some of the properties. Observe that SpeedE additionally changes the distance function of ExpressivE. However, this does not affect ExpressivE's inference capabilities, i.e., which inference patterns can be captured. Careful inspection of the proofs of inference capabilities given in (Pavlović and Sallinger, 2023b) shows that the only property required of the distance function is that scores within the hyper-parallelogram are larger than those outside. As the newly defined distance function of SpeedE keeps this property, the change of distance function between the two models does not affect the proofs of the inference capabilities given in (Pavlović and Sallinger, 2023b). Hence, the same proof argument can be applied.

The other observation that we will make in general before giving the specific proofs is that the "exactly" part, proved in (Pavlović and Sallinger (2023b), Propositions F.1-F.7), of "exactly and exclusively" capturing patterns is not affected by the changes in the model. These proofs are all based on embedding pairs of entities as points in the virtual triple space and relations as hyper-parallelograms, which is still the case in SpeedE. Thus, we now proceed to proving that SpeedE captures the core inference patterns exactly and exclusively.

Proposition H.2 (Inversion (Exactly and Exclusively)). *Let* $\boldsymbol{m_h^+} = (\boldsymbol{M^+}, \boldsymbol{f_h^+})$ *be a relation configuration and* $r_1, r_2 \in \boldsymbol{R}$ *be relations where* $r_1(X,Y) \Leftrightarrow r_2(Y,X)$ *holds for any entities* $X, Y \in \boldsymbol{E}$*. Then* $\boldsymbol{m_h^+}$ *can capture* $r_1(X,Y) \Leftrightarrow r_2(Y,X)$ *exactly and exclusively.*

Proof. The proof of this property in Expressive (Pavlović and Sallinger (2023b), Proposition G.3) is based on a key assumption, namely that there is an $\boldsymbol{m_h}$ such that $\boldsymbol{f_h(r_1)}$ is the mirror image of $\boldsymbol{f_h(r_2)}$ with $\boldsymbol{f_h(r_1)} \neq \boldsymbol{f_h(r_2)}$. This is straightforward in ExpressivE but more complex in SpeedE. We will show this next.

Let us first observe that in SpeedE, it is not trivially given that there is an $\boldsymbol{m_h^+} = (\boldsymbol{M^+}, \boldsymbol{f_h^+})$ such that $\boldsymbol{f_h^+(r_1)}$ is the mirror image of $\boldsymbol{f_h^+(r_2)}$ with $\boldsymbol{f_h^+(r_1)} \neq \boldsymbol{f_h^+(r_2)}$, as $\boldsymbol{f_h(r_j)}$'s width embedding $\boldsymbol{w_j^{ht}}$ has been replaced by a shared width constant w in $\boldsymbol{f_h^+(r_j)}$ with $j \in \{1,2\}$. Thus, what needs to be shown is that there is a relation configuration $\boldsymbol{m_h^+}$ such that $\boldsymbol{f_h^+(r_1)}$ is the mirror image of $\boldsymbol{f_h^+(r_2)}$ with $\boldsymbol{f_h^+(r_1)} \neq \boldsymbol{f_h^+(r_2)}$, as then the original proof of ExpressivE can be directly applied to prove Proposition H.2's claim, i.e., that $\boldsymbol{m_h^+}$ can capture $r_1(X,Y) \Leftrightarrow r_2(Y,X)$ exactly and exclusively. Now, it is interesting to see that fixing the width parameter in SpeedE as opposed to ExpressivE not only changes the model but actually allows a quite elegant construction witnessing this property.

Let us now give this construction, thereby showing the claim. Specifically, let $\boldsymbol{f_h^+(r_1)} = (\boldsymbol{c_1^{ht}}, w, \boldsymbol{s_1^{th}})$ with $\boldsymbol{c_1^{ht}} = (\boldsymbol{c_1^h} || \boldsymbol{c_1^t}) \in \mathbb{R}^{2d}$, $w \in \mathbb{R}_{>0}$, and $\boldsymbol{s_1^{th}} = (\boldsymbol{s_1^t} || \boldsymbol{s_1^h}) \in \mathbb{R}^{2d}$. Furthermore, let $\boldsymbol{f_h^+(r_2)} = (\boldsymbol{c_2^{ht}}, w, \boldsymbol{s_2^{th}})$ with $\boldsymbol{c_2^{ht}} = (\boldsymbol{c_1^t} || \boldsymbol{c_1^h}) \in \mathbb{R}^{2d}$, $w \in \mathbb{R}_{>0}$, and $\boldsymbol{s_2^{th}} = (\boldsymbol{s_1^h} || \boldsymbol{s_1^t}) \in \mathbb{R}^{2d}$. We will, in the following, show that the constructed $\boldsymbol{f_h(r_2)}$ is the mirror image of $\boldsymbol{f_h(r_1)}$ to prove our claim. Let $X, Y \in \boldsymbol{E}$ be arbitrary entities and let $\boldsymbol{f_v}$ be an arbitrary virtual assignment function defined over (X,Y) and (Y,X) with $\boldsymbol{f_v}(X,Y) = \boldsymbol{e_{xy}}$ and $\boldsymbol{f_v}(Y,X) = \boldsymbol{e_{yx}}$. Then by Inequality 5, a triple $r_1(X,Y)$ is captured to be true by $\boldsymbol{m^+} = (\boldsymbol{M^+}, \boldsymbol{f_h^+}, \boldsymbol{f_v})$ if Inequality 6 is satisfied.

$$(\boldsymbol{e_{xy}} - \boldsymbol{c_1^{ht}} - \boldsymbol{s_1^{th}} \odot \boldsymbol{e_{yx}})^{|.|} \preceq w \tag{6}$$

$$(\boldsymbol{e_{yx}} - \boldsymbol{c_1^{th}} - \boldsymbol{s_1^{ht}} \odot \boldsymbol{e_{xy}})^{|.|} \preceq w \tag{7}$$

$$(\boldsymbol{e_{yx}} - \boldsymbol{c_2^{ht}} - \boldsymbol{s_2^{th}} \odot \boldsymbol{e_{xy}})^{|.|} \preceq w \tag{8}$$

Since Inequality 6 is element-wise, one can equivalently reformulate it by arbitrarily exchanging its dimensions. Using this insight, we can replace the head and tail dimensions for each embedding, thereby obtaining Inequality 7. Finally, by our construction of $\boldsymbol{f_h^+}(r_2)$, we have that $\boldsymbol{c_2^{ht}} = \boldsymbol{c_1^{th}}$ and $\boldsymbol{s_2^{th}} = \boldsymbol{s_1^{ht}}$. We substitute these equations into Inequality 7, thereby obtaining Inequality 8. Now, Inequality 8 states by the definition of a triple's truth (i.e., Inequality 5) that $r_2(Y,X)$ is captured by m_h^+. Since Inequalities 6-8 are all equivalent, we have shown that $\boldsymbol{f}_{\boldsymbol{h}}^{+}(r_1)$ is the mirror image of $\boldsymbol{f}_{\boldsymbol{h}}^{+}(r_2)$. Since, it is now easy to see that an $\boldsymbol{m}_{\boldsymbol{h}}^{+}$ exists such that $\boldsymbol{f}_{\boldsymbol{h}}^{+}(\boldsymbol{r_1})$ is the mirror image of $\boldsymbol{f}_{\boldsymbol{h}}^{+}(\boldsymbol{r_2})$ with $\boldsymbol{f}_{\boldsymbol{h}}^{+}(\boldsymbol{r_1}) \neq \boldsymbol{f}_{\boldsymbol{h}}^{+}(\boldsymbol{r_2})$, the proof of (Pavlović and Sallinger (2023b), Proposition G.4) can be directly applied to SpeedE. Thus, we have proven Proposition H.2, i.e., that $\boldsymbol{m}_{\boldsymbol{h}}^{+}$ can capture $r_1(X, Y) \Leftrightarrow r_2(Y, X)$ exactly and exclusively. ☐

Table 8: Relation embeddings of a relation configuration $\boldsymbol{m}_{\boldsymbol{h}}^{+}$ that captures hierarchy (i.e., $r_1(X, Y) \Rightarrow r_2(X, Y)$) exactly and exclusively using width $w = 1$.

	$\boldsymbol{c}^{\boldsymbol{h}}$	$\boldsymbol{s}^{\boldsymbol{t}}$	$\boldsymbol{c}^{\boldsymbol{t}}$	$\boldsymbol{s}^{\boldsymbol{h}}$
r_1	-2.5	0.5	1.5	0
r_2	1	-2	4.5	2

Proposition H.3 (Hierarchy (Exactly and Exclusively)). *Let* $\boldsymbol{m}_{\boldsymbol{h}}^{+} = (\boldsymbol{M}^{+}, \boldsymbol{f}_{\boldsymbol{h}}^{+})$ *be a relation configuration and* $r_1, r_2 \in \boldsymbol{R}$ *be relations where* $r_1(X, Y) \Rightarrow r_2(X, Y)$ *holds for any entities* $X, Y \in \boldsymbol{E}$. *Then* $\boldsymbol{m}_{\boldsymbol{h}}^{+}$ *can capture* $r_1(X, Y) \Rightarrow r_2(X, Y)$ *exactly and exclusively.*

Proof. The proof of this property in Expressive (Pavlović and Sallinger (2023b), Proposition G.4) is based on a key assumption, namely that there is an $\boldsymbol{m}_{\boldsymbol{h}}$ such that $\boldsymbol{f}_{\boldsymbol{h}}(\boldsymbol{r_1}) \subset \boldsymbol{f}_{\boldsymbol{h}}(\boldsymbol{r_2})$ with $\boldsymbol{f}_{\boldsymbol{h}}(\boldsymbol{r_1}) \neq \boldsymbol{f}_{\boldsymbol{h}}(\boldsymbol{r_2})$. This is straightforward in ExpressivE but much more complex in SpeedE. We will show this next.

Let us first observe that in SpeedE, it is not trivially given that there is an $\boldsymbol{m}_{\boldsymbol{h}}^{+} = (\boldsymbol{M}^{+}, \boldsymbol{f}_{\boldsymbol{h}}^{+})$ such that $\boldsymbol{f}_{\boldsymbol{h}}^{+}(\boldsymbol{r_1}) \subset \boldsymbol{f}_{\boldsymbol{h}}^{+}(\boldsymbol{r_2})$ with $\boldsymbol{f}_{\boldsymbol{h}}^{+}(\boldsymbol{r_1}) \neq \boldsymbol{f}_{\boldsymbol{h}}^{+}(\boldsymbol{r_2})$, as $\boldsymbol{f}_{\boldsymbol{h}}(\boldsymbol{r_j})$'s width embedding $\boldsymbol{w}_{\boldsymbol{j}}^{\boldsymbol{ht}}$ has been replaced by a shared width constant w in $\boldsymbol{f}_{\boldsymbol{h}}^{+}(\boldsymbol{r_j})$ with $j \in \{1, 2\}$. Thus, what needs to be shown is that there is a relation configuration $\boldsymbol{m}_{\boldsymbol{h}}^{+}$ such that $\boldsymbol{f}_{\boldsymbol{h}}^{+}(\boldsymbol{r_1}) \subset \boldsymbol{f}_{\boldsymbol{h}}^{+}(\boldsymbol{r_2})$ with $\boldsymbol{f}_{\boldsymbol{h}}^{+}(\boldsymbol{r_1}) \neq \boldsymbol{f}_{\boldsymbol{h}}^{+}(\boldsymbol{r_2})$, as then the original proof of ExpressivE can be directly applied to prove Proposition H.3's claim, i.e., that $\boldsymbol{m}_{\boldsymbol{h}}^{+}$ can capture $r_1(X, Y) \Rightarrow r_2(X, Y)$ exactly and exclusively. In the following, we construct such a relation configuration $\boldsymbol{m}_{\boldsymbol{h}}^{+} = (\boldsymbol{M}^{+}, \boldsymbol{f}_{\boldsymbol{h}}^{+})$, where $\boldsymbol{f}_{\boldsymbol{h}}^{+}(\boldsymbol{r_1}) \subset \boldsymbol{f}_{\boldsymbol{h}}^{+}(\boldsymbol{r_2})$ with $\boldsymbol{f}_{\boldsymbol{h}}^{+}(\boldsymbol{r_1}) \neq \boldsymbol{f}_{\boldsymbol{h}}^{+}(\boldsymbol{r_2})$ to prove the claim of Proposition H.3:

Figure 1 (given on Page 5 of the main body) visualizes the relation configuration $\boldsymbol{m}_{\boldsymbol{h}}^{+} = (\boldsymbol{M}^{+}, \boldsymbol{f}_{\boldsymbol{h}}^{+})$ provided in Table 8. As can be easily seen in Figure 1, $\boldsymbol{m}_{\boldsymbol{h}}^{+}$ captures $\boldsymbol{f}_{\boldsymbol{h}}^{+}(\boldsymbol{r_1}) \subset \boldsymbol{f}_{\boldsymbol{h}}^{+}(\boldsymbol{r_2})$ with $\boldsymbol{f}_{\boldsymbol{h}}^{+}(\boldsymbol{r_1}) \neq \boldsymbol{f}_{\boldsymbol{h}}^{+}(\boldsymbol{r_2})$. Thus, we have proven Proposition H.3, as (1) we have shown the existence of an $\boldsymbol{m}_{\boldsymbol{h}}^{+}$ that captures $\boldsymbol{f}_{\boldsymbol{h}}^{+}(\boldsymbol{r_1}) \subset \boldsymbol{f}_{\boldsymbol{h}}^{+}(\boldsymbol{r_2})$ with $\boldsymbol{f}_{\boldsymbol{h}}^{+}(\boldsymbol{r_1}) \neq \boldsymbol{f}_{\boldsymbol{h}}^{+}(\boldsymbol{r_2})$ and (2) the proof of (Pavlović and Sallinger (2023b), Proposition G.4) can be directly applied to SpeedE since an $\boldsymbol{m}_{\boldsymbol{h}}^{+}$ exists such that $\boldsymbol{f}_{\boldsymbol{h}}^{+}(\boldsymbol{r_1}) \subset \boldsymbol{f}_{\boldsymbol{h}}^{+}(\boldsymbol{r_2})$ with $\boldsymbol{f}_{\boldsymbol{h}}^{+}(\boldsymbol{r_1}) \neq \boldsymbol{f}_{\boldsymbol{h}}^{+}(\boldsymbol{r_2})$. ☐

Table 9: Relation embeddings of a relation configuration $\boldsymbol{m}_{\boldsymbol{h}}^{+}$ that captures intersection (i.e., $r_1(X, Y) \wedge r_2(X, Y) \Rightarrow r_3(X, Y)$) exactly and exclusively using width $w = 1$.

	$\boldsymbol{c}^{\boldsymbol{h}}$	$\boldsymbol{s}^{\boldsymbol{t}}$	$\boldsymbol{c}^{\boldsymbol{t}}$	$\boldsymbol{s}^{\boldsymbol{h}}$
r_1	-3.75	0.5	1	0
r_2	1	-2	5	2
r_3	-3.5	0.5	0.5	-1

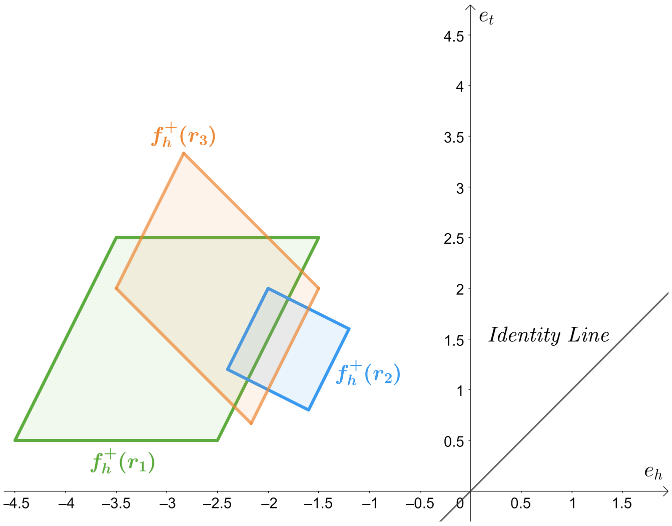

Figure 4: Relation embeddings of a relation configuration $\boldsymbol{m_h}$ that captures intersection (i.e., $r_1(X,Y) \wedge r_2(X,Y) \Rightarrow r_3(X,Y)$) exactly and exclusively using width $w = 1$.

Proposition H.4 (Intersection (Exactly and Exclusively)). *Let $\boldsymbol{m_h^+} = (\boldsymbol{M^+}, \boldsymbol{f_h^+})$ be a relation configuration and $r_1, r_2, r_3 \in \boldsymbol{R}$ be relations where $r_1(X,Y) \wedge r_2(X,Y) \Rightarrow r_3(X,Y)$ holds for any entities $X, Y \in \boldsymbol{E}$. Then $\boldsymbol{m_h^+}$ can capture $r_1(X,Y) \wedge r_2(X,Y) \Rightarrow r_3(X,Y)$ exactly and exclusively.*

Proof Sketch. This is similar in construction to the previous proof. Hence, we only give a proof sketch for ease of readability. To prove Proposition H.4, observe that in (Pavlović and Sallinger (2023b), Proposition G.5) an ExpressivE relation configuration m_h with several different width embeddings is constructed. However, the key observation we will make is that choosing the width embeddings differently is not necessary. In fact, an interested reader inspecting the original proof can obtain a proof applicable to SpeedE by following the proof of (Pavlović and Sallinger (2023b), Proposition G.5) analogously for the SpeedE relation configuration m_h^+ described in Table 9 and visualized by Figure 4. Thus, the proof for Proposition H.4 is straightforward given m_h^+ defined in Table 9 and (Pavlović and Sallinger (2023b), Proposition G.5). □

Table 10: Relation embeddings of a relation configuration $\boldsymbol{m_h^+}$ that captures composition (i.e., $r_1(X,Y) \wedge r_2(Y,Z) \Rightarrow r_3(X,Z)$) exactly and exclusively using width $w = 1$.

	$\boldsymbol{c^h}$	$\boldsymbol{s^t}$	$\boldsymbol{c^t}$	$\boldsymbol{s^h}$
r_1	-7	3	5	1
r_2	-7.5	1	2	3
r_3	-19.5	2	13	2

Proposition H.5 (Composition (Exactly and Exclusively)). *Let $r_1, r_2, r_3 \in \boldsymbol{R}$ be relations and let $\boldsymbol{m_h^+} = (\boldsymbol{M^+}, \boldsymbol{f_h^+})$ be a relation configuration, where $\boldsymbol{f_h^+}$ is defined over r_1, r_2, and r_3. Furthermore let r_3 be the composite relation of r_1 and r_2, i.e., $r_1(X,Y) \wedge r_2(Y,Z) \Rightarrow r_3(X,Z)$ holds for all entities $X, Y, Z \in \boldsymbol{E}$. Then $\boldsymbol{m_h^+}$ can capture $r_1(X,Y) \wedge r_2(Y,Z) \Rightarrow r_3(X,Z)$ exactly and exclusively.*

Proof Sketch. This is similar in construction to the proof of Proposition H.3. Hence, we only give a proof sketch for ease of readability. To prove Proposition H.5, observe that in (Pavlović and Sallinger (2023b), Proposition G.6), an ExpressivE relation configuration m_h with several different width embeddings is constructed. However, choosing the width embeddings differently is not necessary. In fact, an interested reader inspecting the original proof can obtain a proof applicable to SpeedE by following the proof of (Pavlović and Sallinger (2023b), Proposition G.6) analogously for the SpeedE relation configuration m_h^+

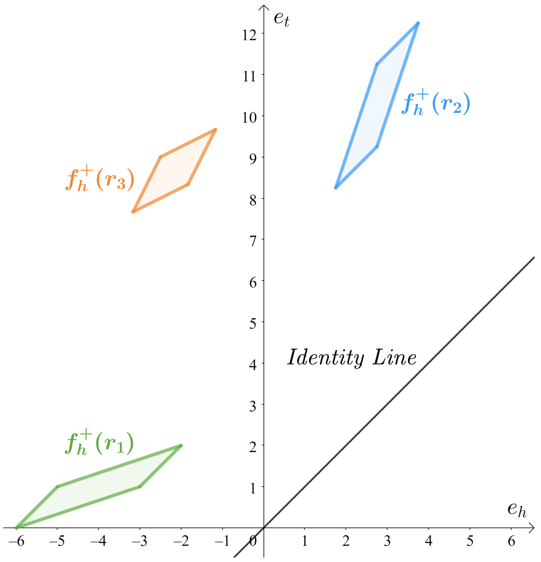

Figure 5: Relation embeddings of a relation configuration $\boldsymbol{m_h}$ that captures composition (i.e., $r_1(X,Y) \wedge r_2(Y,Z) \Rightarrow r_3(X,Z)$) exactly and exclusively using width $w = 1$.

described in Table 10 and visualized by Figure 5. Thus, the proof for Proposition H.5 is straightforward given m_h^+ defined in Table 10 and (Pavlović and Sallinger (2023b), Proposition G.6). □

Proposition H.6 (**Symmetry (Exactly and Exclusively)**). *Let* $\boldsymbol{m_h^+} = (\boldsymbol{M^+}, \boldsymbol{f_h^+})$ *be a relation configuration and* $r_1 \in \boldsymbol{R}$ *be a symmetric relation, i.e.,* $r_1(X,Y) \Rightarrow r_1(Y,X)$ *holds for any entities* $X, Y \in \boldsymbol{E}$*. Then* $\boldsymbol{m_h^+}$ *can capture* $r_1(X,Y) \Rightarrow r_1(Y,X)$ *exactly and exclusively.*

Proposition H.7 (**Anti-Symmetry (Exactly and Exclusively)**). *Let* $\boldsymbol{m_h^+} = (\boldsymbol{M^+}, \boldsymbol{f_h^+})$ *be a relation configuration and* $r_1 \in \boldsymbol{R}$ *be an anti-symmetric relation, i.e.,* $r_1(X,Y) \wedge r_1(Y,X) \Rightarrow \perp$ *holds for any entities* $X, Y \in \boldsymbol{E}$*. Then* $\boldsymbol{m_h^+}$ *can capture* $r_1(X,Y) \wedge r_1(Y,X) \Rightarrow \perp$ *exactly and exclusively.*

The proofs for Proposition H.6-H.7 are straightforward and work analogously to the proofs of (Pavlović and Sallinger (2023b), Proposition G.1-G.2). This is the case, as (1) any of these patterns contain at most one relation, (2) thus we solely need to show that no unwanted patterns over at most one relation are captured, as any considered pattern over more than one relation (precisely inversion, hierarchy, intersection, and composition) requires by Definition H.1 at least two or three *distinct* relations and thus is not applicable, and (3) it is easy to see that, for instance, a relation hyper-parallelogram can be symmetric without being anti-symmetric, or vice versa (i.e., without capturing any unwanted pattern).

Proposition H.8 (**Mutual Exclusion (Exactly and Exclusively)**). *Let* $\boldsymbol{m_h^+} = (\boldsymbol{M^+}, \boldsymbol{f_h^+})$ *be a relation configuration and* $r_1, r_2 \in \boldsymbol{R}$ *be mutually exclusive relations, i.e.,* $r_1(X,Y) \wedge r_2(X,Y) \Rightarrow \perp$ *holds for any entities* $X, Y \in \boldsymbol{E}$*. Then* $\boldsymbol{m_h^+}$ *can capture* $r_1(X,Y) \wedge r_2(X,Y) \Rightarrow \perp$ *exactly and exclusively.*

The proof for Proposition H.8 is trivial, as it is straight-forward to see that (1) there is an $\boldsymbol{m_h^+} = (\boldsymbol{M^+}, \boldsymbol{f_h^+})$ such that $\boldsymbol{f_h^+}(r_1) \cap \boldsymbol{f_h^+}(r_2) = \emptyset$, thereby $\boldsymbol{m_h^+}$ captures $r_1(X,Y) \wedge r_2(X,Y) \Rightarrow \perp$ exactly, (2) neither $\boldsymbol{f_h^+}(r_1)$ nor $\boldsymbol{f_h^+}(r_2)$ need to be symmetric, thereby no unwanted symmetry pattern is captured, (3) $\boldsymbol{f_h^+}(r_1)$ does not need to be the mirror image of $\boldsymbol{f_h^+}(r_2)$, thus no unwanted inversion pattern is captured, and finally (4) since $\boldsymbol{f_h^+}(r_1)$ and $\boldsymbol{f_h^+}(r_2)$ are disjoint, neither $\boldsymbol{f_h^+}(r_1)$ can subsume $\boldsymbol{f_h^+}(r_2)$ nor vice versa, thus no unwanted hierarchy pattern is captured. Thus by Points 1-4, we have shown that $\boldsymbol{m_h^+}$ captures $r_1(X,Y) \wedge r_2(X,Y) \Rightarrow \perp$ exactly and that it does not capture any unwanted positive pattern that is applicable, i.e., requires at most two different relations (symmetry, inversion, and hierarchy). Thus, we have shown Proposition H.8, i.e., that $\boldsymbol{m_h^+}$ can capture $r_1(X,Y) \wedge r_2(X,Y) \Rightarrow \perp$ exactly and exclusively.

Finally, by Propositions H.2-H.8, we have shown Theorem 5.1, i.e., that SpeedE captures the core inference patterns exactly and exclusively.

I Experimental Details

The details of our experiment's setup, benchmarks, and evaluation protocol are covered in this section. Specifically, details on SpeedE's implementation and about reproducing our results are covered in Section I.1. Each benchmark's properties are discussed in Section I.2. Our experimental setup is described in Section I.3, including details about the chosen learning setup, hardware, and hyperparameters. The evaluation protocol and the used metrics are discussed in Section I.4. Finally, the size of CO2 emissions resulting from our experiments is estimated in Section I.5.

I.1 Implementation Details & Reproducibility

Following Pavlović and Sallinger (2023b), we have implemented our gKGE using PyKEEN 1.7 (Ali et al., 2021), a Python library that runs under the MIT license and offers support for numerous benchmarks and gKGEs. In doing so, we facilitate the comfortable reuse of SpeedE for upcoming benchmarks and applications. To ease reproducing our findings, we provide SpeedE's source code in a public GitHub repository[2]. Additionally, the repository contains a ReadMe.md file stating library dependencies and running instructions.

I.2 Benchmarks and Licenses

The details of the three standard KGC benchmarks, WN18RR (Dettmers et al., 2018), FB15k-237 (Toutanova and Chen, 2015), and YAGO3-10 (Mahdisoltani et al., 2015) used in our experiments are discussed in this section. WN18RR is extracted from the WordNet database (Miller, 1995), representing lexical relations between English words, thus naturally containing many hierarchical relations (e.g., hypernym-of) (Chami et al., 2020). FB15k-237 is a subset of a collaborative database consisting of general knowledge (in English) called Freebase (Bollacker et al., 2007), which contains both hierarchical relations (e.g., part-of) and non-hierarchical ones (e.g., nationality) (Chami et al., 2020). YAGO3-10 is a subset of YAGO3, which is a KG describing people that, similarly to FB15k-237, contains both hierarchical relations (e.g., actedIn) and non-hierarchical relations (e.g., isMarriedTo). Table 2 (given on Page 6 of the main body) has already stated important characteristics of the benchmarks, including their number of entities, relations, and metrics describing how hierarchical the relations within the benchmark are. WN18RR, FB15k-237, and YAGO3-10 (Mahdisoltani et al., 2015) already provide a split into a training, validation, and testing set, which we directly adopted in any reported experiments. Table 11 lists characteristics of these splits, specifically the number of training, validation, and testing triples. Furthermore, the table lists the number of entities and relations of each benchmark. Finally, concerning licensing, we did not find a license for WN18RR nor its superset WN18 (Bordes et al., 2013). Also, we did not find a license for FB15k-237, but we found that its superset FB15k (Bordes et al., 2013) uses the CC BY 2.5 license. For YAGO3-10, we also did not find a license, but we found that its superset YAGO3 (Mahdisoltani et al., 2015) uses the CC BY 3.0 license.

Table 11: Benchmark split characteristics: Number of entities, relations, and training, validation, and testing triples.

Dataset	$\|\boldsymbol{E}\|$	$\|\boldsymbol{R}\|$	#training triples	#validation triples	#testing triples
FB15k-237	14,541	237	272,115	17,535	20,466
WN18RR	40,943	11	86,835	3,034	3,134
YAGO3-10	123,143	37	1,079,040	4,978	4,982

I.3 Training Setup

Training Details. We have trained each model on one of four GeForce RTX 2080 Ti GPUs of our internal cluster. In particular, during the training phase, we optimize the self-adversarial negative sampling loss (Sun et al., 2019) using the Adam optimizer (Kingma and Ba, 2015). We use gradient descent to optimize SpeedE's parameters, stopping the training after 1000 epochs early if the H@10 score did not rise by at

---

[2] https://github.com/AleksVap/SpeedE

least 0.5% for WN18RR and YAGO3-10 and 1% for FB15k-237. Any experiment was run three times to average over light performance variations. We will discuss the optimization of hyperparameters in the following paragraph.

Hyperparameter Optimization. Following similar optimization principles as Balazevic et al. (2019a); Chami et al. (2020); Pavlović and Sallinger (2023b), we manually tuned the following hyperparameters within the listed ranges: (1) the learning rate $\lambda \in \{b * 10^{-c} \mid b \in \{1,2,5\} \wedge c \in \{2,3,4,5,6\}\}$, (2) the negative sample size $n \in \{100,150,200,250\}$, (3) the loss margin $\gamma \in \{2,3,4,5,6\}$, (4) the adversarial temperature $\alpha \in \{1,2,3,4\}$, (5) the batch size $b \in \{100,250,500,1000,2000\}$, and (6) constraining the distance slope parameters to be equal — i.e., $s_j^i = s_j^o$ for each relation $r_j \in \boldsymbol{R}$ — or not $EqDS \in \{true, false\}$. Following the literature (Chami et al., 2020; Lu and Hu, 2020), we used for the large YAGO3-10 benchmark a wider range for the negative sampling size n, in particular $n \in \{100,200,500,1000,2000\}$. Similar to Lu and Hu (2020), we also increased the range for margins γ to include 50 and 100 for YAGO3-10. In accordance with Pavlović and Sallinger (2023b), we chose self-adversarial negative sampling (Sun et al., 2019) for generating negative triples. We list the best hyperparameters for SpeedE split by benchmark and embedding dimensionality in Table 12. Following Chami et al. (2020), we used one parameter set for any low-dimensional experiment (i.e., $d \leq 50$) and one parameter set for any high-dimensional experiment (i.e., $d > 50$). Furthermore, for ExpressivE, we used the hyperparameters of Pavlović and Sallinger (2023b) under high-dimensional conditions, as they report the best-published results for ExpressivE. For low-dimensional conditions, ExpressivE's best hyperparameter setting was unknown. Thus, we optimized ExpressivE's hyperparameters manually, finding the hyperparameters of Table 13 to produce the best KGC results for ExpressivE under low dimensionalities. For RotH, we used the hyperparameters of Chami et al. (2020), as they report the best-published results for RotH. Finally, we used the same hyperparameters for each of SpeedE's model variants to directly compare SpeedE to them, i.e., Min_SpeedE, Diff_SpeedE, and Eq_SpeedE.

Table 12: Hyperparameters of SpeedE models that achieve the best performance on WN18RR, FB15k-237, and YAGO3-10 split by low-dimensional (i.e., $d \leq 50$) and high-dimensional setting (i.e., $d > 50$).

Dataset	Embedding Dimensionality	Margin	Learning Rate	Adversarial Temperature	Negative Sample Size	Batch Size	EqDS
WN18RR	$d \leq 50$	3	$5 * 10^{-3}$	2	200	250	false
WN18RR	$d > 50$	3	$1 * 10^{-3}$	2	200	250	true
FB15k-237	$d \leq 50$	2	$5 * 10^{-4}$	4	250	100	false
FB15k-237	$d > 50$	4	$1 * 10^{-4}$	4	150	1000	false
YAGO3-10	$d \leq 50$	100	$1 * 10^{-2}$	2	2000	2000	false

Table 13: Hyperparameters of ExpressivE that achieve the best performance on WN18RR, FB15k-237, and YAGO3-10 under low-dimensional conditions (i.e., $d \leq 50$).

Dataset	Embedding Dimensionality	Margin	Learning Rate	Adversarial Temperature	Negative Sample Size	Batch Size
WN18RR	$d \leq 50$	2	$5 * 10^{-3}$	3	200	250
FB15k-237	$d \leq 50$	2	$5 * 10^{-4}$	4	250	100
YAGO3-10	$d \leq 50$	100	$1 * 10^{-2}$	2	2000	2000

I.4 Evaluation Protocol

Following the standard KGC evaluation protocol as described by Sun et al. (2019); Balazevic et al. (2019b); Chami et al. (2020); Pavlović and Sallinger (2023b), we have evaluated ExpressivE by measuring the ranking quality of each test set triple $r_i(e_h, e_t)$ over all possible heads e'_h and tails e'_t: $r_i(e'_h, e_t)$ for all $e'_h \in \boldsymbol{E}$ and $r_i(e_h, e'_t)$ for all $e'_t \in \boldsymbol{E}$. The typical metrics for evaluating the KGC performance are the mean reciprocal rank (MRR) and H@k (Bordes et al., 2013). In particular, we have presented the filtered metrics (Bordes et al., 2013), i.e., all triples occurring in the training, validation, and testing set are deleted from the ranking (apart from the test triple that must be ranked), as scoring these triples highly does not indicate a wrong inference. The most used metrics for assessing gKGEs are the filtered MRR, H@1, and H@10 (Sun et al., 2019; Trouillon et al., 2016; Balazevic et al., 2019b; Abboud et al., 2020). Finally, we will briefly review how these metrics are defined: The proportion of true triples among the predicted triples whose rank is at maximum k is represented by H@k, whereas the MRR reflects the average of inverse ranks ($1/$*rank*).

I.5 CO2 Emissions

The sum of all reported experiments took less than 150 GPU hours. This corresponds to an estimate of approximately $16.20 kg\ CO_2\text{-}eq$, based on the OECD's 2014 carbon efficiency average of $0.432 kg/kWh$ and the usage of an RTX 2080 Ti on private infrastructure. We computed these estimates using the MachineLearning Impact calculator (Lacoste et al., 2019).

Language Guided Exploration for RL Agents in Text Environments

Abstract

Real-world sequential decision making is characterized by sparse rewards and large decision spaces, posing significant difficulty for experiential learning systems like *tabula rasa* reinforcement learning (RL) agents. Large Language Models (LLMs), with a wealth of world knowledge, can help RL agents learn quickly and adapt to distribution shifts. In this work, we introduce Language Guided Exploration (LGE) framework, which uses a pre-trained language model (called GUIDE) to provide decision-level guidance to an RL agent (called EXPLORER). We observe that on ScienceWorld (Wang et al., 2022), a challenging text environment, LGE outperforms vanilla RL agents significantly and also outperforms other sophisticated methods like Behaviour Cloning and Text Decision Transformer. [1]

1 Introduction

Reinforcement Learning (RL) has been used with great success for sequential decision making tasks. AI assistants whether text based (Li et al., 2022; Huang et al., 2022) or multi-modal (Chang et al., 2020; Patel et al., 2023), have to work with large action spaces and sparse rewards. In such settings, the approach of random exploration is inadequate. One needs to look for ways to use external information either to create a dense reward model or to reduce the size of action space. In this work we focus on the latter approach.

We make a simple observation that, in many cases, the textual description of the task or goal contains enough information to completely rule out certain actions, thereby greatly reducing the size of the effective action space. For example, as shown in Fig.1, if the task description is *"Determine if a metal fork is electrically conductive"*, then one can safely rule out actions that involve objects like sink, apple, and actions like eat, smell, etc. Motivated by this observation, we introduce the **L**anguage **G**uided **E**xploration (LGE) framework that uses an RL agent but augments it with a *Guide* model that uses world knowledge to rule out large number of actions that are infeasible or highly unlikely. Along with removing irrelevant actions, the frameworks supports generalization in unseen environments where new objects may appear. For example, if the model observed an apple in the environment during training, at test time, the environment may contain an orange instead. But the guide, which posses commonsense may understand that all fruits are equally relevant or irrelevant for the given task.

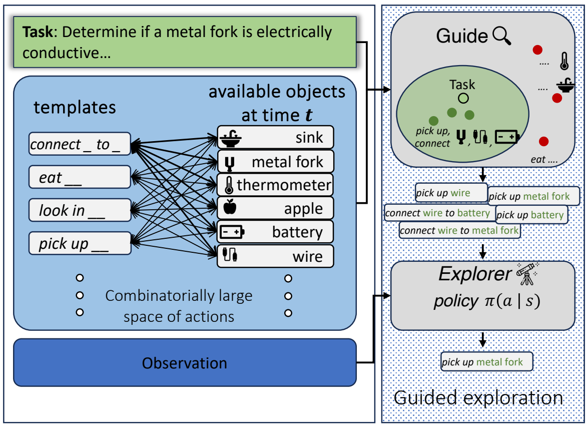

Figure 1: The Language Guided Exploration (LGE) Framework: The *Guide* uses contrastive learning to produce a set of feasible action given the task description thereby reducing substantially the space of possible actions. The *Explorer* , an RL agent, then uses the set of actions provided by the *Guide* to learn a policy and pick a suitable action using it.

To test our framework, we use the highly challenging benchmark called SCIENCEWORLD (Wang et al., 2022), which consists of a purely text based environment where the observations, actions, and inventory are expressed using natural language text.

Findings of the Association for Computational Linguistics: NAACL 2024, pages 93–102
June 16-21, 2024 ©2024 Association for Computational Linguistics

SCIENCEWORLD embodies the major challenges faced by RL agents in realy world applications: the template based actions with slots for verbs and objects produce a combinatorially large action space, the long natural language based observations make for a challenging state representation, and the rewards signals based mainly on the completion of challenging tasks create a delayed and sparse reward signal. Following are the main contributions of our work:

We propose a novel way to allow language guided exploration for RL agents. The task instructions are used to identify relevant actions using a contrastively trained LM. The proposed GUIDE model that uses contrastive learning has not been explored for text environments before.

We demonstrate significantly stronger results on the SCIENCEWORLD environment when compared to methods that use Reinforcement Learning, and more sophisticated methods like Behaviour Cloning (Wang et al., 2023) and Text Decision Transformer (Chen et al., 2021).

2 Related Work

Guided exploration for agents Language models have been used to aid with various parts of the RL pipeline (Du et al., 2023; Hendrycks et al., 2021). Due to its importance, the topic of exploration has received a lot of attention, with most classical methods focusing on intrinsically motivated exploration (Aubret et al., 2019). The recent advent of general-purpose language models has created a wave of resurgent interest in the topic, with works that use pre-trained language models in various ways to explore efficiently. Zhong et al. (2024) uses an LLM to remove undesirable actions by inspecting policy rollouts, followed by imitation learning using desirable rollouts. Yao et al. (2020), on the other hand simply trains a sequence model using imitation learning using gold trajectories. Triantafyllidis et al. (2023) proposes a framework for intrinsic exploration using LLMs. Previous works have also used symbolic knowledge from knowledge graphs along with language models to constrain or guide the exploration for RL agents (Basu et al., 2024; Atzeni et al., 2022; Ammanabrolu and Hausknecht, 2020). In this work, we take a different perspective, instead of guiding intrinsic exploration, we focus on reducing the action space in a meaningful manner such that simple classical exploration strategies like ϵ-exploration or entropy maximization can work well. We also propose a novel way of reducing the effective size of the action space using a contrastively trained language model.

Text-based games Text-based environments (Lebling et al., 1979; Yin and May, 2019; Murugesan et al., 2020; Côté et al., 2019) provide a low-cost alternative to complex 2D/3D environments, and real world scenarios, for the development of the high-level learning and navigation capabilities of the AI agents. As these games require multi-step reasoning, Reinforcement Learning serves as the default method to model these agents (He et al., 2016; Zahavy et al., 2018; Yao et al., 2020). Another way to model these agents is to view this task as a imitation learning task. Using knowledge graphs in conjunction with RL agents (Ammanabrolu and Hausknecht, 2020) utilizes the constrained actions from the Knowledge graphs created dynamically with each trajectory, however the filtered actions are still inefficient to distinguish relevant actions from irrelevant ones. Behavior cloning (Chen et al., 2021) shows success in the realm of text games, but the utilization of LLM's to predict the next action also suffers from the problem of removing spurious actions, even when the LLM's are fine-tuned on expert gold trajectories. In our work, we address the problem of reducing the action space of the agent, in order to learn the action selections in a much simpler way, directly addressing the problem of predicting irrelevant actions.

3 Methodology

Notation: The text environment, a partially observable Markov decision process (POMDP) consists of $(S, T, A, R, \tilde{O}, \Omega)$. In SCIENCEWORLD, along with the description of the current state, the observation also consists of a task description $\tau \in \mathcal{T}$ that stays fixed throughout the evolution of a single trajectory, i.e., $\tilde{O} = O \times \mathcal{T}$, where O is the set of textual descriptions of the state and $\mathcal{T}$ is the set of tasks (including different variations of each task). Note that the set of tasks are divided into different types and each type of task has different variations, i.e., $\mathcal{T} = \bigcup_{\gamma=1}^{\Gamma} \bigcup_{v=1}^{V_\gamma} \tau_{\gamma,v}$, where Γ is the number of task types and V_γ is the number of variations for the task type γ. Gold trajectories $G_{\gamma,v} = \{a_1, a_2, .., a_L\}$ are available for each γ, v.

3.1 The LGE framework

We propose a Language Guided Exploration Framework (LGE), which consists of an an RL agent called the EXPLORER, and an auxiliary model that scores each action called the GUIDE . The EXPLORER starts in some state sampled from initial state distribution d_0. At any time step t, a set of all valid actions $A_{\gamma,v,t}$ is provided by the environment. This set, constructed using the cross product of action templates and the set of objects (see Fig.1) is extremely large, typically in thousands. The pretrained GUIDE with frozen weights uses the task description $\tau_{\gamma,v}$, to produce a set of most relevant actions $\hat{A}_{\gamma,v,t} \subset A_{\gamma,v,t}$. With a probability $1-\epsilon$ (resp. ϵ), the EXPLORER samples an action from $\hat{A}_{\gamma,v,t}$ using its policy $\pi(a|s_t)$ (resp., from $A_{\gamma,v,t}$).

The pre-training of the GUIDE is outlined in 3.1.2, which is followed by the training of the EXPLORER. Algorithm 1 in Appendix A.1 outlines the steps involved in the LGE framework using a DRRN (He et al., 2016) based EXPLORER.

3.1.1 EXPLORER 🔭

The EXPLORER learns a separate policy π_γ for each task type $\gamma \in \Gamma$ by exploring the the environment.[2] We use the Deep Reinforcement Relevance Network (DRRN) (He et al., 2016) as our EXPLORER, as it has shown to be the strongest baseline in Wang et al. (2022). However, our framework allows to swap the DRRN with any other RL agent. The DRRN uses Q-learning with with prioritized experience replay to perform policy improvement using a parametric approximation of the action value function $Q(s,a)$.[3] The current state s_t is represented by concatenating the representations of the past observation o_{t-1}, inventory i_t and look around l_t, each encoded by separate GRUs, i.e., $h_{s_t} = (\, f_{\theta_o}(o_{t-1}) : f_{\theta_i}(i_t) : f_{\theta_l}(l_t)\,)$. Each relevant action $a \in A_{\text{rel},t}$ is encoded in the same manner: $h_{a_t} = f_{\theta_a}(a_t)$. Here f_* are the respective GRU encoders, θ_* their parameters and " : " denotes concatenation. The value function $Q(s,a)$ is represented using a linear layer over the concatenation of the action and state representations $Q(s_t, a_t|\theta) = W^T \cdot (h_{s_t} : h_{a_t}) + b$, where θ is a collection of θ_o, θ_i, θ_l, θ_a, W and b. During training, a stochastic policy based on the value function is used: $\hat{a} \sim \pi(a|s) \propto Q(s,a|\theta)$, while at inference time we use greedy sampling: $\hat{a} = \arg\max_a Q(s,a|\theta)$.

3.1.2 GUIDE 🔍

While LLMs are capable of scoring the relevant actions without any finetuning, we observed that due to the idiosyncrasies of the SCIENCEWORLD environment, it is beneficial to perform some finetuning. We use SimCSE (Gao et al., 2021), a contrastive learning framework, to finetune the GUIDE LM. The training data $\{\tau_i, G_i\}_{i=1}^M$, which consists of task descriptions $\tau_i = \tau_{\gamma,v} \in \mathcal{T}$ along with the set of corresponding gold actions $G_i = G_{\gamma,v}$. The GUIDE model g_ϕ is used to embed the actions and the task descriptions into a shared representation space where the similarity score of a task and an action is expressed as $s(\tau,a) = \frac{g_\phi(\tau)\cdot g_\phi(a)}{\lambda}$, with λ being the temperature parameter. The training objective is such that the embeddings of a task are close to those of the corresponding relevant actions, expressed using the following loss function:

$$l(\phi;\tau_i,G_i) = -\log \frac{e^{s(\tau_i,\,a^+)}}{e^{s(\tau_i,a^+)} + \sum\limits_{a^- \in N_i} e^{s(\tau,a^-)}},$$

where $a^+ \sim G_i$ is a relevant action and N_i is a fixed sized subset of irrelevant actions.[4]

Note that since we only have access to a small amount of gold trajectories (3442) for training, we take special steps to avoid overfitting, which is the main issue plaguing the imitation learning based methods. First, we only provide the task description to the GUIDE and not the full state information. Second, unlike the EXPLORER, which uses different policy for each task type, we train a common GUIDE across all tasks, and its weights are frozen during the training of the EXPLORER.

4 Experiments and Results

As done in Wang et al. (2022), the variations of each task type are divided into training, validation and test sets. Both GUIDE and EXPLORER are trained only using the training variations.

4.1 Evaluating the GUIDE

Before the joint evaluation, we evaluate the GUIDE in isolation. We sample 5 variations from the validation set for each task type and compute the three

---

[2] The agent learns a separate policy of each task type but this policy is common across all variations for that particular task type.

[3] We follow the implementation of DRRN provided in Hausknecht et al. (2019).

[4] Details of the models used and the training data are provided in Appendix A.1.

Model	top-k	RSR	MAP	GAR	GAR (%)	GARR
G_g	50	0.71	0.52	N/A	N/A	N/A
G_τ	50	0.9	0.66			
Guide	50	0.99	0.68	7.4 ± 16.2	1.8 ± 9.4	0.31 ± 2.3
	20	0.94	0.67			
	10	0.79	0.61			

Table 1: Various metrics used to evaluate the GUIDE in isolation. Note that for the baselines G_g and G_τ, we cannot compute GAR.

metrics: GAR, RST and MAP. We use the following two intuitive but strong baselines:

(1) Gold per-task (G_τ): We create a set of 50 most most used actions in gold trajectories of all training variations of a particular task. The Gold per-task baseline, predicts an action to be relevant if it belongs to this set.

(2) Gold Global (G_g) : Similar to Gold per-task but we use 50 most used actions in Gold trajectories of all training variations for all tasks.

Gold Action Rank (GAR): At any time step t, $GAR(\gamma, v, t)$ is defined as the rank of the gold a_t in the set of valid actions $A_{\gamma,v,t}$, and the Gold Action Reciprocal Rank (GARR) is defined as 1/GAR. Since the size of $A_{\gamma,v,t}$ is variable for every t, we also report percent GAR. As seen in Table 1, the gold action gets an average rank of 7.42, which is impressive because $|A_{\gamma,v,t}|$ averages around 2000.

Relevant Set Recall (RSR): GAR ranks a single optimal action at any time, but multiple valid action sequences may exist for task completion. Although all viable paths are not directly accessible, we estimate them. For each time step t in variation $\tau_{\gamma,v}$, a set of gold relevant actions $\tilde{A}_{\gamma,v,t}$ is identified by intersecting the gold trajectory $G_{\gamma,v}$ with valid actions at t, so $\tilde{A}_{\gamma,v,t} = \{a \,|\, a \in G_{\gamma,v} \cap A_{\gamma,v,t}\}$. The GUIDE's effectiveness is measured by its recall of this set, considering its top-k predicted actions $\hat{A}_{\gamma,v,t}$. Relevant Set Recall (RSR) is calculated as $RSR(\gamma, v, t) = \frac{|\hat{A}_{\gamma,v,t} \cap \tilde{A}_{\gamma,v,t}|}{|\tilde{A}_{\gamma,v,t}|}$. As seen in Table 1, the GUIDE has almost perfect average recall of 0.99 while selecting top 50 actions for the EXPLORER at every step of the episode.

Mean Avg. Precision (MAP): The GUIDE also functions as a binary classifier, predicting the relevance of each action in $A_{\gamma,v,t}$. Using a threshold-free metric like average precision score (Pedregosa et al., 2011), the GUIDE achieves a superior average precision score of 0.68 compared to baselines. Coupled with perfect recall at 50, this indicates the GUIDE's strong generalization ability on new variations and robust performance across various thresholds. We observe that the threshold that produces best MAP is 0.52, which corresponds to $|\hat{A}_{\gamma,v,t}| = 28$ on average. So, to be conservative, we use $k = 50$ in the subsequent evaluations. Table 5 shows an example of the set of actions selected by GUIDE for the task "Change of state".

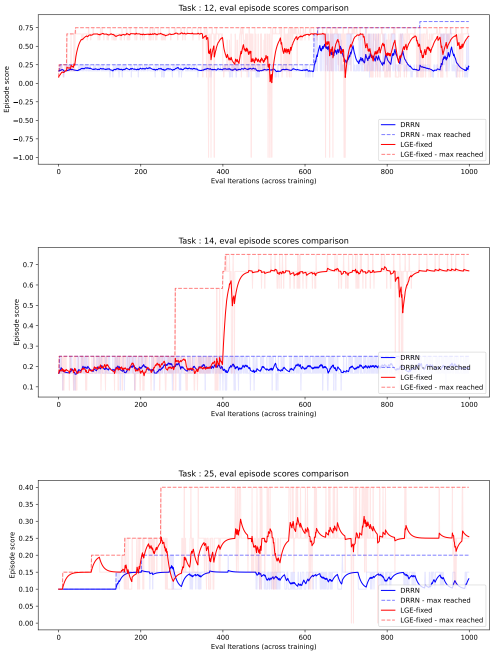

Figure 2: Episode scores on unseen variations of tasks 12, 14 and 25, plotted as the training progresses. The solid line plots are the exponential moving averages of episode scores, while the dotted lines are the maximum episode score achieved till that point. We see both the ability to reach higher scores and better sample efficiency for LGE as compared to the DRRN. This trend is observed in most tasks. Plots for more tasks are in the Appendix- Figure 3

4.2 Evaluating LGE

We follow the same evaluation protocol as (Wang et al., 2022) and evaluate two versions of the LGE framework, one with a fixed ϵ of 0.1 and the other with ϵ increasing from 0 to 1. Table 3 reports the means returns for each task.

LGE improves significantly over the RL baseline. The DRRN agent, which only uses RL, performs the best among the baselines. The proposed LGE framework (last two columns), improves the performance of DRRN on 20 out of 30 tasks. On average the LGE with $\epsilon = 0.1$, improves the mean

Relevant Gold Actions	Selected By GUIDE
open cupboard,focus on soap in kitchen, move soap in kitchen to metal pot, move metal pot to stove, go to outside,wait1, pick up thermometer, pick up metal pot,look around,activate stove	pick up metal pot,move metal pot to sink,pour metal pot into metal pot, open cupboard, activate stove,move metal pot to stove, pick up thermometer, open freezer, wait, go to outside, open glass jar,look around, open drawer in cupboard, open drawer in counter,open oven,move ceramic cup to sink,pick up ceramic cup,open fridge, open door to hallway, activate sink, mix metal pot, pour ceramic cup into ceramic cup, pick up sodium chloride, wait1, focus on metal pot, pick up soap in kitchen

Table 2: Column 1 shows the relevant gold actions for the task “Change of State (variation 1 from the dev set)”, and column two shows the set of actions selected by the GUIDE. The missed gold actions are in Red, while selected gold actions are in Green

returns by 35% (0.17 → 0.23). As seen in the Figure 2, for many tasks, LGE allows the Explorer to reach rewards earlier (leading to better sample efficiency), and often reach better states which were unattainable with DRRN.

LGE is better than much more complex, specialized methods. The behaviour cloning (BC) model, uses a Macaw (Tafjord and Clark, 2021) model fine-tuned on the gold trajectories to predict the next action. The Text Decision Transformer (TDT) (Chen et al., 2021) models the complete POMDP trajectories as a sequence and is capable of predicting actions that maximize long-term reward. As seen in Table 3, the simpler LGE framework outperforms both TDT and BC. This shows the importance of having an RL agent in the framework that can adapt to the peculiarities of the environment.

Using an increasing ϵ schedule is slightly worse LGE-inc uses an increasing ϵ schedule, where the reliance on the Guide is slowly weaned away, as the Explorer's learning matures. We observe that as the actions provided by the GUIDE almost always contain the right action, LGE-inc is almost competitive with LGE-fix, but slightly worse. LGE-inc should be better in more difficult environments with not-so-perfect Guide for better generalization.

Task	DRRN*	BC*	TDT*	LGE inc	LGE fix	Delta

Table 3: Zero-shot performance of the agents on test variations of across all tasks. The columns with * are reported from Wang et al. (2022). The Delta column is the difference between DRRN and the best LGE model. The LGE performance values are averaged across 3 separate runs. The names of the tasks are in Table 4 in Appendix.

5 Conclusion

We proposed a simple and effective framework for using the knowledge in LMs to guide RL agents in text environments, and showed its effectiveness on the SCIENCEWORLD environment when used with DRRN. Our framework is generic and can extend to work with other RL agents. We believe that the positive results observed in our work will pave the way for future work in this area.

6 Limitations

This paper focuses on the ScienceWorld environment, which is an English only environment. Moreover, it focuses mainly on scientific concepts and skills. To explore other environments in different languages with different RL agents will be an interesting future work. There is also a large room for improvement to approach human-level performance which may come from improving the RL agent and using a larger LM as the Guide. Also, our current methodology requires supervised demonstrations to train the GUIDE, so extending this method to semi/un-supervised settings now becomes a relevant direction for future work.

A Appendix

A.1 Implementation details

A.1.1 Guide's architecture

We use a BERT-base model (Devlin et al., 2019) as the Guide. We also performed a rudimentary experiment of fine-tuning the Encoder part of the 770M Macaw (Tafjord and Clark, 2021) model (T5 Large model pretrained on Question Answering datasets in Science Domain), but could not achieve the same quality of pruning post training as the smaller BERT-base model. This could be attributed to two reasons:

1. The size of the training dataset may not be enough to train the large number of parameters in the bigger Macaw model (thus leading to underfitting).

2. We used a smaller batch size for training the Macaw model using similar compute as the BERT-base model (16GB GPU memory). As the contrastive loss depends on in-batch examples for negative samples, the smaller batch-size could mean less effective signal to train the model. We would explore a fairer comparison with similar training settings as the BERT model in future work.

The code for this work is available at `https://github.com/hitzkrieg/drrn-scienceworld-clone`.

A.1.2 Training the Guide

The supervised contrastive loss framework in (Gao et al., 2021) needs a dataset consisting of example triplets of form (x_i, x_i^+ and x_i^-) where x_i and x_i^+ are semantically related and x_i^- is an example of a hard negative (semantically unrelated to x_i, but more still more similar than any random sample).

For training the Guide, we want to anchor the task descriptions closer in some embedding space to relevant actions and away from irrelevant actions. Thus we prepare a training data $\{(\tau_i, a_i^+, a_i^-)\}_{i=1}^{M}$, consists of tuples of task descriptions $\tau_i = \tau_{\gamma,v} \in \mathcal{T}$ along with a relevant action $a_i^+ \sim G_{\gamma,v}$ and an irrelevant action $a_i^- \sim \mathcal{N}_\gamma$ (fixed size set of irrelevant actions for every task γ).

Preparing $\mathcal{N}_\gamma$: We simulate gold trajectories from 10 random training variations for each task-type $\gamma \in \Gamma$, and keep taking a union of the valid actions at each time step to create a large union of valid actions for that task-type. $\mathcal{N}_\gamma = \bigcup_{v=1}^{10} \bigcup_t A_{\gamma,v,t}$. Now, this set is used for sampling hard negatives for a given task description. For a batch of size N, the loss is computed as:

$$l(\phi) = -\sum_{i=1}^{N} \log \frac{e^{s(\tau_i, a_i^+)}}{\sum_{j=1}^{N} e^{s(\tau_i, a_j^-)} + e^{s(\tau_i, a_j^+)}}, \tag{1}$$

TaskID	Task Name
T0	Changes of State (Boiling)
T1	Changes of State (Any)
T2	Changes of State (Freezing)

T29	Mendelian Genetics (unknown plants)

Table 4: List of Task Names with their task ID's

The final training dataset to train the Guide LM on 30 task-types consisting of 3442 training variations had 214535 tuples. The LM was trained with a batch size of 128, on 10 epochs and with a learning rate of 0.00005.

A.1.3 Training and evaluating the Explorer

We use similar approach as (Wang et al., 2022) to train and evaluate the Explorer. The DRRN architecture is trained with embedding size and hidden size = 128, learning rate = 0.0001, memory size = 100k, priority fraction (for experience replay) =

0.5. The model is trained simultaneously on 8 environment threads at 100k steps per thread. Episodes are reset if they reach 100 steps, or success/failure state.

After every 1000 training steps, evaluation is performed on 10 randomly chosen test variations. The final numbers reported in table 4 are the average score of last 10% test step scores.

A.2 More examples

Table 2 and Table 5 show examples of the out sample usage of the GUIDE.

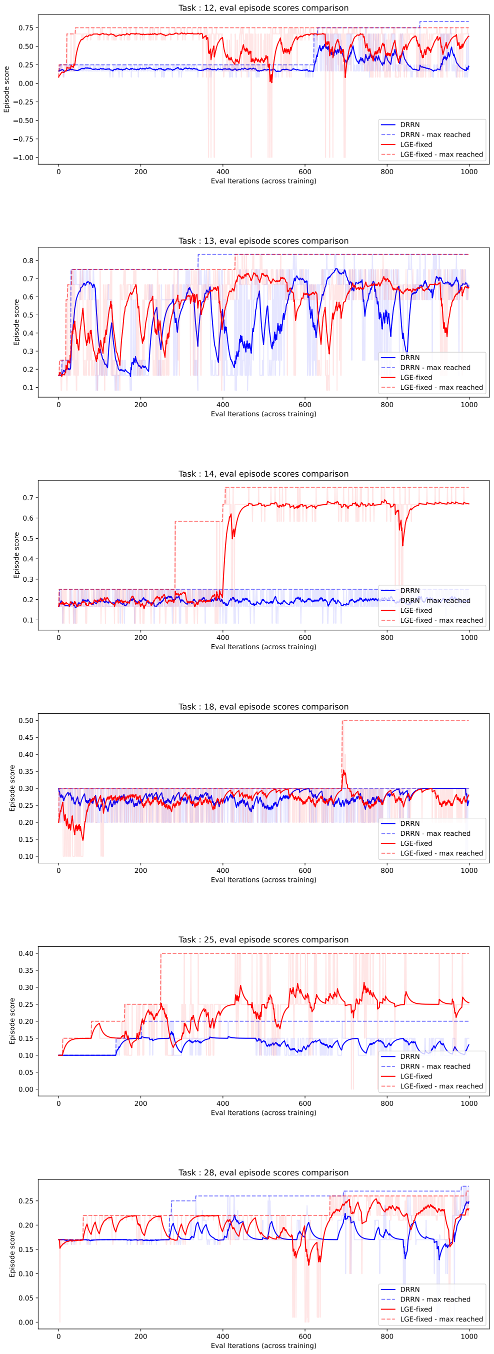

Figure 3: Episode scores on unseen variations validated throughout training. The line plots for DRRN and LGE-fixed are plotted with exponential moving average. We see both the ability to reach higher scores and better sample efficiency for LGE as compared to the DRRN baseline on some tasks.

Algorithm 1 Training Algorithm: LANGUAGE GUIDED EXPLORATION FRAMEWORK with DRRN Explorer

```
Initialize replay memory $D$ to capacity $C$
Initialize Explorer's Q-network with random weights $\theta$
Initialize $updateFrequency, totalSteps$
for episode $= 1$ to $M$ do
    $env, v, d \leftarrow$ sampleRandomEnv('train', $\gamma$)
    Sample initial state $s_1$ from $d_0$ and get $A_{\gamma,v,1}$
    for $t = 1$ to $N$ do
        $totalSteps \mathrel{+}= 1$
        Identify $k$ most relevant actions using Guide:
        $\hat{A}_{\gamma,v,t} \leftarrow$ Guide.top_k$(A_{\gamma,v,t}, k, d_{T,v})$
        $randomNumber \sim$ Uniform$(0, 1)$
        if $randomNumber > \epsilon$ then
            $a_t \sim$ Multinomial(softmax$(\{Q(s_t, a|\theta)$ for $a \in \hat{A}_{\gamma,v,t}\}))$
        else
            $a_t \sim$ Multinomial(softmax$(\{Q(s_t, a|\theta)$ for $a \in A_{\gamma,v,t}\}))$
        Execute $a_t$, observe $r_{t+1}$, $s_{t+1}$, $A_{\gamma,v,t+1}$
        Store $(s_t, a_t, r_{t+1}, s_{t+1}, A_{\gamma,v,t+1})$ in $D$
        if $totalSteps \mod updateFrequency = 0$ then
            Sample batch from $D$
            $L_{\text{cumulative}} = 0$
            for each $(s, a, r, s', A')$ in batch do
                $\delta = r + \gamma \max_{a' \in A'} Q(s', a'|\theta) - Q(s, a|\theta)$
                Compute Huber loss $L$:
                $L = \begin{cases} \frac{1}{2}\delta^2 & \text{if } |\delta| < 1 \\ |\delta| - \frac{1}{2} & \text{otherwise} \end{cases}$
                $L_{\text{cumulative}} \mathrel{+}= L$
            Update $\theta$ with Adam optimizer:
            $\theta \leftarrow$ AdamOptimizer$(\theta, \nabla_\theta L_{\text{cumulative}})$
        Update state: $s_t \leftarrow s_{t+1}$
```

GPT-who:
An Information Density-based Machine-Generated Text Detector

Abstract

The *Uniform Information Density* (UID) principle posits that humans prefer to spread information evenly during language production. We examine if this UID principle can help capture differences between Large Language Models (LLMs)-generated and human-generated texts. We propose GPT-who, the first psycholinguistically-inspired domain-agnostic statistical detector. This detector employs UID-based features to model the unique statistical signature of each LLM and human author for accurate detection. We evaluate our method using 4 large-scale benchmark datasets and find that GPT-who outperforms state-of-the-art detectors (both statistical- & non-statistical) such as GLTR, GPTZero, DetectGPT, OpenAI detector, and ZeroGPT by over 20% across domains. In addition to better performance, it is computationally inexpensive and utilizes an interpretable representation of text articles. We find that GPT-who can distinguish texts generated by very sophisticated LLMs, even when the overlying text is indiscernible. UID-based measures for all datasets and code are available at `https://github.com/saranya-venkatraman/gpt-who`.

1 Introduction

The recent ubiquity of Large Language Models (LLMs) has led to more assessments of their potential risks. These risks include its capability to generate misinformation (Zellers et al., 2019; Uchendu et al., 2020), memorized content (Carlini et al., 2021), plagiarized content (Lee et al., 2023), toxic speech (Deshpande et al., 2023), and hallucinated content (Ji et al., 2023; Shevlane et al., 2023). To mitigate these issues, researchers have proposed automatic and human-based approaches to distinguish LLM-generated texts (i.e., machine-generated) from human-written texts (Zellers et al., 2019; Pu et al., 2022; Uchendu et al., 2023; Mitchell et al., 2023).

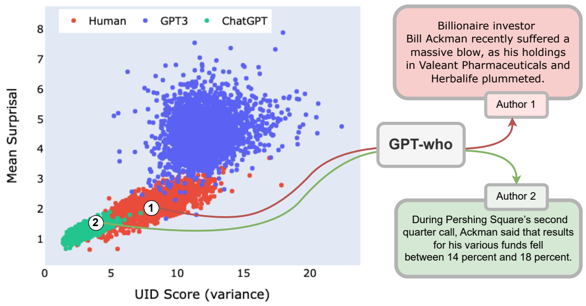

Figure 1: GPT-who leverages psycholinguistically motivated representations that capture authors' information signatures distinctly, even when the corresponding text is indiscernible.

Automatically detecting machine-generated texts occurs in two settings- *Turing Test* (TT) which is the binary detection of human vs. machine; and *Authorship Attribution* (AA) which is the multi-class detection of human vs. several machines (e.g., GPT-3.5 vs. LLaMA vs. Falcon) (Uchendu et al., 2021). While the TT problem is more rigorously studied, due to the wide usage of different LLMs, in the future, it will be imperative to build models for the AA tasks to determine which LLMs are more likely to be misused. This knowledge will be needed by policymakers when they inevitably institute laws to guard the usage of LLMs.

To that end, we propose GPT-who, the first psycholinguistically-inspired supervised domain-agnostic task-independent multi-class statistical-based detector. GPT-who calculates interpretable Uniform Information Density (UID) based features from the statistical distribution of a piece of text and automatically learns the threshold (using Logistic Regression) between different authors. Such features are calculated using the surprisals of tokens in a text, for example, the variance of surprisals, the mean, and so on (elaborated in Section 3.1). To showcase the detection capabilities of GPT-who, we use 4 large LLM benchmark datasets: Turing-

Findings of the Association for Computational Linguistics: NAACL 2024, pages 103–115
June 16-21, 2024 ©2024 Association for Computational Linguistics

Bench (Uchendu et al., 2021), GPABenchmark (Liu et al., 2023b), ArguGPT (Liu et al., 2023a), and Deepfake Text in-the-wild (Li et al., 2023). We find that GPT-who outperforms state-of-the-art statistical detectors and is at par with task and domain-specific fine-tuned LMs. This performative gain is consistent across benchmark datasets, types of LLMs, writing tasks, and domains.

In addition to improved detection performance, GPT-who is computationally inexpensive as it eliminates the need for any LLM fine-tuning. It utilizes a freely available off-the-shelf LM to compute token probabilities, followed by logistic regression using a small set of carefully crafted and theoretically motivated UID features. GPT-who also provides a means to interpret and understand its prediction behaviors due to the rich feature space it learns from. UID-based features enable observable distinctions in the surprisal patterns of texts, which help in understanding GPT-who's decision-making on authorship (Figure 1).

We also analyze the UID feature distributions of different LLMs and human-generated texts for the 4 datasets and find that humans distribute information more unevenly and diversely than models. In addition, UID features are reflective of differences in LLM architectures or families such that models that share architectures have similar UID distributions within but not outside their category. We find that UID-based features are a consistent predictor of authorship. Even when there are no glaring differences between uniform and non-uniform text, the differences in UID distributions are easily detectable and a powerful predictor of authorship, since they capture patterns that go beyond the lexical, semantic, or syntactic properties of text. Our work indicates that psycholinguistically-inspired tools can hold their ground in the age of LLMs and a simpler theoretically-motivated approach can outperform complex and expensive uninterpretable black-box approaches for machine text detection.

2 Related Work

2.1 Uniform Information Density (UID)

Shannon's Information Theory states that information exchange is optimized when information travels across the (noisy) channel at a uniform rate (Shannon, 1948). For language production, this uniform rate of information content is the basis of the UID hypothesis that posits that humans prefer to spread information evenly, avoiding sharp and sudden peaks and troughs in the amount of information conveyed per linguistic unit. The information content or **"surprisal"** of a word is inversely proportional to its probability in a given context. Less predictable words have more surprisal while highly predictable words convey lower information.

UID in human language production has been studied by measuring the amount of information content per linguistic unit (number of words) or by studying any sudden changes in surprisal at the onset of a word or sentential element (Xu and Reitter, 2016; Jaeger and Levy, 2007). A rich body of work in psycholinguistics has led to the finding that, in language production, humans try to spread information content or surprisal evenly and maintain UID through their lexical, syntactic, phonological, and semantic choices (Frank and Jaeger, 2008; Xu and Reitter, 2018; Jaeger, 2010; Mahowald et al., 2013; Tily and Piantadosi, 2009).

2.2 Machine-Generated Text Detection

Large Language Models (LLMs) such as GPT-3.5, GPT-4 (OpenAI, 2023), LLaMA (Touvron et al., 2023), Falcon (Penedo et al., 2023), have the capacity to generate human-like-quality texts, which can be easily construed as human-written (Sadasivan et al., 2023; Chakraborty et al., 2023; Zhao et al., 2023). However, while such LLMs are remarkable, it, therefore, makes them susceptible to malicious use. These include the generation of toxic and harmful content, like misinformation and terrorism recruitment (Shevlane et al., 2023; Zellers et al., 2019; Uchendu et al., 2021). Due to such potential for misuse, we must develop techniques to distinguish human-written texts from LLM-generated ones to mitigate these risks.

To mitigate this potential for misuse of LLMs, researchers have developed several types of automatic detectors. These techniques include supervised (Uchendu et al., 2021; Zellers et al., 2019; Uchendu et al., 2020; Zhong et al., 2020; Kushnareva et al., 2021; Liu et al., 2022) and unsupervised approaches (Gehrmann et al., 2019; Mitchell et al., 2023; Gallé et al., 2021; He et al., 2023; Su et al., 2023). These supervised approaches tend to be stylometric-, deep learning- and ensemble-based models while most unsupervised approaches are statistical-based detectors (Uchendu et al., 2023; Yang et al., 2023).

More recently, due to the increased ubiquity of LLMs, we need more interpretable, and less deep learning-based models. Deep learning models have been shown to be the most susceptible to adversarial perturbations than others (Pu et al., 2022). To that end, we propose a supervised statistical-based technique, that calculates UID-based features of a given text and uses a classical machine learning model to automatically decide thresholds.

3 Our Proposal: GPT-who

We propose a psycholinguistically-motivated statistical-based machine-generated text detector GPT-who that uses a **GPT**-based language model to predict **who** the author of an article is. GPT-who works by exploiting a densely information-rich feature space motivated by the UID principle. UID-based representations are sensitive to intricate "fluctuations" as well as "smoothness" in the text. Specifically, operationalizations of UID are aimed at capturing the evenness or smoothness of the distribution of surprisal per linguistic unit (tokens, words), as stated by the UID principle. For example, in Figure 2, we show sequences of tokens that correspond to the highest and lowest UID score spans within an article. Here, the differences between the two segments of texts might not be obvious at the linguistic level to a reader, but when mapped to their surprisal distributions, the two segments have noticeably distinct surprisal spreads as can be seen by the peaks and troughs i.e. variance of token surprisals along the y-axis about the mean (dotted line). Most approximations of this notion of "smoothness" of information spread and UID, thus, formulate it as the variance of surprisal or as a measure of the difference of surprisals between consecutive linguistic units (Jain et al., 2018; Meister et al., 2020; Wei et al., 2021; Venkatraman et al., 2023).

In measuring the distribution of surprisal of tokens, UID-based features can capture and amplify subtle information distribution patterns that constitute distinct information profiles of authors. Using just an off-the-shelf language model to calculate UID-based features, GPT-who learns to predict authorship by means of a simple classifier using UID representations. In addition, as these features can be directly mapped to their linguistic token equivalents, GPT-who offers a more interpretable representation of its detection behavior, unlike current black-box statistical detectors, as illustrated in Figure 2. The use of a psycholinguistically motivated representation also enables us to better interpret the resulting representation space. It can capture surprisal distributions indicative of and commonly occurring in human-written or machine-generated text. GPT-who is one of the first text detectors that focus on informing a simple classifier with theoretically motivated and intuitive features, as it only requires a fixed-length UID-based representation of length 44 and learns to predict authorship based on just these features, without the need for the full text or any LM fine-tuning in the process (See GPT-who's complete pipeline in Figure 3).

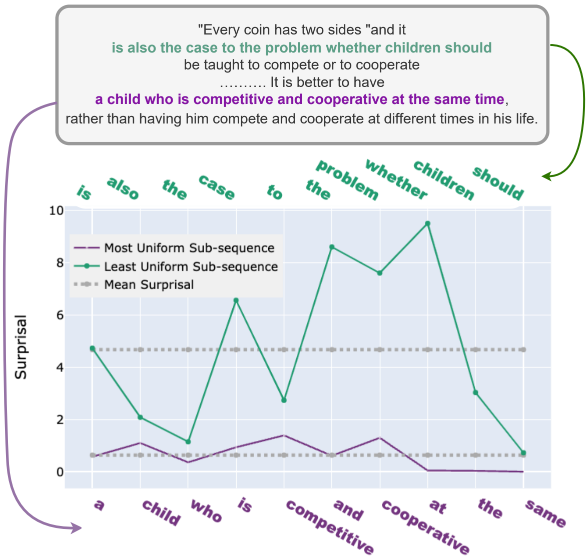

Figure 2: An example of UID span feature extraction that selects the most uniform and non-uniform segments from the token surprisal sequence. As can be seen in this example, two texts that read well can have very different underlying information density distributions in a given context. UID features capture these hidden statistical distinctions that are not apparent in their textual form.

3.1 UID-based features

We use the 3 most widely used measures of UID scores as defined in previous works (Jain et al., 2018; Meister et al., 2020; Wei et al., 2021; Venkatraman et al., 2023) as follows: We first obtain the conditional probability p of each token (y_t) in an article using a pre-trained LM (GPT2-XL). The surprisal (u) of a token y_t is,

$$u(y_t) = -\log(p(y|y < t)), \qquad (1)$$

for $t \geq 1$ where $y_0 =< BOS >$, and t = time step.

The lower the probability of a token, the higher its surprisal and vice-versa. Thus, surprisal indicates how unexpected a token is in a given context.

1. **Mean Surprisal** (μ) of an article (y) of length

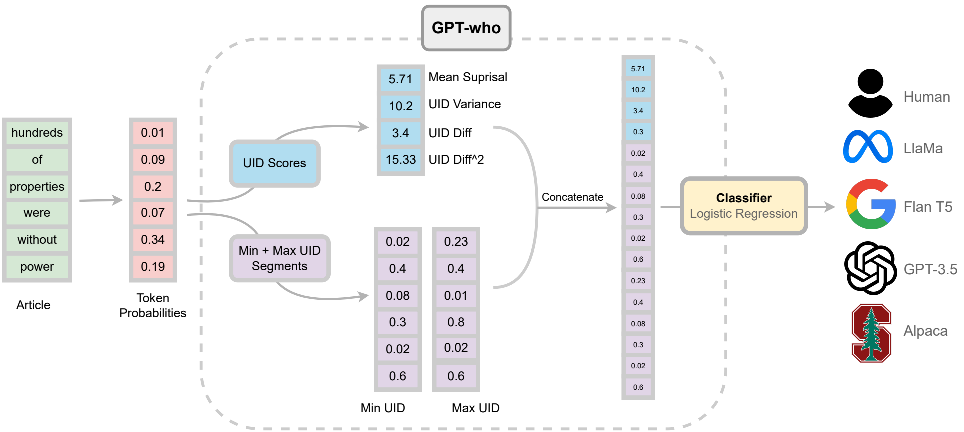

Figure 3: GPT-who uses token probabilities of articles to extract UID-based features. A classifier then learns to map UID features to different authors, and identify the author of a new unseen article.

|y| in number of tokens is defined as follows:

$$\mu(y) = \frac{1}{|y|} \sum_{t} (u(y_t)) \tag{2}$$

2. **UID** ($Variance$) score or **global** UID score of an article (y) is calculated as the normalized variance of the surprisal:

$$\mathrm{UID}(y) = \frac{1}{|y|} \sum_{t} (u(y_t) - \mu)^2 \tag{3}$$

   From this formulation, a perfectly uniform article would have the same surprisal at every token and hence 0 UID (variance) score.

3. **UID** ($Difference$) score or **local** UID score of an article (y) is calculated as the average of the difference in surprisals of every two consecutive tokens $\mu(y_{t-1})$ and $\mu(y_t)$:

$$\mathrm{UID}(y) = \frac{1}{|y|-1} \sum_{t=2}^{|y|} abs(\mu\left(y_t\right) - \mu\left(y_{t-1}\right)) \tag{4}$$

4. **UID** ($Difference^2$) score is defined as the average of the squared difference in surprisals of every two consecutive tokens $\mu(y_{t-1})$ and $\mu(y_t)$:

$$\mathrm{UID}(y) = \frac{1}{|y|-1} \sum_{n=2}^{|y|} (\mu\left(y_t\right) - \mu\left(y_{t-1}\right))^2 \tag{5}$$

   From this formulation, both local measures of UID capture any sudden bursts of unevenness in how information is dispersed in consecutive tokens of the articles.

Maximum and minimum UID spans In addition to previously used approximations of UID, we also craft a new set of features using the most and least uniform segments of an article. Our intuition for this feature is to focus on the extremities of the UID distribution in an article, as the most and least uniform spans would be the most expressive and distinct sequences from a UID perspective. All other spans or segments in an article necessarily lie in between these two extremities. Thus taking account of these two spans would ensure coverage of the whole range of surprisal fluctuations within an article. Thus, for each article, we calculate UID (variance) scores for all spans of consecutive tokens of a fixed length using a sliding window approach. We tuned this window size and found that a window size of 20 tokens per span sufficiently represented an article's UID range. We also experimented with randomly drawn and re-ordered spans and found that random features did not contribute to task performance (see Table 1 for ablation study results). We use the surprisal values corresponding to the highest and lowest UID scoring span as additional features and obtain fixed length UID features of length 44 for each article.

4 Empirical Validation

We use Meister et al. (2021)'s implementation of UID-based scores[1] and use the publicly available off-the-shelf pre-trained GPT2-XL language model[2] to obtain conditional probabilities. For all our experiments, we calculate the UID features for the publically released train and test splits of all

Table 1: Max. & Min. UID spans ablation study: Setting a span length of N=20 tokens maximized performance (F1 score) across large-scale datasets (N>30 leads to subsequently lower and eventually consistent performance). It can be seen that our min/max features tremendously impact performance against randomly sampled or no span features at all.

datasets of each of the 4 benchmarks as they were released by the dataset developers. We train a logistic regression model[3] using these features on the train splits and report performance on the test splits. We averaged performance over 3 different random seeds and set the number of maximum iterations hyperparameter to 10k after testing a set of values. We replicate all the original evaluation settings and metrics for each of the datasets (except one setting from the ArguGPT (Liu et al., 2023a) dataset that required access to unreleased human evaluation data). We do this to be able to directly compare the performance of GPT-who with current state-of-the-art detection methods reported so far.

4.1 Datasets

To test the applicability of GPT-who across text detection tasks, we run all experiments across 4 large-scale and recent datasets that span over 15 domains and 35 recent LMs.

TuringBench Benchmark (Uchendu et al., 2021) dataset is the largest multi-class authorship attribution dataset that contains over 168k news articles generated by 19 neural text generators using 10K prompts from CNN and the Washington Post.

GPABenchmark (Liu et al., 2023b) or GPT Corpus for Academia is a multi-domain (Computer Science (CS), Humanities and Social Sciences (HSS) and Physics (PHX)) academic articles dataset aimed at helping detection of LLM use or misuse in academic writing. It contains 150k human and 450k ChatGPT-generated articles for 3 task settings (completion, writing, and polishing).

ArguGPT (Liu et al., 2023a) is a prompt-balanced dataset of argumentative essays containing over 4k human-written essays and 4k articles generated by 7 recent LLMs (including many variants of ChatGPT) using prompts from English datasets such as TOEFL11 (Blanchard et al., 2013) and WECCL (Wen et al., 2005) datasets.

---

[3] https://scikit-learn.org/stable/

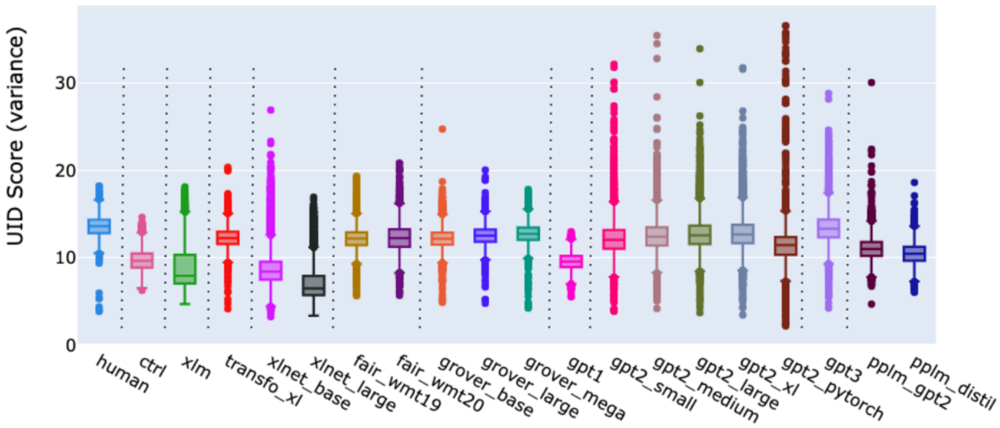

Figure 4: Distribution of UID Scores of 20 authors from the TuringBench dataset grouped (dotted line) by architecture type. LMs that share architectures tend to distribute UID scores similarly.

"InTheWild" Deepfake Text Detection in the Wild (Li et al., 2023) dataset is, to our knowledge, the largest text detection dataset consisting of over 447k human-written and machine-generated texts from 10 tasks such as story generation, news article writing, and academic writing. They use 27 recent LLMs such as GPT-3.5, FLAN-T5, and LLaMA. We refer to this dataset as the **"InTheWild"** dataset going forward for brevity.

4.2 Baselines & Detectors

We compare our proposed method against the following: DetectGPT [4] (Mitchell et al., 2023), GLTR[5] (Gehrmann et al., 2019), an open-source implementation[6] of GPTZero (Tian and Cui, 2023), ZeroGPT (ZeroGPT, 2023), OpenAI's detector (Solaiman et al., 2019), Li et al. (2023)'s LongFormer-based detector[7] tuned for the InTheWild benchmark (we refer to this method as **"ITW"**), a stylometric detector[8] (Abbasi and Chen, 2008) and fine-tuned BERT[9] (Kenton and Toutanova, 2019). We are unable to report results for exhaustively all methods across all datasets due to inherent inapplicability in certain task settings. For example, most SOTA text detectors cannot be applied to the ArguGPT dataset as it only contains text written by multiple machines, while most text detectors are designed to differentiate between human-written and machine-generated texts. Beyond such limitations, we have utilized all applicable methods for 4 benchmark datasets.

4.3 UID Signatures of Authors

Given that humans tend to optimize UID, we study if different models spread surprisal in ways that are distinguishable from each other and human-written text and if we can observe unique UID signatures of different LM families. To this end, we plot the UID score distributions of different text generators across (see Figures 4, 5a, and 5b). We observe that, generally, the UID scores of human-written text have a higher mean and larger standard deviation than most machine-written text across writing task types, domains, and datasets. This implies that human-written text tends to be more non-uniform and diverse in comparison to machine-generated text. Hence, machines seem to be spreading information more evenly or smoothly than humans who are more likely to have fluctuations in their surprisal distributions. Going a step further, if we compare models to other models, we see that models that belong to the same LM family by architecture tend to follow similar UID distribution. For example, in Figure 4, the dotted lines separate LMs by their architecture type and it can be seen, for example, that all GPT-2 based models have similar UID distributions, all Grover-based models have similarities, but these groups are distinct from each other. This indicates that UID-based features can capture differences in text generated by different LM families. To our knowledge, this is the first large-scale UID-based analysis of recent machine and human-generated text across writing tasks and domains.

4.4 Machine Text Detection Performance

Overall, GPT-who outperforms other statistical-based detectors and is at par with transformers-based fine-tuned methods for 2 out of 4 benchmarks. For **GPABenchmark** (Table 2), across all task types and domains, GPT-who outperforms GPTZero, ZeroGPT, DetectGPT and, OpenAI's detector by over **40%**. The machine-generated texts for this task are from 7 very recent and highly sophisticated LLMs (including GPT3.5, GPT3 variants), making the detection of machine-generated text a much more challenging task on which GPT-who outperforms other detectors.

For **TuringBench** (Table 3), GPT-who significantly outperforms GLTR by **0.32 F1** points, and at par with BERT fine-tuned for the task. The **InTheWild** dataset contains 6 testbeds with varying levels of detection difficulties, such as out-of-domain, out-of-distribution, and unseen-task test sets. We used all 6 testbeds to analyze the performance of GPT-who in detecting machine-generated texts across increasing levels of 'wildness' and find that overall, GPT-who outperforms all other methods except the one specifically tuned to the task (ITW) across all testbeds. More importantly, GPT-who performs well even for the most challenging or 'wildest' testbed settings of unseen model and unseen domain distributions (see Table 4).

For the **ArguGPT** dataset (Table 5), we find that GPT-who outperforms human experts and stylometry in predicting authorship by **0.31 F1** points, but is outperformed by fine-tuned BERT. Although unable to perform as well as BERT, GPT-who is one of the only statistical-based detectors that can handle distinctions between machine-only texts. We were unable to evaluate other detectors as their human-generated texts were not publicly released, and they only work in human v/s machine settings.

GPT-who is a statistical-based approach that outperforms other statistical-based approaches but is unsurprisingly outperformed by fine-tuned methods in 2 out of 4 benchmarks. In the case of statistical-based methods, it is typically very hard to come close to fine-tuned performance as such methods rely only on derived properties of the text and do not utilize the full raw text in training as is the case in the latter (Jawahar et al., 2020). Despite this, GPT-who can exceed fine-tuned LM performance by 10% for 2 benchmarks.

4.5 Running Time

We measured the time taken for the one-time training or fine-tuning and inference for 6 testbeds from the InTheWild Dataset (the largest of all our benchmarks). We compare the average running times of DetectGPT, BERT, GPT-who and a stylometric detector in Table 6 and find that GPT-who is the fastest as it eliminates the need for any LM fine-tuning and makes a single inference call per text sample. Other methods require either LM fine-tuning or multiple inference calls (for example, DetectGPT). This computational load is greater than a single forward inference pass through one LM (GPT2) followed by logistic regression which is what GPT-who requires.

Method	**One-Time Training**	**Inference**
DetectGPT	>10 hours	60 sec
BERT	~1.5 hours	2 sec
Stylometry	~1.5 hours	2 sec
GPT-who	20 min	0.8 sec

Table 6: Average Running time over 6 testbeds from the InTheWild dataset.

5 Discussion

We turn to the UID principle, which states that *humans prefer to spread information evenly in language*, to automatically extract features that measure the spread and flow of information content or surprisal in texts. Our UID-based features are formulated to capture how surprisal is distributed in an article as they measure the local and global variance, mean, and most uniform and non-uniform segments of a text. This rich and succinct representation space drives the predictive capability of our proposed detector and the interpretability of its representations. Analysis of this feature space reveals that **human-written text tends to be more non-uniform in comparison to machine-generated text**. Hence, machines seem to be spreading information more evenly or smoothly than humans who are more likely to have fluctuations in their surprisal distributions. However, this finding does not imply that humans are not producing uniform text. It is important to note that our work cannot provide support for or refute the UID hypothesis which comes from psycholinguistic studies such as those in Section 2.1. Our work shows that, given our operationalization of UID based on prior works, machine text is relatively more uniform than human-written text. While this might seem contradictory to UID theory, it does not still disprove that humans are uniform in their language production.

We conjecture that this unexpected finding is because we use GPT-2's probability distribution to calculate surprisal, which is potentially a poor approximation of the "human" probability distribution. A closer-to-human probability distribution might (or might not) show humans to be more uniform than machines, though this determination is not within the scope of this work. It is crucial to note that uniformity is relative, and while machines are more uniform under this operationalization, it would still be true that human text is uniform as per the human's probability distribution (that we do not have access to and can only approximate using some LM distribution, for example, GPT2-XL in our case). UID theory does not make any predictions on where machine-generated text might lie in the uniform to non-uniform spectrum but only indicates that humans are arranging utterances evenly as per their own language distribution.

Irrespective of its alignment with what theory suggests, we find that the UID-based features are very useful in distinguishing authors, which is the focus of this work. This is an important consideration and helps disentangle the utility of UID-inspired features from the cognitive plausibility of those feature calculations or UID approximations.

Thus, this operationalization of UID does not imply that humans are "less human" or machines are "more human" as it is an approximation of a theory that states that humans are uniform as per their language distribution. It does not have any further implications for machine-generated text and is unable to predict what happens in the case of machines.

We find that UID-based features can capture differences between text generated by not only humans and models but also capture differences between multiple models and LM families. Our main contribution is a psycholinguistically-inspired domain-agnostic statistical-based machine-generated text detector, GPT-who, that:

- Outperforms statistical approaches across 4 large-scale benchmark datasets that include texts from over 35 LLMs across more than 10 domains.
- Generalizes better to out-of-distribution datasets than SOTA detectors.
- Computationally more efficient than other supervised detectors as it does not require the fine-tuning or training of any LLMs.
- Interpretable due to its psycholinguistically motivated UID-based feature space.

While our detector may not significantly outperform fine-tuned transformers-based models, it is essential to highlight its independence from fine-tuning, offering nearly comparable performance at significantly lower computational costs and remains one of the only statistical-based detectors that can operate in multi-author settings beyond the Turing Test. These findings indicate that approaches rooted in psycholinguistic theories that delineate indicators of "human-like" language use hold enormous and untapped potential in tackling the fast catapulting and ever-changing LLM landscape. This work has implications for cognitively plausible and explainable solutions to complex challenges arising from ever-growing automated text generators.

6 Conclusion

We propose GPT-who, a statistical-based machine-generated text detector that utilizes features inspired by the Uniform Information Density (UID) principle rooted in the observation that humans tend to evenly distribute information or surprisal in language. We leverage UID-based features, including variance of surprisals and minimally/maximally uniform sub-sequences extracted from the surprisal sequence generated by an off-the-shelf LM. We demonstrate that these features are highly effective in discerning machine-generated text from human-generated text as they capture nuances in how models and humans distribute surprisal in their texts. Our findings have implications for enhanced text authenticity assessment.

Limitations

In our pursuit of a comprehensive examination of texts produced by recent large language models, we encountered limitations arising from resource constraints and the availability of publicly accessible datasets. These factors constrained our ability to encompass a more diverse array of models and tasks, including summarization and question-answering. Furthermore, our study did not delve into whether UID-based methods extend their utility beyond detecting machine-generated text to identify potential issues such as misinformation and plagiarism. We acknowledge these constraints as part of our ongoing commitment to refining and expanding our efforts in future research endeavors.

Ethical Statement

It is important to note that there are inherent limitations of AI-based tools and automated machine text detectors such as in this work. Acknowledging the fallibility of these detectors, particularly in generating false positives, we note that there is still a crucial need for human oversight and discretion in the usage of such detectors in real-world settings. For example, ethical concerns surrounding over-vigilance in scrutinizing student-written text are an important consideration for striking a balance between the convenience of automated detection and the preservation of academic integrity. By advocating for responsible development and implementation, we hope to contribute to a landscape where ethical considerations guide the integration of automatic text detection systems in educational settings, safeguarding against undue reliance and promoting fairness, equity, and respect for individual expression.

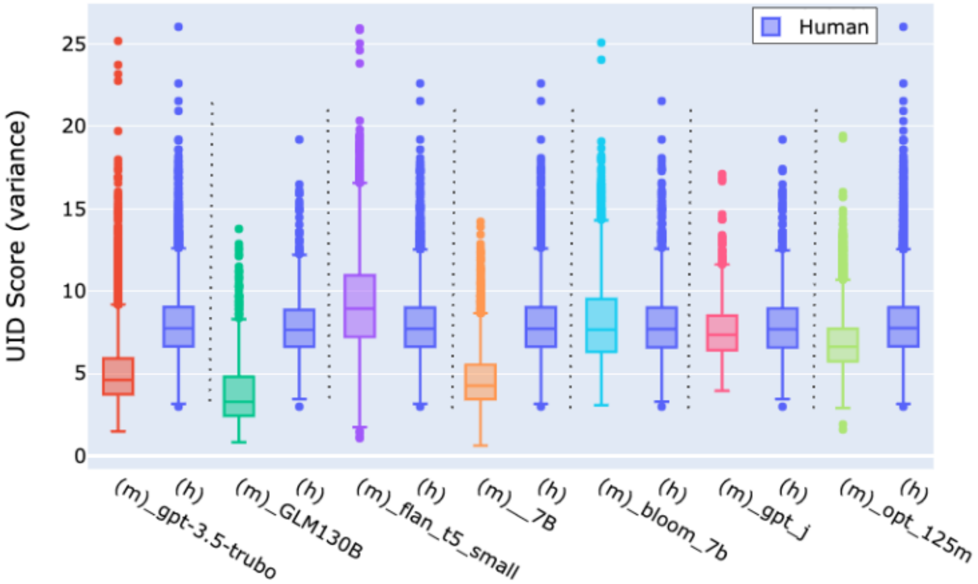
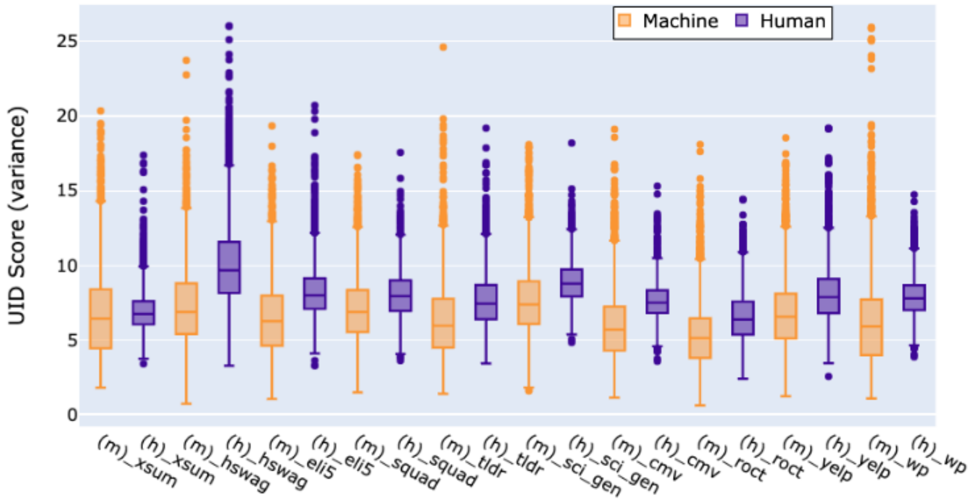
A Appendix

A.1 UID Score distributions of authors

We see that for most cases, humans have a higher UID (variance) score than machines, as can be seen by the higher means of their scores in the box plots. This holds when comparing human-written texts with multiple machine-generated texts over shared tasks (Figure 5a), and also when comparing their differences between tasks (Figure 5b).



(a) Pairwise comparisons of human and different machine-generated texts for shared tasks: Distribution of UID Scores of 8 authors (7 models + human) from the InTheWild dataset. (m) indicates machine and (h) indicates human written texts. This is followed by the model name along the x-axis labels to indicate the different authors.



(b) Pairwise comparisons of human and different machine-generated texts for different tasks: Distribution of UID Scores of humans v.s. machines per task type. (m) indicates machine and (h) indicates human written texts. This is followed by the writing task type along the x-axis labels to indicate the different tasks.

DEED: Dynamic Early Exit on Decoder for Accelerating Encoder-Decoder Transformer Models

Abstract

Encoder-decoder transformer models have achieved great success on various vision-language (VL) and language tasks, but they suffer from high inference latency. Typically, the decoder takes up most of the latency because of the auto-regressive decoding. To accelerate the inference, we propose an approach of performing Dynamic Early Exit on Decoder (DEED). We build a multi-exit encoder-decoder transformer model which is trained with deep supervision so that each of its decoder layers is capable of generating plausible predictions. In addition, we leverage simple yet practical techniques, including shared generation head and adaptation modules, to keep accuracy when exiting at shallow decoder layers. Based on the multi-exit model, we perform step-level dynamic early exit during inference, where the model may decide to use fewer decoder layers based on its confidence of the current layer at each individual decoding step. Considering different number of decoder layers may be used at different decoding steps, we compute deeper-layer decoder features of previous decoding steps just-in-time, which ensures the features from different decoding steps are semantically aligned. We evaluate our approach with three state-of-the-art encoder-decoder transformer models on various VL and language tasks. We show our approach can reduce overall inference latency by 20%-74% with comparable or even higher accuracy compared to baselines.

1 Introduction

Transformer models with auto-regressive decoders have shown great success on vision-language (VL) (Wang et al., 2022; Biten et al., 2022; Chen et al., 2022; Appalaraju et al., 2024; Tang et al., 2024) and language tasks (Raffel et al., 2020; Tay et al., 2022; Radford et al., 2019; Vaswani et al., 2017). Among many successful models tackling these tasks, encoder-decoder transformer models (Wang et al., 2022; Biten et al., 2022; Chen et al., 2022; Appalaraju et al., 2021, 2024; Tang et al., 2024; Raffel et al., 2020; Tay et al., 2022) usually show the best accuracy thanks to the strong representation ability of encoder and the strong generative ability of the decoder.

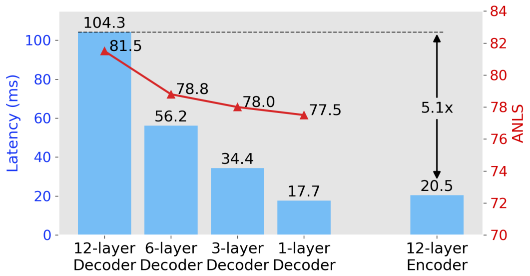

Figure 1: Inference latency and accuracy (ANLS (Mathew et al., 2021)) of LaTr++ (Biten et al., 2022) using different number of decoder layers on the DocVQA validation set. The decoder takes most of the inference time compared to the encoder (104.3 ms *vs*. 20.5 ms). In addition, even using one decoder layer can achieve decent accuracy (77.5% *vs*. 81.5%), implying that most examples do not need all decoder layers during inference.

Nevertheless, encoder-decoder models rely on the auto-regressive decoding to bring its ability into full play at inference. With auto-regressive decoding, each output token is generated conditioned on previous tokens. Therefore, it has to generate tokens one after another, and repeat the feed-forward in each layer as many times. This mechanism leads to high inference latency in the decoder, and makes the decoder take up most of the total inference latency, as shown in Figure 1. Interestingly, even using only one decoder layer, an encoder-decoder model can still get decent prediction accuracy (see Figure 1), which means samples got correct by the one decoder layer do not need the excessive computations in the deeper decoder layers.

Findings of the Association for Computational Linguistics: NAACL 2024, pages 116–131
June 16-21, 2024 ©2024 Association for Computational Linguistics

Inspired by these facts, we propose an approach to dynamically allocate adequate amount of computation at a particular decoding step in order to speed-up inference without sacrificing accuracy. Specifically, we build Dynamic Early Exit on Decoder (DEED), a multi-exit model with an early exit strategy to let the model decide whether or not to exit at a specific decoder layer at each decoding step dynamically. Following existing work (Xin et al., 2020; Liu et al., 2021, 2020; Zhang et al., 2022; Geng et al., 2021; Xin et al., 2021; Zhou et al., 2020), we employ confidence-based dynamic early exit where the decoder may decide to exit when it is confident about its prediction. Unlike encoder acceleration, the dynamic early exit for auto-regressive decoder is more challenging. The challenge is two-fold:

- **Multi-exit model**, *i.e.*, a model that can exit / make prediction at each layer. To get accurate predictions out of dynamic early exit, we must build and train a strong multi-exit encoder-decoder model, where each of the decoder layers have strong generative ability.
- **Semantic misalignment at inference**. Tokens can be generated at different decoder layers at different decoding steps. But the auto-regressive decoding requires n-layer features from all the previous steps if the current step is inferring at layer n. They won't be available if the previous decoding steps exit at shallower layers. This semantic misalignment between different layers imposes difficulties when applying naive early exit strategy, leading to degraded accuracy.

Previous approaches address the first challenge by using different prediction heads after each transformer layer (Schwartz et al., 2020; Xin et al., 2020; Geng et al., 2021; Xin et al., 2021). In contrast, we build our multi-exit model by sharing the generation head among different decoder layers and training with deep supervision. The generation head generates the output sequence prediction, *e.g.*, the answer text for visual question answering (Biten et al., 2022; Chen et al., 2022; Alayrac et al., 2022; Lu et al., 2022) or box coordinates for referring expression comprehension (Wang et al., 2022; Lu et al., 2022). In addition, we insert an adaptation module between decoder layers and the generation head. This design helps to strengthen the generative ability of shallow decoder layers by sharing the common generation knowledge among different decoder layers. Moreover, to maintain the generative ability when exiting at the final layer, we proposes a loss function that emphasizes the learning of the final layer. These simple yet effective techniques help to improve the accuracy of shallow decoder layers without sacrificing the accuracy at the final decoder layer.

To address the second challenge, we propose a novel algorithm that dynamically computes required deeper-layer features for previous decoding steps just-in-time. This algorithm effectively resolves the semantic misalignment among different layers at different generation steps. In contrast, the existing work, DAT (Elbayad et al., 2019) and CALM (Schuster et al., 2022), which uses the shallow-layer features as the deeper-layer features directly for later decoding steps, failed to mitigate such semantic misalignment and thus substantially undermine the generative ability of the model.

Our contributions are summarized as follows:

- We propose DEED, a multi-exit model with step-level dynamic early exit on decoder to speed-up inference without sacrificing accuracy for encoder-decoder transformer models.
- We apply our approach to three state-of-the-art encoder-decoder transformer models and evaluate on various VL and language tasks. Our approach is able to reduce 20%-74% overall inference latency with comparable or even higher accuracy compared to baseline models and other dynamic early exit approaches.

2 Related Work

Encoder-Decoder Models for Vision-Language and Language Tasks Transformer models, when first proposed, consist of encoder and decoder and are mainly for language tasks (Vaswani et al., 2017). Following researches improve encoder-decoder transformer models by introducing better unsupervised pre-training strategies and small model architecture changes (Raffel et al., 2020; Tay et al., 2022). Recently, encoder-decoder transformer models have pushed the edge for Vision-Language (VL) tasks (Alayrac et al., 2022; Wang et al., 2022; Biten et al., 2022; Lu et al., 2022; Chen et al., 2022; Appalaraju et al., 2024; Tang et al., 2024) because of strong representation ability of encoder and generative ability of decoder. For example, Flamingo (Alayrac et al., 2022) uses a vision encoder to encode input images and a text decoder to generate text predictions for various VL tasks. LaTr (Biten et al., 2022) utilizes the sequence generation ability in decoder and layout in multi-modality learning and achieves state-of-the-art accuracy on text-based VQA tasks. OFA (Wang et al., 2022) proposes a unified sequence-to-sequence learning framework to incorporate various VL tasks into the encoder-decoder scheme. Our work focuses on accelerating the decoder inference for this type of encoder-decoder transformer models on VL and language tasks.

Dynamic Early Exit Using Dynamic Early Exit (DEE) is a popular strategy to reduce the inference latency of transformer models (Xin et al., 2020; Liao et al., 2021; Liu et al., 2021, 2020; Zhang et al., 2022; Geng et al., 2021; Xin et al., 2021; Zhou et al., 2020; Li et al., 2021; Hou et al., 2020; Kim and Cho, 2021; Akbari et al., 2022). For example, DeeBERT (Xin et al., 2020) and RomeBERT (Geng et al., 2021) applies DEE to BERT (Kenton and Toutanova, 2019) based on classification confidence scores from different encoder layers. BERxiT (Xin et al., 2021) learns a policy for dynamic early exit. TOKEE (Li et al., 2021) introduces a token-level early exit approach for sequence labelling. However, these encoder-focused approaches cannot be applied to transformer decoders directly, due to the challenges imposed by the auto-regressive mechanism in decoder models.

DAT (Elbayad et al., 2019) is one approach tackling decoder early exit. It introduces a halt-and-copy approach, which halts the computation at a layer if the prediction is confident, and copies the feature from shallow decoder layers to deeper layers in later decoding steps when needed. CALM (Schuster et al., 2022) follows the same halt-and-copy approach for decoder early exit. However, this approach suffers strong semantic misalignment because the semantic information from different decoder layers are not compatible. Thus the later decoding step at deeper layers cannot obtain meaningful features from previous steps, leading to significant accuracy drops. In contrast, our approach dynamically computes the deeper-layer features from earlier steps just-in-time to resolve the semantic misalignment and to achieve high accuracy.

Multi-exit Models The most straightforward way of building multi-exit models is adding deep supervision to each layer (Lee et al., 2015; Teerapittayanon et al., 2016; Schwartz et al., 2020). Nonetheless, it often degrades the accuracy of the final prediction layer. To preserve the final layer accuracy, DeeBERT (Xin et al., 2020) proposes a two-stage training strategy, in which the final prediction layer and the backbone are trained firstly, and other prediction layers are trained secondly with the rest of the parts frozen. However, this two-stage training strategy leads to reduced accuracy of shallow layers. RomeBERT (Geng et al., 2021) designs an approach to increase the accuracy of shallow layers using self-distillation and gradient regularization. BERxiT (Xin et al., 2021) uses an alternating training scheme to improve the accuracy of shallow layers. It alternates between two training objectives: the loss of the final layer only and the loss of all layers. Unlike previous work, we build the multi-exit model by sharing the prediction head among all layers and inserting adaptation modules to align the feature spaces. Our approach shows the best trade-off between final layer accuracy and shallow layer accuracy.

Other Directions for Latency Reduction Apart from dynamic early exit, there are attempts in other directions to reduce latency for transformers. For example, knowledge distillation (Hinton et al., 2015; Jiao et al., 2020; Lin et al., 2022; Sanh et al., 2019) is applied to reduce the model size and latency by distilling information from a large teacher model to a small student model. Model pruning (Gordon et al., 2020; Michel et al., 2019) reduces model size by removing redundant parameters. Non-autoregressive generation (Gu et al., 2018; Qian et al., 2021) avoids the time-consuming step-by-step generation by decoding the predictions in parallel. These directions are orthogonal to dynamic early exit, hence they are not our focus.

3 Approach

We propose DEED, a dynamic early exit on decoder approach to accelerate encoder-decoder transformer models for VL and language tasks. Specifically, we leverage confidence-based step-level dynamic early exit to decide which decoder layer to exit based on how confident we are at each decoding step. At training, we train our multi-exit model with deep supervision (Lee et al., 2015), where the output features of each decoder layer are input to a shared generation head and supervised using the ground truth. At inference, we apply dynamic early exit on the auto-regressive decoder. At each decoding step, the model decides how many decoder layers to use based on its confidence about the output token – hence different number of layers may be used at different decoding steps. In the follow sections, we first introduce the autoregressive decoding process and the challenge of semantic misalignment in dynamic early exit on decoder in Section 3.1. Then we describe our multi-exit model architecture and our training strategy in Section 3.2. Finally we show how we resolve the semantic misalignment problem with just-in-time computation of decoder features in Section 3.3.

3.1 Background

Auto-Regressive Decoding At inference, decoder typically generates the prediction in an auto-regressive decoding way, *i.e.*, decoder generates tokens step-by-step and the generated token in each step is conditioned on the previously generated tokens. Theoretically, all the previous tokens are supposed to be input to the decoder to generate the current token, which would cause redundant computation for the previous tokens as their features have been computed at previous decoding steps. In common practice, to reduce redundant computation, the key-value features in the multi-head self-attention layers are all saved and provided for later steps. This practice decreases computation complexity and reduces inference latency, by avoid re-computing key-value features of earlier decoder steps at later steps.

Semantic Misalignment In step-level dynamic early exit, each decoding step can use a different number of decoder layers. As a result, the past key-value features may not always be available for every layer. This misalignment makes it difficult to implement the step-level dynamic early exit, as it cannot retrieve the cached key-value features from previous steps when the current step uses deeper layers. One option is to copy shallower-layer features to deeper-layers (Elbayad et al., 2019; Schuster et al., 2022). However, the deeper-layer features encode higher-level semantics compared to shallower-layer features. A mixture of them across decoding steps will cause semantic misalignment and undermine the generative ability of the model. An easy workaround is to constrain the model to always exit at the same decoder layer, but this would upset our observation that some tokens are harder to generate than others. In experiments, we will show that this constrained approach is not desirable in terms of accuracy and latency. While we have to stick to step-level dynamic early exit and solve semantic misalignment, pre-computing the deeper-layer key-value features is not efficient because we do not know how many layers the following steps will use. To address this issue, we do step-level dynamic early exit with just-in-time computation, see Section 3.3.

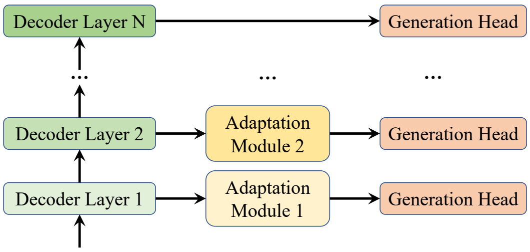

Figure 2: Decoder architecture of our multi-exit model. We share the generation head across different decoder layers and insert adaptation modules between early decoder layers and the generation head.

3.2 Multi-exit Model

To perform step-level dynamic early exit, it is crucial to have a multi-exit model to ensure each decoder layer is capable of generating plausible predictions. So we introduce our multi-exit model here before moving on to how we do step-level dynamic early exit.

Model Architecture In our multi-exit encoder-decoder transformer model, we have a generation head that maps decoder features into tokens. In contrast to existing work (Geng et al., 2021; Xin et al., 2020, 2021), we share the generation head across different decoder layers to share the common generation knowledge among different decoder layers, which strengthens the generative ability of shallow decoder layers. In addition, we insert separate adaptation modules between the shallow decoder layers and the generation head to adapt the features from shallow decoder layers to the semantic space of features from the final decoder layer (see Figure 2). Specifically, the adaptation module is composed of a linear layer followed by layer normalization.

Model Training To train the multi-exit model, the most straightforward way is to add deep supervision (Lee et al., 2015) after outputs of each decoder layer as follows

$$\mathcal{L}_{avg} = \frac{1}{N}\sum_{n=1}^{N}\mathcal{L}_n, \tag{1}$$

where $N, \mathcal{L}_n, \mathcal{L}_{avg}$ correspond to the total number of decoder layers, the loss for the n-th decoder layer, and the average loss across all decoder layers, respectively. However, this approach does not optimize the model for the final decoder layer solely. As a result, the model suffers from degraded accuracy of the final decoder layer, which will cap the

Algorithm 1 Step-level dynamic early exit with just-in-time computation

```
Require: Current decoding step $i$, saved past key-value features $\mathcal{P} = \{\mathbf{p}_n^{i'}\}$, saved hidden states $\mathcal{H} = \{\mathbf{h}_n^{i'}\}$, decoder layers $\mathcal{D} = \{D_n\}$, the number of decoder layers $N$, confidence score threshold $\tau$.
Ensure: Decoded token output $t^i$.
1: for $n = 1$ to $N$ do
2:     Get saved past key-value features $\mathbf{p}_n^{1:j}$ and hidden states $\mathbf{h}_{n-1}^{j+1:i}$.
3:     Feed $\mathbf{p}_n^{1:j}$ and $\mathbf{h}_{n-1}^{j+1:i}$ into $D_n$ to compute $\mathbf{p}_n^{j+1:i}$, $\mathbf{h}_n^{j+1:i}$, $t_n^i$ with confidence score $c_n^i$.
4:     Save $\mathbf{p}_n^{j+1:i}$ to $\mathcal{P}$ and $\mathbf{h}_n^{j+1:i}$ to $\mathcal{H}$.
5:     if $c_n^i > \tau$ then
6:         Set $t^i$ to $t_n^i$ and terminate the for loop.
7:     end if
8: end for
```

accuracy of our approach. To address this issue, we emphasize the loss of the final layer so as to maintain high accuracy for the final decoder layer. To this end, we add the final decoder layer loss to the training objective as follows

$$\mathcal{L} = \mathcal{L}_{avg} + \mathcal{L}_N. \quad (2)$$

3.3 Step-Level Dynamic Early Exit with Just-in-Time Computation

We perform step-level dynamic early exit at inference on top of the multi-exit model. To avoid semantic misalignment and improve efficiency, we design an algorithm to compute the past key-value features just-in-time. For step i and decoder layer n, we denote the decoder layer n as D_n, the past key-value features as $\mathbf{p}_n^i$, the decoded token output as t_n^i, the corresponding confidence score as c_n^i, and the confidence score threshold as τ. We use colon separated numbers to denote intervals, *e.g.*, $i : j$ denotes the decoding steps from i to j (inclusive). Apart from $\mathbf{p}_n^i$, we also save any output hidden states $\mathbf{h}_n^i$ of D_n at step i if it is computed.

As shown in Algorithm 1, for each decoding step, we go through the decoder one layer per iteration. At decoding step i, first we prepare saved past key-value features $\mathbf{p}_n^{1:j}$ and hidden states $\mathbf{h}_{n-1}^{j+1:i}$ (for the decoding steps where the key-value features are absent), where j ($< i$) corresponds to the sequence length of saved past key-value features for D_n, see line 2 in Algorithm 1. Next we feed $\mathbf{p}_n^{1:j}$ and $\mathbf{h}_{n-1}^{j+1:i}$ into D_n to compute key-value features $\mathbf{p}_n^{j+1:i}$, hidden states $\mathbf{h}_n^{j+1:i}$, decoded token output t_n^i, and the corresponding confidence score c_n^i, see line 3 in Algorithm 1. We save these newly computed $\mathbf{p}_n^{j+1:i}$ and $\mathbf{h}_n^{j+1:i}$ for future use, see line 4 in Algorithm 1. Taking the decoding process in Figure 3 as an example, at decoding step 3 when the model is about to enter layer 2, the past key-value features $\mathbf{p}_2^1$ are available but p_2^2 are absent, so $\mathbf{p}_2^1$ along with the saved hidden states $\mathbf{h}_1^{2:3}$ will be fed into decoder layer 2. We repeat the same process for every decoder layer until the predicted confidence score c_n^i is larger than a threshold τ, where c_n^i is computed by the classification score after softmax, see line 5-6 in Algorithm 1. Note that although the deeper-layer features are computed for the previous decoding steps, the previous token outputs will not be updated with those features, because each token is supposed to be dependent on the past and any change in the previous tokens will break the dependency.

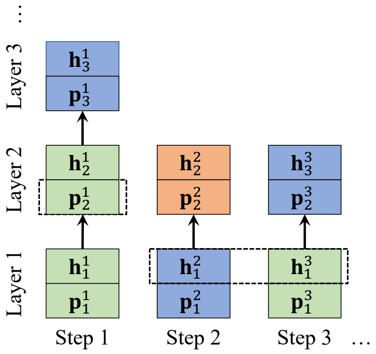

Figure 3: Step-level dynamic early exit with just-in-time computation. Blue boxes: the decoder layers where the model exits. Green boxes: the internal decoder layers. Orange boxes: the layer used for just-in-time computation. Features/hidden states in the dashed boxes are inputs to decoder layer 2 at decoding step 3.

One may notice that our approach assumes the availability of $\mathbf{h}_{n-1}^{j+1:i}$ at decoding step i. This is assured by our per-layer traversal - the hidden states are always computed and saved at the previous decoder layer.

4 Experiments

We evaluate DEED on LaTr++ (Biten et al., 2022) and OFA (Wang et al., 2022) with various vision-language tasks and on T5 (Raffel et al., 2020) with various language tasks. We do auto-regressive prediction for all the tasks.

4.1 DEED on LaTr++

LaTr (Biten et al., 2022) is the state-of-the-art approach for text-based visual question answering (text-VQA). LaTr uses multi-modal encoder-decoder transformer models with OCR text, layout, and visual features as inputs. We improve LaTr by using a better vision backbone and adding better unsupervised pre-training tasks, see Section A.2 for more details. We refer to the improved LaTr as LaTr++ here. Following LaTr, we focus on the text-VQA task.

4.1.1 Settings

We evaluate on four text-VQA datasets: DocVQA (Mathew et al., 2021), OCR-VQA (Mishra et al., 2019), ST-VQA (Biten et al., 2019), and TextVQA (Singh et al., 2019), using accuracy and latency as the metric. For accuracy, we follow the standard protocol to report the metrics on each dataset, *i.e.*, Average Normalized Levenshtein Similarity (ANLS) (Biten et al., 2019; Mathew et al., 2021) for DocVQA and ST-VQA, and accuracy of exact text match between groundtruth and prediction for OCR-VQA and TextVQA. For latency, we report both the total inference latency and the decoder-only latency, as our approach only affects the decoder inference. The latency is measured w.r.t. wall-clock time on the same machine which has 1 Nvidia A100 GPU with 40GB memory. All approaches are implemented in Pytorch (Paszke et al., 2017) with Huggingface (Wolf et al., 2019). To measure the most accurate per sample latency, we use batch size 1 in inference to avoid unnecessary padding. See Section A.3 for more details.

Baselines We compare DEED to the original model, the SOTA approach CALM (Schuster et al., 2022), and two strong baselines SLEX and FTEX we proposed and built:

- **Original**: the vanilla LaTr++ model, on which no early-exit or deep-supervision is applied.
- **CALM** (Schuster et al., 2022): CALM is the state-of-the-art decoder speed-up algorithm. At the step when the model exits at a deeper layer, it simply copies the features of the shallow layer from previous steps to all deeper layers.

OFA	85.7	89.9	78.6	142.7	197.9	87.2	87.6	132.5	187.6
DEED	85.3	89.6	77.9	61.6	117.9	87.0	87.4	83.0	138.1

Table 3: Accuracy and latency (in ms) of OFA and DEED on various multi-modal tasks using the large size model.

- **Sequence-level early exit (SLEX)**: the decoder always exits at layer m at each decoding step. m is chosen by the accumulated confidence score of the entire sequence. More precisely, for each decoder layer, SLEX needs to infer all decoding steps to get the accumulated confidence score, which makes this baseline unpractical. This baseline is similar to ReasoNet (Shen et al., 2017) for machine comprehension.
- **First-token early exit (FTEX)**: the decoder always exit at layer m at each decoding step. Unlike SLEX, m is chosen based on the confidence score of the first token, which makes FTEX more practical than SLEX because FTEX only needs to infer the first decoding step to make the decision.

Note that in our experiments, SLEX, FTEX, and CALM use the same multi-exit model trained for DEED for fair comparisons, which improves the accuracy of the shallow layers.

Implementation Details We evaluate our approach DEED on both base (-b) and large (-L) variations of LaTr++. The base version has 12 encoder and 12 decoder layers, and the large version has 24 encoder and 24 decoder layers. We follow LaTr (Biten et al., 2022) to do pre-training first and fine-tuning later. We add deep supervision loss in Eq. (2) in both pre-training and fine-tuning. The confidence score threshold τ is selected using cross-validation, specifically, 0.99 on DocVQA and 0.95 for other datasets. See Section A.4 for more details.

4.1.2 Results

Table 1 and Table 2 show the comparisons of accuracy and latency among DEED and baselines.

Our approach shows excellent performance compared to the original model. It consistently reduces the inference latency for both base and large variations, while maintaining the evaluation accuracy on all benchmark datasets. The latency reduction on decoder is between 40% and 73% across all model and dataset combinations. Specifically, on DocVQA, DEED reduces the decoder latency on the larger variation from 181.5ms to 49.2ms, achieving a large 72.9% reduction, while its ANLS is 0.3 higher than the original LaTr++. DEED also always outperforms other baseline approaches with clear margins. CALM (Schuster et al., 2022) reduces the decoder latency slightly, but it suffers from major accuracy degradation, due to the semantic misalignment introduced by the copy mechanism. SLEX can maintain high accuracy as it makes the decision based on the entire sequence, but its latency improvement is minor compared to DEED . FTEX can reach significant inference acceleration as it can decide to use a shallow layer after the first decoding step. However, it often sacrifices more accuracy because the layer with the maximum first token confidence might not have the best generation for the entire sequence. In contrast, our approach makes exit decisions at each layer and each step, and recomputes the deeper features when necessary, which helps it achieve the best accuracy and latency comparing to all other approaches.

Notice that there is usually more the latency reduction on the large model, because the large model has more decoder layers and early exit still happens at very shallow layers instead of going deeper. In addition, our approach can improve the accuracy of the vanilla LaTr++ in most cases, because our multi-exit model with deep supervision pre-training significantly improves the accuracy for shallow layers (see Section 4.4), and DEED often chooses the layer with the best generative ability based on the confidence scores. In fact, shallow layers can have better predictions than deeper layers on certain examples. If we can choose which layer to make the prediction according to groundtruth, the base model can obtain ANLS 85.0 on DocVQA.

4.2 DEED on OFA

OFA (Wang et al., 2022) is an encoder-decoder model that unifies multiple modalities and multiple VL tasks with a single paradigm. The encoder and decoder are chosen based on the task.

Experimental Setup Following (Wang et al., 2022), we evaluate DEED with OFA on various multi-modal downstream tasks, specifically, VQAv2 (Goyal et al., 2017) for VQA, and RefCOCO/RefCOCO+/RefCOCOg (Yu et al., 2016; Mao et al., 2016) for referring expression comprehension. We also report the accuracy, the total inference latency, and the decoder-only latency and compare DEED to the baseline model, as described in Section 4.1. For each dataset, the latency is averaged on samples from all splits. Here we only compare to the original OFA model. We use the original pre-trained OFA model and the same fine-tuning procedure as in (Wang et al., 2022) to reproduce the OFA results and train DEED. We do not pre-train the model with deep supervision due to its overwhelming computational costs. We use the large size OFA model and the threshold τ is chosen via cross-validation, *i.e.*, 0.96 for VQA and 0.1 for RefCOCO/RefCOCO+/RefCOCOg.

Results The accuracy and latency of the original OFA and DEED are shown in Table 3. The results of OFA are reproduced using the official code, which are very close to the reported numbers. Again DEED consistently reduces the decoder inference latency with marginal accuracy drops. Specifically, it achieves an average 36.2% and 44% decoder latency reduction on the VQA task and the referring expression comprehension task respectively. In addition, even without deep-supervision pre-training, DEED obtains comparable accuracy compared to the original OFA. The accuracy of DEED should be boosted if we do deep-supervision pre-training for OFA as well. These results demonstrate that our approach can be generalized to different encoder-decoder transformer models and various VL tasks.

4.3 DEED on T5

Experimental Setup Following (Bae et al., 2023), we evaluate DEED with the large size T5 model on various language tasks, specifically, SQuAD (Rajpurkar et al., 2016) for text question answering, CNN/DailyMail (See et al., 2017) and SamSum (Gliwa et al., 2019) for text summarization. We report the accuracy, the total inference latency, and the decoder-only latency and compare DEED to the baseline model and CALM (Schuster et al., 2022). For each dataset, the latency is averaged on samples from all splits. We pre-train T5 with deep supervision on 5M tokens from C4 (Raffel et al., 2020) first and follow the same fine-tuning procedure as in (Bae et al., 2023) to reproduce the T5 results and train DEED.

Results The accuracy and latency of the original T5, CALM (Schuster et al., 2022), and DEED are shown in Table 4. Similar to vision-language experiments, DEED reduces the decoder inference latency with comparable accuracy compared to the original T5 large model without early exit. Specifically, DEED achieves 74% overall latency reduction on the text question answering dataset SQuAD. These results confirm that our DEED approach can be generalized to other encoder-decoder models and more than vision-language tasks.

4.4 Ablation Study

We study the contribution of each component in DEED. All ablation studies are conducted on DocVQA with LaTr++ base variation. Also see Section B for more ablation studies on the confidence score threshold, the distribution of tokens exiting at each layer, and the number of parameters.

Model Architecture We inspect the effect of shared generation head (SH) and the adaptation module (AM) for multi-exit model. We compare the models of using SH only, using AM only, and using both (SH + AM), to the baseline trained with unshared generation heads without the adaptation module. We use $\mathcal{L}_{avg}$ in Eq. 1 for training and we do not do deep-supervision pre-training. Figure 4a shows results of different approaches. By using both the shared generation head and the adaptation module, the model achieves consistently better accuracy than the baseline, except for the 9-th layer. Notice that the improvement on the first layer is the greatest ($>$1%), which hugely contributes to the overall latency reduction as more examples can exit at layer 1 without sacrificing the accuracy. However, without the adaptation module, the shared generation head has inferior performance due to the mis-alignment between the generation head and the intermediate features for generation.

Training Objective In Figure 4b, we visualize the ANLS of models trained with the vallina deep supervision $\mathcal{L}_{avg}$ in Eq. 1, alternating training (AT) (Xin et al., 2021), and the additional final layer loss (FL) $\mathcal{L}_N$ in Eq. 2. We can see both AT and FL can improve the accuracy of the deep (> 8) layers, which helps DEED achieve the same or even better accuracy compared to the original model. FL gives better accuracy for most layers than AT, which confirms the effectiveness of our proposed training objective.

Pre-training In our experiments, we found that pre-training the model with deep supervision can significantly improve the accuracy of the shallow layers, as shown in Figure 4c. The magenta curve is the model pre-trained with the deep supervision while the brown curve is the one without. Pre-training with deep supervision increases the accuracy of the first layer by 3%. It also consistently increases the ANLS between layer 2 and layer 8. We argue that deep supervision during the pre-training stage helps the model learn strong generative ability in the shallow layers.

5 Conclusions

We propose DEED, a multi-exit model with step-level dynamic early exit on decoder for encoder-decoder transformer model acceleration. DEED leverages confidence-based step-level dynamic early exit to reduce the computation at each decoding step. To improve the accuracy when exiting at shallow layers, we build a multi-exit model leveraging multiple techniques including deep supervision, shared generation head, adaptation modules, and emphasizing the learning of the final decoder layer. We apply our approach to three state-of-the-art encoder-decoder transformer models. Results on various vision-language and language tasks show that our approach significantly reduces the inference latency with comparable or even higher accuracy compared to baselines. In the future, we will explore DEED for decoder-only models.

This is the appendix for the main DEED paper. Here we discuss the architecture and results of LaTr++, and the results of our reproduced OFA *vs*. the original OFA results.

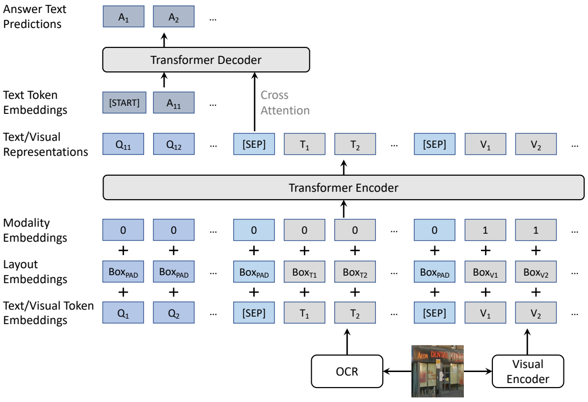

Figure 5: The architecture of LaTr++ for text-VQA.

A LaTr++

LaTr (Biten et al., 2022) obtains the state-of-the-art results on the text-based visual question answering (text-VQA) task. LaTr uses multi-modal encoder-decoder transformer models which takes OCR text, layout, and visual features as inputs. We improve LaTr by replacing the ViT-based vision backbone (Dosovitskiy et al., 2020) with simple multi-layer perceptrons and adding more unsupervised pre-training tasks, following DocFormerv2 (Appalaraju et al., 2024). We refer to the improved LaTr as LaTr++. See Figure 5 for the architecture of LaTr++ and more details below.

A.1 Architecture

In LaTr++, given an input image, we resize the image to size 500x384 and split the image into 196 patches with patch size 32x32. Instead of using ViT (Dosovitskiy et al., 2020), we simply use a linear projection layer to generate 196 visual token embeddings for each patch. We further use one more linear layer with the intention of compressing the extracted 196 visual tokens to only 128 visual tokens. These visual tokens are then concatenated with word embeddings, from here the architecture is identical to LaTr (Biten et al., 2022) and T5 (Raffel et al., 2020). Arguably our LaTr++ architecture is much more simpler than LaTr (Biten et al., 2022) as we do not have a pre-trained ViT as a dependency, hence our model has less number of parameters for equal model size compared to LaTr (Biten et al., 2022).

A.2 Pre-training

We use the IDL dataset[1] described in the main paper to pre-train the LaTr++ models. We use

Table 6: Accuracy comparisons between the original OFA and our reproduced OFA.

the standard T5 denoising pre-training task (Raffel et al., 2020) as in the original LaTr paper (Biten et al., 2022). In addition, to make the LaTr++ a more competitive baseline we add two more unsupervised pre-training tasks at the encoder: a) Line prediction task - in order to teach the model the relative position semantic information between text tokens, we randomly pick two text tokens and ask the model to predict how many lines are between them. There are only three labels: 0, 1 and 2. Any text token pairs that have more than 2 lines between them are assigned to 2 because distant text tokens are not related and the model does not need the precise number of lines between them. b) Token-to-grid task - To utilize global information the task involves creating a virtual 3x3 grid and asking the network to predict which grid each text token falls in. Losses of all three tasks, *i.e.*, standard denoising, line prediction, and token-to-grid, are added to form the final pre-training loss for LaTr++.

A.3 Settings

We evaluate on four text-VQA datasets: DocVQA (Mathew et al., 2021), OCR-VQA (Mishra et al., 2019), ST-VQA (Biten et al., 2019), and TextVQA (Singh et al., 2019). DocVQA is a VQA dataset dedicated to document text understanding, and OCR-VQA focuses on question-answering on book covers. ST-VQA and TextVQA contain natural images of everyday scenes with textual information and require the understanding of the text in the image to answer the question. Following (Biten et al., 2022), we use Amazon Textract[2] for DocVQA, Amazon Text-in-Image[3] for ST-VQA and TextVQA, and Rosetta (Borisyuk et al., 2018) for OCR-VQA, to extract text information from images.

A.4 Implementation Details

We pre-train our models on the Industrial Document Library (IDL) dataset[4], using the tasks described in Section A.2. We add deep-supervision loss of the T5 denoising task on all decoder layers for DEED, because we found it considerably improves the generative ability of shallow layers, as discussed in our main paper. We pre-train the base version with deep supervision on 5M IDL data for 30 epochs. For the large variation, to reduce the computational costs while achieving competitive performance, we firstly pre-train the model on 64M IDL data for 1.5 epochs without deep supervision, and then pre-train it on 64M IDL data with deep supervision using batch size 18 for 60k steps. The models are then fine-tuned on each dataset following the same settings as in (Powalski et al., 2021; Biten et al., 2022). We follow the convention of fine-tuning on the combination of ST-VQA and TextVQA training sets when evaluating on these two datasets (Biten et al., 2022). Label smoothing is used to calibrate the confidence scores (Müller et al., 2019). The confidence score threshold τ is selected using cross-validation, specifically, 0.99 on DocVQA and 0.95 for other three datasets.

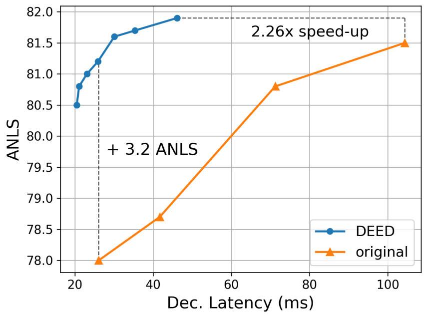

Figure 6: ANLS against decoder latency for DEED and the original model on the DocVQA validation set. DEED are obtained by tuning the confidence threshold τ . The original model is trained with different numbers of decoder layers.

A.5 Results

Here we compare LaTr++ to LaTr on three text-VQA datasets: ST-VQA (Biten et al., 2019), TextVQA (Singh et al., 2019), and OCR-VQA (Mishra et al., 2019). For ST-VQA and TextVQA, we train LaTr++ on the combination of ST-VQA and TextVQA training sets, following LaTr (Biten et al., 2022). For OCR-VQA, we train LaTr++ on the OCR-VQA training set only. All results are reported on the validation sets of these three datasets. As we can see in Table 5, LaTr++ obtains better results than state-of-the-art approach LaTr on the text-VQA task.

B More Ablation Studies

B.1 The Influence of the Confidence Score Threshold

DEED can realize different trade-offs between the accuracy and latency by tuning the confidence score threshold τ, to fit in different use cases without retraining the model. In Figure 6, we visualize the decoder latency and ANLS of DEED w.r.t. different thresholds ([0.5, 0.99]). We compare DEED to the original LaTr++ trained with 2, 4, 8, and 12 decoder layers. When using the threshold 0.99, our approach reaches the highest ANLS score of 81.9, which exceeds the vanilla 12-layer LaTr++, while achieving 2.26X decoder speed-up. At the other end of the spectrum, DEED can reduce the decoder latency to 25.9ms (4.03X speed-up *vs.* 12-layer LaTr++) with ANLS score of 81.2. In contrast, to reduce the latency to 26ms, the original model can only use 2 decoder layers, resulting in a significant 3.2 ANLS drop compared to DEED.

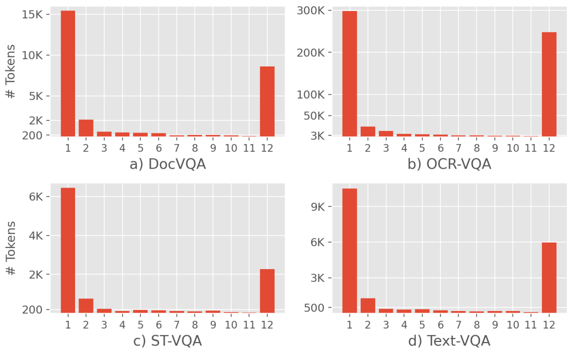

Figure 7: Histogram of layer at which our model exits when evaluated on the validation set of different VQA datasets.

	# Parameters		
	Baseline	Ours	Previous
LaTr++ (-b)	232M	239M	503M
LaTr++ (-L)	750M	774M	1507M

Table 7: # parameters of the baseline model (Baseline), our approach (Ours), and previous approaches (Previous).

B.2 The Distribution of Tokens Exiting at Each Layer

We visualize the distribution of tokens exit at each layer on four text-VQA datasets in Figure 7. The majority of the tokens exit at the first layer, then the last layer. Only a small amount of tokens exit at middle layers. This shows that the model exits at shallow layers for easy predictions, which aligns with our observation that most samples do not need all decoder layers during inference. In addition, from Figure 4 in the main paper, the second most samples are hard samples that can be correctly predicted by the final decoder layer or even the final decoder layer fails, so the second peak of the histogram appears at the final decoder layer (*i.e.*, decoder layer 12).

B.3 Analyses on the Number of Parameters

Compared to the previous multi-exit models, one advantage of our multi-exit model is fewer number of parameters. For LaTr++, the base version (-b) has 232M parameters with hidden size (d_{model}) 768, 12 encoder layers, and 12 decoder layers. The large version (-L) has 750M parameters with d_{model} 1024, 24 encoder layers, and 24 decoder layers. Each adaptation module consists of a linear layer ($d_{model} \times d_{model}$ parameters) followed by layer normalization (d_{model} parameters). There-

Table 8: Error cases of DEED vs. baseline (LaTr++) with base model size on DocVQA. The baseline outputs are the identical to the ground truth for these examples.

fore, each adaption module only has 0.6M parameters (-b) and 1.05M parameters (-L). The adaption modules from all layers only increase ∼3% of the full model parameters. In contrast, a generation head has 24.7M parameters (-b) and 32.9M parameters (-L) due to the output dimension (32128). Using unshared generation heads increases the total number of parameters by >100%. So our adaptation module has much fewer parameters than unshared generation heads in previous approaches. See Table 7 for more details.

C OFA Results

We use the original pre-trained OFA model and the same fine-tuning procedure as in (Wang et al., 2022) to reproduce the OFA results and train DEED, using the official code[5]. The only exception is RefCOCOg - we fine-tune our model on top of the RefCOCO fine-tuned model, because RefCOCOg has fewer training samples than RefCOCO and RefCOCO+, which makes the accuracy on RefCOCOg inferior if we fine-tune our model on RefCOCOg directly. Here we compare our reproduced OFA results and the original OFA results on VQAv2 (Goyal et al., 2017) for VQA and RefCOCO/RefCOCO+/RefCOCOg (Yu et al., 2016; Mao et al., 2016) for referring expression comprehension. As we can see, our reproduced results are close to the reported numbers.

D Qualitative Results

We provide some qualitative results of DEED on DocVQA to help understand the behavior of our method and its impact on the accuracy. Specifically, we list the error cases of DEED where the predictions of the baseline model are correct. The outputs from DEED and the baseline model are tabulated in Tab. 8. From the error cases, we observed a few

---

[5] `https://github.com/OFA-Sys/OFA`

patterns of the errors from DEED :

1. Missing words at the end of the prediction (e.g., `2193`, `45675`, `63045`, etc.).
2. Making errors on rare words like names (e.g., `51502`: `"forsyth"` → `"fors"`, `42105`: `"accumyn"` → `"accaccyn"`, etc.).
3. Repeating the same word (e.g., `22076`: `gerard jean` → `gerard jean jean ...`, etc.).

Attention Alignment and Flexible Positional Embeddings Improve Transformer Length Extrapolation

Abstract

An ideal length-extrapolatable Transformer language model can handle sequences longer than the training length without any fine-tuning. Such long-context utilization capability relies heavily on a flexible positional embedding design. Upon investigating the flexibility of existing large pre-trained Transformer language models, we find that the T5 family deserves a closer look, as its positional embeddings capture rich and flexible attention patterns. However, T5 suffers from the dispersed attention issue: the longer the input sequence, the flatter the attention distribution. To alleviate the issue, we propose two attention alignment strategies via temperature scaling. Our findings show improvement on the long-context utilization capability of T5 on language modeling, retrieval, multi-document question answering, and code completion tasks without any fine-tuning. This suggests that a flexible positional embedding design and attention alignment can go a long way toward Transformer length extrapolation. The code is released at: `https://github.com/chijames/T5-Attention-Alignment`

1 Introduction

Pre-training large Transformer language models on long sequences is inherently expensive due to self-attention's quadratic complexity w.r.t the input sequence length (Vaswani et al., 2017). Even with the help of memory-efficient attention (Rabe and Staats, 2021; Dao et al., 2022), the maximum supported input length of current open-source pre-trained Transformer language models are capped at 4,096 tokens (Touvron et al., 2023), limiting their efficacy in handling long-context tasks.

One notable research topic aiming to lift the input length restriction is *Length Extrapolation* (Press et al., 2022). Ideally, a length-extrapolatable Transformer language model is trained on short sequences and can perform equally well on longer ones without any further fine-tuning. This is made possible with carefully designed positional embeddings (Press et al., 2022; Chi et al., 2022, 2023). Unfortunately, existing approaches are tailored for natural language modeling, a task known to have strong recency bias, and they often do not perform well on other seemingly simple tasks such as passkey, topic, and line retrieval (Mohtashami and Jaggi, 2023; Li et al., 2023).

Criteria	Retrieval Tasks					
	Topic		Line		Passkey	
	512	15k	512	15k	512	15k
$P_{\max}$	0.28	0.12	0.27	0.11	0.32	0.24
H	3.47	6.63	3.47	7.04	3.09	5.97

Table 1: **The Dispersed Attention Issue of Flan-T5-XL Encoder.** $P_{\max}$ is the average maximum probability and H is the average entropy. After increasing the sequence length from 512 to 15k, we observe larger entropy and smaller maximum probability, implying a flatter self-attention distribution.

To circumvent the recency bias, we sift through the positional embeddings of existing open-source large pre-trained Transformer language models, shown in Table 2, to find a flexible design, and the T5 family (Raffel et al., 2020) comes to our attention. As visualized in Figure 1, the flexibility of T5's positional embeddings allows it to encourage recency bias on one head and discourage that on another head. However, there is no free lunch: T5 suffers from the dispersed attention issue as shown in Table 1. That is, the attention distributions of long input sequences tend to be flatter than those of short input sequences. As a remedy, we propose two fine-tuning-free attention alignment strategies via Softmax temperature scaling (Yao et al., 2021; Su, 2021) to mitigate the dispersed attention issue: maximum probability ($P_{\max}$) and entropy (H) alignment.

We validate the effectiveness of our alignment

strategies on tasks including language modeling, retrieval, multi-document question answering, and code completion. We also provide a theoretical analysis of how the alignment strategies work under the hood by investigating the relation between the Softmax temperature and data distribution.

2 Related Work

Transformer Positional Embeddings Transformer-based models rely on positional embeddings to encode positional information. We summarize open-source large pre-trained Transformer language models and their positional embeddings in Table 2. The relative variants are widely adopted due to their better empirical performance (Su et al., 2021) and possible length-extrapolation capability (Press et al., 2022). In this work, we place special focus on the T5 positional embeddings due to their flexibility as shown in Figure 1.

Transformer Length Extrapolation Existing research on Transformer length extrapolation is mostly confined to the task of natural language modeling (Press et al., 2022; Chi et al., 2022, 2023). Unfortunately, the reported positive results do not carry over to long-context retrieval (Mohtashami and Jaggi, 2023; Li et al., 2023). This contrastive observation can be explained by models' short empirical receptive field (Chi et al., 2023). In short, the strong decaying prior of positional embeddings prevents models from accessing distant tokens that may be necessary for retrieval tasks. In this work, we improve the flexible positional embeddings of T5 to get around this limitation.

Transformer Position Interpolation Instead of performing direct length extrapolation, a different line of research conducts model fine-tuning on long input sequences (Chen et al., 2023), where the main focus is to identify the most efficient fine-tuning scheme that can improve long-context utilization. Positive results have been reported on retrieval tasks (Li et al., 2023). However, we argue that fine-tuning incurs additional costs since it needs 1) GPU resources to perform long sequence fine-tuning with large models and 2) a pre-defined target sequence length, which still imposes a sequence length upper limit. Our proposed methods can circumvent these two limitations.

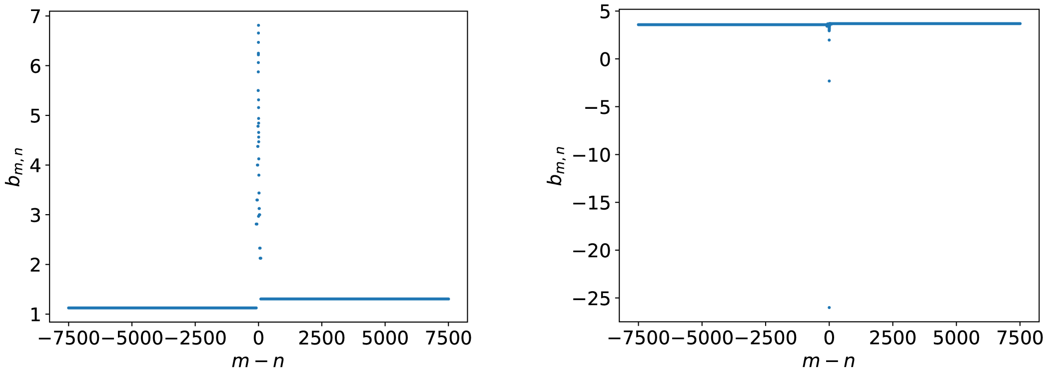
Retrieval Tasks with Transformers Transformer-based approaches often consist of a retriever and a reader to overcome the context length restriction (Guu et al., 2020; Lewis et al., 2020; Izacard and Grave, 2021; Borgeaud et al., 2022). The retriever retrieves relevant text snippets from a very large database and the reader digests the retrieved information to generate the correct output. Our proposed attention alignment strategy can be used to significantly increase the input sequence length of the reader, thereby allowing more retrieved information to participate in the decision process. For small-scale retrieval problems, our methods even obviate the need for context segmentation and the external key-value store used in prior work (Mohtashami and Jaggi, 2023), serving as a more elegant approach.

Softmax Temperature Scaling To increase the length extrapolation capability of Transformers, previous work (Yao et al., 2021; Su, 2021; Peng et al., 2023) scales the temperature of Softmax logarithmically w.r.t the sequence length. Our entropy alignment strategy is also inspired by this line of research except that we adopt a different procedure outlined below in Algorithm 1. Interestingly, our results in § 7 show that the logarithmic temperature scaling scheme is more similar to our proposed maximum probability alignment strategy.

3 Long-context Retrieval Tasks with T5

3.1 Why Retrieval?

As suggested by recent work (Mohtashami and Jaggi, 2023; Li et al., 2023), the task of long-context retrieval serves as a controllable benchmark to measure how well a Transformer language model utilizes long-context inputs. One prominent characteristic of retrieval tasks is that only a subset of the input is of interest, requiring a model to accu-



(a) 1^{st} Attention Head

(b) 27^{nd} Attention Head

Figure 1: **Visualization of T5 Positional Embeddings.** To plot figures of $b_{m,n}$, we set $m = 7500$ and vary the value of n from 0 to 15k. Each attention head of a Flan-T5-XL encoder learns a set of positional embeddings that capture different attention bias. For example, the positional embeddings in the left figure encourage the model to focus on nearby tokens. In contrast, the ones in the right figure let the model focus on only remote tokens.

rately pick up the necessary information. The other characteristic is that the key information can sit anywhere in an input, requiring a model to attend flexibly. Finally, the controllable aspect allows us to gradually increase the input sequence length to test the models' length extrapolation capability.

3.2 Why T5?

To solve retrieval tasks using Transformer language models, it is necessary to choose a positional embedding design that permits accurate and flexible length-extrapolatable attention. After checking through the existing positional embeddings in Table 2, we find that the T5 family (Raffel et al., 2020) fits our needs. As for other candidates, learnable absolute positional embeddings (Vaswani et al., 2017; Zhang et al., 2022) must be evaluated within the training length. ALiBi (Press et al., 2022) and Rotary (Su et al., 2021) have a recency bias; they cannot extrapolate easily without fine-tuning.

For each attention head, T5 encoder maintains a bucket (B) of 32 learnable parameters and assigns the relative positional bias (rpe bias) $b_{m,n}$ as[1]

$$b_{m,n} = \begin{cases} \mathrm{B}[m-n], \text{ if } 0 \leq m-n < 8 \\ \mathrm{B}[n-m+16], \text{ if } -8 < m-n < 0 \\ \mathrm{B}[\min(15, 8 + \lfloor \frac{\log((m-n)/8)}{\log(128/8)} \cdot 8 \rfloor)], \text{ if } 8 \leq m-n \\ \mathrm{B}[\min(31, 24 + \lfloor \frac{\log((n-m)/8)}{\log(128/8)} \cdot 8 \rfloor)], \text{ if } m-n \leq -8, \end{cases}$$

where $0 \leq m < L$ and $0 \leq n < L$ are two position indices. $b_{m,n}$ will be added to the (m,n)-th entry of the $L \times L$ self-attention matrix. The summation becomes the input to the temperature-scaled Softmax. We plot the learned rpe bias of a T5 encoder in Figure 1. We can tell that its attention heads encode rich attention patterns. For example, head 1 learns to focus on the nearby tokens whereas head 27 learns to ignore the nearby tokens and allow access to faraway tokens.

3.3 The Dispersed Attention Issue of T5 Encoder

Unfortunately, directly applying T5 models on retrieval tasks does not yield perfect results. Upon inspecting the intermediate model states, we find that a longer input sequence consists of more tokens competing for the same amount (i.e., Softmax sums to 1) of attention, resulting in the dispersed attention issue. In Table 1, we see that the longer the input sequence, the flatter the self-attention distribution. The situation is not hopeless if the desired information still attains a higher attention weight than the remaining tokens. Our proposed solution in § 4 will let the key information stand out.

4 Proposed Methods

A natural solution to the dispersed attention issue described in § 3 is to sharpen the self-attention distribution. This can be achieved by reducing the temperature τ during extrapolation. We set the extrapolation temperature τ_{ex} such that the sharpness during training with $\tau_{tr} = 1$ and that during extrapolation with $\tau_{ex} < 1$ are roughly the same. As a measurement of sharpness, we explore the maxi-

```

mum probability or entropy of a distribution. In other words, our proposed solution is to align the maximum probability or entropy of training and extrapolation distributions by adjusting τ_{ex}.

Concretely, let $l^{(i)} \in \mathbb{R}^L$ be the i-th pre-Softmax logit vector of a T5 encoder, where $L \in \{L_{tr}, L_{ex}\}$ is the sequence length. The post-Softmax distribution of $l^{(i)}$ is $\text{P}^{(i)}(\tau) = \text{Softmax}_\tau(l^{(i)})$. The maximum probability and entropy of $\text{P}^{(i)}(\tau)$ are $\text{P}^{(i)}_{\max}(\tau)$ and $\text{H}^{(i)}(\tau)$, respectively.

Take the maximum probability alignment strategy as an example: We first run the forward pass and compute the average maximum probability under temperature τ over all logit vectors: $\overline{\text{P}_{\max}}(\tau) = (1/N)\sum_i \text{P}^{(i)}_{\max}(\tau)$ where $N = R \times H \times L$ is the number of logit vectors in a T5 encoder with R layers, H heads, and length-L sequences. Since the temperature is 1 during training and τ_{ex} during extrapolation, we denote the average maximum probability during training as $\overline{\text{P}^{tr}_{\max}}(1)$ and that during extrapolation as $\overline{\text{P}^{ex}_{\max}}(\tau_{ex})$. Finally, to align the maximum probabilities, we adjust τ_{ex} s.t. $\overline{\text{P}^{ex}_{\max}}(\tau_{ex}) \approx \overline{\text{P}^{tr}_{\max}}(1)$. In practice, we do a grid search on τ_{ex} from 1.0 to 0.5. We outline the procedure of the alignment strategies in Algorithm 1.

Note that our proposed methods do not require any model fine-tuning or gradient computations. The only overhead is estimating the temperature τ_{ex} using Algorithm 1 and a few length L_{ex} sequences. Once the temperature is decided, it will be held fixed, rendering our methods simple and efficient. In addition, our fine-tuning free methods do not lead to performance regression on short L_{tr} sequences commonly observed on long-context fine-tuned models (Roziere et al., 2023).

5 Experiments

We compare the two alignment strategies against the length-only Softmax temperature scaling scheme $\tau = \log_{L_{ex}} L_{tr}$ (Yao et al., 2021; Su, 2021) and LongChat-13B-16K (Li et al., 2023). Note that LongChat-13B-16K (Li et al., 2023), the best baseline, was fine-tuned from LLaMA (Touvron et al., 2023) on long sequences of length 16k while our proposed methods do not need any fine-tuning. Our experiments are conducted on an A6000 GPU.

Table 3: **Language Modeling Performance.** We report the average perplexity of 500 sequences. The lower the better.

5.1 Language Modeling

We use the LM-Adapted T5 models[2] for this experiment. We set $L_{tr} = 512$. Following previous work on Transformer length extrapolation, we perform an intrinsic evaluation on language modeling (Press et al., 2022; Chi et al., 2022, 2023). Ideally, our proposed methods should alleviate the perplexity explosion problem during extrapolation. As we can see in Table 3, both alignment strategies dramatically improve (lower) the perplexity. We also observe that scaling the temperature solely based on sequence lengths is not the optimal strategy, as indicated by the sudden perplexity increase of the $\log_{L_{ex}} L_{tr}$ strategy. We will provide an in-depth

Table 4: **Performance of Retrieval Tasks.** Each number is the averaged accuracy computed over 100 sequences. The LongChat model corresponds to LongChat-13B-16K (Li et al., 2023). It is a LLaMA-13B (Touvron et al., 2023) model fine-tuned on sequences of length 16k using positional interpolation (Chen et al., 2023). Flan-T5-XXL has 11B parameters. The maximum sequence lengths (L_{ex}) of the three tasks are around 14.5k to 15.5k tokens.

discussion on this topic in § 7. Note that perplexity is not our primary focus since it often cannot accurately reflect the long-context utilization capability of Transformers on practical tasks (Li et al., 2023).

5.2 Long-context Retrieval

The tasks are formulated in the Question Answering (QA) format; therefore, we use the Flan-T5 models to leverage their instruction-following capability. We set $L_{tr} = 512$. Inspired by recently proposed retrieval tasks, we evaluate the proposed alignment strategies on three of these. Topic retrieval requires a model to retrieve the first topic in a long and multi-topic conversation (Li et al., 2023). Line retrieval has a long series of key-value pairs, and a model needs to retrieve the value corresponding to the given key (Li et al., 2023). Passkey retrieval hides a passkey in a long junk text snippet, and a model needs to return that passkey (Mohtashami and Jaggi, 2023).

As we can see in Table 4, the retrieval performance is greatly boosted after the Flan-T5 models are equipped with our proposed attention alignment strategies. In particular, the maximum probability alignment strategy provides better results across the board. Other baselines such as MPT (Team, 2023) and ChatGLM2 (Du et al., 2022) perform worse than LongChat. Please refer to Li et al. (2023) for more details. We also present the optimal temperature given by Algorithm 1 in Table 10 in Appendix A.5. In short, the temperature decreases when the input sequence length increases. We will provide additional temperature analysis below, in § 7.

5.3 Multi-document Question Answering

We again use the Flan-T5 models to leverage their instruction-following capability. We set $L_{tr} = 512$. We follow the multi-document question-answering task settings and data splits detailed in Liu et al. (2023). In short, the input consists of a question Q and multiple documents extracted from NaturalQuestions (Kwiatkowski et al., 2019) related to Q, where one of the documents (golden doc) contains the ground truth answer to Q. As shown in Table 5, when a model is equipped with the proposed maximum probability alignment strategy, it consistently outperforms the original model across model sizes and number of input documents.

Apart from the better task performance, we believe that the attention dispersed attention issue discussed in § 3 can help demystify the lost-in-the-middle phenomenon (Liu et al., 2023) of this task: Transformer models tend to perform worse when the ground truth sits near the middle of the input context. Let us recall the relative positional embedding of head 27 learned in Figure 1, if the ground truth answer sits in the middle, it will have long contexts from both sides competing for the attention weight. If this hypothesis is correct, we can

Table 5: **Performance of Multi-document QA.** Numbers are accuracy. Full score is 100. The maximum sequence length (L_{ex}) of 30 documents is around 5k. The improvement row represents the absolute accuracy improvement after a Flan-T5 model is equipped with our proposed maximum probability alignment strategy. For the full performance breakdown, please refer to Table 15 in Appendix A.7.

expect the performance boost to be more prominent when the answer appears near the middle. We reveal the performance breakdown when the number of input documents is 30. As we can see in the improvement row, those cases indeed achieve greater improvements.

Our strategies are not always perfect: The performance drops if the ground truth answer is at position 29. We believe T5 might have already handled this case pretty well due to the recency bias learned on some attention heads, and our additional temperature scaling sharpens the distribution too aggressively. We acknowledge this trade-off in § 9.

5.4 Code Key Retrieval and Completion

To test the generalizability of the alignment strategies, we apply our methods to the CodeT5+ model (Wang et al., 2023)[3] that was pre-trained on code data with 770M parameters. We set $L_{tr} = 768$. We do not experiment with larger CodeT5+ models since they do not follow the T5 architecture, but use other positional embeddings. We conduct two experiments on the LCC dataset (Guo et al., 2023), which is highly similar to the classic PY150 dataset (Raychev et al., 2016) except that the input context length is much longer.

For the code key retrieval experiment, we sample several code files from LCC along with a special function that only returns an integer from 1 to 100. We concatenate them and ask a model to generate the returned integer at the end (Roziere et al., 2023). Considering that this is essentially a passkey retrieval task in the code domain, we briefly report the average accuracy of 100 test cases when the input sequence length is around 16k: 0 (Original CodeT5+), **87** (w/ $\mathrm{P}_{\max}$), 80 (w/ H), and 85 (w/ $\log_{L_{ex}} L_{tr}$). We can see that the maximum probability alignment strategy performs the best.

For the code completion experiment, a model needs to generate the next line of code given some prior code as the context. The metrics are Exact Match (EM) and Edit similarity (ES) on a per line basis (Svyatkovskiy et al., 2020). We report the results in Table 6 using the context length bucketing format. While both alignment strategies improve the performance substantially, $\mathrm{P}_{\max}$ is better; however, its EM performance lags behind $\log_{L_{ex}} L_{tr}$ when the sequence length increases. We additionally include an extrapolation-free baseline, *truncation*, that truncates the long input context to the most recent $L_{tr} = 768$ tokens. Both $\mathrm{P}_{\max}$ and $\log_{L_{ex}} L_{tr}$ perform better than this baseline when $L_{ex} < 6000$, indicating that they can indeed benefit from longer ($6000/768 = 7.8$x) contexts without any fine-tuning.

Table 6: **Code Completion Performance.** Full score is 100. We set $L_{tr} = 768$. The bucket nk contains the data with length in [nk, (n+1)k), $n \in [1, 6]$. For example, the bucket 3k contains data with length in [3000, 4000). See Table 13 and 14 in Appendix A.6 for the full performance breakdown of L_{ex} up to 16k tokens.

5.5 Overall Observations

First, the maximum probability alignment strategy is the most reliable and best-performing method across most tasks and settings, echoing our discussion in § 3.1: For most data, only a subset of the input is useful for a model process at a time. The maximum probability alignment strategy captures this characteristic naturally, thereby outperforming the entropy alignment strategy that cares more about the holistic distribution.

Second, deciding the optimal temperature solely based on sequence lengths, e.g. $\tau = \log_{L_{ex}} L_{tr}$, is not robust enough. For example, the perplexity of $\log_{L_{ex}} L_{tr}$ suddenly increases (worse) on T5-XXL-LM, in Table 3, while the other strategies maintain stable results. As another example, it fails to improve the retrieval performance on the Flan-T5-Large model, shown in Table 4.

5.6 Application to Other Models

We also tried applying our proposed method to models using Rotary positional embeddings. However, we are not able to achieve the same length-extrapolatable performance without fine-tuning. Two immediate questions follow:

Why is fine-tuning needed when we apply our method to Rotary-based models? Because Rotary still suffers from the recency bias issue as we discussed in § 3.2, while T5 does not. To the best of our knowledge, such recency bias can only be overcome via long sequence fine-tuning. Take a concurrent work that focuses on models equipped with Rotary, YaRN (Peng et al., 2023), as an example: If we omit its fine-tuning step, its performance on the passkey retrieval task drops substantially as shown in Table 7.

How costly is the long sequence fine-tuning step? Let us take a look at the numbers reported by the authors of YaRN[4]: "Our run was around 300s/epoch on an 8x A100 node as well. Took about 24 hours to train for 400 steps." Using AWS, the fine-tuning expenses will be 32.77*24=786.48 USD.[5] In contrast, finding the optimal softmax scaling temperature of the longest inference sequence of a task using our method with a T5 model only takes 20 seconds on an A6000 GPU.

6 Theoretical Analysis

6.1 Assumptions

To shed more light on the underlying mechanisms of the two alignment strategies, we establish the connection between the softmax temperature τ and data distribution under empirically verified assumptions. We focus on the 0-th layer (closest to the input embeddings) and take the average over all logit vectors across attention heads. Note that this is just a crude approximation of Algorithm 1 for analysis purposes since 1) a Transformer language model typically encompasses multiple layers, and 2) in Algorithm 1, we take the maximum probability or entropy of individual logit vectors as opposed to the average one.

Assumption 1. *The length L average logit vector is normally distributed, i.e., its entry $l_i \sim N(0, \sigma^2)$.*

To compute the *average logit vector*, we start with a input sequence of length L. Using a Transformer model with H attention heads (specifically, a T5 Encoder in our context), we generate $H \times L$ pre-softmax logit vectors, each with a length of L. Here, the number of layers is 1 because we focus on the 0-th layer. These logit vectors are then individually sorted, and we subsequently calculate the

[5] 32.77 is the on-demand price per hour of a p4d.24xlarge instance.

Model	Sequence Length				
	512	1024	2048	4096	8192
YaRN w/ fine-tuning	100	100	100	100	95
YaRN w/o fine-tuning	85	85	75	50	30
Ours Flan-T5-XL w/o fine-tuning	100	99	100	100	100

Table 7: **The Effect of Fine-tuning for Passkey Retrieval.** Numbers are accuracy. Full score is 100. The flexibility of T5 allows our method to extrapolate well on long sequences without any fine-tuning. In contrast, YaRN (Peng et al., 2023) requires a costly fine-tuning step on long sequences to regain performance.

average of all $H \times L$ sorted logit vectors, resulting in the average logit vector of length L.

To assess whether the average logit entries follow a Gaussian distribution, we make use of QQ plots, as illustrated in Figure 2. The linearity of the plot serves as an indicator – the closer the points are to the identity line, the more Gaussian the distribution.

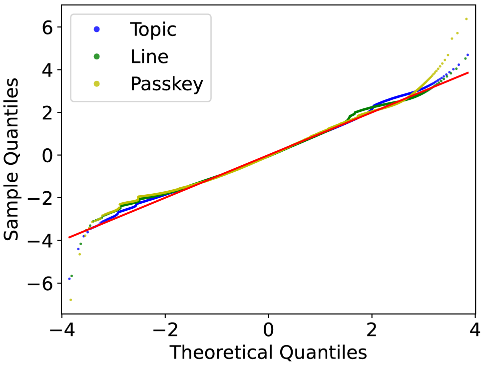

Figure 2: **QQ plots of Flan-T5-XL.** We experiment with short and long sequences. The red reference line is y=x. We use sequences of length around 512 for this plot. The plot for sequences of length around 15k looks highly similar. Please refer to Appendix A.1 for details.

Assumption 2. *The largest logit entry of the average logit vector during training and extrapolation is the same:* $l^{ex}_{\max} = l^{tr}_{\max}$. *See Table 8.*

Criteria	Retrieval Tasks					
	Topic		Line		Passkey	
	512	15k	512	15k	512	15k
$l_{\max}$	8.61	8.80	8.71	8.97	8.75	8.85

Table 8: **Largest Logit Entry of Flan-T5-XL.** $l_{\max}$ is the largest logit entry of the average logit vector.

6.2 Maximum Probability Alignment

Proposition 1. *Under Assumption 1 and 2, we can adjust the temperature* τ *to align the maximum probability* $\mathrm{P}^{tr}_{\max} = \mathrm{P}^{ex}_{\max}$

$$\tau \approx \frac{\log L_{tr} + \log \mathrm{P}^{tr}_{\max} + \sigma^2_{tr}/2}{\log L_{ex} + \log \mathrm{P}^{tr}_{\max} + \sigma^2_{ex}/(2\tau^2)}.$$
$$= \frac{B}{A + \frac{C}{\tau^2}} = \frac{B\tau^2}{A\tau^2 + C}.$$

Assuming $\tau \neq 0$, *we solve the quadratic equation* $A\tau^2 - B\tau + C = 0$ *to get* τ. *We pick the larger root as our final solution. See proof in Appendix A.2.*

6.3 Entropy Alignment

Proposition 2. *Under Assumption 1, we can adjust the temperature* τ *to align the entropy* $H_{tr} = H_{ex}$

$$\tau \approx \frac{\sigma_{ex}}{\sqrt{\sigma^2_{tr} + 2\log\frac{L_{ex}}{L_{tr}}}}$$

See proof in Appendix A.3.

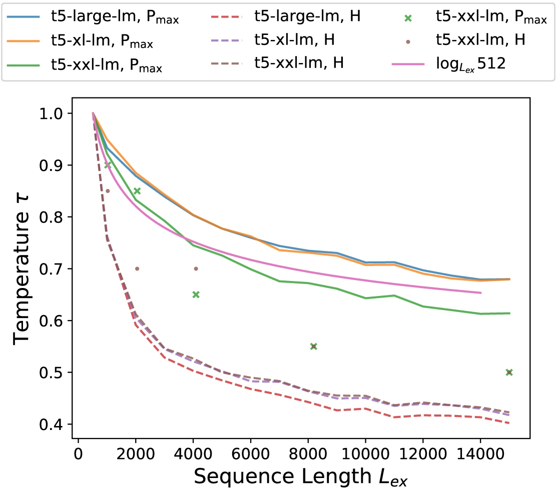

Figure 3: **Language Modeling Temperature Analysis.** Curves are from Proposition 1 & 2. Dots and crosses are from Algorithm 1.

7 Discussion

The goal of this section is to explain the observations made in § 5 via the lens of temperature

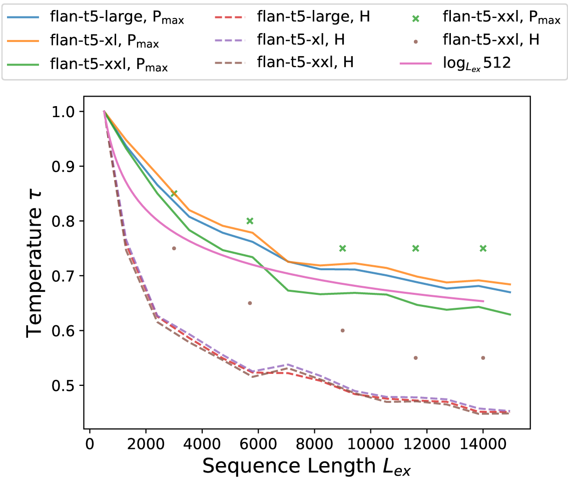

Figure 4: **Topic Retrieval Temperature Analysis.** Curves are from Proposition 1 & 2. Dots and crosses are from Algorithm 1.

analysis. We visualize Proposition 1 and 2 by plotting the temperature curves in Figure 3 and 4. We evaluate $P^{tr}_{\max}$ and σ_{tr} at the training length and σ_{ex} at every extrapolation length considering only the 0-th layer. You may find the temperature curves for the other tasks in Appendix A.4.

First, while both proposed strategies lower the temperature when the input sequence length increases, the entropy alignment strategy does so more aggressively, possibly leading to its inferior performance observed in Table 4 and 5 (w/ H). This can be seen by comparing the curves from Propositions 1 and 2 or dots from Algorithm 1.

Second, deciding the optimal temperature based on sequence lengths, e.g. $\tau = \log_{L_{ex}} L_{tr}$, is not the most robust method. It gives too high of a temperature in Figure 3 compared to Algorithm 1. In other words, it does not sharpen the distribution enough, possibly explaining its perplexity spike in Table 3. On the other hand, it overly lowers the temperature in Figure 4, thereby failing to improve the retrieval performance on Flan-T5-Large in Table 4.

8 Conclusion

In this paper, we show that the T5 model family has great potential when it comes to Transformer length extrapolation. We propose the maximum probability and entropy alignment strategies to fix T5's dispersed attention issue without model fine-tuning. We conduct experiments on natural language modeling, retrieval, multi-document question answering, and code completion tasks to demonstrate the effectiveness of our proposed methods. Finally, we present a simplified theoretical analysis to elucidate how the temperature is scaled to achieve attention alignment. We hope that our work can inspire future length-extrapolatable Transformer designs.

9 Limitations

We base our theoretical analysis on a simplified Transformer language model, which might be further improved by taking all the layers and their interactions into account. In addition, we find that different layers have different degrees of distribution flatness, which could be leveraged in future work to perform per-layer fine-grained attention alignment. Finally, our temperature scaling scheme sometimes sharpens a distribution too aggressively in the multi-document question-answering and code completion experiments. This drawback could be possibly improved by designing a more fine-grained attention alignment strategy.

10 Ethics Statement

Our work improves the amount of context a Transformer language model can process. Inappropriate usage of the proposed technique might lead to negative societal impacts including the potential loss due to wrong predictions and ethical challenges on the improper use of the model. However, these implications apply to most language model research and are not unique to this specific work.

A Appendix

A.1 QQ Plots for Assumption 1

A QQ plot (Wilk and Gnanadesikan, 1968) is a graphical technique used for comparing two probability distributions by plotting their quantiles against each other. A point (x, y) corresponds to a quantile from the second distribution (y-coordinate) plotted against the same quantile from the first distribution (x-coordinate). When the two distributions under comparison are similar, the points in the QQ plot will roughly align with the identity line, y = x. In our case, where we aim to determine the degree of Gaussian behavior in the average logit vector, the linearity of the plot serves as an indicator – the closer the points are to the identity line, the more Gaussian the distribution.

We present the QQ plots for two lengths, 512 and 15k, on the three retrieval tasks in Figure 5. They are all close to the red reference line, indicating that their form is highly Gaussian.

A.2 Detailed Derivation of Proposition 1

Let $l_{\max}$ be the largest value in the logit vector l. Let τ be the temperature of the Softmax function. The probability of the largest entry is

$$\mathrm{P}_{\max} = \frac{e^{l_{\max}/\tau}}{\sum_{i=1}^{L} e^{l_i/\tau}}.$$

Since Softmax is shift-invariant, the logit vector can always be made zero-mean: $\sum_i l_i = 0$. Next, according to Assumption 1, the denominator of Softmax can be approximated as

$$\sum_{i=1}^{L} e^{l_i/\tau} \approx L \cdot \mathbb{E}[e^{l_i/\tau}] = L \cdot e^{\sigma^2/(2\tau^2)} \tag{1}$$

This implies $\mathrm{P}_{\max}$ is approximately

$$\mathrm{P}_{\max} \approx \frac{e^{l_{\max}/\tau}}{L e^{\sigma^2/(2\tau^2)}}$$

During the training stage, the temperature τ is 1

$$\mathrm{P}^{tr}_{\max} \approx \frac{e^{l^{tr}_{\max}}}{L_{tr} e^{\sigma^2_{tr}/2}},$$

which gives an expression of the largest logit entry during the training stage

$$l^{tr}_{\max} \approx \log\left(\mathrm{P}^{tr}_{\max} L_{tr} e^{\sigma^2_{tr}/2}\right) \tag{2}$$

According to Assumption 2, the largest probability during the extrapolation stage can be simplified as

$$\begin{aligned}\mathrm{P}^{ex}_{\max} &\approx \frac{e^{l^{ex}_{\max}/\tau}}{L_{ex} e^{\sigma^2_{ex}/(2\tau^2)}} \overset{\text{A. }2}{=} \frac{e^{l^{tr}_{\max}/\tau}}{L_{ex} e^{\sigma^2_{ex}/(2\tau^2)}} \\ &\overset{(2)}{\approx} \frac{\left(\mathrm{P}^{tr}_{\max} L_{tr} e^{\sigma^2_{tr}/2}\right)^{1/\tau}}{L_{ex} e^{\sigma^2_{ex}/(2\tau^2)}}\end{aligned}$$

Since τ is a free parameter during extrapolation, we adjust it to carry out the maximum probability alignment strategy. Rearranging the terms gives Proposition 1.

A.3 Detailed Derivation of Proposition 2

The entropy of a discrete probability computed by Softmax is

$$H = -\sum_i \frac{e^{l_i/\tau}}{D} \log \frac{e^{l_i/\tau}}{D} = \log D - \frac{\sum_i \frac{l_i}{\tau} e^{l_i/\tau}}{D},$$

where $D = \sum_i e^{l_i/\tau}$ is the denominator of Softmax, which can be approximated using Eq. (1). On the other hand, we note that $\sum_i l_i e^{l_i} \approx L\mathbb{E}[le^l]$. When $l \sim N(0, \sigma^2)$, $\mathbb{E}[le^l]$ is approximated as

$$\begin{aligned}\mathbb{E}[le^l] &= \int_{-\infty}^{\infty} \frac{le^l}{\sigma\sqrt{2\pi}} e^{-\frac{l^2}{2\sigma^2}} dl \\ &= \int_{-\infty}^{\infty} \frac{l}{\sigma\sqrt{2\pi}} e^{\frac{2\sigma^2 l - l^2}{2\sigma^2}} dl \\ &= \int_{-\infty}^{\infty} \frac{l}{\sigma\sqrt{2\pi}} e^{-\frac{(l-\sigma^2)^2 - \sigma^4}{2\sigma^2}} dl \\ &= e^{\sigma^2/2} \int_{-\infty}^{\infty} \frac{l}{\sigma\sqrt{2\pi}} e^{-\frac{(l-\sigma^2)^2}{2\sigma^2}} dl \\ &= e^{\sigma^2/2}\sigma^2\end{aligned} \tag{3}$$

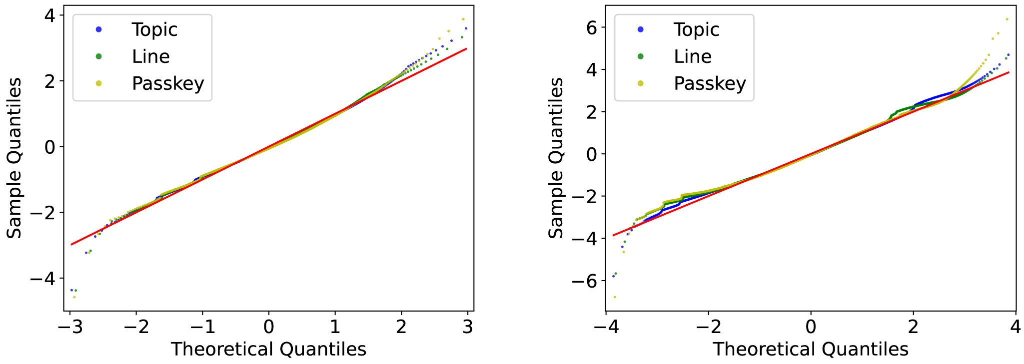
Thus, combining Eq. (1) and (3), the entropy H is approximated as

$$\begin{aligned}H &\approx \log L + \frac{\sigma^2}{2\tau^2} - \frac{L e^{\sigma^2/(2\tau^2)} \frac{\sigma^2}{\tau^2}}{L e^{\sigma^2/(2\tau^2)}} \\ &= \log L - \frac{\sigma^2}{2\tau^2}\end{aligned}$$

Since τ is set to 1 during the training stage, we have $H_{tr} \approx \log L_{tr} - \frac{\sigma^2_{tr}}{2}$. During extrapolation, we align the entropy (i.e., $H_{ex} = H_{tr}$) by adjusting τ.

$$\log L_{ex} - \frac{\sigma^2_{ex}}{2\tau^2} \approx H_{ex} = H_{tr} \approx \log L_{tr} - \frac{\sigma^2_{tr}}{2}.$$

Since τ is a free parameter during extrapolation, we adjust it to apply the entropy alignment strategy. Rearranging the terms gives Proposition 2.



(a) Short sequences around 512

(b) Long sequences around 15k

Figure 5: **QQ plots of Flan-T5-XL.** We experiment with short and long sequences. The red reference line is y=x. The more closely the scatter plots follow the red reference line, the more Gaussian they are.

A.4 More Real-world Temperature Plots

We verify Proposition 1 and 2 on the remaining tasks by plotting the temperature curves in Figure 6, 7, 8, and 9. We empirically evaluate σ_{tr} at the training length and σ_{ex} every extrapolation length considering only the 0-th layer.

The real temperatures given by Algorithm 1 are usually higher than those derived from the two propositions. After checking the per-layer attention distributions, we find that the 0-th layer has flatter distributions compared to higher layers. Because the two propositions are derived based on the 0-th layer and a flatter distribution needs a lower temperature to correct, the temperatures given by them tend to be lower than the ones given by Algorithm 1 that takes the average of temperatures across all layers.

A.5 Detailed Temperature Breakdown

We report the temperatures for all tasks across model sizes given by Algorithm 1 in Table 9, 10, 11, and 12.

A.6 Performance Breakdown of Code Completion

We report the performance breakdown of Exact Match and Edit Similarity across lengths in Table 13 and 14.

A.7 Performance Breakdown of Multi-document Question Answering

We report the performance breakdown of different numbers of input documents in Table 15.

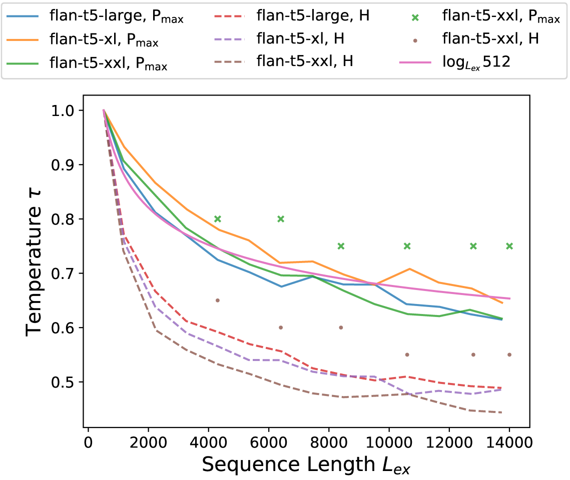


Figure 6: **Line Retrieval Temperature Analysis.** Curves are given by Proposition 1 and 2. Cross signs and dots are given by Algorithm 1. $\log_L 512$ is given by Yao et al. (2021); Su (2021).

B Scientific Artifacts

The pretrained models we used belong to the T5 model family, which is released under the Apache 2.0 license. The models are used in this work for research purposes only. For the data used to train T5 models, please refer to Raffel et al. (2020); Lester et al. (2021); Chung et al. (2022) for details. Except for the LCC Python data, other task data is written in English. We already report the number of data instances in § 5 for the language modeling and retrieval tasks. As for the multi-doc QA and code related tasks, we follow the original data splits.

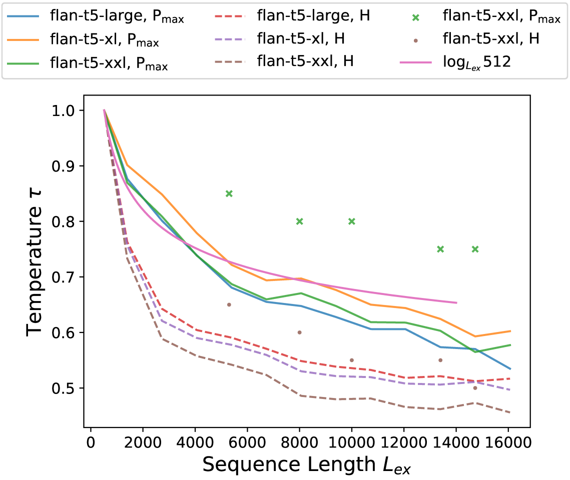

Figure 7: **Passkey Retrieval Temperature Analysis.** Curves are given by Proposition 1 and 2. Cross signs and dots are given by Algorithm 1. $\log_L 512$ is given by Yao et al. (2021); Su (2021).

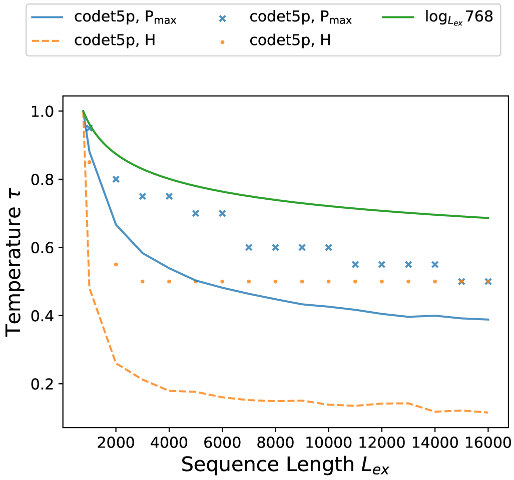

Figure 9: **Code Completion Temperature Analysis.** Curves are given by Proposition 1 and 2. Cross signs and dots are given by Algorithm 1. $\log_L 768$ is given by Yao et al. (2021); Su (2021).

Abstract

Alignment serves as an important step to steer large language models (LLMs) towards human preferences. In this paper, we propose an automatic way to construct contrastive data for LLM, using preference pairs from multiple models of varying strengths (e.g., InstructGPT, ChatGPT and GPT-4). We compare the contrastive techniques of SLiC and DPO to SFT baselines and find that DPO provides a step-function improvement even after continuing SFT saturates. We also explore a data curriculum learning scheme for contrastive post-training, which starts by learning from "easier" pairs and transitioning to "harder" ones, which further improves alignment. Finally, we scale up our experiments to train with more data and larger models like Orca. Remarkably, our automatic contrastive post-training further improves the performance of Orca, already a state-of-the-art instruction learning model tuned with GPT-4 outputs, to outperform ChatGPT.

1 Introduction

The rapid evolution of Large Language Models (LLMs) has ushered in a new era of natural language processing capabilities. These models, when scaled to billions of parameters and pretrained over trillions of text tokens, demonstrate unprecedented proficiency in a wide array of tasks (Brown et al., 2020; Chowdhery et al., 2022). Various *post-training* procedures like supervised instruction tuning and Reinforcement Learning from Human Feedback (RLHF) fine-tune pretrained LLMs to better align with human expectations and preferences (Ouyang et al., 2022; OpenAI, 2023; Touvron et al., 2023a). This additional alignment procedure is crucial, because the pretraining objective of essentially predicting the next token in a text sequence is known to produce LLMs whose outputs are at times incorrect, irrelevant, or unsafe (Bai et al., 2022a).

Traditionally, these post-training techniques rely on human preference annotations to inform an LLM of which behaviors it ought to adopt in the scenario at hand. For instance, RLHF fits a reward model on these preference pairs, against which an LLM policy is then optimized (Ziegler et al., 2019; Bai et al., 2022a; Touvron et al., 2023b). However, such human feedback is expensive to obtain and often noisy (Stiennon et al., 2020; Ouyang et al., 2022; Bai et al., 2022a).

To align an LLM without human feedback, other methods such as Reinforcement Learning from AI Feedback (RLAIF) harvest preference signals via automatic feedback from another LLM (Lee et al., 2023; Bai et al., 2022b). However, studies have found AI feedback has a low agreement rate with humans (Perez et al., 2022; Casper et al., 2023b; Lee et al., 2021). Also, these methods suffer from the same drawbacks as RLHF, such as reward hacking (Skalse et al., 2022).

Recently, certain *contrastive post-training* techniques such as Sequence Likelihood Calibration (SLiC) and Direct Preference Optimization (DPO) offer appealing alternatives to RLHF (Zhao et al., 2023b,a). DPO is proven to optimize the same objective as RLHF, but instead of optimizing against a reward model, it works by increasing the LLM's relative probability of generating the preferred output over the unfavorable one — making it much simpler to implement (Rafailov et al., 2023). The difference between the post-training methods is illustrated in Figure 1.

In this work, we study the intersection of *contrastive post-training* and RLAIF: one can employ LLMs to automatically generate preference pairs which can then be optimized directly via contrastive objectives like DPO. However, without feedback from human annotations, LLM-feedback, or a reward model to distinguish them, the key question becomes how to automatically construct pairs that 1) contain meaningful directional signal on a

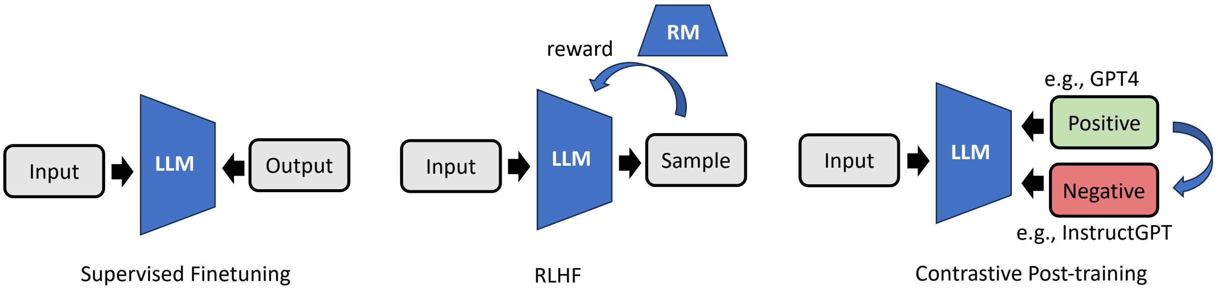

Figure 1: Difference betwen SFT, RLHF, and contrastive post-training. For SFT, the model optimizes the negative log-likelihood for the next token. RLHF samples an output from the LLM and use a reward model to provide feedback for PPO to update the LLM. For contrastive post-training, a contrastive loss is used to steer the model towards preferred outputs.

Model	vs.	Win Rate
GPT-4	InstructGPT	95.3%
GPT-4	ChatGPT	83.5%
ChatGPT	InstructGPT	89.4%

Table 1: The win rates of GPT models against each other on the official Alpaca Eval leaderboard motivate our automatic pair construction.

per-example basis; and 2) in aggregate adhere to the values and principles that humans expect.

This paper explores a simple yet effective answer to this question: contrast outputs from LLMs of varying sizes and capabilities, as motivated in Table 1. We automatically construct training pairs of responses generated from InstructGPT (Ouyang et al., 2022), ChatGPT, and GPT-4 (OpenAI, 2023) as demonstrations of desirable and undesirable behaviors. We believe this choice provides a solid foundation to better understand the efficacy of various contrastive training techniques when it comes to "bridging the gap" between stronger and weaker models. On a more general level, we wish to apply our findings to improve model distillation (Hinton et al., 2015), i.e., preserve the quality of larger, more capable models in a smaller target model which is cheaper and faster to deploy at scale, as explored in many recent works (Chiang et al., 2023; Xu et al., 2023b; Geng et al., 2023).

We show through carefully crafted experiments that contrastive post-training techniques maintain a step-function advantage over continuous supervised fine-tuning, which holds even at larger scales of models and training examples. For example, a key result of our study is that enhancing Orca (Mukherjee et al., 2023) — already a state-of-the-art instruction learning model — with DPO over pairs of GPT4-vs-InstructGPT is more beneficial than additional supervised fine-tuning on only the GPT-4 outputs, all else being equal. In fact, the contrastive fine-tuning of Orca is preferred 55%-45% against ChatGPT in head-to-head comparison on the Alpaca Eval benchmark.

Additionally, we structure how and when the model is exposed to various types of pairs in the style of curriculum learning (Bengio et al., 2009; Soviany et al., 2022). We discover that reordering the training data to start from "easy pairs" and warm up to "harder pairs" leads to considerable performance improvements.

2 Related Works

Improving downstream performance of Large Language Models (LLMs) and aligning them with user preference and designed intents are important to deployment and applications. This can be achieved by fine-tuning these models on responses written by humans or generated with human-written labels and templates. Previous works have applied supervised fine-tuning (SFT) on both instruction data (Sanh et al., 2022; Wei et al., 2022; Chung et al., 2022; Taori et al., 2023; Peng et al., 2023) and dialogue data (Chiang et al., 2023; Xu et al., 2023b; Geng et al., 2023). Although SFT can successfully adapt an LLM to instruction learning or chatting, the model can be further improved by post-training (Ouyang et al., 2022) to meet human preference. A straightforward solution to optimize the human preference is to use reinforcement learning. Reinforcement Learning with Human Feedback (RLHF, Ziegler et al., 2019) first trains a Bradley-Terry reward model (Bradley and Terry, 1952) on human-labeled preference pairs. Then, it samples output from the model and scores the output with the reward model. A reinforcement learning algorithm, such as Proximal Policy Optimization (PPO, Schulman et al., 2017) is used to optimize the language model for better rewards. RLHF has seen successful applications in downstream tasks (Kreutzer et al., 2018; Stiennon et al., 2020). However, RLHF methods are infamous for their instability, inefficiency, reward misgeneralization and hacking (Casper et al., 2023a; Skalse et al., 2022).

Recently, there are studies proposing methods for post-training without reinforcement learning. These methods optimize human preference with human-labeled contrastive pairs. Besides RLHF, DPO and SLiC, FeedMe (OpenAI, 2022) samples model output multiple times and fine-tunes on the best response picked by human labelers. Rank responses to align human feedback (RRHF, Yuan et al., 2023) adds a ranking loss to the SFT loss. The ranking loss promotes responses based on preference ranked by humans or a reward model.

Human preference is expensive to collect thus difficult to scale up. Recently, there have been attempts to automate post-training by replacing the human preference data with model-generated feedback. Self-distillation with feedback (SDF, Xu et al., 2023b) samples multiple outputs from the model and prompts ChatGPT to pick the best response for fine-tuning the model. RL from AI Feedback (RLAIF, Lee et al., 2023) uses an off-the-shelf LLM to replace human labels in the standard RLHF. Following that, reinforcement learning from contrast distillation (RLCD, Yang et al., 2023) constructs model-generated contrastive pairs by prompting an off-the-shelf LLM to act differently on certain properties, e.g., harmlessness and helpfulness. Different from these works, our approach is an offline algorithm, which does not require time-consuming sampling during training. Our approach does not require training a reward model and can be easily scaled up.

3 Preliminaries

Reinforcement Learning from Human Feedback (RLHF) To optimize the human preference with reinforcement learning, we need to first train a reward model $r_\tau(x, y)$ that outputs a reward for a given prompt x and the LLM output y. When training the target model, RLHF (Ziegler et al., 2019) uses a reinforcement learning algorithm (usually PPO, Schulman et al., 2017) to optimize the reward of a sampled output y from the target model P_θ. To regularize the optmization and prevent model degeneration, a KL penalty term between the sequences of distributions over tokens of the target model and a reference model (e.g., SFT model) is added to the reward (Korbak et al., 2022). This prevents the RL policy from deviating substantially away from the reference model, which often leads to incoherent text output (Ziegler et al., 2019).

Sequence Likelihood Calibration (SLiC) In contrast to RLHF, SLiC can exploit pairwise human feedback data and train offline (i.e., without sampling from the target model each time). SLiC takes a positive example y^+, a negative example y^- and a reference output y_{ref} from the SFT model. In essence, SLiC encourages the target LM to output sequences those resemble the positive sequence and penalizes those that resemble the negative sequence, while using the reference sequence from the SFT model for regularization. The loss function for SLiC is:

$$\begin{aligned}\mathcal{L}_{\text{SLiC}}(\theta) = \max(0, \delta - \log P_\theta(y^+|x) + \\ \log P_\theta(y^-|x)) - \lambda \log P_\theta(y_{ref}|x)\end{aligned} \quad (1)$$

where δ and λ are two hyperparameters, controlling the margin for the ranking loss and regularization weight. SLiC is memory-efficient, as both its positive-negative pairs and reference sequences are offline.

Direct Preference Optimization (DPO) Similar to SLiC, DPO is an offline preference optimization method. DPO takes a pair of (pre-computed) positive and negative examples and optimizes the difference between the target model and the reference model (i.e., SFT model), which increases the likelihood of the positive example and decreases the likelihood of the negative example. The loss function of DPO is shown below:

$$\begin{aligned} r^+(\theta) &= \beta(\log P_\theta(y^+|x) - \log P_{ref}(y^+|x)) \\ r^-(\theta) &= \beta(\log P_\theta(y^-|x) - \log P_{ref}(y^-|x)) \\ \mathcal{L}_{\text{DPO}}(\theta) &= -\log \text{sigmoid}(r^+(\theta) - r^-(\theta)) \end{aligned} \quad (2)$$

where β is a temperature hyperparameter; r^+ and r^- are the two pseudo-rewards that resemble the reward function in RLHF. Despite DPO having a similar form, there are key differences between SLiC and DPO: at train time, SLiC requires only the sampled outputs from a reference model, while

DPO requires the logits from that (frozen) reference model for both the positive and negative sequence. Rafailov et al. (2023) also conduct a theoretical analysis of DPO and prove that optimizing the DPO loss is identical to the RLHF loss.

4 Contrastive Post-training over Pairwise Data Curriculum

Contrastive Post-training Contrastive post-training involves the construction of positive y^+ and negative y^- sequences in response to the same input x. Under the traditional settings of human-feedback, it is often the case that for some $(y_1, y_2) \sim P(x)$ sampled from the *same* LLM, human annotators provide a preference as to which is the positive. As this process is expensive, to reduce costs, recent studies (Xu et al., 2023b; Lee et al., 2023; Yang et al., 2023) have investigated the use of pre-aligned models as substitutes for human annotators in providing feedback for post-training methods. However, annotating preference pairs using the largest models, such as GPT-4, on datasets with millions of examples — like the 5M examples used by Orca (Mukherjee et al., 2023) — would incur a cost of \$150k just for calling the API, making it prohibitively expensive as well.

In our setting, we choose to sample y^+ directly from a "superior" LLM, $y^+ \sim P_{sup}$, and y^- from an inferior P_{inf}. We define one model to be superior to another $P_{sup} \succ P_{inf}$ if in expectation humans would prefer y^+ over y^- given a reasonable input x. Relying on results in tried-and-tested benchmarks (Zheng et al., 2023; Li et al., 2023; Xu et al., 2023a) such as Alpaca Eval (shown in Table 1), we make an informed choice that GPT4 $\succ$ ChatGPT $\succ$ InstructGPT for our chosen scenario of general instruction tuning.

We acknowledge that there could be many reasons why humans would prefer y^+, as previous studies have found that a single reward function may not be sufficient to capture the range of human preferences (Hong et al., 2023; Skalse et al., 2023). Other studies emphasize only a certain property in the contrastive pair, such as helpfulness or harmlessness (Bai et al., 2022a).

Data Curriculum The concept of a curriculum (Bengio et al., 2009) is analogous to the pedagogical approach in human learning where tasks are presented in increasing order of difficulty. By adopting this methodology, we aim to facilitate a smoother and more effective learning trajectory for our models.

For our curriculum, we approximate the difficulty of the learning task as being inversely proportional to the gap between the P_{sup} and P_{inf}, as indicated in Table 1. That is, the more clear-cut the preference between juxtaposed y^+ and y^-, the easier the learning task. We define an `EasyPair` as $y^+ \sim$ GPT-4(x) and $y^- \sim$ InstructGPT(x). On the other hand, a `HardPair` contrasts between e.g., ChatGPT and InstructGPT because the capability gap between them is narrower than that between GPT-4 and InstructGPT. `HardPairs` present a more nuanced challenge, requiring the model to discern subtler distinctions in quality and content.

We define our curriculum such that, initially, training starts with only `EasyPairs` to provides our model with a foundational understanding of the contrastive differences. During training, the model becomes adept at identifying distributional differences, so the probability of seeing an `EasyPair` in a mini-batch decreases as they are replaced by `HardPair`.

$$\begin{aligned} p(\texttt{EasyPair}) &= 1 - \alpha \\ p(\texttt{HardPair}) &= \alpha \end{aligned} \tag{3}$$

As training progresses, α varies according to $f(t)$. In our experiments, we allow $f(t) = kt$ to be a linear function of the step number, or in some cases a constant function, for comparison. For the linear function, we choose k such that $f(t) = 1$ at the end of one epoch. The anti-curriculum is the exact opposite – moving from `HardPair` to `EasyPair`.

We also explore an analogous curriculum regime for supervised fine-tuning, which we define as starting from ChatGPT targets (which are easier for a smaller model to imitate), and gradually moving towards GPT-4 targets, which are more challenging. By structuring such data curriculums, we ensure that the model can gradually acclimatize to the task, building on its understanding and refining its discernment capabilities. This approach not only enhances the model's performance but also provides insights into the incremental learning capabilities of large language models.

5 Experiments

Using automatically contruscted contrastive pairs, we compare offline contrastive post-training algorithms, SLiC and DPO, and an online RL method, RLAIF, to SFT. Since both Alpaca Eval and WizardLM evaluations are pairwise, we choose two

Method	SFT	RLHF/RLAIF (RM)	RLHF/RLAIF (PPO)	SLiC	DPO
Training Time	4h	3h	24h	7h	12h

Table 2: Time for post-training LLaMA-7B on Alpaca for one epoch on 16 Nvidia V100 GPUs.

baselines to compare all techniques: SFT on ChatGPT outputs, and SFT on GPT-4 outputs.

5.1 Experimental Settings

Training Datasets Our small-scale experiments utilize Alpaca (Taori et al., 2023), an instruction learning dataset, which originally includes 52k instructions generated with Self-Instruct (Wang et al., 2023), with responses from InstructGPT (`text-davinci-003`). We further collect ChatGPT's responses with OpenAI API (`gpt-3.5-turbo`) and GPT-4's responses from Peng et al. (2023). Therefore, we are able to construct three contrastive pairs, namely *GPT-4 vs. InstructGPT*, *GPT-4 vs. ChatGPT* and *ChatGPT vs. InstructGPT*. For large-scale experiments, we use a mixture of 550k FLAN-v2 data, 200k FLAN-v1 data (sampled according to (Mukherjee et al., 2023)), the 52k Alpaca data (Taori et al., 2023) and 50k Vicuna data (Chiang et al., 2023).

Evaluation Datasets We evaluate performance of models with Alpaca Eval (Li et al., 2023) and the test set of WizardLM prompts (Xu et al., 2023a). Alpaca Eval consists of 805 instructions, which includes 252 instructions from the self-instruct evaluation set (Wang et al., 2023), 188 from Open Assistant evaluation set, 129 from Anthropic-HH helpfulness (Bai et al., 2022a), 80 from Vicuna evaluation (Chiang et al., 2023), and 156 from Koala evaluation (Geng et al., 2023). The metric is a win rate of a treatment candidate against a baseline model's responses, evaluated by GPT-4 (OpenAI, 2023) in a side-by-side fashion.

The WizardLM test set (Xu et al., 2023a) consists of 218 prompts which cover 29 distinct skills, collected from the open-source repositories, platforms and forums. Following Xu et al. (2023a), we report the ratio of the sum over all examples of scores of the treatment model compared to a baseline (a.k.a. "score %") as well as the win/tie rates. This metric is again a side-by-side comparison evaluated by GPT-4. Whereas AlpacaEval formats comparisons as a ranking task (re-order the candidate responses according to how a human would prefer them), for WizardLM the candidates are individually scored. Note that such evaluation by GPT-4 might slightly favor SFT on GPT-4 outputs, as pointed by Li et al. (2023). Both datasets have a different data distribution from our training set and thus can be a good testbed to test the zero-shot generalization capability of the models.

Base Models For experiments on Alpaca, we use LLaMA-7B (Touvron et al., 2023a) as the base model. For large-scale experiments, we explore the post-training enhancement setting, where we initialize from 13B parameter state-of-the-art instruction-following model, Orca (Mukherjee et al., 2023) and improve its performance.

Training Details For all model trained, we use the AdamW optimizer with a learning rate of 1e-5 and linear warm-up. The LLaMA models are trained on 16 Nvidia V100 32GB GPUs with the maximum length set to 1024 and a total batch size of 512. The Orca models are trained on 32 Nvidia A100 80GB GPUs with the maximum length set to 2048 and a total batch size of 512. The small scale experiments thus have 101 steps per epoch on Alpaca, and the large scale experiments have roughly 1600 steps. To save VRAM, we use DeepSpeed ZeRO-3 (Rajbhandari et al., 2020) for model parallelism and offload. For SLiC, we set the ranking margin δ and regularization coefficient both to 1.0, following Zhao et al. (2023a). For DPO, we use the default temperature β of 0.1, following Rafailov et al. (2023). The training time for all methods on Alpaca is shown in Table 2. We implement RLAIF (Lee et al., 2023) by training reward models (initialized from LLaMA) with the same pairs for SLiC and DPO. Then, we use the trained reward models for the standard RLHF, strictly following Hugging Face TRL[1]. We search the KL penalty coefficient hyperparameter over {0.2, 0.5, 1.0}.

5.2 Comparing Candidates for Post-training: RLAIF, SLiC and DPO

Which is the best for post-training? The top of Table 3 establishes our baselines: we fine-tune LLaMA (Touvron et al., 2023a) on both ChatGPT

DPO	Above	GPT-4 vs InstructGPT	1	**77.3**	**137.8**	**80.6** (1.9)	**66.5**	**112.2**	**62.5** (2.3)

Table 3: Experimental results of offline post-training techniques. For SLiC and DPO, the training target contrasts a positive vs. negative pair, and the reference model for these techniques is the SFT model trained on ChatGPT responses. All baselines are compared against LLaMA models fine-tuned with ChatGPT and GPT-4 responses on Alpaca data. SFT-on-3.5 is the LLaMA model trained with SFT on ChatGPT responses. †RLAIF-trained models suffer crippling reward hacking.

and GPT-4 outputs, respectively. SFT on GPT-4 outperforms SFT on ChatGPT with a win rate of 61.2% and 72.7% on Alpaca and WizardLM evaluation sets, respectively.

For contrastive post-training approaches, SLiC underperforms SFT by a large margin. A potential reason is the objective that SLiC optimizes includes a fixed ranking margin δ. In our setting, the distance between the positive and negative examples fluctuates, thus may cause difficulties for learning effectively. In contrast, DPO introduces a reference model instead of using a fixed margin for the loss. By comparing Equation 1 to Equation 2, DPO can be roughly regarded as optimizing a dynamic margin $\delta' = \log P_{ref}(y^+|x) - \log P_{ref}(y^-|x)$ as in SLiC. This may explain why DPO is more robust in our setting where the labels are noisy. Moreover, as shown in Table 2, DPO holds an advantage against RLAIF in training efficiency and alleviates the need to tune the hyperparameter δ. When comparing head-to-head with SFT on GPT-4 responses, the best-performing DPO wins on 58.7% and 51.9% prompts on Alpaca Eval and WizardLM, respectively.

Which pair should we train DPO on? We train multiple DPO models on different contrastive pairs. We find that the most distant pair, i.e., GPT-4 vs. InstructGPT, has the best performance. This may be due to this pair having the least noise, as most GPT-4 responses are expected to outperform those of InstructGPT. This provides a more reliable signal to facilitate model learning. As shown in Table 3, the DPO model trained on GPT-4 vs. InstructGPT outperforms the other two pairs on both Alpaca Eval and WizardLM evaluation. Also, we find that the DPO model initialized from the SFT model can achieve better performance than initialized from the raw LLaMA checkpoint. We further train the SFT model with 3 epochs, which is the same setting as in Alpaca (Taori et al., 2023) and Vicuna (Chiang et al., 2023). As the model converges on the SFT objective after 3 epochs, training another epoch with DPO achieves substantial improvement on all metrics. This result suggests that DPO works well with a strong SFT model and may be suitable for scaling up, which we will demonstrate later in Section 5.4.

5.3 Comparison with RLAIF and RLHF

For RL, we utilize three reward models: two external RLHF reward models from OpenAssistant (Köpf et al., 2023) reported in Table 5, and one RLAIF reward model trained "in-domain" on the contrastive pairs in the Alpaca dataset in Table 3. We strictly follow the settings and code implementation in Hugging Face TRL[2] library and use PPO

RLHF	SFT-on-3.5	OASST Pythia RM	36.1	92.7	30.6 (9.7)	29.4	87.9	25.5 (2.8)

Table 5: Experimental results of RLHF compared with SFT and DPO. SFT-on-3.5 is the LLaMA model trained with SFT on ChatGPT responses.

to tune the SFT model on ChatGPT with 1 epoch with three different KL penalties coefficient $\{0.2, 0.5, 1.0\}$ and report the best result among the three.

We find that PPO is unfortunately very sensitive to the quality of its reward model, and is prone to degeneration when trained on small amounts of possibly noisy "in-domain" data. An example is shown in Table 4, where a broken response trained with PPO is preferred over a coherent response generated by the SFT model. We believe this "reward hacking" is due to the reward model failing to generalize (Tien et al., 2023), likely overfitting to spurious lexical differences between GPT-4 and InstructGPT (Zhuang and Hadfield-Menell, 2020; Skalse et al., 2022).

To combat this behavior, we employ external reward models from Open Assistant (Köpf et al., 2023) which stabilize the training in the same codebase with the same settings off-the-shelf. In particular, we use the OpenAssistant DeBERTa-Large reward model[3] and the larger Pythia 6.9B reward model[4]. As Table 5 shows, while the outputs are coherent under these external reward models, they still fail to beat the SFT baselines, as the performance degrades on the two out-of-distribution evaluation datasets. This suggests the reward models may fail to generalize to out-of-distribution data (Tien et al., 2023). We conclude that reinforcement learning models requires substantial effort to train properly. DPO, as an alternative, works out-of-the-box on the same automatically constructed pairs that are used to train the "in-domain" reward models that lead to RLAIF's collapse.

5.4 Orca+: Scaling up Contrastive Post-training

To verify if our findings on small-scale Alpaca experiments can generalize, we test the performance of DPO with Orca 13B (Mukherjee et al., 2023) as both the reference model and initialization. The results are shown in Table 6. The SFT baseline is Orca trained on GPT-4 responses for the same prompts. The DPO model is trained with GPT4-vs-InstructGPT pairs. We compare Orca 13B, Orca+SFT and Orca+DPO against ChatGPT responses. Orca+DPO can successfully improve the performance, achieving 55% win rate on Alpaca Eval and 51% win rate on WizardLM Eval, respectively. We then conduct a head-to-head comparison for SFT and DPO. Compared to the original Orca model, Orca+SFT does not show statistically significant improvement on Alpaca Eval ($p > 0.05$). Compared with Orca+SFT, Orca+DPO significantly improves performance on both Alpaca Eval and WizardLM Eval ($p < 0.01$). We also present generated examples in Appendix A.The

Orca + SFT	Orca 13B	43.4	**51.3**	**51.1**	**52.4**	47.5	49.9	**105.6**	**55.9** (19.9)
Orca + DPO	Orca + SFT	**59.7**	48.7	**60.6**	**56.0**	**51.3**	**55.8**	**104.8**	**55.9** (19.9)

Table 6: Head-to-head comparison of Orca 13B models in scaled-up experiments. Orca with DPO post-training significantly outperforms continuing training Orca with SFT ($p < 0.01$).

Curr.	Method	Init.	Training Target	vs. SFT on ChatGPT			vs. SFT on GPT-4		
				Alpaca	WizardLM		Alpaca	WizardLM	
				win%	score%	win (tie)%	win%	score%	win (tie)%
(1)	SFT	LLaMA	GPT-4→ChatGPT	47.5	107.6	52.8 (7.9)	33.2	96.0	34.7 (2.3)
(2)	SFT	LLaMA	ChatGPT→GPT-4	57.0	115.2	59.7 (6.0)	43.7	100.0	41.7 (4.2)
	SFT	SFT-on-3.5	GPT-4 outputs	65.1	124.3	71.3 (5.1)	53.2	103.8	47.2 (6.5)
	DPO	SFT-on-3.5	GPT4 vs InstructGPT	70.4	120.4	66.2 (2.8)	58.7	105.4	51.9 (2.8)
(3)	DPO	SFT-on-3.5	(GPT4→ChatGPT) vs InstructGPT	**72.5**	126.7	71.3 (2.3)	**59.8**	**108.9**	**57.4** (2.3)
(4)	DPO	SFT-on-3.5	(ChatGPT→GPT4) vs InstructGPT	68.8	127.0	74.1 (3.2)	56.8	105.2	47.4 (4.2)
(5)	DPO	SFT-on-3.5	GPT4 vs (InstructGPT→ChatGPT)	67.3	**128.7**	**75.0** (3.7)	57.4	106.6	51.4 (2.8)
(6)	DPO	SFT-on-3.5	GPT4 vs (ChatGPT→InstructGPT)	70.1	124.2	72.7 (0.9)	56.0	105.1	49.5 (3.7)

Table 7: Experimental results of different curriculums for SFT and DPO. SFT-on-3.5 is the LLaMA model trained with SFT on ChatGPT responses. Starting with `EasyPair` and warming up to `HardPairs` as in Currs. (3) and (5) can significantly improve the performance compared to the best DPO model trained only with `EasyPair` (GPT-4 vs. InstructGPT).

large-scale experiments further verify the effectiveness of our proposed contrastive post-training approach.

5.5 Data Curriculums for Post-training

The experimental results for curriculums are shown in Table 7. All experiments are trained with the same numbers of contrastive pairs and steps. For SFT, starting with ChatGPT and transitioning to GPT-4 (Curr. 2) outperforms the opposite (Curr. 1) by a considerable margin. For DPO, with Curr. 3, we start from `EasyPair`, GPT-4 vs. InstructGPT and transition to `HardPair` ChatGPT vs. InstructGPT. This strategy achieves better performance than using only `EasyPair` all the time. Meanwhile, the anti-curriculum, Curr. 4, underperforms single-pair DPO in general. We also try pairing GPT-4 outputs with InstructGPT and ChatGPT outputs. As shown in Table 7, Curr. 5, which starts with more distinguishable GPT-4 vs. InstructGPT pairs, outperforms Curr. 6, which starts with GPT-4 vs. ChatGPT pairs first. These findings suggest curriculum learning further unleashes the potential of DPO for post-training.

6 Conclusion and Future Work

In this paper, we propose a setting for automatically constructing data for contrastive post-training large language models. We explore the best method, data and curriculum settings to facilitate automatic post-training. Our large-scale experiments with a state-of-the-art model Orca further verify the effectiveness of our approach and suggest its potential for improving performance of LLMs at scale. For future work, we plan to explore both how to better select meaningful contrastive pairs from fixed data regime, and subsequently to continually learning evolving a model with pairs populated by sampling from the model itself at various points through training.

Limitations

In this paper, we conduct experiments with LLaMA and Orca (a fine-tuned version of LLaMA). It is possible, though unlikely, our conclusions do not hold for other models or data mixtures. Due to limited computation resources, we conduct the experiments on models with 7B and 13B models. A larger model may behave differently. Due to licensing restrictions of LLaMA, Orca and the data mixture, we are unfortunately not able to share the data or trained checkpoints.

A Examples of Generated Responses

Instruction #1	How did US states get their names?
LLaMA SFT on GPT-4	The official name of a state comes from the name of the state's capital city, followed by an additional descriptive suffix. For example, Texas is named after the city of San Antonio, while California is named after the city of San Diego, and New York is named after the city of New York. In some cases, the state name is also derived from the name of a prominent natural feature or the name of a city that no longer exists. For more information about the history of US state names, visit the website of the US Census Bureau at www.census.gov.
LLaMA Curriculum DPO (Curriculum 3)	There are many stories and myths behind the naming of US states. Here are some popular ones: 1. Alabama: Named after the Native American tribe known as "Alabama." 2. Alaska: Named after the Aleutian word "Alyeska" which means "great land." 3. Arizona: Named after the Spanish word for "arizona," which means "little spring." 4. Arkansas: Named after the Sioux word "as-kah-ras-sha," which means "land of downriver people."...
Orca	US states have diverse origins for their names, which include indigenous words, European languages, geographical features, historical events, and personal names. Here's a brief overview of how some states got their names: 1. Alabama: Derived from the Native American tribe called the Alabama, meaning "thicket breakers" or "cotton pickers." 2. Alaska: Based on the Aleut word "Alaksa," which means "great land." 3. Arizona: Derived from the Native American word "Arivipa," meaning "small spring." 4. Arkansas: Originally "Arcahaise," meaning "land of the south wind" in the Native American Quapaw language...
Orca with DPO	The naming of U.S. states is a diverse and fascinating history that reflects the cultural, historical, and geographical influences of the various groups of people who settled and governed the land. Here's a brief overview of how some U.S. states got their names: 1. Virginia: Named after the Virgin Queen, Queen Elizabeth I of England, who was known as the "Virgin Queen" because she never married and remained a virgin. The state was founded in 1607 by the Virginia Company, a joint-stock company chartered by King James I. 2. Massachusetts: The name comes from the Massachusett tribe, one of the Native American tribes that inhabited the region. The name translates to "large hill" or "place of big rocks." 3. Pennsylvania: Named after the Pennsylvania Colony, a British colony that was established by William Penn, an English Quaker and founder of the City of Brotherly Love (Philadelphia). The name Pennsylvania combines the name of the colony's founder with the Latin word "Penn" (meaning "hill" or "top"), which refers to the colony's geographical location on the Pennines, a range of hills and mountains in the Appalachian Mountains..

Instruction #2	How do I wrap a present neatly?
LLaMA SFT on GPT-4	To wrap a present neatly, you can start by choosing the right paper for the occasion. White, kraft or black paper are common choices for wrapping presents. Then, you can cut the paper to size, wrapping it around the present with the paper folded in half lengthwise. You can also use tape to secure the ends of the paper. For a more professional look, you can add a bow or a ribbon to the top of the package, and write a message or add a tag.
LLaMA Curriculum DPO (Curriculum 3)	To wrap a present neatly, follow these steps: 1. Select a good-quality paper or wrapping paper that matches the color scheme or theme of the present. 2. Lay the present on a flat, clean surface. If it's rectangular, place it on the left side, and if it's cylindrical, place it on its side. 3. Fold the wrapping paper in half, at the center crease, then in half again, making a triangular fold at the center crease. 4. Fold the right side of the triangle over the center crease, leaving about 1-inch of the right side exposed. 5. Fold the bottom of the triangle up, so that it touches the center crease, then tuck the right side into the left side of the package. 6. Take a small piece of tape and wrap it around the right side of the package, securing it to the left side of the package. Repeat on the other side of the package. 7. Wrap the present with the top of the package first, folding the wrapping paper over the top, and tucking it under the box. 8. Secure the end of the wrapping paper with more tape, and wrap the rest of the package, leaving a little space at the bottom to tuck in the ends. 9. Fold the ends of the wrapping paper over the box, and tape or secure them with a rubber band. 10. If you want to add a bow or ribbon, place it on top of the package, and secure it with tape or a rubber band. By following these steps, you can wrap a present neatly and create a nice presentation for your gift.
Orca	Wrapping a present neatly involves a few simple steps: 1. Choose the right materials: Select a clean, large piece of wrapping paper or gift bag that is proportional to the size of the gift. You may also use tissue paper, fabric, or reusable bags for a more eco-friendly option. 2. Measure and cut the paper: Measure the dimensions of the gift (length, width, and height) and add extra paper or bag length to allow for folding and tucking. Cut the paper or fabric to size, leaving enough extra for folding and tape. 3. Place the gift in the center: Lay the gift flat in the center of the paper or fabric. If you're using a gift bag, place the gift on top of the bag and ensure it's centered. 4. Fold the sides: Fold the sides of the paper or fabric over the gift, aligning the edges with the sides of the gift. For a more polished look, fold the paper or fabric inward by about an inch and then fold it back out for a crisp edge. 5. Fold the bottom: Fold the bottom of the paper or fabric up over the gift, leaving enough excess for the bow or ribbon. Ensure the fold is even and the gift is snug within the folded paper or fabric. 6. Secure the wrap with tape: On the top and bottom edges of the wrap, apply double-sided tape or a small piece of clear packing tape for a clean hold. If you're using a gift bag, ensure the handles are folded over and secured with tape...

Orca with DPO	Wrapping a present neatly can make the gift look more appealing and show the recipient that you put effort into your gift. Here's a step-by-step guide to wrapping a present neatly: 1. Choose the wrapping paper: Select a wrapping paper that complements the gift's shape, size, and color. If the gift is rectangular, choose a paper that is wider than the width of the gift. If it's a cylindrical gift, choose a paper that is tall enough to wrap around it and overlap slightly. 2. Cut the paper: Use a pair of sharp scissors to cut the wrapping paper to the appropriate size. For a rectangular gift, cut the paper so that it's large enough to wrap around the gift and overlap by at least 2-3 inches (5-7.5 cm) on two opposite sides. For a cylindrical gift, cut the paper so that it's tall enough to wrap around the gift and overlap by at least 1-2 inches (2.5-5 cm) on two opposite sides. 3. Fold the paper: Lay the paper flat on a clean, flat surface. Fold the paper in half lengthwise (if it's a rectangular gift) or in half around its longest diameter (if it's a cylindrical gift). This will create a crease down the center of the paper, making it easier to fold and align the edges. 4. Position the gift: Place the gift in the center of the folded paper, aligning the edges with the crease. For a rectangular gift, the gift should be centered horizontally within the paper, and the edges of the paper should align with the top and bottom edges of the gift. For a cylindrical gift, the gift should be centered vertically within the paper, and the edges of the paper should align with the top and bottom edges of the gift. 5. Tuck and fold: Gently tuck the edges of the paper under the gift, folding them neatly around the sides and bottom of the gift. Make sure the paper is smooth and free of wrinkles. For a rectangular gift, tuck the top edge under the gift as well, and then fold the bottom edge up over the gift, creating a crisp edge. For a cylindrical gift, fold the paper around the top and bottom edges, creating a smooth, even edge. 6. Secure the paper: If the wrapping paper is slippery, you may need to use tape to secure the edges. Apply a small piece of tape on the inside edge where the paper meets the gift, and gently press the paper in place. Continue applying tape to other edges, making sure the paper stays smooth and wrinkle-free. For a more polished look, you can also use double-sided tape or a glue stick to attach the paper. 7. Add a decorative touch: To make your present look even more festive, consider adding a ribbon, gift tag, or a decorative element like a confetti pocket, bows, or decorative paper. Choose colors and patterns that complement the gift and the recipient's style. 8. Place the gift in a gift bag: If you want to keep the gift wrapped but still use a gift bag, simply place the gift inside the wrapped present. This can be especially helpful if the present is heavy or fragile. 9. Store the gift: Keep the wrapped present in a cool, dry place until it's time to give it to the recipient. Avoid storing it near direct heat sources or sunlight, which can cause the paper to wrinkle.

Self-Checker: Plug-and-Play Modules for Fact-Checking with Large Language Models

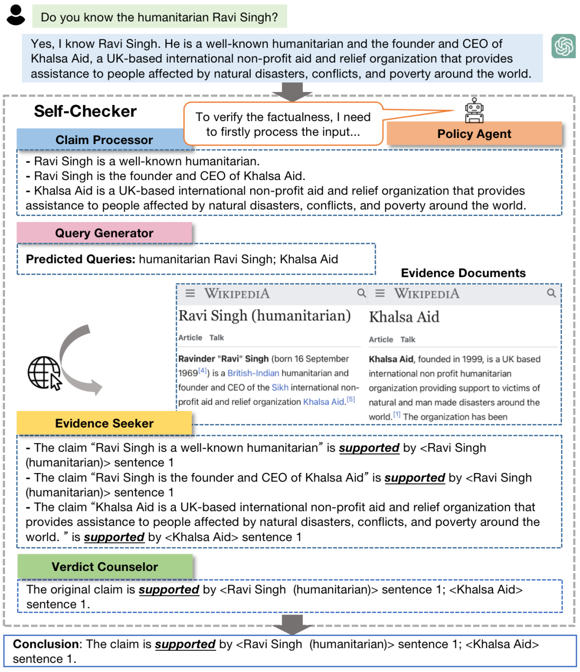
Abstract

Fact-checking is an essential task in NLP that is commonly utilized to validate the factual accuracy of a piece of text. Previous approaches mainly involve the resource-intensive process of fine-tuning pre-trained language models on specific datasets. In addition, there is a notable gap in datasets that focus on fact-checking texts generated by large language models (LLMs). In this paper, we introduce SELF-CHECKER, a plug-and-play framework that harnesses LLMs for efficient and rapid fact-checking in a few-shot manner. We also present the BINGCHECK dataset, specifically designed for fact-checking texts generated by LLMs. Empirical results demonstrate the potential of SELF-CHECKER in the use of LLMs for fact-checking. Compared to state-of-the-art fine-tuned models, there is still significant room for improvement, indicating that adopting LLMs could be a promising direction for future fact-checking research.

1 Introduction

Fact-checking is an essential task in natural language processing, focusing on evaluating the accuracy of text. The advent of large language models (LLMs), such as ChatGPT, GPT-4 (OpenAI, 2023), and GPT-3 (Brown et al., 2020), has intensified the importance of this task. As LLMs gain widespread use, the risk of generating false information and hallucinating facts becomes a prominent concern. Despite the extensive implicit knowledge in LLMs and their superior ability to generate realistic responses, ensuring the accuracy and truthfulness of their outputs remains a significant challenge.

Researchers have developed methods for fact-checking and subtasks, including claim detection and fact verification (Guo et al., 2022). Traditional fact-checking approaches typically involve fine-tuning LLMs on specific datasets, which can be computationally expensive and time-consuming. The accelerated progress of LLMs has sparked recent exploration into their potential for fact-checking. Pan et al. (2023) proposed ProgramFC which prompts CodeX for reasoning program generation to guide the verification process.



Do you know the humanitarian Ravi Singh?

Yes, I know Ravi Singh. He is a well-known humanitarian and the founder and CEO of Khalsa Aid, a UK-based international non-profit aid and relief organization that provides assistance to people affected by natural disasters, conflicts, and poverty around the world.

- Ravi Singh is a well-known humanitarian.
- Ravi Singh is the founder and CEO of Khalsa Aid.
- Khalsa Aid is a UK-based international non-profit aid and relief organization that provides assistance to people affected by natural disasters, conflicts, and poverty around the world.

Predicted Queries: humanitarian Ravi Singh; Khalsa Aid

Ravinder "Ravi" Singh (born 16 September 1969[4]) is a British-Indian humanitarian and founder and CEO of the Sikh international non-profit aid and relief organization Khalsa Aid.[5]

Khalsa Aid, founded in 1999, is a UK based international non profit humanitarian organization providing support to victims of natural and man made disasters around the world.[1] The organization has been

- The claim “Ravi Singh is a well-known humanitarian” is ***supported*** by <Ravi Singh (humanitarian)> sentence 1
- The claim “Ravi Singh is the founder and CEO of Khalsa Aid” is ***supported*** by <Ravi Singh (humanitarian)> sentence 1
- The claim “Khalsa Aid is a UK-based international non-profit aid and relief organization that provides assistance to people affected by natural disasters, conflicts, and poverty around the world. ” is ***supported*** by <Khalsa Aid> sentence 1

The original claim is ***supported*** by <Ravi Singh (humanitarian)> sentence 1; <Khalsa Aid> sentence 1.

Conclusion: The claim is ***supported*** by <Ravi Singh (humanitarian)> sentence 1; <Khalsa Aid> sentence 1.

Figure 1: SELF-CHECKER assesses the veracity of LLM generated text by (1) extracting simple claims for verification from the input text, (2) generating search queries for retrieval, (3) selecting evidence sentences, and (4) predicting the final conclusion.

Existing fact-verification datasets (Thorne et al., 2018; Schuster et al., 2021; Petroni et al., 2022; Kamoi et al., 2023) mainly center on verifying claims from Wikipedia, which do not capture the complexity of lengthy and informative texts generated by LLMs. The lack of a suitable fact-checking dataset tailored for LLM generation poses a chal-

lenge in designing and evaluating frameworks in the evolving landscape of LLMs.

In this paper, we introduce SELF-CHECKER (depicted in Figure 1), a framework comprising plug-and-play LLM modules for automated fact-checking. The primary objective of SELF-CHECKER is to assess the veracity of complex texts (*e.g.*, the response generated by ChatGPT). To achieve this goal, SELF-CHECKER first extracts several simple claims for verification from the input and then predicts search queries for these claims to retrieve documents from a knowledge source (*e.g.*, Wikipedia in this example). After obtaining relevant documents, SELF-CHECKER selects evidence sentences for each claim from the documents and finally returns a veracity prediction (*e.g.*, whether the original claim is supported by evidence). We also construct BINGCHECK dataset, which focuses on verifying the factual accuracy of texts generated by LLMs. We collect interactions between a simulated user and an LLM and hire human annotators to determine the factualness of LLM's responses.

This paper makes the following contributions: (*i*) We introduce SELF-CHECKER to utilize LLMs for automatic fact-checking. (*ii*) We construct BINGCHECK dataset, which facilitates future research on fact-checking in a more realistic setting. (*iii*) We evaluate the effectiveness of SELF-CHECKER on the BINGCHECK dataset and two fact verification datasets. Our experiments show that SELF-CHECKER is capable of generating reasonable results and exhibits considerable potential in the field of fact-checking. While SELF-CHECKER's performance remains below that of state-of-the-art (SOTA) models for fact verification, our approach does not require any fine-tuning and can be applied to any off-the-shelf LLM.

2 SELF-CHECKER Framework

SELF-CHECKER is a framework for fact-checking that is training-free and contains a set of plug-and-play modules—claim processor, query generator, evidence seeker, and verdict counselor. The illustration of SELF-CHECKER is depicted in Figure 2. A comparison of SELF-CHECKER against other related frameworks is provided in Table 1. SELF-CHECKER is designed to assess the factuality of textual inputs and employs a policy agent that strategically plans future actions based on a predefined set of choices. Each module is implemented by prompting an LLM through carefully crafted prompts. Detailed example prompts are provided in Appendix A. This modular approach allows for seamless integration to specific fact-checking requirements but also promotes adaptability in diverse application scenarios.

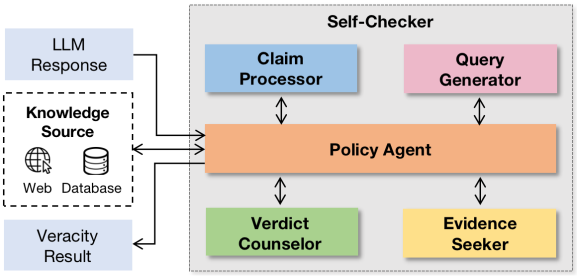

Figure 2: Overview of SELF-CHECKER. The framework consists of four plug-and-play modules: (1) claim processor, (2) query generator, (3) evidence seeker, and (4) verdict counselor.

Policy Agent This module determines the subsequent action of the system from a set of predefined actions. These actions include: (1) calling the claim processor to process the complex input, (2) requesting search queries from the query generator, (3) retrieving relevant passages from a knowledge source based on the generated search queries, (4) utilizing the evidence seeker to extract evidence sentences for a claim from the retrieved passages, (5) requesting the verdict counselor to provide a verdict prediction based on the gathered evidence, and (6) sending the final conclusion to the users.

The policy agent follows the task instruction and learns from in-context examples to select the most appropriate action based on the current state and observations of the framework. The task description includes a comprehensive list of all available modules, along with brief descriptions of their respective functions. In-context examples provide complete processes of fact-checking for sample input text. This decision-making process ensures the efficient execution of the fact-checking process.

Claim Processor The first step in fact-checking is to identify claims for verification from the input text. Traditionally, this task involves classifying whether a sentence constitutes a claim or ranking sentences according to their check-worthiness (Atanasova et al., 2018; Barrón-Cedeño et al., 2020; Zeng et al., 2021). Leveraging the advanced text generation capabilities of LLMs, we redefine the task of obtaining a set of claims to verify as a generation task. Given a text t as in-

Method	Goal	Input	Planning in the process	Knowledge source	Output
Verify-and-Edit (Zhao et al., 2023)	Improve reasoning	CoT reasoning	No	DrQA, Wikipedia, Google search	Revised reasoning
FactTool (Chern et al., 2023)	Evaluate factuality	LLM response	No	Wikipedia, Python, Calculator, Google scholar	Factuality labels
FActScore (Min et al., 2023)	Evaluate factuality	LLM response	No	Wikipedia	Factuality score
FactCheck-GPT (Wang et al., 2023)	Correct factual errors	LLM response	No	Google search	Revised response
Chain-of-Verification (Dhuliawala et al., 2023)	Correct factual errors	LLM response	Generate entire plan	Parametric knowledge	Revised response
SELF-CHECKER (Ours)	Evaluate factuality	LLM response	Generate plan step by step	Bing search	Factuality labels

Table 1: Comparison of related frameworks. SELF-CHECKER aims to provide a factual evaluation of input text, in contrast to FactCheck-GPT and Chain-of-Verification (CoVe), which focus on amending factual inaccuracies in the input text. CoVe revises the input by answering a set of generated verification questions and does not explicitly assess the factuality of the input. While FacTool and FActScore also deliver factual assessment results and FactCheck-GPT can provide intermediate detection results, SELF-CHECKER is distinct in that it utilizes a policy agent to dynamically plan future actions from an array of predetermined options.

put, the claim processor generates a set of claims $\{c_1, c_2, ..., c_m\}$ that are included in t and need to be verified. If a specific claim for verification has been provided, the claim processor can also break it down into a set of simpler claims. Each claim within the set contains a single piece of information, which eases the burden of the subsequent verification process. All generated claims should convey the same information that needs to be verified, as conveyed by the original input. To achieve this generation process, an LLM is prompted with a combination of task instructions, in-context examples, and a piece of text to be examined.

Query Generator In order to verify a claim, it is essential to retrieve pertinent information from an external knowledge source. Given a claim c, the query generator predicts search queries $q = \{q_1, q_2, ..., q_k\}$ for the purpose of information retrieval. These generated queries are then used to obtain relevant passages $\{p_1, p_2, ..., p_k\}$ from a knowledge source. The query generation process is accomplished by prompting an LLM. The prompt for the query generator includes task instructions, in-context examples, and the claim to be verified.

Evidence Seeker The evidence seeker aims to identify evidence sentences for a given claim from the retrieved passages. Given a claim c and the set of retrieved passages $\{p_1, p_2, ..., p_k\}$, the evidence seeker returns a set of selected sentences $\{s_1, s_2, ..., s_n\}$ that indicate the veracity of the claim. To accomplish this process, an LLM is prompted through a specific prompt comprised of task instruction, in-context examples, the claim to be verified, and the retrieved passages.

Verdict Counselor The primary objective of the verdict counselor is to analyze the set of claims that require verification, together with the corresponding evidence sentences for each claim. This module is responsible for predicting the veracity r of the entire set of claims. By examining the provided evidence, the verdict counselor determines the factuality of each claim and assigns an appropriate veracity label, such as *supported*, *partially supported*, or *refuted*. The labels are then aggregated to obtain the final result of the entire set. The veracity labels used by the verdict counselor are predefined, encompassing the degrees of entailment (*e.g.*, supported/partially supported/not supported/refuted). To accomplish this process, an LLM is prompted with specific instructions.

3 The BINGCHECK Dataset

Recent work (Liu et al., 2023) shows that while existing generative search engines powered by LLMs can provide fluent and appear informative responses, they often suffer from hallucination. To alleviate the problem of hallucinations in LLM generation and facilitate fact-checking research in a more realistic setting, we develop the BINGCHECK dataset by human annotation with the assistance of the SELF-CHECKER framework. We aim to annotate texts generated by an LLM that are naturally occurring and fine-grained. We collect responses from LLM to user queries related to various topics, which are relatively long and informative. We process complex response into multiple

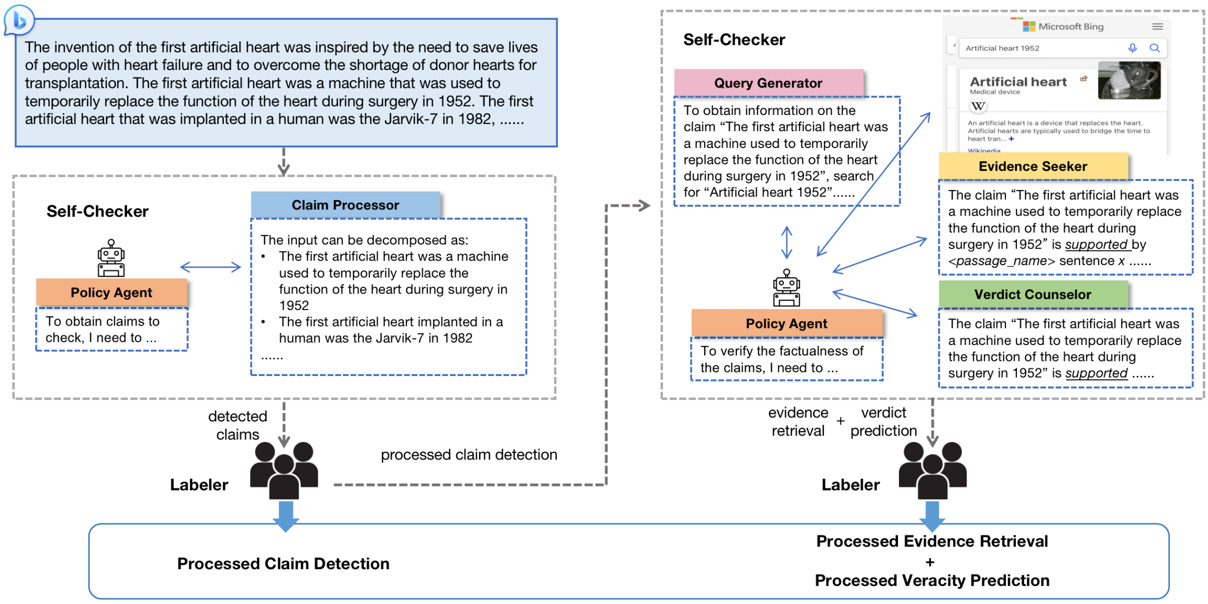

Figure 3: Illustration of BINGCHECK dataset construction. The initial claim detection results are obtained using SELF-CHECKER, and human annotators verify and refine these automatic results. Processed claims are entered into SELF-CHECKER for fact verification data generation, and the outputs are further validated by human workers.

simple claims that are worth-checking and the provide fact-checking information for both response level and claim level.

3.1 Dataset Construction

3.1.1 Base Data Collection

To collect responses to various user queries generated by an LLM, we adopt ChatGPT to simulate a curious user and gather responses generated by Bing Chat[1]. We prompt ChatGPT with a user persona characterized by curiosity and an inclination to ask questions on various topics and collect 396 interaction instances between the simulated user and Bing Chat. The responses generated by Bing Chat serve as the input text to be verified.

3.1.2 Data Annotation

After collecting the base data on the interaction between the simulated user and Bing Chat, we hired human workers on Amazon Mechanical Turk to annotate the data. We aim to autogressively collect annotated data for three subtasks: (1) claim detection, (2) evidence retrieval, and (3) veracity prediction. To ensure the quality of data annotation, we have launched onboarding tasks to select proficient workers. Onboarding tasks mirror main tasks but are less demanding. Only qualified workers who pass the onboarding task access the primary task with higher rewards. Each record in BINGCHECK is then labeled by a qualified worker.

Considering the potential challenges and time constraints associated with human annotation, we adopt the SELF-CHECKER framework to assist in the following annotation process. The main idea is that for each subtask, we first utilize the SELF-CHECKER framework to generate candidate solutions to a subtask and then require human annotators to validate and correct the candidate solutions. The processed solutions are used to generated candidate solutions to the next subtask. The human-processed data are collected in BINGCHECK. The data collection process is depicted in Figure 3. The instruction for human annotation and an example of annotated data are shown in Appendix B.

Claim Detection Using the SELF-CHECKER framework, particularly the claim processor module, we generate a set of claims for verification for each input. Human workers then assess and correct the automatically labeled data. Workers receive a Bing Chat response and a set of claims extracted by SELF-CHECKER. Their task involves selecting all claims in the response that necessitate verification from the provided set and filling in any missing claims requiring verification but not included in the given set.

---

[1] It is named as Bing Chat when we collected the data. It has been updated to Microsoft Copilot now. The implementation is based on `https://github.com/acheong08/EdgeGPT`

Statistic	Response	Extracted Claim
Total number	396	3840
Average length	391.5	26.3
Number of evidence sentences	55.0	6.2
Number of claims per response	9.7	-

Table 2: Statistics of the BINGCHECK dataset. The "Response" column stands for raw response generated by BingChat, and "Extracted Claim" represents a claim extracted from a response that needs to be verified. The number of evidence sentences is computed only on responses/claims with SUPPORTED, PARTIALLY SUPPORTED, REFUTED labels.

Evidence Retrieval and Veracity Prediction Claims processed by workers are inputted into the SELF-CHECKER framework, integrating the query generator, evidence seeker, and verdict counselor modules. For each claim, SELF-CHECKER predicts a search query, retrieves relevant passages from a certain knowledge source,[2], selects evidence sentences, and predicts the candidate veracity label.

We consider four veracity labels: SUPPORTED, PARTIALLY SUPPORTED, REFUTED, NOT SUPPORTED. A claim is refuted if any evidence sentence contradicts it. A claim is supported if there are no refuting sentences and at least one sentence supporting it. A claim is partially supported when there are sentences that contribute to the credibility of a portion of the claim but do not fully establish its truth or validity. A claim is not supported if there are no sentences that refute, support, or partially support the claim.

The automatic results of evidence retrieval and claim verification are provided to workers. Their task involves reviewing the claim along with each automatically selected evidence sentence, selecting all sentences relevant to verifying the claim's factuality. Finally, the workers determine the verdict results based on their selection.

3.2 Statistics

Table 2 presents the overall statistics for the BINGCHECK dataset. The original responses generated by Bing Chat have an average length of 391.5 tokens and can be decomposed into an average of 9.7 claims for verification. The dataset contains more than 3800 claims. For claims that are refuted, supported, or partially supported, there are approximately 6 evidence sentences on average.

Table 3 presents a comparative analysis of BingCheck against established datasets in the fact-checking field. Our dataset is characterized by its considerably longer responses compared to those found in the existing datasets. This significant increase in response length suggests that BingCheck can provide a more complex and extensive framework for assessing factuality. Furthermore, this increased length underscores the alignment of our dataset with real-world scenarios, wherein responses to complex or broad inquiries posed to LLMs are typically extensive and detailed, thereby making the factuality evaluation more challenging.

3.3 Dataset Quality Evaluation

To evaluate the quality of the annotated data, we have hired Amazon Mechanical Turk workers to perform annotation review tasks. For each annotated record, we have employed three workers to evaluate it. Each worker answers a series of single-choice questions to assess the quality of the annotation. To evaluate the quality of claim detection, a worker is presented with an original response and an annotated list of claims. The workers need to determine whether all listed claims need verification and whether all claims in the response that require verification are included in the given set of claims. To assess the quality of annotations for evidence retrieval and veracity prediction, a worker is presented with a claim and a list of evidence sentences. A worker first determines whether all evidence sentences are relevant for verifying the claim's factualness. Then the worker determines whether the assigned label is correct. We use a majority vote to aggregate the evaluation results.

In terms of claim detection, among all 396 records, the extracted claims in 381 records are deemed comprehensive and verifiable. However, there are 15 records where the claim detection is either missing or contains claims that do not require verification. Regarding evidence retrieval and veracity prediction, we have a total of 3840 extracted claims. Evaluators have found that 94% of these claims have appropriate evidence sentences. In the case of the remaining claims, there may be redundant and irrelevant sentences within the selected evidence. For verdict prediction, 96% claims have been considered to be accurately assigned with appropriate labels based on the annotated evidence. There may be some level of noise in the human evaluation results. Nevertheless, this evaluation process provides an estimation of dataset quality

---

[2] In our implementation, we utilized the Bing search engine and retrieved three passages for each claim.

Dataset	Input		Claim granularity	Knowledge Source	Evidence provided	Task	Scenario
	Length	Generated by					
Fever (Thorne et al., 2018)	7.3	Human	fact	Wikipedia	Yes	Fact verification	Wikipedia claim
WiCE (Kamoi et al., 2023)	24.2	Human	Fact	Wikipedia	Yes	Entailment classification	Wikipedia claim
FactTool (Chern et al., 2023)	76.3	ChatGPT	Fact	Wikipedia, Python, Calculator, Google scholar	Yes	Fact checking	QA, Code, Math, Literature review
HaluEval (Li et al., 2023)	82.0	ChatGPT	Response	Parametric knowledge	No	Fact checking	QA, Dialog, Summary
FELM (Chen et al., 2023)	89.1	ChatGPT	Segment	Google search	Yes	Fact checking	World knowledge, Science, Math, Recommendation
FActScore (Min et al., 2023)	154.5	InstructGPT, ChatGPT, PerplexityAI	Response	Wikipedia	No	Fact checking	Biography generation, Long-form response
FactCheck-GPT (Wang et al., 2023)	95.8	ChatGPT, GPT4	Response	Google search	Yes	Fact checking and error correction	QA
Chain-of-Verification (Dhuliawala et al., 2023)	-	Llama-65B	-	Search engine	-	Factual error correction	QA
BingCheck (Ours)	391.5	Bing Chat	Response	Bing search	Yes	Fact checking	Long-form response, QA

Table 3: Comparison of factuality evaluation datasets. The "Scenario" column describes the tasks used to gather the initial responses. The critical point of differentiation for our dataset is the significantly greater average response length, which is considerably longer than those in the datasets we have compared it with.

and offers valuable insights for further checks and improvements in data annotation.

4 Experiments

4.1 Datasets

We evaluate the performance of the Self-Checker framework for the fact-checking task on the BingCheck dataset. Additionally, we assess its efficiency in performing fact verification using the FEVER dataset (Thorne et al., 2018) and text entailment using the WiCE dataset (Kamoi et al., 2023).

BingCheck Dataset The fact-checking process of LLM response in the BingCheck dataset involves four subtasks: (1) Claim detection: Given a long paragraph t, models are required to generate a set of claims $\{c_1, c_2, ..., c_m\}$ that require evidence or proof to support their accuracy or truthfulness. (2) Document retrieval: Given a claim c, models are expected to predict search queries $\{q_1, q_2, ..., q_k\}$ to retrieve relevant articles from a knowledge source. (3) Sentence retrieval: Given a claim c and relevant passages $\{p_1, p_2, ..., p_k\}$, models are required to select evidence sentences $\{s_1, ..., s_n\}$ from the articles. These evidence sentences can either (partially) support or refute the claim, depending on the veracity label design. (4) Verdict prediction: Given a claim c and the evidence sentences $\{e_1, ..., e_n\}$, models are required to predict the veracity label. The fact-checking process requires the claim processor, query generator, evidence seeker, and verdict counselor modules.

FEVER Dataset In the FEVER (Thorne et al., 2018) dataset, claims consist of a single piece of information and do not require further decomposition. The verification of a claim in FEVER involves document retrieval, sentence retrieval and verdict prediction. The FEVER dataset uses three identification labels: Supported, Refuted, and NotEnoughInfo. A claim is verified as NotEnoughInfo if there is insufficient information in Wikipedia to support or refute the claim, either because the claim is too general or too detailed. The dataset provides the names of evidence Wikipedia passages and the indices of evidence sentences. In the verification process, the names of evidence articles serve as search queries. To verify a claim in the FEVER dataset, the Self-Checker framework adopts query generator, evidence seeker, and verdict counselor. We follow the experiment setting in the previous research (Zhao et al., 2023) and use the same subset of Fever.

WiCE Dataset The WiCE dataset is specifically designed for verifying Wikipedia citations and consists of claims grounded in cited articles from Wikipedia. Unlike the FEVER dataset, the claims in WiCE contain multiple pieces of information. The verification process in WiCE involves claim detection, sentence retrieval, and verdict prediction. Complex claims in WiCE are decomposed into simpler subclaims. Verifying claims in WiCE primarily entails sentence retrieval for the cited articles and subsequent verdict prediction. The veracity labels in WiCE include SUPPORTED, PARTIALLYSUPPORTED, and NOTSUPPORTED. A claim is classified as PARTIALLYSUPPORTED if some tokens within the claim are not supported by any evidence sentence. The prediction results are collected at subclaim levels. The veracity label of the original claim is set to SUPPORTED or NOTSUPPORTED, depending on whether all subclaims are supported or not supported. Otherwise, the original claim is considered PARTIALLYSUPPORTED. To verify a claim in the WiCE dataset, the SELF-CHECKER framework adopts claim processor, evidence seeker, and verdict counselor modules.

4.2 Experimental Setup

Implementation All modules in the SELF-CHECKER are implemented using OpenAI GPT-3.5 (text-davinci-003) API with temperature 0.2. The prompt for policy agent consists of three examples due to the length constraint. The prompts for claim processor, query generator, evidence seeker, and verdict counselor contain fifteen examples. As for the knowledge source, we employ Bing search engine for BingCheck and Wikipedia for FEVER. Up to three retrieved passages are considered for further evidence selection. In the implementation, we stored FEVER preprocessed Wikipedia passages in a database. The retrieval mechanism automatically incorporates passages whose titles precisely match the generated search query or exhibit partial alignment with the predicted search query.

Evaluation Metrics We report label accuracy and F1 score for evidence retrieval, which is computed between all predicted sentences and the golden evidence sentences for claims requiring evidence. Consistent with baseline studies (Kamoi et al., 2023; Thorne et al., 2018), we present the F1 score for verdict prediction on the WiCE dataset and the FEVER score for results on the FEVER dataset. The FEVER score is the strict accuracy with the requirement of providing correct evidence for the SUPPORTED/REFUTED predictions.

Baselines We evaluate SELF-CHECKER against various methods. Standard prompting directly predicts verdict labels based on input claims, while Chain-of-thought prompting (Wei et al., 2022) generates explanations before making predictions. ReAct (Yao et al., 2023) follows a reason-and-act framework with an external knowledge source[3]. The setup of the knowledge source is similar to that in SELF-CHECKER. We also compare with a related method Verify-and-Edit (Zhao et al., 2023) on Fever dataset. These prompt-based methods are implemented using the OpenAI GPT-3.5 API.

In addition, we compare our approach to the initial baseline model (Thorne et al., 2018) and the state-of-the-art (SOTA) model BEVERS (DeHaven and Scott, 2023) on the FEVER dataset. The baseline model consists of a DrQA (Chen et al., 2017) document retrieval module, a DrQA-based sentence retrieval module, and an entailment module based on decomposable attention (Parikh et al., 2016). The SOTA model adopts BERT for evidence retrieval and claim verification, along with meticulous hyperparameter tuning. For the WiCE dataset, we include the initial baseline model (Kamoi et al., 2023), implemented by fine-tuning T5-3B (Raffel et al., 2020) on WiCE.

4.3 Main Results

Evaluation Results on BINGCHECK Dataset The evaluation results on BINGCHECK are presented in Table 4. We observe the inherent challenge LLMs face when determining the factualness of complex paragraphs based solely on pre-trained parametric knowledge. It is notable that LLMs prompted with standard and chain-of-thought prompts tend to align with the input, tending to recognize it as supported information. The integration of external knowledge contributes to the improvements in fact-checking. However, a performance gap persists between baseline models and the proposed framework, which underscores the importance of incorporating modules capable of decomposing complex paragraphs into simpler claims, conducting explicit analysis of retrieved passages, and predicting verdicts. Furthermore, the availability of intermediate results from the fact-checking process enhances our ability to identify performance bottlenecks within SELF-CHECKER, making it possible to guide further improvements. Despite the introduction of SELF-CHECKER, there are limitations in achieving optimal results on BINGCHECK, highlighting the inherent difficulty in fact-checking LLM-generated content and prompting further exploration.

---

[3] ReAct is not evaluated on the WiCE dataset as the knowledge retrieval is not included in the verification process for claims in WiCE.

Model	Accuracy	Evidence Retrieval		
		F1	Precision	Recall
Standard Prompt	19.4	-	-	-
Chain-of-Thought	15.7	-	-	-
ReAct (Yao et al., 2023)	21.0	-	-	-
SELF-CHECKER	63.4	45.0	30.5	86.1

Table 4: Evaluation results on BINGCHECK. The accuracy is computed on the response level.

Evaluation Results on FEVER Dataset The evaluation results on the FEVER dataset are presented in Table 5. Compared to prompt-based baselines, SELF-CHECKER improves verification accuracy with explicit evidence retrieval results. Comparing the performance of the baselines and SELF-CHECKER, we observe that LLMs possess a robust capacity to learn from few examples and perform various tasks, including query generation, retrieval and verdict prediction. However, the significant performance gap between the SOTA model and the SELF-CHECKER highlights the need to improve the efficiency of the SELF-CHECKER.

Evaluation Results on WiCE Dataset The evaluation results for the WiCE dataset are in Table 6. The F1 score for label prediction is quite low for the LLM with standard prompting, as it tends to predict the supported claim as partially or not supported. In line with earlier findings, SELF-CHECKER demonstrates superior efficiency compared to the prompt-based baselines. A noticeable performance gap emerges when comparing SELF-CHECKER with the model fine-tuned on the WiCE dataset. Specifically, in evidence retrieval, evidence seeker tends to overlook evidence in the passages, highlighting a potential bottleneck in overall performance.

4.4 Ablation Study

To assess the impact of each module on overall performance, we conduct an ablation study on three datasets. The evaluation results on BINGCHECK are shown in Table 7. The first row reflects end-to-end fact-checking performance, encompassing claim detection, document retrieval, sentence retrieval, and verdict prediction. When comparing the first and second rows, we note that providing golden claims results in improvements across all metrics. The marginal difference between results with and without golden documents suggests the low-temperature setting of the API in the query generator module ensures stable search query generation, with retrieval results for a fixed query exhibiting consistency. Even with golden evidence sentences, the label accuracy at the response level does not exceed 70, indicating potential for further enhancements in the verdict counselor module to improve the accuracy of veracity prediction. In terms of evidence retrieval performance, it is unsurprising to observe an inclination to over-select more evidence sentences. This behavior stems from the dataset construction process, where human workers filter evidence sentences selected by SELF-CHECKER, removing less relevant ones.

Analyzing the incorrect predictions with golden evidence sentences, we observe a tendency in SELF-CHECKER to be overly optimistic, classifying claims that are only partially supported as fully supported. For instance, the claim “Brain virus was released on 19 January 1986 by two brothers from Pakistan, Basit and Amjad Farooq Alvi.” is partially supported by the evidence sentence “In 1986, Brain was developed by the Pakistani brothers Basit and Amjad Farooq Alvi, who were annoyed at having their heart monitoring software copied for free.” However, SELF-CHECKER overlooks the lack of mention of the exact release date of the Brain virus and predicts the claim as supported based on the evidence.

5 Related Work

The framework for automated fact-checking involves claim detection and factual verification (Zeng et al., 2021; Guo et al., 2022). Claim detection identifies statements needing verification, while factual verification includes evidence retrieval and assessment of claim validity.

Claim detection has been approached as a binary classification task, determining if a sentence represents a claim (Hassan et al., 2017), or as a ranking task, ordering sentences based on their check-worthiness (Jaradat et al., 2018).

Fact verification requires models to assess the veracity of a given claim by examining evidence information. FEVER dataset (Thorne et al., 2018) is one of the most popular datasets in this area, and fueled the development of fact verification models (Soleimani et al., 2020; Jiang et al., 2021; Krishna et al., 2022). The fact verification in FEVER dataset consists of document retrieval, sentence selection, and verdict prediction.

The Vitamin C dataset (Schuster et al., 2021) is proposed for a contrastive fact verification paradigm which requires models to be sensi-

Table 7: Ablation results on BINGCHECK. "Golden Claims" indicates whether the golden claims are given. "Golden Evidence" indicates whether the golden documents and sentences are provided.

tive to changes in evidence and claims. The WAFER dataset (Petroni et al., 2022) contains instances from Wikipedia inline citations. The WiCE dataset (Kamoi et al., 2023) provided fine-grained annotation of supporting evidence and non-supported tokens in claims.

While many work focused on verifying claims against raw text evidence, other recent datasets cover verification against various evidence, such as table (Chen et al., 2019; Gupta et al., 2020; Akhtar et al., 2022), knowledge graph (Zhu et al., 2021; Vedula and Parthasarathy, 2021; Kim et al., 2023) and other multimodal evidence (Alam et al., 2022).

Factual error correction is a task closely related to fact-checking. After assessing the factualness of claims within the input text, a subsequent step is addressing any inaccuracies to improve factual integrity. Recent studies have explored methods for refining the factualness of text outputs by leveraging retrieved evidence (Thorne and Vlachos, 2021; Iv et al., 2022; Huang et al., 2023). In addition to approaches specialized in correcting factual errors, some recent frameworks first assess the factualness of its initial generation and then amend any detected inaccuracies to enhance the overall veracity of the generation (Wang et al., 2023; Dhuliawala et al., 2023; Fatahi Bayat et al., 2023).

6 Conclusion and Future Work

We present SELF-CHECKER, a framework for automated fact-checking with plug-and-play modules implemented through prompting LLMs. Additionally, we introduce the BINGCHECK dataset, which serves as a valuable resource for future research in fact-checking of LLM-generated responses. Experimental results demonstrate the significant potential of SELF-CHECKER in the fact-checking task.

In future work, a key direction to explore is to enhance the efficiency of SELF-CHECKER. One potential avenue is the incorporation of additional working memory to accelerate the verification process by using past information. Furthermore, investigating more efficient strategies for utilizing LLMs in each subtask of fact-checking holds promise for optimizing performance.

Limitations

One limitation of SELF-CHECKER is its inability to account for information updates. If there is out-of-date information that contradicts a claim, SELF-CHECKER may classify the claim as refuted even if it is actually supported by the most up-to-date information. This limitation arises due to the mixed and unrefined sources of information used by SELF-CHECKER during the fact-checking process. SELF-CHECKER does not contain a module to postprocess and filter the retrieved articles. Another limitation of SELF-CHECKER is its high computational cost due to the involvement of multiple chained LLM calls in the process of fact-checking. To ensure the reliability of predictions, we adopt the majority voting approach by running evidence seeker and verdict counselor multiple times. Although this approach can improve accuracy and stability, it may result in slower response times. However, we anticipate that this limitation can be mitigated in the future with the advancement of more efficient and accessible LLMs. In addition, we will explore providing options to achieve a balance between accuracy and waiting time, allowing users to make informed trade-offs based on their specific requirements. Another limitation is the sensitivity of SELF-CHECKER to prompts. In our preliminary experiments, we have observed variations in performance when using different prompts. Enhancing the robustness of LLMs to prompts is an avenue for future exploration, aiming to improve the reliability and consistency of SELF-CHECKER. Furthermore, the current prompts are manually designed, which may be heuristic in nature. We consider investigating automated methods for selecting in-context learning examples and generating strong prompts in the future work. Additionally, the selection of hyperparameters in SELF-CHECKER currently relies on heuristics. Exploring more efficient automated approaches for hyperparameter tuning could improve the overall efficiency of the framework.

A potential limitation of the BINGCHECK dataset is the potential bias during annotation. The classification of the veracity of a claim can be subjective. It is important to consider this factor when interpreting and utilizing the BINGCHECK dataset for research purposes.

Ethics Statement

In this work, we focus on utilizing SELF-CHECKER to tackle the problem of hallucinations in the generation results of LLMs. However, it is important to acknowledge that LLMs' generation can also exhibit other potential issues, including the production of offensive and harmful content. Currently, SELF-CHECKER does not address these problems. To mitigate these concerns, future work on SELF-CHECKER could incorporate a dedicated module specifically designed to detect and remove offensive and harmful content.

A Example Prompts for Self-Checker

The example prompts for modules in Self-Checker are shown in Figure 4, 5, 6, 7, 8.

B BingCheck Dataset

B.1 Human Annotation Instruction

We collected human annotated data for BingCheck in two steps. The design of annotation for claim decomposition is shown in Figure 9. The design of annotation for evidence retrieval and veracity prediction is shown in Figure 10.

B.2 Data Format in BingCheck

A record in BingCheck contains user query, original LLM response, and fact-checking annotation. The fact-checking annotation involves claims to verify, search queries, search results, selected evidence, and verdict labels. Figure 11 shows an annotated record example.

Try your best to determine if the given input response is factually accurate.

<tool introduction>

Use the following format:

Response: the response of language model to the user query. you must verify the factual accuracy of the response. If the input is to long, summarize it without changing factualness.
Thought: you should always realize what you have known and think about what to do and which tool to use.
Action: the action to take, should be one of [actions]
Action Input: the input to the action, must follow instructions of tools
Observation: the result of the action
... (this Thought/Action/Action Input/Observation can repeat N times)
Thought: I can give an answer based on the evidence
Final Answer: should be in the form: supported, partially supported, not supported, refuted

<in-context examples>

Begin!

<text to verify>

Figure 4: Example prompt for the policy agent.

You and your partners are on a mission to fact-check a claim that may contain multiple subclaims that need to be verified. A sentence that needs to be verified is any statement or assertion that requires evidence or proof to support its accuracy or truthfulness. For example, “Titanic was first released in 1997” necessitates verification of the accuracy of its release date, whereas a claim like "Water is wet" does not warrant verification. Each subclaim is a simple, complete sentence with single point to be verified. Imagine yourself as an expert in processing complex paragraphs and extracting subclaims. Your task is to extract clear, unambiguous subclaims to check from the input paragraph, avoiding vague references like ’he,’ ’she,’ ’it,’ or ’this,’ and using complete names.

To illustrate the task, here are some examples:
<in-context examples>

Now, let’s return to your task. You are given the following input paragraph, please extract all subclaims that need to be checked.

Input: <input>
Subclaims: <extracted claims>

Figure 5: Example prompt for the claim processor module. <Extracted claims> is the expected output of the LLM for claim processor.

You and your partners are on a mission to fact-check a paragraph. Subclaims requiring verification have been extracted from the paragraph. Imagine yourself as an internet research expert. Your task is to generate a search query for each subclaim to find relevant information for fact-checking. You will be provided with the context of a claim and the specific claim for which you should create a search query.

To illustrate the task, here are some examples:
<in-context examples>

Now, let’s return to your task. You are given the following claim and its context, please predict the most appropriate search query for it.

Context: <original input text>
Claim: <claim to verify>
Query: <predicted search queries>

Figure 6: Example prompt for the query generator module. <Predicted search queries> is the expected output of the LLM for query generator.

You and your partners are on a mission to fact-check a claim. Your mission is to verify a claim's factual accuracy. As experts in reading comprehension, you'll receive a claim and a passage. You should first read the claim and the passage carefully. Make sure you understand what information you are looking for. Then select sentences that either support, partially support, or refute the claim. A sentence supports the claim if it provides evidence for all statements in the claim. A sentence partially supports the claim if it confirms some details but not all. A sentence refutes the claim if it contradicts any statement in the claim. Exercise caution in your selection and judgment, avoiding overstatement. Choose the most relevant evidence and refrain from including noisy information. Base decisions solely on provided information without implying additional details.

To illustrate the task, here are some examples:
<in-context examples>

Now, let's focus on your task. You are given a claim and a passage. Please read the passage carefully and copy sentences that contain information supporting or refuting the claim.

Claim: <claim to verify>
Passage: <passage>
Evidence: <selected evidence>

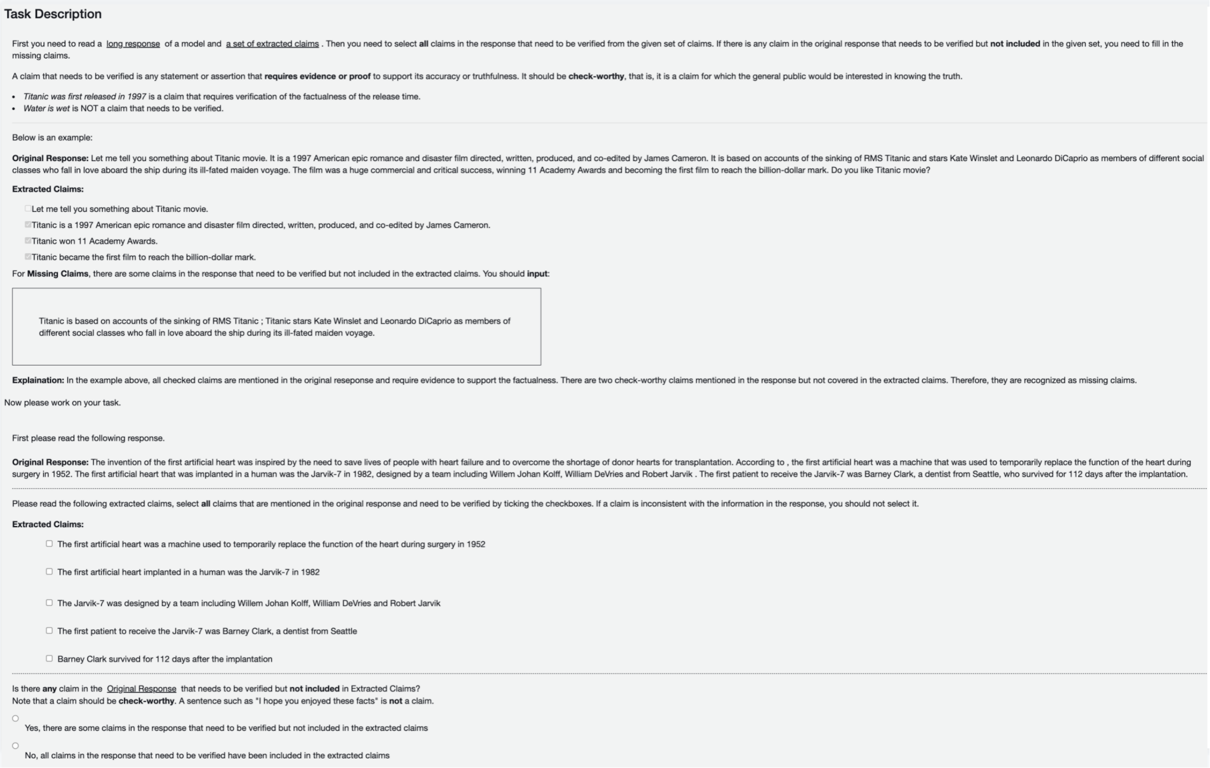
Figure 7: Example prompt for the evidence seeker. <Selected evidence> is the expected output of the LLM for evidence seeker.

You and your partners are on a mission to fact-check a claim. Your mission is to verify the factual accuracy of a claim using provided evidence. Your partners have collected evidence, and your expertise lies in assessing the claim's factualness based on this evidence. You are required to determine whether the claim is supported, refuted, or lacks sufficient information based on the provided evidence. The evidence supports the claim if it confirms all statements and details in the claim. The evidence refutes the claim if it contradicts or disproves any statement in the claim. 'Not enough info' applies when the evidence lacks sufficient data, details, or reasoning to support or refute the claim. Even if the evidence supports part of the claim, it should be considered "not enough info" if there is any detail or statement in the claim that cannot be confirmed by the evidence. Please exercise caution in making judgments and avoid overstatement. Base decisions solely on the provided information without implying additional details.

Here are examples to illustrate the task:
<in-context examples>

Claim: <claim to verify>
Evidence: <selected evidence>
Analysis: <verdict prediction>

Figure 8: Example prompt for the verdict counselor. <Verdict prediction> is the expected output of the LLM for verdict counselor.



Task Description

First you need to read a long response of a model and a set of extracted claims . Then you need to select **all** claims in the response that need to be verified from the given set of claims. If there is any claim in the original response that needs to be verified but **not included** in the given set, you need to fill in the missing claims.

A claim that needs to be verified is any statement or assertion that **requires evidence or proof** to support its accuracy or truthfulness. It should be **check-worthy**, that is, it is a claim for which the general public would be interested in knowing the truth.

- *Titanic was first released in 1997* is a claim that requires verification of the factualness of the release time.
- *Water is wet* is NOT a claim that needs to be verified.

Below is an example:

Original Response: Let me tell you something about Titanic movie. It is a 1997 American epic romance and disaster film directed, written, produced, and co-edited by James Cameron. It is based on accounts of the sinking of RMS Titanic and stars Kate Winslet and Leonardo DiCaprio as members of different social classes who fall in love aboard the ship during its ill-fated maiden voyage. The film was a huge commercial and critical success, winning 11 Academy Awards and becoming the first film to reach the billion-dollar mark. Do you like Titanic movie?

Extracted Claims:

☐ Let me tell you something about Titanic movie.
☑ Titanic is a 1997 American epic romance and disaster film directed, written, produced, and co-edited by James Cameron.
☑ Titanic won 11 Academy Awards.
☑ Titanic became the first film to reach the billion-dollar mark.

For **Missing Claims**, there are some claims in the response that need to be verified but not included in the extracted claims. You should **input**:

Titanic is based on accounts of the sinking of RMS Titanic ; Titanic stars Kate Winslet and Leonardo DiCaprio as members of different social classes who fall in love aboard the ship during its ill-fated maiden voyage.

Explaination: In the example above, all checked claims are mentioned in the original reseponse and require evidence to support the factualness. There are two check-worthy claims mentioned in the response but not covered in the extracted claims. Therefore, they are recognized as missing claims.

Now please work on your task.

First please read the following response.

Original Response: The invention of the first artificial heart was inspired by the need to save lives of people with heart failure and to overcome the shortage of donor hearts for transplantation. According to , the first artificial heart was a machine that was used to temporarily replace the function of the heart during surgery in 1952. The first artificial heart that was implanted in a human was the Jarvik-7 in 1982, designed by a team including Willem Johan Kolff, William DeVries and Robert Jarvik . The first patient to receive the Jarvik-7 was Barney Clark, a dentist from Seattle, who survived for 112 days after the implantation.

Please read the following extracted claims, select **all** claims that are mentioned in the original response and need to be verified by ticking the checkboxes. If a claim is inconsistent with the information in the response, you should not select it.

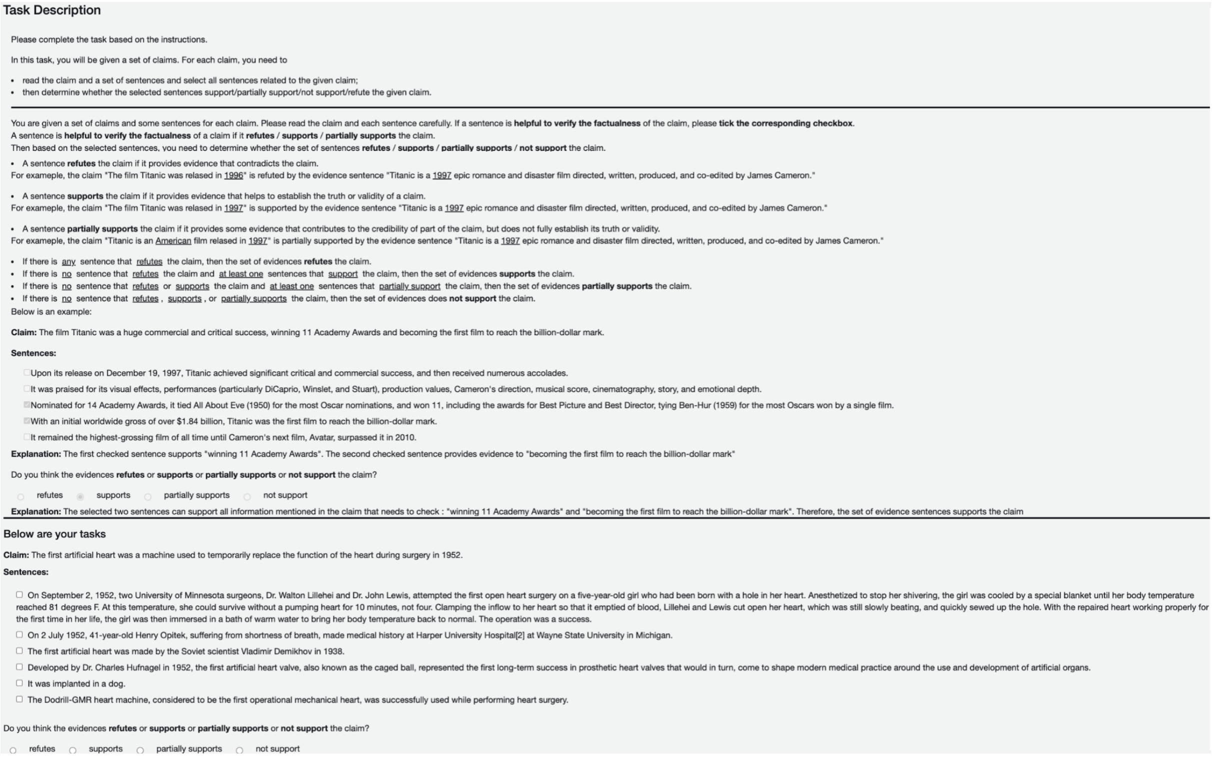
Extracted Claims:

☐ The first artificial heart was a machine used to temporarily replace the function of the heart during surgery in 1952
☐ The first artificial heart implanted in a human was the Jarvik-7 in 1982
☐ The Jarvik-7 was designed by a team including Willem Johan Kolff, William DeVries and Robert Jarvik
☐ The first patient to receive the Jarvik-7 was Barney Clark, a dentist from Seattle
☐ Barney Clark survived for 112 days after the implantation

Is there **any** claim in the Original Response that needs to be verified but **not included** in Extracted Claims?
Note that a claim should be **check-worthy**. A sentence such as "I hope you enjoyed these facts" is **not** a claim.

○ Yes, there are some claims in the response that need to be verified but not included in the extracted claims
○ No, all claims in the response that need to be verified have been included in the extracted claims

Figure 9: Design of human annotation for claim detection



Task Description

Please complete the task based on the instructions.

In this task, you will be given a set of claims. For each claim, you need to

- read the claim and a set of sentences and select all sentences related to the given claim;
- then determine whether the selected sentences support/partially support/not support/refute the given claim.

You are given a set of claims and some sentences for each claim. Please read the claim and each sentence carefully. If a sentence is **helpful to verify the factualness** of the claim, please **tick the corresponding checkbox**.
A sentence is **helpful to verify the factualness** of a claim if it **refutes** / **supports** / **partially supports** the claim.
Then based on the selected sentences, you need to determine whether the set of sentences **refutes** / **supports** / **partially supports** / **not support** the claim.

- A sentence **refutes** the claim if it provides evidence that contradicts the claim.

For exameple, the claim "The film Titanic was relased in 1996" is refuted by the evidence sentence "Titanic is a 1997 epic romance and disaster film directed, written, produced, and co-edited by James Cameron."

- A sentence **supports** the claim if it provides evidence that helps to establish the truth or validity of a claim.

For exameple, the claim "The film Titanic was relased in 1997" is supported by the evidence sentence "Titanic is a 1997 epic romance and disaster film directed, written, produced, and co-edited by James Cameron."

- A sentence **partially supports** the claim if it provides some evidence that contributes to the credibility of part of the claim, but does not fully establish its truth or validity.

For exameple, the claim "Titanic is an American film relased in 1997" is partially supported by the evidence sentence "Titanic is a 1997 epic romance and disaster film directed, written, produced, and co-edited by James Cameron."

- If there is any sentence that refutes the claim, then the set of evidences **refutes** the claim.
- If there is no sentence that refutes the claim and at least one sentences that support the claim, then the set of evidences **supports** the claim.
- If there is no sentence that refutes or supports the claim and at least one sentences that partially support the claim, then the set of evidences **partially supports** the claim.
- If there is no sentence that refutes , supports , or partially supports the claim, then the set of evidences does **not support** the claim.

Below is an example:

Claim: The film Titanic was a huge commercial and critical success, winning 11 Academy Awards and becoming the first film to reach the billion-dollar mark.

Sentences:

☐ Upon its release on December 19, 1997, Titanic achieved significant critical and commercial success, and then received numerous accolades.
☐ It was praised for its visual effects, performances (particularly DiCaprio, Winslet, and Stuart), production values, Cameron's direction, musical score, cinematography, story, and emotional depth.
☑ Nominated for 14 Academy Awards, it tied All About Eve (1950) for the most Oscar nominations, and won 11, including the awards for Best Picture and Best Director, tying Ben-Hur (1959) for the most Oscars won by a single film.
☑ With an initial worldwide gross of over $1.84 billion, Titanic was the first film to reach the billion-dollar mark.
☐ It remained the highest-grossing film of all time until Cameron's next film, Avatar, surpassed it in 2010.

Explanation: The first checked sentence supports "winning 11 Academy Awards". The second checked sentence provides evidence to "becoming the first film to reach the billion-dollar mark"

Do you think the evidences **refutes** or **supports** or **partially supports** or **not support** the claim?

○ refutes ● supports ○ partially supports ○ not support

Explanation: The selected two sentences can support all information mentioned in the claim that needs to check : "winning 11 Academy Awards" and "becoming the first film to reach the billion-dollar mark". Therefore, the set of evidence sentences supports the claim

Below are your tasks

Claim: The first artificial heart was a machine used to temporarily replace the function of the heart during surgery in 1952.

Sentences:

☐ On September 2, 1952, two University of Minnesota surgeons, Dr. Walton Lillehei and Dr. John Lewis, attempted the first open heart surgery on a five-year-old girl who had been born with a hole in her heart. Anesthetized to stop her shivering, the girl was cooled by a special blanket until her body temperature reached 81 degrees F. At this temperature, she could survive without a pumping heart for 10 minutes, not four. Clamping the inflow to her heart so that it emptied of blood, Lillehei and Lewis cut open her heart, which was still slowly beating, and quickly sewed up the hole. With the repaired heart working properly for the first time in her life, the girl was then immersed in a bath of warm water to bring her body temperature back to normal. The operation was a success.
☐ On 2 July 1952, 41-year-old Henry Opitek, suffering from shortness of breath, made medical history at Harper University Hospital[2] at Wayne State University in Michigan.
☐ The first artificial heart was made by the Soviet scientist Vladimir Demikhov in 1938.
☐ Developed by Dr. Charles Hufnagel in 1952, the first artificial heart valve, also known as the caged ball, represented the first long-term success in prosthetic heart valves that would in turn, come to shape modern medical practice around the use and development of artificial organs.
☐ It was implanted in a dog.
☐ The Dodrill-GMR heart machine, considered to be the first operational mechanical heart, was successfully used while performing heart surgery.

Do you think the evidences **refutes** or **supports** or **partially supports** or **not support** the claim?

○ refutes ○ supports ○ partially supports ○ not support

Figure 10: Design of human annotation for evidence retrieval and veracity prediction

User Query: What inspired the invention of the first artificial heart?

LLM Response: The invention of the first artificial heart was inspired by the need to save lives of people with heart failure and to overcome the shortage of donor hearts for transplantation. According to, the first artificial heart was a machine that was used to temporarily replace the function of the heart during surgery in 1952. The first artificial heart that was implanted in a human was the Jarvik-7 in 1982, designed by a team including Willem Johan Kolff, William DeVries and Robert Jarvik. The first patient to receive the Jarvik-7 was Barney Clark, a dentist from Seattle, who survived for 112 days after the implantation.

Fact-checking Annotation:

Claim 1: The invention of the first artificial heart was inspired by the need to save lives of people with heart failure and to overcome the shortage of donor hearts for transplantation.
Search Query: Artificial heart invention inspiration and purpose
Evidence:
The purpose is to develop a temporary machine or pump for a person who has a disease of the heart and their survival without transplant is impossible.
These temporary devices can provide enough time for the patient until a donor heart is available.

Figure 11: An example in BingCheck. A record contains a user query, original LLM response, and fact-checking annotation. The fact-checking annotation involves claims to verify, search queries, search results, selected evidence, and verdict labels. The search results and the part of selected evidence are omitted due to space limit.

Model	Golden Evidence		FEVER Score	Accuracy	Evidence Retrieval		
	Document	Sentence			F1	Precision	Recall
SELF-CHECKER	✗	✗	51.3	62.7	55.9	64.1	49.5
	✓	✗	64.1	72.8	75.8	90.3	65.4
		✓	-	81.20	-	-	-

Table 8: Ablation results on entire FEVER test set. "Golden Evidence" indicates whether the golden documents/sentences are provided.

Model	Golden Evidence	Claim Split	F1	Accuracy	Evidence Retrieval		
					F1	Precision	Recall
T5-3B (Kamoi et al., 2023)	✗	✓	65.3	77.1	67.4	65.0	81.7
	✓	✓	78.0	84.4	-	-	-
SELF-CHECKER	✗	✓	64.4	68.4	42.1	70.2	30.1
	✗	✗	35.6	35.8	23.5	91.1	13.5
	✓	✓	78.7	78.8	-	-	-
	✓	✗	71.5	47.7	-	-	-

Table 9: Ablation results on WiCE. "Golden Evidence" indicates whether golden sentences are provided. "Claim Split" indicates whether claim decomposition is performed. Note that we compare with the model finetuned on WiCE dataset (Kamoi et al., 2023).

C Ablation Study

Ablation Study Results on FEVER dataset Comparing the first and second rows of Table 8, we observe substantial improvements across all metrics when predicted documents are replaced with golden evidence documents. This improvement suggests the importance of exploring more effective strategies for generating appropriate search queries and improving document retrieval accuracy. Furthermore, the inclusion of golden evidence sentences can further improve the accuracy of veracity prediction by more than 8 points. However, even with golden evidence sentences, the SELF-CHECKER lags behind the SOTA model in label accuracy, indicating the need for further enhancements in the verdict counselor's performance.

Ablation Study Results on Wice Dataset The evaluation results on WiCE dataset is shown in Table 9. The slight improvement in verdict prediction between the first and third rows of the SELF-CHECKER results suggests that the evidence seeker module's efficiency is unlikely to be the primary bottleneck in the SELF-CHECKER's performance. However, comparing the second row of the baseline with the third row of the SELF-CHECKER results highlights that the verdict counselor module's performance is the primary bottleneck in the overall performance of SELF-CHECKER. This finding aligns with the results obtained on the FEVER dataset, indicating the significant potential for enhancing verdict prediction despite LLMs' superior capabilities in various NLP tasks. Consistent with prior findings (Kamoi et al., 2023), we find that decomposing complex claims into simpler sub-claims improves both evidence retrieval and verdict prediction.

Low-resource neural machine translation with morphological modeling

Antoine Nzeyimana
University of Massachusetts Amherst
anthonzeyi@gmail.com

Abstract

Morphological modeling in neural machine translation (NMT) is a promising approach to achieving open-vocabulary machine translation for morphologically-rich languages. However, existing methods such as sub-word tokenization and character-based models are limited to the surface forms of the words. In this work, we propose a framework-solution for modeling complex morphology in low-resource settings. A two-tier transformer architecture is chosen to encode morphological information at the inputs. At the target-side output, a multi-task multi-label training scheme coupled with a beam search-based decoder are found to improve machine translation performance. An attention augmentation scheme to the transformer model is proposed in a generic form to allow integration of pre-trained language models and also facilitate modeling of word order relationships between the source and target languages. Several data augmentation techniques are evaluated and shown to increase translation performance in low-resource settings. We evaluate our proposed solution on Kinyarwanda ↔ English translation using public-domain parallel text. Our final models achieve competitive performance in relation to large multi-lingual models. We hope that our results will motivate more use of explicit morphological information and the proposed model and data augmentations in low-resource NMT.

1 Introduction

Neural Machine Translation (NMT) has become a predominant approach in developing machine translation systems. Two important innovations in recent state-of-the-art NMT systems are the use of the Transformer architecture (Vaswani et al., 2017) and sub-word tokenization methods such as byte-pair encoding (BPE) (Sennrich et al., 2016). However, for morphologically-rich languages(MRLs), BPE-based tokenization is only limited to the surface forms of the words and less grounded on exact lexical units (i.e. morphemes), especially in the presence morphographemic alternations (Bundy and Wallen, 1984) and non-concatenative morphology (Kastner et al., 2019). In this work, we tackle the challenge of modeling complex morphology in low-resource NMT and evaluate on Kinyarwanda, a low-resource and morphologically-rich language spoken by more than 15 million people in Eastern and Central Africa[1].

To model the complex morphology of MRLs in machine translation, one has to consider both source-side modeling (i.e. morphological encoding) and target-side generation of inflected forms (i.e. morphological prediction). We explicitly use the morphological structure of the words and the associated morphemes, which form the basic lexical units. For source-side encoding, morphemes are first produced by a morphological analyzer before being passed to the source encoder through an embedding mechanism. On the target side, the morphological structure must be predicted along with morphemes, which are then consumed by an inflected form synthesizer to produce surface forms. Therefore, this approach enables open vocabulary machine translation since morphemes can be meaningfully combined to form new inflected forms not seen during training.

Previous research has shown that certain adaptations to NMT models, such as the integration of pre-trained language models (Zhu et al., 2020; Sun et al., 2021), can improve machine translation performance. We explore this idea to improve low-resource machine translation between Kinyarwanda and English. Our model augmentation focuses on biasing the attention computation in the transformer model. Beside augmentation from pre-trained language model integration, we also devise an augmentation based solely on the

Findings of the Association for Computational Linguistics: NAACL 2024, pages 182–195
June 16-21, 2024 ©2024 Association for Computational Linguistics

word order relationship between source and target languages. These model augmentations bring substantial improvement in translation performance when parallel text is scarce.

One of the main challenges facing machine translation for low-resource languages obviously is parallel data scarcity. When the training data has limited lexical coverage, the NMT model may tend to hallucinate (Raunak et al., 2021; Xu et al., 2023). Additionally, for a morphology-aware translation model, there is a problem of misaligned vocabularies between source and target languages. This makes it harder for the model to learn to copy unknown words and other tokens that need to be copied without translation such as proper names. To address these challenges, we take a data-centric approach by developing tools to extract more parallel data from public-domain documents and websites. We also use various data augmentation techniques to increase lexical coverage and improve token copying ability where necessary. By combining these data-centric approaches with our morphology-aware NMT model, we achieve competitive translation performance in relation to larger multi-lingual NMT models. To have a comprehensive evaluation, we evaluate our models on three different benchmarks covering different domains, namely Wikipedia, News and Covid-19.

In short, our contribution in this work can be summarized as follow:

- We propose and evaluate methods for source-side and target-side morphological modeling in neural machine translation of morphologically-rich languages.
- We propose a generic method for attention augmentation in the transformer architecture, including a new cross-positional encoding technique to fit word order relationships between source and target language.
- We evaluate on Kinyarwanda↔English translation across three benchmarks and achieve competitive performance in relation to existing large multi-lingual NMT models.
- We release tools for parallel corpus construction from public-domain sources and make our source code publicly available to allow reproducibility[2].

2 Methods

Machine translation (MT) can be considered as the task of accurately mapping a sequence of tokens (e.g. phrase, sentence, paragraph) in the source language $S = (s_1, s_2, ...s_n)$ to a sequence of tokens in the target language $T = (t_1, t_2, ...t_m)$ with the same meaning. The learning problem is then to estimate a conditional probability model that produces the optimal translation T^*, that is:

$$T^* = \arg\max_{T} P(T|S, T_<; \Theta),$$

where $T_<$ accounts for the previous output context and Θ are parameters of the model (that is a neural network in the case of NMT).

In this section, we describe our model architecture as an extension of the basic Transformer architecture (Vaswani et al., 2017) to enable morphological modeling and attention augmentation. We also describe our data-centric approaches to dataset development and augmentation in the context of the low-resource Kinyarwanda↔English machine translation.

2.1 Model architecture

The transformer architecture (Vaswani et al., 2017) for machine translation uses a multi-layer bidirectional encoder to process source language input, and then feeds to an auto-regressive decoder to produce the target language output. Our adaptation of the transformer encoder is depicted in Figure 1 while the decoder is shown in Figure 2. They both use pre-LayerNorm configuration (Nguyen and Salazar, 2019) of the transformer.

The **attention module** of the transformer architecture is designed as querying a dictionary made of key-value pairs using a softmax function and then projecting a weighted sum of value vectors to an output vector, that is:

$$Attention(Q, K, V) = Softmax(\frac{QK^T}{\sqrt{d}})V, \quad (1)$$

where K,Q,V are projections of the hidden representations of inputs at a given layer. Given a hidden representation of a token v_i attending to a sequence of tokens with hidden representations $(w_1, w_2, ...w_n)$, the output of the attention module

---

[2] `https://github.com/anzeyimana/KinMT_NAACL2024`

corresponding to v_i can be formulated as:

$$v_i^{'} = \sum_{j=1}^{n} \frac{\exp(\alpha_{ij})}{\sum_{j'=1}^{n} \exp(\alpha_{ij'})}(w_j W_V),$$
$$\text{where the logits } \alpha_{ij} = \frac{1}{\sqrt{d}}(v_i W_Q)(w_j W_K)^T, \quad (2)$$

with $W_Q \in \mathbb{R}^{d \times d_K}, W_K \in \mathbb{R}^{d \times d_K}$, and $W_V \in \mathbb{R}^{d \times d_V}$ being learnable projection matrices. d, d_K and d_V are the dimensions of the input, key and value respectively.

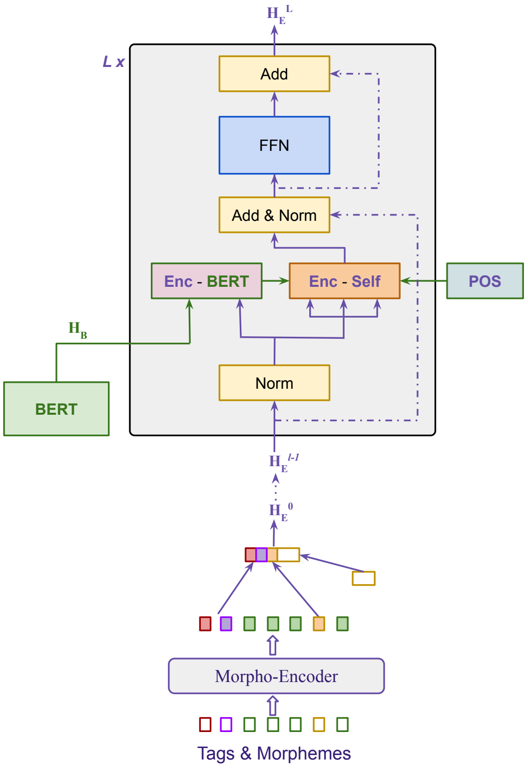

Figure 1: Encoder architecture

2.1.1 Attention augmentations

Ke et al. (2020) proposed to add bias terms to the logits α_{ij} in Equation 2 as untied positional encoding, disentangling a mixing of token and position embeddings. We generalize this structure by allowing more biases to be added to the logits α_{ij} in Equation 2.

Specifically, we explore augmenting two attention components in the transformer architecture by making the following extensions:

1. *For* ***Source-to-source self-attention*** *at each encoder layer*: We integrate embeddings from a pre-trained BERT (Devlin et al., 2019) model. This adds rich contextual information as BERT models are pre-trained on large monolingual data and perform well on language understanding tasks. We also add positional encodings at this level, similar to (Ke et al., 2020). Therefore, the logits α_{ij} at encoder layer l become:

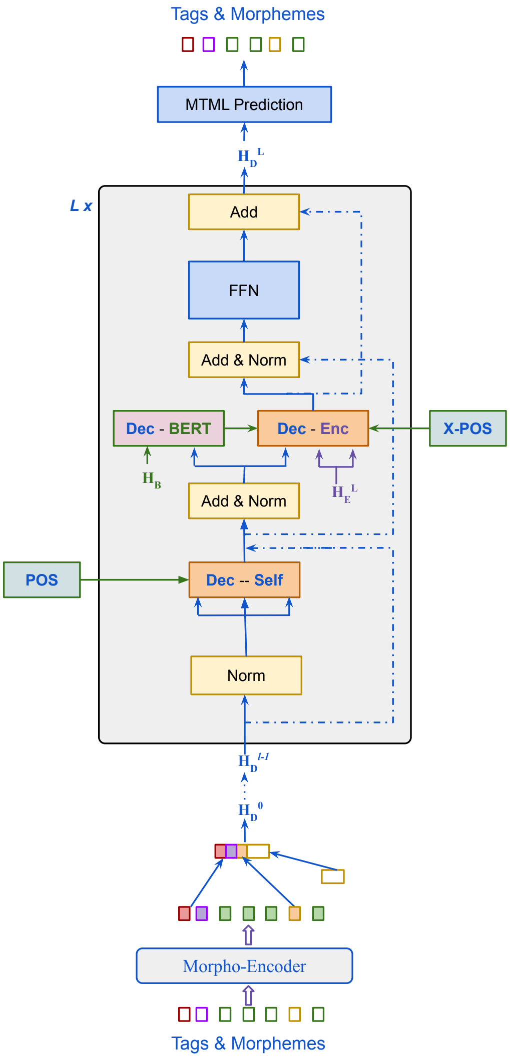

Figure 2: Decoder architecture

$$\begin{aligned}\alpha_{ij} = \frac{1}{\sqrt{3d}}[&(x_i^{(l)}W_Q^{(l)})(x_j^{(l)}W_K^{(l)})^T \\ &+ (p_iU_Q)(p_jU_K)^T + r_{j-i} \\ &+ (x_i^{(l)}V_Q^{(l)})(b_jV_K^{(l)})^T],\end{aligned} \quad (3)$$

where $x_i^{(l)}$ and $x_j^{(l)}$ are hidden representations of source tokens at positions i and j respectively of the encoder layer l; p_i and p_j are absolute position embeddings; r_{j-i} is a relative position embedding; b_j is a pre-trained BERT embedding of token at position j and

$W_Q^{(l)}, W_K^{(l)}, U_Q, U_K, V_Q^{(l)}$ and $V_K^{(l)}$ are learnable projection matrices. We note that this formulation requires the source encoder to match the same token vocabulary as the BERT embedding model.

2. *For* ***target-to-source cross-attention*** *at each decoder layer l*, we also augment the attention logits with pre-trained BERT embeddings of the source sequence. Additionally, we propose a new type of embedding: **cross-positional embeddings**. These are embeddings that align target sequence positions to input sequence positions. Their role can be thought as of learning word order relationships between source and target languages. Their formulation is closely similar to the untied positional encoding proposed by (Ke et al., 2020), but they cross from target to source positions, thus, we name them cross-positional (XPOS) encodings. The attention logits α'_{ij} at this level thus become:

$$\begin{aligned}\alpha'_{ij} = \frac{1}{\sqrt{3d}}[&(y_i^{(l)} W_Q^{'(l)})(x_j^{(L)} W_K^{'(l)})^T \\ &+ (p'_i U'_Q)(p'_j U'_K)^T + r'_{j-i} \\ &+ (y_i^{(l)} V_Q^{'(l)})(b_j V_K^{'(l)})^T],\end{aligned} \tag{4}$$

where $y_i^{(l)}$ is the hidden representation of the target token at position i and $x_j^{(L)}$ is the hidden representation of source token at position j of the final encoder layer L. p'_i and p'_j are absolute target and source XPOS embeddings, r'_{j-i} is a target-to-source relative XPOS embedding, b_j is a pre-trained BERT embedding of source token at position j and $W_Q^{'(l)}, W_K^{'(l)}, U'_Q, U'_K, V_Q^{'(l)}$ and $V_K^{'(l)}$ are the learnable projection matrices.

2.1.2 Morphological encoding

For most transformer-based encoder-decoder models, the first layer inputs are usually formed by mapping each sub-word token, such as those produced by BPE, to a learnable embedding vector. However, BPE-produced tokens do not always carry explicit lexical meaning. In fact, they cannot model non-concatenative morphology and other morphographemic processes as these BPE tokens are solely based on the surface forms. Inspired by the work of Nzeyimana and Rubungo (2022), we explore using a small transformer encoder to form a word-compositional model based on the morphological structure and the associated morphemes.

Depicted at the input layers in Figure 1 and Figure 2, the morphological encoder or *Morpho-Encoder* is a small transformer encoder that processes a set of four embedding units at the word composition level: (1) **the stem**, (2) a **variable number of affixes**, (3) a coarse-grained **part-of-speech (POS) tag** and, (4) a fine-grained **affix set index**. An affix set represents one of many frequent affix combinations observed empirically. Thus, the affix set index is equivalent to a fine-grained **morphological tag**.

The *Morpho-Encoder* processes all word-compositional units as a set without any ordering information. This is because none of these units can be repeated in the same word. In cases of stem reduplication phenomena (Inkelas and Zoll, 2000), only one stem is used, while the reduplication structure is captured by the affix set. At the output of the *Morpho-Encoder*, hidden representations corresponding to units other than the affixes are pulled and concatenated together to form a word hidden vector to feed to the main sequence model. In addition to this, a new stem embedding vector at the sequence level is also concatenated with the pulled vectors from the *Morpho-Encoder* to form the final hidden vector representing the word.

In our experiments, we use 24,000 most frequent affix combinations as affix sets. Any infrequent combination of affixes can always be reduced to a frequent one by removing one or more affixes. However, all affixes still contribute to the word composition via the *Morpho-Encoder*.

We note that the *Morpho-Encoder* applies to both the encoder and the auto-regressive decoder's input layers for all types of tokens. While the word-compositional model above relates mostly to inflected forms, we are able generalize this to other typed of tokens such as proper names, numbers and punctuation marks. For these other tokens, we process them using BPE and consider the resulting sub-word tokens as special stems without affixes.

2.1.3 Target-side morphology learning

Considering the morphological model employed at the input layer, the decoder outputs for a morphologically-rich target language must be used to predict the same types of morphological units used at the input layer, namely, the stem, affixes, the POS tag and the affix set. This becomes a multi-task and multi-label (MTML) classification problem which requires optimizing multiple objectives, corresponding to 4 types loss functions:

$$\begin{aligned}\ell_S &= \ell_{CE}(f_S(h^L), y_S)\\ \ell_A^{(i)} &= \ell_{BCE}(f_A(h^L), y_A^{(i)}), \forall i \in \mathcal{A}\\ \ell_P &= \ell_{CE}(f_P(h^L), y_P)\\ \ell_{AS} &= \ell_{CE}(f_{AS}(h^L), y_{AS}),\end{aligned} \tag{5}$$

where h^L is the decoder output, $\mathcal{A}$ is the set of affix indices, f_S, f_A, f_P, and f_{AS} are prediction heads transforming the decoder output to probabilities over the sets of stems, affixes, POS tags and affix sets respectively. y_S, y_A, y_P, and y_{AS} respectively correspond to the stem, affixes, POS tags and affix set of a target word y. ℓ_{CE} is a cross-entropy loss function and ℓ_{BCE} is a binary cross-entropy loss function.

A naive approach to the MTML problem consists of summing up all the losses and optimizing the sum. However, this can lead to a biased outcome since individual losses take on different ranges and have varying levels of optimization difficulty. Complicating the problem further is the fact that individual objectives can contribute conflicting gradients, making it harder to train the multi-task model with standard gradient descent algorithms. A potential solution to this problem comes form the multi-lingual NMT literature with a scheme called Gradient Vaccine (Wang et al., 2020). This method attempts to mediate conflicting gradient updates from individual losses by encouraging more geometrically aligned parameter updates. We evaluate both the naive summation and the Gradient Vaccine methods in our experiments.

2.1.4 Morphological inference

The decoder architecture presented in subsection 2.1.3 only predicts separate probabilities for stem, POS tag, affix set and affixes. But the translation task must produce surface forms to generate the output text. The challenge of this task is that greedily picking the items with maximum probability may not produce the best output and may even produce incompatible stems and affixes, that is, we must produce a stem and affixes of the same inflection group (e.g. verb, noun, pronoun, etc..). It is also known that beam search algorithm generally produces better sequence outputs than greedy decoding. Therefore, we design an adaptation of the beam search algorithm, where at each step, we produce a list of scored candidate surface forms together with their morphological information to feed back to the decoder's input. The design criteria is to make sure the top predicted items can form compatible pairs of stems and affix sets. The main requirement for the algorithm is the availability of a morphological synthesizer that can produce surface forms given an inflection group, the stem and compatible affixes. The morphological synthesizer must also respect all existing morphographemic rules for the language. We we provide detailed pseudocode for the decoding algorithm in Appendix C. The algorithm has 4 basic steps:

1. voting on inflection group
2. filtering out less probable stems and affixes
3. selecting target affixes, and finally
4. morphological synthesis for each final stem and affixes combination.

2.2 Dataset

Dataset development and data-centric approaches to neural machine translation (NMT) are of paramount importance for low-resource languages. This is because the most limiting factor is the scarcity of parallel data. While describing the data collection process and pre-processing steps is important, it is equally important to fully disclose the data provenance as there are typically a limited number of sources of parallel data per language. We conduct our experiments using public-domain parallel text. In this section, we describe our parallel data gathering process as well as the reliable sources we used to source Kinyarwanda-English bitext. We also describe simple data augmentation techniques we used to boost the performance of our experimental models. Due to copyright and licensing restrictions, we cannot redistribute our experimental dataset. Instead, we release the tools used for their construction from original sources. The sizes of the parallel datasets we gathered are provided in Appendix B.

2.3 Official Gazette

Official gazettes are periodical government journals typically with policy and regulation content. When a country has multiple official languages, content may be available as parallel text with each paragraph of the journal available in each official language. We took this opportunity and collected an experimental parallel text from the Official Gazette of the Republic of Rwanda[3], where Kinyarwanda,

---

[3] `https://www.minijust.gov.rw/official-gazette`

French, English and Swahili are all official languages. This is an important source of parallel text given that it covers multiple sectors and is usually written with high standards by professionals, part of a dedicated government agency.

The main content of Rwanda's official gazette is provided in a multi-column portable document format (PDF), mostly 3 columns for Kinyarwanda, English and French. In our experiments, we process page content streams by making low level modifications to Apache PDFBox Java library[4], where the inputs are unordered set of raw characters with their X-Y page coordinates and font information. We track columns by detecting margins (by sorting X-coordinates of glyphs) and reconstruct text across consecutive pages. A key opportunity for parallel alignment comes from the fact that most official gazettes paragraphs are grouped by consecutive article numbers such as "Ingingo ya 1/Article 1", "Ingingo ya 2/Article 2", and so on. We use these article enumerations as anchors to finding parallel paragraphs across the three languages. A language identification component is also required to know which column correspond with which language as the column ordering has been changing over time.

2.4 Jw.org website

Jw.org website publishes religious and biblical teachings by Jehovah's Witnesses, with cross-references into multiple languages. While this website data has been used for low-resource machine translation before (Agić and Vulić, 2019), the isolated corpus is no longer available due to license restrictions. However, the content of the original website is still available to web browsers and crawlers. We take this advantage and gather data from the site to experiment with English↔Kinyarwanda machine translation.

2.5 Bilingual dictionaries

Bilingual dictionaries are also useful for low-resource machine translation. While most of their parallel data are made of single words, they can still contribute to the translation task, albeit without any sentence-level context. The 2006 version of the Iriza dictionary (Habumuremyi and Uwamahoro, 2006) is generally publicly available in PDF format. Similar to the Official Gazette case, we use low level modifications to the Apache PDFBox library and extract dictionary entries grouped by a source word and a target synset. Another bilingual dictionary we used is *kinyarwanda.net* website[5], which was developed by volunteers to help people learning Kinyarwanda or English. In addition to these bilingual dictionaries, we manually translated about 8,000 Kinyarwanda words whose stems could not be found in any of the existing parallel data sources. Some of these terms include recently incorporated but frequently used Kinyarwanda words such as loanwords and also alternate common spellings. Examples include words such as: 'abazunguzayi' (*hawkers*), 'akabyiniro' (*night club*), 'canke' (from Kirundi: *or*), 'mitiweli' (from French: "mutuelle santé"). Together with data from bilingual dictionaries, the above dataset forms a special training subset we call 'lexical data', because it augments the lexical coverage of our main dataset. We evaluate its effectiveness in our experiments.

2.6 Monolingual data

Backtranslation (Edunov et al., 2018) is a proven technique for leveraging monolingual data in machine translation. We developed a corpus of Kinyarwanda text by crawling more than 200 websites and extracting text from several books to form a monolingual dataset to use for back-translation. The final corpus contains about 400 million words and tokens or 16 million sentences. We also formed an English text corpus of similar size by crawling eight major Rwandan and East African English newspapers (3.3 million sentences) in addition to Wikipedia English corpus (7.3 million sentences)[6] and global English news data (5.4 million sentences)[7].

2.7 Data augmentations

Source to target copying in NMT is a desirable ability when faced with untranslatable terms such as proper names. However, when the source and target vocabularies are not shared, it is harder for the model to learn this ability. In order to enforce this copying ability in our NMT model, we take a data-centric approach by including untranslatable terms in our dataset with the same source and target text. This augmentation includes the following

---

[4] `https://pdfbox.apache.org/`

[5] `https://kinyarwanda.digital/`

[6] `https://www.kaggle.com/datasets/mikeortman/wikipedia-sentences`

[7] `https://data.statmt.org/news-crawl/en/news.2020.en.shuffled.deduped.gz`

datasets: (1) All numeric tokens and proper names from our Kinyarwanda monolingual corpus, (2) Names of locations from the World Cities dataset[8], and (3) Names of people from CMU Names corpus (Kantrowitz and Ross, 2018) and the Names Dataset (Remy, 2021).

We also add synthetic data for number spellings by using rule-based synthesizers to spell 200,000 random integers between zero and 999 billions. For Kinyarwanda side, we developed our own synthesizer, while we used `inflect` python package[9] for English.

Code-switching is one characteristic of some low-resource languages such as Kinyarwanda. To cope with this issue, we add foreign language terms and their English translations to the training dataset for Kinyarwanda → English models as if the foreign terms were valid Kinyarwanda inputs. For this, we include all English phrases from *kinyarwanda.net* online dictionary, 100 popular French terms and 20 popular Swahili terms.

3 Experiments

3.1 Experimental setup

The model presented in section 2.1 was implemented from scratch using PyTorch framework (Paszke et al., 2019) version 1.13.1. Our model hyper-parameters along with training and inference hyper-parameters are provided in appendix A. Training was done using a hardware platform with 8 Nvidia RTX 4090 GPUs, with 256 gigabytes of system memory, on a Linux operating system. We used mixed precision training with lower precision in BFLOAT-16 format. For Kinyarwanda→English model, one gradient update step takes 0.5 second and convergence is achieved after 40 epochs. For English→Kinyarwanda model with Gradient Vaccine scheme, one gradient update step takes 1.1 seconds while convergence is achieved after 8 epochs.

In all our experiments on Kinyarwanda ↔ English translation, only Kinyarwanda side (as source or target) is morphologically modelled, while the English side always uses sub-word tokenization. For Kinyarwanda source side with attention augmentation, we use a pre-trained BERT model similar to KinyaBERT (Nzeyimana and Rubungo, 2022) whose input units/token ids are the same as for the NMT encoder. In fact, this pre-trained KinyaBERT model has the same two-tier architecture as the NMT encoder. Therefore, they are aligned to the same words/tokens. We use a Kinyarwanda morphological analyzer[10] to perform both tokenization, morphological analysis and disambiguation (Nzeyimana, 2020).

On English sides (either source or target), we do not perform morphological analysis and only use a standard single-tier transformer architecture. On the source side, we use a BPE-based tokenization and a corresponding pre-trained RoBERTA model provided by fairseq package (Ott et al., 2019). Similarly, on English target side, we use a BPE-based tokenization from a Transformer-based auto-regressive English language model (Ng et al., 2019) from the same fairseq package.

3.2 Evaluation

We evaluate our models on three different benchmarks that include Kinyarwanda, namely FLORES-200 (Costa-jussà et al., 2022), MAFAND-MT (Adelani et al., 2022) and TICO-19 (Anastasopoulos et al., 2020). This allow us to have a picture on how the models perform on different domains, respectively Wikipedia, News and Covid-19. Our main evaluation metric is ChrF++ (Popović, 2017) which includes both character-level and word-level n-gram evaluation, does not rely to any sub-word tokenization and has been shown to correlate better with human judgements than the more traditional BLUE score. We use TorchMetrics (Detlefsen et al., 2022) package's default implementation of ChrF++. For Kinyarwanda→ English translation, we also evaluate with BLEURT scores (Sellam et al., 2020), an embedding-based metric with higher correlation with human judgement. We use a pre-trained PyTorch implementation of BLEURT[11]. We did not use BLEURT scores for English→Kinyarwanda because there was no available pre-trained BLEURT model for Kinyarwanda and the pre-training cost is very high.

The baseline BPE-based models in Table 4 and Table 5 use a SentencePiece (Kudo and Richardson, 2018) tokenizer, with 32K-token vocabularies for either source or target. The SentencePiece tokenizers are trained/optimized on 16M sentences of text for each language. Source and target vocabularies are not shared. The NMT models

in this case use the same Transformer backbone as the morphological models, but without morphological modeling or BERT attention augmentation.

3.3 Results

Results in Table 1 through Table 5 show our ablation study results, evaluating the various contributions. In Table 1, we show the improvement across all three benchmarks from adding proper names data to induce token-copying ability. In Table 2, we evaluate the impact of our attention augmentation scheme. The results show substantial improvement by adding BERT and XPOS attention augmentations. Table 3 confirms the effectiveness of adding bilingual dictionary data to the training set. In Table 4 and Table 5, we find a large performance gap between standard transformer with BPE-based tokenization (BPE Seq2Seq) and our morphology-based models (Morpho), which confirms the effectiveness of our morphological modeling. Finally, in Table 6 and Table 7, we use back-translation and train 400M-parameter models that perform better than strong baselines including NLLB-200 (3.3B parameters for English→ Kinyarwanda, 600M parameters for both directions) and fine-tuned mBART (610M parameters). For English→Kinyarwanda, we achieve performance exceeding that of Google Translate on the out-of-domain TICO-19 benchmark.

4 Related Work

Morphological modeling in NMT is an actively researched subject often leading to improvements in translation. However most of this research has focused on European languages. Ataman and Federico (2018) shows that an RNN-based word compositional model improves NMT on several languages. Weller-Di Marco and Fraser (2020) evaluates both source-side and target-side morphology modeling between English and German using a lemma+tag representation. Passban et al. (2018) proposes using multi-task learning of target-side morphology with a weighted average loss function. However, Macháček et al. (2018) does not find improvement when using unsupervised morphological analysers. Our studies differs in that it uses a different morphological representation, that is the two-tier architecture, and we also evaluate on a relatively lower resourced language.

The idea of model augmentation with pre-trained language models (PLM) have been previously explored by Sun et al. (2021), and Zhu et al. (2020) who use a drop-net scheme to integrate BERT embeddings. Also, there have been attempts to model word order relationships between source and target languages (Li et al., 2017; Murthy et al., 2019). Our model architecture provides a more generic approach through the attention augmentation.

5 Conclusion

This work combines three techniques of morphological modeling, attention augmentation and data augmentation to improve machine translation performance for a low-resource morphologically-rich language. Our ablation results indicate improvement from each individual contribution. Baseline improvements from morphological modeling are more pronounced at the target side than at the source side. This work expands the landscape of modeling complex morphology in NMT and provides a potential framework-solution for machine translation of low-resource morphologically rich languages.

6 Limitations

Our morphological modeling proposal requires an effective morphological analyzer and was only evaluated on one morphologically-rich language, that is Kinyarwanda. Morphological analyzers are not available for all languages and this will limit the applicability of our technique. The proposed data augmentation technique for enabling proper name copying ability works in most cases, but we also observed some few cases where inexact copies are produced. Similarly, even with lexical data added to our training, we still observe some cases of hallucinated output words, mostly when the model encounters unseen words. Finally, the proposed morphological decoding algorithm is slower than standard beam search because of the filtering steps and morphological synthesis performed before producing a candidate output token.

Given the above limitations, our model does not grant complete reliability and the produced translations still require post-editing to be used in high-stake applications. However, there are no major risks for using the model in normal use cases as a translation aid tool.

A Model, training and inference hyper-parameters

Our model hyper-parameters along with training and inference hyper-parameters are provided in Table 8.

Hyper-parameter	**Value**
Model	
Transformer hidden dimensions	768
Transformer feed-forward dimension	3072
Transformer attention heads	12
Transformer encoder layers with BERT	5
Transformer encoder layers without BERT	8
Transformer decoder layers with GPT	7
Transformer decoder layers without GPT	8
Morpho-Encoder hidden dimension	128
Morpho-Encoder feed-forward dimension	512
Morpho-Encoder attention heads	4
Morpho-Encoder layers	3
Dropout	0.1
Maximum sequence length	512
Training	
Batch size	32K tokens
Peak learning rate	0.0005
Learning rate schedule	inverse sqrt
Warm-up steps	8000
Optimizer	Adam
Adam's β_1, β_2	0.9, 0.98
Maximum training epochs	40
Morphological inference	
Beam width	4
Top scores M	8
Cut-off gap δ	0.3
Minimum affix probability γ	0.3
Global correlation weight α	0.08
Surface form score stop gap $log(\beta)$	2.0

Table 8: Hyper-parameter settings

B Dataset summary

Subset	**Size**
Parallel sentences	
Jw.org website	562,417 sentences
Rwanda's official gazette	113,127 sentences
Lexical data	
Iriza dictionary 2006	108,870 words
Kinyarwanda.net	10,653 words
Manually translated	8,000 words
Augmented data	
Spelled numbers	200,000 phrases
Copy data (e.g. Proper names)	157,668 words
Code-switching foreign terms	10,276 terms

C Morphological decoding algorithm

Algorithm 1: Inflection generation helper subroutines

```
Subroutine: inflectionGroupProbabilities($T_s, T_p, T_a, P_s, P_p, P_a, M, G$)
    $W \leftarrow M \times G$ array
    $W[i,g] \leftarrow -100, \forall i = 1,2,..M, \forall g = 1,2,..G$
    for $i \leftarrow 1$ to $M$ do
        $g_s \leftarrow$ getInflectionGroup($T_s[i]$)
        $W[i,g_s] \leftarrow \max(W[i,g_s], \log(P_s[T_s[i]]))$
        $g_p \leftarrow$ getInflectionGroup($T_p[i]$)
        $W[i,g_p] \leftarrow \max(W[i,g_p], \log(P_p[T_p[i]]))$
        $g_a \leftarrow$ getInflectionGroup($T_a[i]$)
        $W[i,g_a] \leftarrow \max(W[i,g_a], \log(P_a[T_a[i]]))$
    end for
    $V \leftarrow G$ array
    $V[g] \leftarrow \sum_{i=1}^{M} W[i,g], \forall g = 1,2,..G$
    $P_g \leftarrow \mathrm{softmax}(V)$
    return $P_g$
Subroutine: filterAndCutOff($T, P, g, \delta, \gamma$)
    $T' \leftarrow [\,]$
    $pp \leftarrow 0$
    foreach $i \in T$ do
        if (getInflectionGroup($i$) $= g$) and ($P[i] \geq \gamma$) then
            $T'.append(i)$
            if $(pp - P[i]) > \delta$ then
                break
            $pp \leftarrow P[i]$
    end foreach
    return $T'$
Subroutine: computeScore($T_s, T_p, T_a, P_s, P_p, P_a, \rho[.,.], \alpha$)
    $C \leftarrow |T_s| \times |T_p| \times |T_a|$ array
    $tot \leftarrow 0$
    foreach $s \in Ts$ do
        foreach $p \in Tp$ do
            foreach $a \in Ta$ do
                $c \leftarrow \exp(\alpha \log(\rho[s,a]) + \log P_s[s] + \log P_p[p] + \log P_a[a])$
                $C[s,p,a] \leftarrow c$
                $tot \leftarrow tot + c$
            end foreach
        end foreach
    end foreach
    $C[s,p,a] \leftarrow C[s,p,a]/tot; \forall s \in T_s, \forall p \in T_p, \forall a \in T_a$ // Normalize
    return $C$
```

Algorithm 2: Inflection generation

Input : Probability distributions returned by the neural network (softmax heads) for stems, POS tags, affix sets (P_s, P_p, P_a); probability values returned for each affix (multi-label heads) P_f; M: number of top items (stems, POS tags, affix sets) to consider; N: number of top affixes to consider; number of inflection groups G; $\rho[.,.]$: corpus-computed correlation of stems and affix sets; α: stem-affix set correlation weight; β: maximum probability gap for inflection groups; γ: minimum affix probability; δ: maximum probability gap for stems, POS tags and affix sets.

Output : Candidate inflected forms and their scores.

```
Subroutine generateInflections($(P_s, P_p, P_a, P_f, \rho[.,.], \alpha, \beta, \gamma, \delta)$)
    /* All argSort(.) calls are in decreasing order */
    $T_s \leftarrow$ argSort($(P_s)[:M]$) // Up to $M$ items
    $T_p \leftarrow$ argSort($(P_p)[:M]$)
    $T_a \leftarrow$ argSort($(P_a)[:M]$)
    $T_f \leftarrow$ argSort($(P_f)[:N]$)
    $P_g \leftarrow$ inflectionGroupProbabilities($(T_s, T_p, T_a, P_s, P_p, P_a, M, G)$)
    $G_s \leftarrow$ argSort($(P_g)$)
    $pp \leftarrow 0$
    $R \leftarrow [\,]$ // List of inflections to return
    foreach $g \in G_s$ do
        $T_s^{'} \leftarrow$ filterAndCutOff($(T_s, P_s, g, \delta, 0)$)
        $T_p^{'} \leftarrow$ filterAndCutOff($(T_p, P_p, g, \delta, 0)$)
        $T_a^{'} \leftarrow$ filterAndCutOff($(T_a, P_a, g, \delta, 0)$)
        $T_f^{'} \leftarrow$ filterAndCutOff($(T_f, P_f, g, \delta, \gamma)$)
        $C_g \leftarrow$ computeScore($(T_s^{'}, T_p^{'}, T_a^{'}, P_s, P_p, P_a, \rho[.,.], \alpha)$)
        $L_g \leftarrow$ argSort($(C_g)$)
        foreach $(s, p, a) \in L_s$ do
            // Formulate affixes by merging affix set's
            // own affixes and extra predicted affixes
            $f \leftarrow$ affixMerge($(a, T_f^{'})$)
            // Call morphological synthesizer
            $surface \leftarrow$ morphoSynthesis($(s, f)$)
            if $surface \neq$ null then
                $R.append((surface, s, p, a, f, C_g[s, p, a]))$
        end foreach
        if $(pp - P_g[g]) > \beta$ then
            break
        $pp \leftarrow P_g[g]$
    end foreach
    return $R$
    // The returned inflections will be added to the beam
    // for beam search-based decoding.
```

Self-Cleaning: Improving a Named Entity Recognizer Trained on Noisy Data with a Few Clean Instances

Abstract

To achieve state-of-the-art performance, one still needs to train NER models on large-scale, high-quality annotated data, an asset that is both costly and time-intensive to accumulate. In contrast, real-world applications often resort to massive low-quality labeled data through non-expert annotators via crowdsourcing and external knowledge bases via distant supervision as a cost-effective alternative. However, these annotation methods result in noisy labels, which in turn lead to a notable decline in performance. Hence, we propose to denoise the noisy NER data with guidance from a small set of clean instances. Along with the main NER model we train a discriminator model and use its outputs to recalibrate the sample weights. The discriminator is capable of detecting both span and category errors with different discriminative prompts. Results on public crowdsourcing and distant supervision datasets show that the proposed method can consistently improve performance with a small guidance set.

1 Introduction

Deep learning methods have notably improved the performance of named entity recognition (NER), but need large-scale high-quality labeled data (Lample et al., 2016; Devlin et al., 2018). In practice, collecting large-scale labeled data via crowdsourcing (Rodrigues and Pereira, 2018; Finin et al., 2010) or distant supervision (Liang et al., 2020) is far more cost-effective. However, such data is usually too noisy for direct use without further treatment (Hedderich et al., 2021; Liang et al., 2020; Chu et al., 2020). Extensive efforts have been dedicated to develop data denoising techniques and learning strategies specifically tailored for noisy NER data. Liang et al. (2020) suggested fine-tuning pre-trained language models (PLMs) on such data, employing early stopping and self-training techniques to mitigate overfitting induced by noisy labels. Meng et al. (2021) extended the approach by using a frozen PLM to generate augmented pseudo labels for self-training. Liu et al. (2021a) further eliminated self-training labels with low estimated label confidence. Yet these denoising methods do not have a mechanism to guide error correction, thus suffer from *confirmation bias* (Tarvainen and Valpola, 2017; Arazo et al., 2020), where the learner struggles to correct its own mistakes.

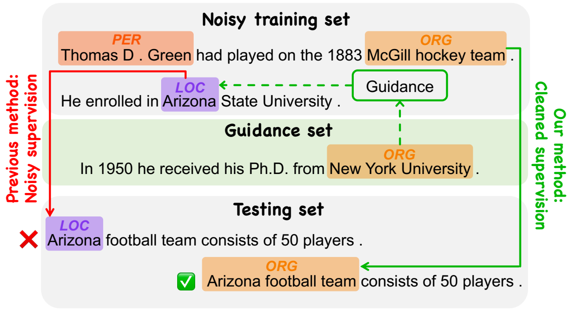

Figure 1: Illustration of the Guided Denoising Framework. The initial noisy label, `Arizona-LOC`, presents a deviation from the patterns observed in the guidance set, where geographical names preceding the term `University` are appropriately categorized into an organization entity (e.g., `New York University-ORG`). The depicted process of guided denoising (highlighted in green) ensures the retention of the accurately supervised label, `McGill hockey team-ORG`, thereby facilitating the acquisition of correct entity recognition patterns.

One natural idea to improve the performance of NER models trained on noisy data is to incorporate a small set of clean instances, which can be obtained at an acceptable cost. For example, one can let a financial professional manually label a subset of financial named entities and use them to guide the learning process on a larger, distantly-supervised financial NER dataset. We refer to the small clean set as the *guidance* set. There are a number of possibilities of how to effectively utilize the guidance set. The most straightforward method is to further fine-tune the model trained on the noisy NER data on the guidance set; we

treat this approach as a baseline to compare against. Jiang et al. (2021) augmented the noisy labels with a confidence score according to their probability of being correct given the clean data. Their heuristic-based approach is not tailored to the noisy NER problem, and as a result, it fails to identify particular types of noise in NER, such as span errors. We present a complementary approach that is effective in correcting NER-specific errors.

We propose a *Guided Denoising Framework* (shown in Figure 1) to better utilize the guidance data by eliminating noisy labels that conflict with the patterns in the guidance set. In this framework, in addition to the NER model, we also use a discriminator specifically designed to detect such conflicts.This discriminator is responsible for evaluating the accuracy of assigned labels and is trained in a few-shot manner (Brown et al., 2020; Liu et al., 2021b) with the small guidance set. Based on the analysis of real-world noisy NER datasets, we equip the discriminator, by designing different prompts, with the ability to detect two error types: span error and category error. The output of the discriminator is used to reweight the samples for the NER model's training. We also design a co-training strategy to improve the discriminator and the NER model in a collaborative manner. In summary, we make the following contributions:

- We propose **Self-Cleaning**, a generic guided denoising framework to improve NER learning on noisy data with a small guidance set. To the best of our knowledge, this is the first instance of a denoising framework making use of an auxiliary model to correct noise in the data.

- We design a prompt-based discriminator to detect noisy NER labels. The discriminator is capable of identifying both span errors and category errors in noisy NER data using distinct prompts.

- We report extensive experiments and ablation studies on NER benchmarks with crowdsourcing and distant-supervision NER data. Empirical results show that our approach boosts the performance.

2 Background

2.1 Named Entity Recognition

NER is the task of identifying named entities in plain text and classifying them into pre-defined entity categories, such as person, organizations, locations, etc (Li et al., 2020). Formally, we denote a sentence consisting of n tokens as $\boldsymbol{x} = [x_1, ..., x_n]$ and their corresponding labels as $\boldsymbol{y} = [y_1, ..., y_n]$. We define $D = \{(\boldsymbol{x}_i, \boldsymbol{y}_i)\}_{i=1}^{|D|}$ to be a labeled set. We use the `BIO` schema (Ramshaw and Marcus, 1999), where the first token of an entity with type `X` is labeled as `B-X`; the consecutive tokens of the entity are labeled as `I-X`; the non-entity tokens are labeled as `O`. An NER model $\hat{\boldsymbol{y}} = f(\boldsymbol{x}; \boldsymbol{\theta})$ takes a sentence $\boldsymbol{x}$ as input and outputs a predicted label sequence $\hat{\boldsymbol{y}}$, where $\boldsymbol{\theta}$ is its parameter set. We train the NER model by minimizing the following loss,

$$\mathcal{L} = \frac{1}{|D|} \sum_{i=1}^{|D|} \ell(\boldsymbol{y}_i, f(\boldsymbol{x}_i; \boldsymbol{\theta})), \tag{1}$$

where $\ell(\cdot, \cdot)$ can be the cross-entropy loss for token-wise classification model or negative likelihood for CRF model (Lafferty et al., 2001; Chu et al., 2019).

Following Meng et al. (2021), we build the NER model upon the RoBERTa model (Liu et al., 2019) by adding prediction heads. Specifically, we set an entity head f^e to predict whether a given token belongs to an entity and also a classification head f^c to predict the class of a given token. Both heads take the contextualized representations from a RoBERTa encoder. We decompose the original label sequence $\boldsymbol{y}$ into a sequence of binary span labels $\boldsymbol{e}$ and a sequence of category labels $\boldsymbol{c}$. The span labels are obtained by transforming `B-X` and `I-X` into positive labels (denoted as `E`), and `O` labels are remained as negative labels. In $\boldsymbol{c}$, only non-empty tokens have category labels (i.e., `B-X` and `I-X`). The entity head f^e is trained on $\boldsymbol{e}$ with the binary cross-entropy loss, while the classification head f^c is trained on $\boldsymbol{c}$ with the cross-entropy loss. This model design allows us to handle span and category errors with distinct treatments, further details of which will be provided in Section 3.3.

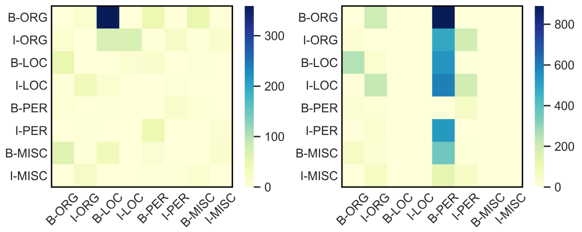
In inference, entities are first identified based on the outputs from the entity head, which are then classified using the classification head. The procedure is formalized as,

$$\hat{y} = \begin{cases} \texttt{O}, & f^e(x) \le t \\ \arg\max f^c(x), & f^e(x) > t \end{cases}, \tag{2}$$

where t is the threshold for entity identification, which is set to 0.5 by default.

2.2 NER with Noisy Data

In the noisy NER setting, the labels in D are typically collected via crowdsourcing (Rodrigues and



(a) Crowdsourcing. (b) Distant supervision.

Figure 2: Confusion matrices of CoNLL03 with crowdsourcing labels and distant supervisions. The x-axis refers to noisy labels while the y-axis are ground-truth labels. The value of each entry is the frequency of this confusion pair (e.g., mistakenly label `B-LOC` as `B-ORG`).

Pereira, 2018; Finin et al., 2010) or with distant supervisions from knowledge bases (Liang et al., 2020), which wrongly recognize many entities and often provide wrong categories for entities. Interartive self-training has proven effective in improving NER performance when learning from noisy data (Liang et al., 2020; Meng et al., 2021): the predicted label sequence $\hat{\boldsymbol{y}}_i$ from the current model iteration serves as pseudo labels for the subsequent iteration,

$$\mathcal{L}_{\text{Self}} = \frac{1}{|D|} \sum_{i=1}^{|D|} \ell(\hat{\boldsymbol{y}}_i, f(\boldsymbol{x}_i; \boldsymbol{\theta})). \tag{3}$$

In this paper, we also require a small guidance set C, the labels of which are examined by domain experts to ensure high quality. Typically, we only require $|C| \ll |D|$. It is both affordable and practical to obtain a small set of high-quality data while collecting large-scale noisy data via crowdsourcing or distant supervision. In Section 3, we will introduce our Self-Cleaning framework to guide the noisy NER learning with the guidance set.

2.3 Noise Pattern Analysis

We investigate the noise patterns on the CoNLL03 dataset with crowdsouring labels collected by Rodrigues et al. (2014) and distant supervisions collected by Liang et al. (2020). We find two types of errors: (1) **Span error**, where the span of the entity is not correctly recognized. For example, an error would occur if only `Arizona` was recognized in `Arizona State University`. The wrong entity span could either be shorter or longer than the span of the ground-truth entity. (2) **Category error**, where the entity is assigned an incorrect category.[1] An example of this would be labeling `Arizona State University` as a `location`.

We first calculated the proportion of entity spans that overlap with but do not perfectly match the ground-truth entity: it is **11.0%** for the crowdsourcing dataset and **12.8%** for the distant supervision dataset, a considerable amount of error that is likely to affect the resulting model. To analyze category errors, we present the confusion matrices on two datasets in Figure 2.[2] In the crowdsourcing dataset, `ORG` is often mislabeled as `LOC`, because the CoNLL dataset contains sports news in which team home cities or countries (locations) are also used as the name of the team (organizations), which easily confuses naive annotators. And due to the entity ambiguity in knowledge bases, all the classes could be mislabeled as `PER` in the distant supervision dataset, especially `ORG`.

Finally, a substantial proportion of ground-truth entities, **28.9%** and **25.3%**, are missing from the crowdsourcing and distant supervision datasets respectively. This finding underscores the importance of self-training, a crucial technique in previous noisy NER learning methods (Meng et al., 2021; Liu et al., 2021a; Liang et al., 2020), as it allows pseudo labels to recover these missing entities. However, in the absence of appropriate guidance, these pseudo labels may perpetuate both span and category errors. These errors, in turn, could be amplified due to the confirmation bias (Tarvainen and Valpola, 2017; Arazo et al., 2020; Chen et al., 2019), leading to a decline in performance.

3 Method: Self-Cleaning

In this section, we introduce Self-Cleaning in detail. We begin with the key component of Self-Cleaning: the prompt-based discriminator, explained in Section 3.1. We then present the training procedure (as shown in Figure 3), which consists of three stages: **Stage I: Demonstrative self-training.** In this stage, high-confidence predictions from the NER model are used as pseudo labels to iteratively refine itself, a process often referred to as self-training (Liang et al., 2020; Meng et al., 2021). To enhance the robustness of the pseudo labels, we propose a mechanism called clean demonstration, in which entities from the guidance set serve as demonstrations to elicit robust predictions from the NER

---

[1] In the rest of the paper, we use the terms *class* and *category* interchangeably.

[2] The values of diagonal entries corresponding to correct labels are set to 0, otherwise the noise patterns in the non-diagonal entries are invisible. There are several crowdsourced annotations for each token, so we aggregate them into one label using majority voting.

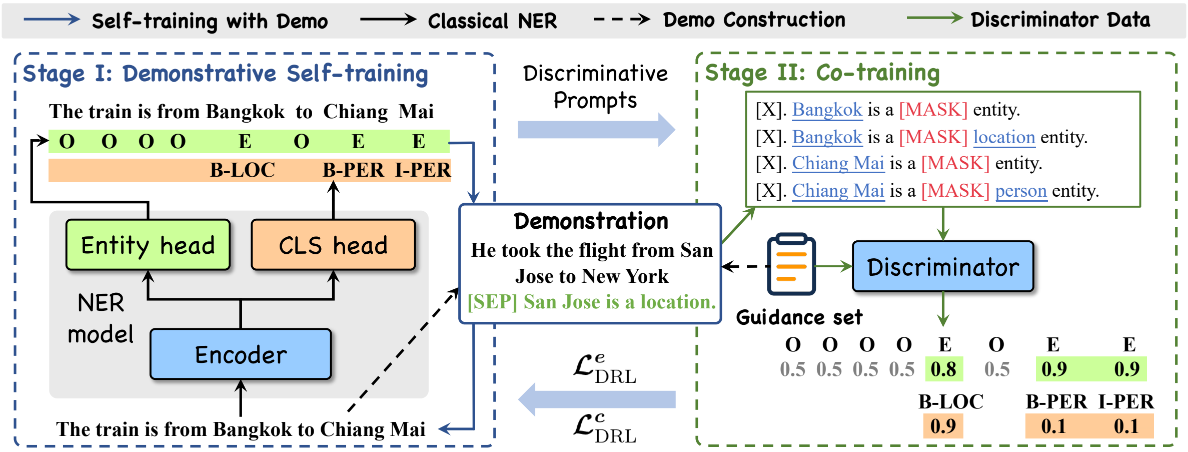


Figure 3: Overview of Self-Cleaning. In Stage I, we use the entities in the guidance set as clean demonstrations to augment the NER model's training. In Stage II, the discriminative prompts is filled with the predictions of the NER model, and then input into the prompt-based discriminator. The NER model is updated by Eq.(4) with the weights $\boldsymbol{w}^e$ and $\boldsymbol{w}^c$ provided by the discriminator. Conversely, the high-quality pseudo labels of the NER model are used to fine-tune the discriminator. In Stage III, we fine-tune the obtained NER model on the guidance set.

model. Details of the clean demonstration mechanism can be found in Section 3.2.

Stage II: Co-training. In this stage, we introduce a co-training strategy to fine-tune the NER model and the discriminator in a collaborative manner. Specifically, the discriminator's outputs are employed to guide the NER model's training by reweighting the training labels, while high-quality predictions from the NER model are chosen to augment the guidance set used for the discriminator's training. Details of the co-training strategy and the criteria for evaluating the quality of predictions are provided in Section 3.3.

Stage III: Fine-tuning. To further improve the performance, we fine-tune the obtained NER model only with the guidance set.

3.1 PLM as a Unified Discriminator

In Self-Cleaning, we use a discriminator g aims to evaluate the accuracy of assigned labels to guide the NER model's training. The rationale is that labels with low accuracy should be downweighted to mitigate their influence during model training, while the accurate labels should be retained.

We identified two error types in the noisy NER data in Section 2.3 which can be straightforwardly modeled by the descriminaror: span error and category error. Instead of training two separate discriminators to handle each type of error, we propose to train a unified discriminator using error-type-specific prompts to elicit different outputs. This approach not only saves memory space, but also leverages the power of prompt tuning, which has been shown to effectively utilize the knowledge embedded in the parameters of pre-trained language models (PLMs) (Brown et al., 2020; Li et al., 2020). With prompt tuning, it is possible to learn an effective discriminator with a small guidance set. In the following, we use RoBERTa (Liu et al., 2019) as the backbone model of the discriminator and respectivly prepare Masked Language Model (MLM) style prompts. It is important to note that other PLMs, such as generative language models (Radford et al., 2019), could be seamlessly integrated into our framework by modifying the prompts accordingly. We design the following two types of discriminative prompts,

- **Span**: `[X]`. `[Y]` is a `[MASK]` entity.
- **Category**: `[X]`. `[Y]` is a `[MASK]` `[Z]` entity.

`[X]` is the placeholder for a sentence $\boldsymbol{x}$, `[Y]` is the placeholder for an entity e and `[Z]` is the placeholder for a class c. The discriminator is trained to fill `correct` in the `[MASK]` token when the entity/class is appropriate given the context sentence, and `wrong` otherwise. The discriminative score of the evaluated entity or class is given by

$$w^e(e) = P_S(\texttt{correct}|\texttt{[X]} = \boldsymbol{x}, \texttt{[Y]} = e)\,,$$
$$w^c(c) = P_C(\texttt{correct}|\texttt{[X]} = \boldsymbol{x}, \texttt{[Y]} = e, \texttt{[Z]} = c)\,,$$

where P_S and P_C represent the probability associated with the span prompt and the category prompt, respectively. Given a sentence and its sequence of labels, we extract the entities in it and their corresponding classes from contiguous spans with `B-X` and `I-X` labels in the data. For example, given `[San Jose is a city]` and `[B-LOC, I-LOC, O, O, O]`, `San Jose` will be extracted as an entity and its class is `LOC`. We transform `LOC` and other category names into a meaningful word `location` which would fit naturally in a sentence. Details of the conversion can be found in Section B.

We first pre-train the discriminator to ensure a good starting point, treating the entities in the guidance set as positive samples. In this context, we will abuse the notation C to denote the set of positive samples drawn from the guidance set. We create incorrect entities and labels using data augmentations. Unlike in classification scenarios involving noisy label learning (Han et al., 2018), simulating noisy NER labels has to also provide negative examples for span errors. We investigate the datasets used in Section 2.3 and find that around 80% span-error entities deviate from the ground-truth entities by a single word. Thus, we create negative entities by randomly adding or removing a word around entities in the guidance set. For example, we transform `Arizona State University` into `State University` as a negative entity. For category errors, we randomly flip the classes of entities in the guidance set. We denote the set of negative samples as B. The discriminator is trained to minimize the following loss function,

$$\begin{aligned}\mathcal{L}_w = &-\mathbb{E}_{e,c\sim C}\left[\log w^e(e) + \log w^c(c)\right] \\ &- \mathbb{E}_{\tilde{e},\tilde{c}\sim B}\left[\log(1-w^e(\tilde{e})) + \log(1-w^c(\tilde{c}))\right],\end{aligned}$$

where $1 - w^e(\tilde{e})$ and $1 - w^c(\tilde{c})$ are essentially $P_S(\texttt{wrong}|\cdot,\tilde{e})$ and $P_C(\texttt{wrong}|\cdot,\tilde{c})$.

3.2 Stage I: Demonstrative Self-training

In this stage, we employ a self-training strategy enriched with demonstrations to improve the performance of the NER model. Previous research (Zhang et al., 2022; Lee et al., 2021) has established that demonstrations can boost the robustness of PLMs. Consequently, we propose to incorporate clean entities from the guidance set into the input of the NER model to stimulate more robust outputs. These enhanced outputs are then used as pseudo-labeles for self-training, as specified in Eq.(3).

Technically, we follow the `instance-oriented` method in (Lee et al., 2021) to find demonstrations. For each sentence in the noisy training set, we first retrieve similar sentences from the guidance set using `SBERT` scores (Reimers and Gurevych, 2019). Then, the entities in the retrieved guidance sentences are used to form the clean demonstrations $\tilde{\boldsymbol{x}}$, which are appended as additional tokens to the original training sentence $\boldsymbol{x}$. The inputs of the NER model become $[\boldsymbol{x};\tilde{\boldsymbol{x}}]$. For example, in Figure 3, `San Jose-LOC` is used to form the clean demonstration $\tilde{\boldsymbol{x}}$ =`[SEP] San Jose is a location`. During inference, we empirically found that demonstrations did not improve performance, and therefore we only input the original sentence $\boldsymbol{x}$ into the NER model.

3.3 Stage II: Co-training

In this stage, we fine-tune the NER model f and the discriminator g collaboratively to improve the performance of both. On the one hand, the discriminator guides the NER model's training by reweighting the training labels. On the other hand, the high-quality pseudo-labels generated by the NER model are used to augment the discriminator's training.

Discriminator-guided training for NER. Even though pseudo labels can effectively improve performance, they can reproduce the noise present in the noisy training set, leading to confirmation bias (Tarvainen and Valpola, 2017) that impedes further model improvement. Therefore, we propose using the discriminator to guide self-training by reweighting the pseudo-labels. As shown in Figure 3, we first extract the pseudo-entities and their corresponding classes from the pseudo-label sequences and then insert them into the discriminative prompts. The outputs of the discriminator are used as weights for the pseudo-labels, resulting in the following discriminative reweight loss (DRL),

$$\mathcal{L}^{e/c}_{\text{DRL}} = -\frac{1}{|D|}\sum_{i=1}^{|D|}\sum_{j=1}^{n} w^{e/c}_{ij}\log f^{e/c}_{\hat{e}_{ij}/\hat{c}_{ij}}(x_{ij};\boldsymbol{\theta}), \tag{4}$$

where $\hat{e}_{ij}$ and $\hat{c}_{ij}$ denote the pseudo span labels and category labels, respectively, for the j-th token in the i-th sentence; and $f^{e/c}_{\hat{e}_{ij}/\hat{c}_{ij}}$ refers to the entry of $\hat{e}_{ij}$ or $\hat{c}_{ij}$ in the corresponding probability distribution. Note that an entity could consist of several tokens, to which we allocate equivalent weights. We set the weights of the negative span labels `O` to 0.5 by default to avoid overfitting them.

Enhancing discriminator with high-quality pseudo-labels. Conversely, we use high-quality pseudo-labels generated by the NER model to enhance the discriminator's performance. We evaluate the quality of pseudo-labels based on two criteria: *accuracy* and *informativeness*. Firstly, We

Table 1: Dataset statistics.

Dataset	#Types	#Train	#Test
CoNLL03-C	4	5,985	3,453
CoNLL03	4	14,041	3,453
OntoNotes	18	59,924	8,262
Wikigold	4	1,142	274

follow Yao et al. (2021) to use Jensen-Shannon divergence (JSD) as a proxy to evaluate the accuracy of the pseudo labels of a token x_i,

$$q(\hat{e}_i) = 1 - \text{JSD}\big(f^e(x_i) \parallel \texttt{one\_hot}(e_i)\big),$$
$$q(\hat{c}_i) = 1 - \text{JSD}\big(f^c(x_i) \parallel \texttt{one\_hot}(c_i)\big),$$

where $\hat{e}_i$ and $\hat{c}_i$ are pseudo span label and category label for token x_i, while $f^e(x_i)$ and $f^c(x_i)$ are their corresponding probabilities from the entity head and classification head. e_i and c_i are observed labels in the training set, which are transformed into distributions by one-hot encoding.[3] However, the *mostly correct* pseudo-labels selected by the above metric are not always helpful for discriminator training, as they may not carry new information. Intuitively, if the discriminator shows uncertainty for its own prediction, that particular pseudo-label becomes more informative. Inspired by active learning (Chu and Wang, 2021; Schröder et al., 2021), we identify the most informative samples using the prediction entropy of the discriminator as a measure of uncertainty. The resulting token-level selection score $s(\cdot)$ is defined as

$$s(\hat{e}_i) = \mathbb{H}\big(w^e(\hat{e}_i)\big) \cdot q(\hat{e}_i)\,,$$
$$s(\hat{c}_i) = \mathbb{H}\big(w^c(\hat{c}_i)\big) \cdot q(\hat{c}_i)\,,$$

where $\mathbb{H}$ is the entropy function while $w^e(\hat{e}_i)$ and $w^c(\hat{c}_i)$ are discriminative scores of pseudo labels. However, our discriminator works at the entity, not token, level. We form the entity-level selection score by averaging the token-level scores within an entity, $\frac{1}{L}\sum_i^L s(\hat{e}_i)$ and $\frac{1}{L}\sum_i^L s(\hat{c}_i)$, where L is the number of tokens in the entity. We select top-K entities as pseudo positive samples for the discriminator, where K is set as a hyper-parameter. For each pseudo positive samples, we simulate pseudo negative samples in the same way as described in Section 3.1 to facilitate discriminator training. To improve the few-shot ability of the discriminator (Gao et al., 2021), we use the approach described in Section 3.2 to generate demonstrations for the discriminator's inputs when fine-tuning and utilizing the discriminator in the co-training stage.

Lastly, in Stage III, we further fine-tune the obtained NER model only with the guidance set, as suggested in Jiang et al. (2021).

4 Experiments

4.1 Experiment Setup

Datasets. We conduct the experiments on two kinds of noisy English NER datasets:

Crowdsourcing. We use a crowdsourced NER dataset (Rodrigues and Pereira, 2018) based on CoNLL03, denoted as CoNLL03-C, where 5,985 sentences are labeled by 47 non-expert annotators. Redundant crowdsourced annotations for each token are aggregated into a single noisy label using majority voting.

Distant supervision. We use three benchmarks for distant supervision datasets including CoNLL03 (Sang and De Meulder, 2003), OntoNotes5.0 (Weischedel et al., 2013) and Wikigold (Balasuriya et al., 2009). We follow BOND (Liang et al., 2020) to obtain distant supervisions using existing knowledge bases. The noise in these datasets is more systematic, as it is mainly caused by entity ambiguity or missing entities.

We randomly sample the small guidance set from the training set with ground-truth labels, ensuring that all types are covered in the guidance set at least $\left\lfloor \frac{|C|}{\#Types} \right\rfloor$ times. We use guidance sets of 200, 500, and 50 sentences on CoNLL03 and CoNLL03-C, OntoNotes5.0, and Wikigold, respectively. For each dataset the guidance sets are less than 5% of the size of the full set. The size of the guidance set C is an important hyperparameter that impacts the final performance, so we further study its influence in Section 4.3. We use `roberta-base` as the backbone model for both the NER model and the discriminator. More implementation details can be found in Appendix A. We also conduct a comprehensive study of different model designs in Appendix D, including using generative language models (Chung et al., 2022) as discriminator backbones and different combinations of backbone models for the NER model and the discriminator.

Baselines. We compare against two broad classes of related solutions as baselines. The first class of baselines is approaches that only use noisy labels and no clean data whatsoever:

---

[3] Label smoothing is used to avoid 0 entries.

Table 2: Results on CoNLL03-C.

Methods	Pre.	Rec.	F1
Distant RoBERTa	0.824	0.796	0.805
BOND	0.775	0.806	0.787
RoSTER	0.790	0.822	0.804
Fine-tune RoBERTa	0.695	0.699	0.694
Fine-tune RoSTER	0.778	0.831	0.802
NEEDLE	0.822	0.863	0.842
GLC	0.803	0.791	0.790
Meta-Reweight	0.768	0.835	0.799
Self-Cleaning	**0.849**	**0.876**	**0.862**

- **Distant RoBERTa**, where a RoBERTa model is fine-tuned using noisy labels.
- **BOND** (Liang et al., 2020) fine-tunes a RoBERTa model on noisy labels with early-stopping, and then self-trains the resulting model.
- **RoSTER** (Meng et al., 2021) combines a noise-robust loss and ensemble training to improve robustness on noisy NER data, and then utilizes a language model augmented self-training.

The second class of baselines covers approaches that similar to Self-Cleaning also utilize a guidance set when training, but the guidance set is used in different ways:

- **Fine-tune RoBERTa**, where a RoBERTa model is fine-tuned on the guidance set.
- **Fine-tune RoSTER**, where the final model of RoSTER is fine-tuned on the guidance set.
- **NEEDLE** (Jiang et al., 2021) estimates the confidence scores of pseudo labels in the self-training stage using the histogram binning heuristic.
- **GLC** (Hendrycks et al., 2018) estimates a class-level confusion matrix using the guidance set, which is used to calibrate the loss on noisy labels.
- **Meta-Reweight** (Wu et al., 2022; Shu et al., 2019) uses a bi-level optimization framework to learn label weights. It learns the weights of pseudo labels by minimizing the meta-loss on the guidance set in the upper level and updates the NER model with the weights in the lower level.

4.2 Main results

We report the results on CoNLL03-C in Table 2 and three distant supervision datasets in Table 3, where Self-Cleaning outperforms all baselines significantly. The performance of the second group of methods is generally better than the first group, which shows the necessity of the guidance from clean data. GLC and Meta-Reweight are directly borrowed from the Machine Learning community;[4] both of them fail to improve the performance with the guidance set. GLC estimates a confusion matrix of labels using the guidance set. However, in the NER scenario, label-level confusion is not meaningful, *e.g.*, all non-empty labels can be labeled as `O` due to span error. NEEDLE uses the guidance set to estimate the confidence scores by heuristics. In contrast, informed by the analysis of noise that we presented, we design a discriminator to handle two types of errors in Self-Cleaning, which has shown to be a more effective way to provide guidance in the learning on noisy NER data. Please refer to Appendix E for a detailed case study that elucidates the workings of both the NER model and the discriminator in Self-Cleaning.

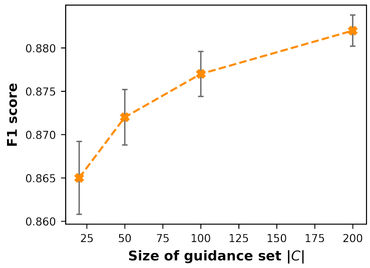

Figure 4: Results with different $|C|$.

4.3 Influence of $|C|$

The size of the guidance set influences the quality of the discriminator, and thus affects the final performance. We study the performance of Self-Cleaning with different sizes of guidance sets. For each $|C|$, we randomly sample 3 guidance sets. Due to the space limit, we report the mean and standard deviation of F1 score on CoNLL03, similar observations were also obtained on other datasets.

We show the results in Figure 4. With a smaller guidance set, the performance of Self-Cleaning drops as the quality of discriminator gets worse. Also, the performance becomes more unstable with smaller guidance sets, since the pattern distribution in different sets is different. The results show that the selection of the guidance set is crucial to the final performance. If the guidance set is of low quality or too small, the quality of the discriminator

---

[4] GLC on OntoNotes5.0 is not reported due to its poor performance.

p-**value**	-	-	<0.005	-	-	<0.001	-	-	<0.001

will be the bottleneck of the final performance.

In additional experiments we find that to reach the compareable performance (an F1 score of 0.880) as Self-Cleaning ($|C| = 200$), RoBERTa (Gold) needs 1,000 clean instances, five times more than Self-Cleaning. Directly fine-tuning a RoBERTa model only on the same guidance set C results in markedly worse performance as seen in Table 3. Noisy labels do effectively improve the sample efficiency of clean data.

4.4 Ablation Study

To evaluate the individual contributions of different components in Self-Cleaning, we conduct an ablation study and create the following variants: Firstly, we remove the span prompts and only reweight the category labels. Secondly, we remove the category prompts, which means the discriminator can only reweight the binary span labels. Thirdly, we remove clean demonstrations. Lastly, we remove the co-training strategy, and only use the pre-trained discriminator. Additionally, we also report the results on Stage I and Stage II.

We present the results in Table 4. As we discussed in Section 2.3, span error is a severe issue in the noisy NER data. Without the ability to detect span errors, the performance drops considerably. Also, without clean demonstrations, the few-shot ability of the discriminator is limited and the NER model lacks of guidance when generating pseudo labels, causing a drop in performance. By comparing the results of Stage I and RoSTER, we also observe that utilizing clean demonstrations leads to an improvement in the robustness of self-training. The co-training strategy is important to improve the discriminator, covering more patterns by involving pseudo positive labels from the NER model. Lastly, the improvement from Stage II to Self-Cleaning shows that fine-tuning on the guidance set can further improve the performance.

Table 4: Results of ablation study on CoNLL03.

Self-Cleaning	0.883	0.882	0.882

5 Conclusion

In this paper, we study how to improve NER models trained on noisy labeled data with a guidance set consisting of a small number of clean instances. Our research is grounded on the noise pattern analysis on the real-world noisy NER data. We identify two NER-specific error types: span error and category error. To address these errors, we propose to use a dedicated discriminator to guide the training of the NER model. This discriminator is tailored to detect the aforementioned errors using pre-defined discriminative prompts, and its outputs are used to reweight the samples for training the NER model. We design a three-stage training procedure to unleash the power of clean instances in guiding noisy NER learning. We evaluate the proposed method on a rich set of NER benchmarks with crowdsourcing labels and distant supervisions. The results show that with a few clean instances, the proposed method can boost the performance significantly.

Limitations

The discriminator is the key part of Self-Cleaning, however, it has several limitations. Firstly, the current version is able to handle noise within recognized entities but it falls short when dealing with noise in non-entity labels, i.e., `O` labels. Secondly, since the discriminator works at the entity level, an entity with even partially incorrect labels is fully downweighted. This approach could lead to the discarding of potentially useful labels, especially when category labels are very sparse. Future work might consider the development of discriminators that operate on the token level.

Additionally, it is also worth noting that in the current discriminator design, we did not make explicit assumptions about the underlying mechanisms generating span and categorical errors. The negative samples are simulated by randomly modifying tokens within entities and flipping their classes. Such negative samples may not be informative enough to capture the salient patterns needed to distinguish correct labels from incorrect ones, thereby limiting the final performance. For a more comprehensive understanding and identification of the root causes of errors in noisy NER data, future work might incorporate more advanced error modeling techniques, such as lexical analysis or cross-validation against external knowledge bases.

Ethics Statement

Learning from noisy NER data diminishes the necessity for large-scale, high-quality labeled data, thereby facilitating its use in domains where obtaining expert knowledge is costly, such as in legal and financial sectors. Our proposed method paves the way for achieving a model with reasonable performance while keeping the cost of expert-labeled data within an acceptable range. It has the potential to lower the entry barrier for novices who have limited data at their disposal.

However, we should notice our method makes it easier to attack the modeling training by poisoning the guidance set. Given the limited size of the guidance set, a subtle change could drastically alter its distribution, potentially leading to the collapse of the entire training pipeline.

A Implementation Details

In Self-Cleaning, we use `roberta-base` as the backbone for both NER model and the discriminator. We use AdamW optimizer to optimize both NER model and the discriminator. We pre-train the discriminator with a learning rate $2e^{-5}$ and $5e^{-6}$ during co-training. The training batch size is fixed as 64. To update the NER model, we use learning rate $5e^{-6}$ for CoNLL03 and Wikigold, and $5e^{-7}$ for OntoNotes5.0. During co-training, we choose $K = 20$ pseudo entities per class to fine-tune the discriminator. We first use the noise-robust loss and ensemble training in Meng et al. (2021) to pre-train the NER model on noisy NER data, and then apply the proposed Self-Cleaning approach on the obtained model. GLC, Meta-Reweight and NEEDLE start with the same pre-trained model as Self-Cleaning. All experiments are repeated with 3 random seeds and 3 randomly sampled guidance sets. The averaged metrics are reported. We run our experiments on 2 NVIDIA GeForce RTX 2080Ti GPUs with 12 GB memory.

Table 5: Results on synthetic noisy CoNLL03.

Methods	Type	Noise Rate 0.2	Noise Rate 0.4	Noise Rate 0.6
RoSTER	**Span**	0.852	0.823	0.462
	Cat.	0.886	0.873	0.667
Self-Cleaning	**Span**	0.901	0.897	0.896
	Cat.	0.899	0.895	0.864

B Verbalizer

We list the mapping between NER labels and words used in our prompt-based discriminator.

- **CoNLL03**: `PER` - person, `LOC` - location, `ORG` - organization, `MISC` - other.
- **OntoNotes5.0**: `WORK_OF_ART` - work of art, `PRODUCT` - product, `NORP` - affiliation, `ORG` - organization, `FAC` - facility, `GPE` - geo-political, `LOC` - location, `PERSON` - person, `EVENT` - event, `LAW` - law, `LANGUAGE` - language, `PERCENT` - percent, `ORDINAL` - ordinal, `QUANTITY` - quantity, `CARDINAL` - cardinal, `TIME` - time, `DATE` - date, `MONEY` - money.
- **Wikigold**: `PER` - person, `LOC` - location, `ORG` - organization, `MISC` - other.

C Experiments on Synthetic Datasets

Settings. We also evaluate Self-Cleaning on synthetic data, where we manually create noisy NER data. We create two kinds of datasets based on CoNLL03 with span and category errors, respectively. For each error type, we control the noise rates. For the span error, the noise rate controls the probability to add or remove a token around a ground-truth entity. For the category error, the noise rate defines the probability of the class of a ground-truth entity to be flipped into a noisy class.
Results. We present the results in Table 5, where we also show the results of RoSTER to study the effect of noise rate. We can observe that with larger noise rate, the performance of RoSTER decreases significantly. But with our dedicated discriminator, both types of errors can be detected and down-weighted, leading to a robust performance.

Table 6: Results of various discriminator backbones.

Backbone	**Pre.**	**Rec.**	**F1**
`roberta-base`	0.883	0.882	0.882
`roberta-large`	0.885	0.883	0.884
`flan-t5-small`	0.878	0.873	0.875
`flan-t5-base`	0.884	0.877	0.878
`flan-t5-large`	0.889	0.877	0.881

D Experiments of different model designs

D.1 Study of Discriminator Backbones

To study the effect of different kinds of discriminators, we also incorporate Self-Cleaning with Generative Language Model (GLM) based discriminator. Specifically, we use Flan-T5, an instruction fine-tuned GLM family (Chung et al., 2022). Accordingly, we design the following two prompts,

- **Span**: `[X]`. `[Y]` is an entity. Is it correct?
- **Category**: `[X]`. `[Y]` is a `[Z]` entity. Is it correct?

The GLM-based discriminator is supposed to choose an answer from [`correct`, `wrong`]. We use the same method in Section 3.1 to create create both positive and negative samples for the pre-training of the discriminator. We consider three Flan-T5 variants with varying parameter sizes to understand the impact of model scaling. Additionally, we include results obtained by using `roberta-large` as the backbone of the discriminator.

In Table 6, we report the results on CoNLL03. We can observe that with a larger backbone model, the final performance is slightly better. Interestingly, both MLM-based and GLM-based discriminators achieve similar final performance. The success of GLM-based discriminators make it possible to introduce more powerful GLMs like the GPT family (Radford et al., 2019) in the future. However, the performance gains from larger models are marginal, suggesting a performance bottleneck. We hypothesize that the randomly generated negative samples may not be sufficiently informative. We leave how to create useful negative samples for the discriminator as an important future work.

D.2 Study of Encoder Configurations

In Self-Cleaning, we employ two `roberta-base` models as encoders for the NER model and the discriminator respectively. Additionally, we experimented with alternative designs, such as building both the NER model and the discriminator on top of a single `roberta-base` encoder. In this configuration, we added an entity head and a classification head for the NER model, while also incorporating an MLM head for the discriminator. We also conducted similar tests using the `roberta-large` model and have reported these results as well.

The results on CoNLL03 are reported in Table 7. The variants utilizing `roberta-large` show better performance than those based on `roberta-base`, owing to the increased power of the backbone model. However, when the NER model and the discriminator share a single encoder, it negatively affects the final performance. Specifically, the RoBERTa encoder, when trained on noisy NER data, tends to propagate its noise to the discriminator, thereby affecting its quality. Therefore, to ensure the isolation between clean and noisy data, we recommend employing separate encoders for the NER model and the discriminator. This design is also more flexible as we are able to use different backbone models for the NER model and the discriminator, as we did in Section D.1.

E Case Study and Analysis

E.1 Case Study of the NER model

In Table 8, we perform case study to understand the advantage of **Self-Cleaning** with a concrete example, by comparing with the best baseline without guidance **RoSTER** and with guidance **NEEDLE**. Without the guidance about the span and category errors, RoSTER fails to detect the correct span of `Sheffield Shield` and classify `Bellerive Oval` even though the span is correct. NEEDLE estimates the confidence scores according to the NER model's outputs via the histogram binning heuristic (Zadrozny and Elkan, 2001), which is ineffective to handle both span and category errors. Self-Cleaning is able to downweight the noisy entities with wrong spans and classes, leading to the correct recognition of the testing sentence.

Table 7: Results of different encoder configurations.

Encoder	Pre.	Rec.	F1
one `roberta-base`	0.881	0.875	0.878
two `roberta-base`	0.883	0.882	0.882
one `roberta-large`	0.889	0.879	0.884
two `roberta-large`	0.897	0.887	0.892

E.2 Case Study of the Discriminator

We present some example outputs of the discriminator in Table 9. Even when the class of an entity is incorrectly identified, the discriminator can still evaluate the span correctly. For instance, in the first example, `China` is correctly recognized as an entity, but is misclassified as `ORG`. The discriminator accurately assigns a low score to the category label and a high score to the span label. However, if the span label is incorrect, the category label will also be downweighted by the discriminator. For example, in the third case, both the span score and category score are low. Intuitively, correct entity recognition is a prerequisite for correct classification, making it meaningless to preserve the category label if the span label is incorrect.

We also investigate the quality of the discriminator in Figure 5. We rank the pseudo entities in ascending order based on discriminator scores and then report the mean accuracy by comparing these pseudo entities with their corresponding ground-truth entities. As seen in the figure, entities with low discriminator scores exhibit poor quality. For instance, the accuracy of the category labels for the bottom 10% of entities is approximately 0.4. As we incorporate more high-scoring entities, the mean accuracy shows a noticeable increase. This trend elucidates the discriminator's role in guiding the training of the NER model, primarily by accurately downweighting noisy labels.

Table 8: Case study of Self-Cleaning and baselines. The sentence is from CoNLL03.

Ground truth	Score on the first day of the four-day [Sheffield Shield]$_{\text{MISC}}$ match between [Tasmania]$_{\text{LOC}}$ and [Victoria]$_{\text{LOC}}$ at [Bellerive Oval]$_{\text{LOC}}$ on Friday.
RoSTER	Score on the first day of the four-day [Sheffield]$_{\text{MISC}}$ Shield match between [Tasmania]$_{\text{LOC}}$ and [Victoria]$_{\text{LOC}}$ at [Bellerive Oval]$_{\text{ORG}}$ on Friday.

Abstract

The success of Natural Language Understanding (NLU) benchmarks in various languages, such as GLUE (Wang et al., 2018) for English, CLUE (Xu et al., 2020) for Chinese, KLUE (Park et al.) for Korean, and IndoNLU (Wilie et al., 2020) for Indonesian, has facilitated the evaluation of new NLU models across a wide range of tasks. To establish a standardized set of benchmarks for Vietnamese NLU, we introduce the first Vietnamese Language Understanding Evaluation (**VLUE**) benchmark[1]. The VLUE benchmark encompasses five datasets covering different NLU tasks, including text classification, span extraction, and natural language understanding. To provide an insightful overview of the current state of Vietnamese NLU, we then evaluate seven state-of-the-art pre-trained models, including both multilingual and Vietnamese monolingual models, on our proposed VLUE benchmark. Furthermore, we present **CafeBERT**, a new state-of-the-art pre-trained model that achieves superior results across all tasks in the VLUE benchmark. Our model combines the proficiency of a multilingual pre-trained model with Vietnamese linguistic knowledge. CafeBERT is developed based on the XLM-RoBERTa model, with an additional pretraining step utilizing a significant amount of Vietnamese textual data to enhance its adaptation to the Vietnamese language. For the purpose of future research, CafeBERT is made publicly available[2] for research purposes.

1 Introduction

Recently, the Vietnamese Natural Language Processing (NLP) research community has achieved remarkable advancements in the development of pre-trained language models for the Vietnamese language (Nguyen and Tuan Nguyen, 2020; Tran et al., 2022, 2023). The integration of these state-of-the-art models, coupled with the progress made in establishing high-quality benchmarks, has paved the way for a diverse array of applications within Vietnam. Notably, these advancements have greatly enhanced capabilities in areas of Machine Reading Comprehension (Van Kiet et al., 2022; Van Nguyen et al., 2021).

Unfortunately, despite the recent progress in developing large language models for Vietnamese, the research community of Vietnamese NLP lacks a common ground for evaluating the performance of these models. This lack of standard evaluation metrics and benchmarks makes it difficult to identify the strengths and weaknesses of different approaches in pre-training new models in Vietnamese and the overall progress of Vietnamese natural language understanding (NLU). As a result, it is crucial for the community to establish a shared set of evaluation metrics and benchmarks that can be used to assess newly proposed language models. Inspired by benchmarks evaluating Natural Language Understanding in other languages (Wang et al., 2018, 2019; Xu et al., 2020; Wilie et al., 2020; Park et al.), in this paper, we propose VLUE (Vietnamese Language Understanding Evaluation) as a shared set of evaluation metrics and benchmarks for pre-trained models in Vietnamese. To the best of our knowledge, our proposed benchmark is the first benchmark for evaluating Vietnamese NLU models. We believe that this benchmark will serve as a valuable resource for researchers and practitioners working in the field of Vietnamese NLU, and will help drive further advancements in this area.

To facilitate the development of new large language models in Vietnamese, we, in this work, introduce Vietnamese Language Understanding Eval-

Findings of the Association for Computational Linguistics: NAACL 2024, pages 211–222
June 16-21, 2024

uation (**VLUE**), a comprehensive language understanding framework that includes five diverse tasks. The tasks include a wide range of applications (Question Answering, Hate Speech Detection, Part-of-Speech, Emotion Recognition, and Natural Language Inference), types of input (single sentences, pair of sentences, sequence of sentences) and objectives of tasks (extracted span, sentence classification, sequence labeling). With its diverse set of benchmarks, VLUE establishes a standardized evaluation framework, enabling comprehensive comparisons and evaluations of different models in the context of Vietnamese.

Within this paper, we commence by introducing our novel VLUE benchmark, designed to evaluate the language prowess of various models. We conduct a comprehensive analysis of seven models, encompassing four multilingual models as well as three monolingual models. Additionally, we present the introduction of a newly developed pretrained model, referred to as **CafeBERT**. This model is constructed by leveraging the large-scale XLM-RoBERTa model and further fine-tuning it on an extensive Vietnamese corpus, thereby enhancing its proficiency in the Vietnamese language and elevating its overall performance. Through in-depth evaluation, we demonstrate that **CafeBERT** achieves state-of-the-art performance across all four tasks presented in our VLUE benchmark.

In this paper, we make the following contributions:

1. Our paper introduces a high-quality Vietnamese natural language understanding benchmark that covers a variety of tasks: Part-of-speech tagging, machine reading comprehension, natural language inference and hate speech spans detection, at different levels of difficulty, in different sizes and domains. This benchmark serves as a common ground for assessing the overall proficiency of language models in the Vietnamese language.

2. We propose an enhanced version of XLM-RoBERTa large that is specifically optimized for Vietnamese. Through comprehensive testing on the VLUE benchmark, we show that our model substantially outperforms existing models. We publicly release our models under the name **CafeBERT** which can serve as a strong baseline for future Vietnamese computational linguistics research and applications.

3. Evaluate the performance of language models on the VLUE benchmark in different aspects, such as data domain and model architecture. The results show that the performance of monolingual models has a better score on social network domain than multilingual models.

The rest of this paper is structured as follows. Section 2 reviews existing NLU benchmarks and pre-trained language models. Section 3 introduces the NLU benchmark for Vietnamese. In particular, we present experiments and benchmark result in Section 4. Then Section 5 presents a new pre-trained language model called CafeBERT. Finally, Section 6 presents conclusions and future work.

2 Related Work

In this paper, we review data benchmark and pre-trained language models related to our work.

2.1 Benchmarks

This work is directly inspired by GLUE benchmark (Wang et al., 2018) which is a multi-task benchmark for natural language understanding (NLU) in the English language. It consists of nine tasks: single-sentence classification, similarity and paraphrase tasks, and Inference Tasks. Later, recognizing that performance of SOTA models on the benchmark has recently surpassed the level of non-expert humans, suggesting limited headroom for further research, Wang et al. (2019) propose SuperGLUE which is GLUE's harder counterpart. SuperGLUE covers question answering, NLI, coreference resolution, and word sense disambiguation tasks.

Following the idea of GLUE and SuperGLUE, different NLU benchmarks are also introduced in other languages such as CLUE (Xu et al., 2020) in Chinese, FLUE (Le et al., 2020) in French, IndoNLU (Wilie et al., 2020) in Indonesian. Besides, in the multilingual setting, we also have XGLUE (Liang et al., 2020) for evaluating Cross-lingual Pre-training, Understanding and Generation.

2.2 Pretrained Language Models

Pre-trained language models have revolutionized the field of natural language processing (NLP) by providing a powerful foundation for various language-related tasks. These models are typically designed based on the architecture of the Transformers model (Vaswani et al., 2017), which has proven to be highly effective in capturing intricate patterns and dependencies in textual data by utilizing attention mechanisms.

The concept of pre-training involves training models using large amounts of text data in semi-supervised tasks. During pre-training, the models learn to predict missing words (Masked Language Model) or determine the coherence between pairs of sentences (Next Sentence Prediction) (Devlin et al., 2019). By learning from diverse and vast text corpora, these models acquire a rich understanding of language, including grammar, semantics, and contextual cues.

Following the groundbreaking success of BERT (Devlin et al., 2019), a wave of enhanced variations has emerged, each pushing the boundaries of pre-trained language models. Noteworthy among these advancements are RoBERTa (Liu et al., 2019), AlBERT (Lan et al., 2020), SpanBERT (Joshi et al., 2020), and DeBERTa (He et al., 2021) are developed. Additionally, several BERT variants have been developed for multilingual applications in over 100 languages, such as mBERT (Devlin et al., 2019) and XLM-RoBERTa (Conneau et al., 2020a).

Following the wave of pre-training in English, researchers worldwide have embarked on pre-training monolingual language models in diverse languages. This linguistic expansion has resulted in the development of notable models like CamemBERT (Chan et al., 2020) in French, GELECTRA (Martin et al., 2020) in German, and BERT and its variations (Cui et al., 2021) in Chinese.

3 VLUE Benchmark

3.1 Overview

VLUE is a collection of five language understanding tasks in Vietnamese. The goal of VLUE is to provide a set of high-quality benchmarks to assess the Vietnamese language understanding of newly proposed models. The selected tasks are guaranteed through many criteria to make the most accurate assessment. VLUE covers a wide variety of tasks with variations in the size of the dataset, the size of the input text, and the comprehension requirements of each task. The datasets should be easy to implement for evaluation so that users can focus on developing models. The selected tasks are challenging for the model but must be solvable. The datasets in the VLUE benchmark are previously published Vietnamese datasets and are easily accessible to researchers. When selecting datasets, we try to ensure each task had an evaluation set that accurately evaluated the performance of the models and covered multiple tasks. For example, VLUE can cover tasks: machine reading comprehension, natural language inference, emotion recognition, hate speech detection, and POS tagging. The domains of the datasets are also covered diversely such as Wikipedia, social networks, and articles. In addition, we also consider choosing datasets that have great room for improvement (such as VSMEC, UIT-ViQuAD 2.0) so that VLUE is more challenging and has more new ideas for researchers. Table 1 presents the overview of the datasets and tasks in VLUE. Data samples for each task are shown in Table 6. We describe each dataset and task as follows.

3.2 Tasks

UIT-ViQuAD 2.0 The Vietnamese Question Answering Dataset 2.0 (Van Kiet et al., 2022) is an updated version of the UIT-ViQuAD 1.0 dataset (Nguyen et al., 2020). UIT-ViQuAD 2.0 is published for the machine reading comprehension shared-task at the Eighth Workshop on Vietnamese Language and Speech Processing (VLSP 2021). This dataset includes $5,173$ paragraphs extracted from 176 articles on the Wikipedia data domain. The hired human annotators then annotate $24,489$ answerable questions and $11,501$ unanswerable questions. The task proposed by this dataset is to extract the answer for a question given a corresponding context. The answer can be empty when models encounter unanswerable questions. Exact Match (EM) and F1-score are used to evaluate the performance of the model.

ViNLI The Vietnamese Natural Language Inference dataset (Huynh et al., 2022) is the first Vietnamese high-quality and large-scale dataset created for the open-domain natural language inference task. The dataset consists of more than $30,000$ human-annotated premise-hypothesis sentence pairs with 13 topics from more than 800 online news articles. The goal of the problem is to predict the relationship of pairs of sentences with the set of relationships that include entailment, neutral, contradiction, and other. Following the original work of ViNLI, we use F1-score and Accuracy as the metrics for the evaluation process.

VSMEC The standard Vietnamese Social Media Emotion Corpus (Ho et al., 2020), or UIT-VSMEC (VSMEC), is the task of classifying the emotion

Dataset	Train	Dev	Test	Domain	Task	Metric
UIT-ViQuAD	28,457	3,821	3,712	Wikipedia	Machine reading comprehension	EM / F1
ViNLI	24,376	3,009	2,991	Online news	Natural language inference	Acc / F1
VSMEC	5,548	686	693	Social networks	Emotion recognition	F1
ViHOS	8,974	1,112	1,128	Social networks	Hate speech spans detection	F1
NIIVTB POS	18,588	1,000	1,000	Online news	Part-of-speech tagging	F1

Table 1: Statistics of the VLUE datasets and tasks. The version of UIT-ViQuAD is 2.0. ViNLI has four classes.

of Vietnamese comments on social networks. The dataset includes $6,927$ manually labeled social media comments. It is a multi-label classification problem with seven emotion labels: anger, disgust, enjoyment, fear, sadness, surprise, and other. Enjoyment label has the most significant rate with about 28%, and surprise is the lowest with less than 5%. Following (Nguyen et al., 2022), the F1-macro is used as a metric to evaluate VSMEC.

ViHOS The Vietnamese Hate and Offensive Span dataset (Hoang et al., 2023) consists of $26,467$ spans on $11,056$ comments (including clean, hate, and offensive comments). The dataset is annotated by humans through three labeling phases. The goal of this task is to extract hate and offensive spans from comments. The dataset is a challenge as about 51% of comments have no span extracted and about 27% of comments have more than one extracted hate speech spans. F1-score is the metric used in this dataset to evaluate the performance of the model.

NIIVTB POS NIIVTB (Nguyen et al., 2016, 2018b) is a constituent treebank in Vietnamese annotated with three layers: word segmentation, part-of-speech (POS), and bracketing. In the VLUE benchmark, we use the POS task in NIIVTB, so we call NIIVTB POS. This treebank has two subsets, NIIVTB-1 and NIIVTB-2, with more than $10,000$ sentences each crawled from two sources: the first set is VLSP[3] raw data from Youth[4] (Tuổi Trẻ) online newspaper with the topic are social and political topics, the second set is collected from Thanhnien[5] online newspaper with 14 different topics. NIIVTB has $20,588$ sentences divided into three sets of train, dev, and test with a ratio of roughly 8: 1: 1. We use F1 as the metric for evaluating the POS task of NIIVTB.

4 Experiments and Benchmark Result

4.1 Experiment settings

Baselines To provide an insightful overview of the current progress of Vietnamese NLU, we implement state-of-the-art models in Vietnamese NLU using the library *Transformers* provided by Huggingface[6]. For the text classification task, we encode the input sentence and then pass the encoded output through a classifier. Similar to text classification tasks, for NLI tasks, we encode the input sentence pair with a separator token and then pass the output through a classifier. For span extraction tasks, we use two fully connected layers after encoding the input to predict the start and end position of the segment to be extracted.

All of our experiments are performed on a single machine with an NVIDIA A100 GPU with 40GB of RAM on a Google Colaboratory environment[7]. We use TensorFlow 2.11.0 (Abadi et al., 2016) and PyTorch 1.12.0 (Paszke et al., 2019) to support the research process.

Models We use the public available pre-trained models that support Vietnamese below to evaluate models on VLUE benchmark. The details of each model are shown in Table 2.

- **mBERT** (Devlin et al., 2019): We use base version model with 12 layers and hidden size of 768. The model has been trained with big data corpus covering 104 languages including Vietnamese.
- **WikiBERT** (Pyysalo et al., 2021): WikiBERT for Vietnamese belongs to a group of 42 WikiBERT models that support 42 different languages. Vietnamese WikiBERT is built using the BERT architecture and trained using data from two sources: Wikipedia (172M tokens) and the Vietnamese Treebank dataset ($20,285$ tokens).

Model	#Params	#Layers	#Heads	Hidden Size	Vocab Size	Language Type	Data Pre-train Source
wikiBERT	-	12	12	768	20101	monolingual	Wikipedia
PhoBERT$_{base}$	135M	12	12	768	64001	monolingual	Wikipedia, News
PhoBERT$_{large}$	370M	24	16	1024	64001	monolingual	Wikipedia, News
mBERT	179M	12	12	768	119547	multilingual	Wikipedia
DistilBERT	134M	6	12	768	119547	multilingual	Wikipedia
XLM-Roberta$_{base}$	270M	12	8	768	250002	multilingual	CommonCrawl
XLM-Roberta$_{large}$	550M	24	16	1024	250002	multilingual	CommonCrawl
CafeBERT	550M	24	16	1024	250002	multilingual	Wikipedia, News

Table 2: The details of baseline models used in VLUE benchmark.

- **DistilBERT** (Sanh et al., 2019): DistilBERT was introduced as a smaller, lighter, and faster version of the previous BERT model but retained 97% of its language comprehension. Multilingual DistilBERT is trained in 104 languages with a hidden size of 768 and 6 layers.
- **PhoBERT** (Nguyen and Tuan Nguyen, 2020): PhoBERT is the state-of-the-art monolingual model in Vietnamese. The model is trained based on the RoBERTa model with a dataset including Vietnamese Wikipedia and news articles. PhoBERT has two versions, including PhoBERT$_{base}$ and PhoBERT$_{large}$.
- **XLM-RoBERTa** (Conneau et al., 2020b): XLM-RoBERTa is a large-scale pre-trained multilingual model. This model was trained on a Transformers-based masked language task using two terabytes of CommonCrawl data across more than a hundred languages. The model has two versions, XLM-RoBERTa$_{base}$ and XLM-RoBERTa$_{large}$.

These models currently achieve state-of-the-art performance on most Vietnamese language processing benchmarks. Among the models above, the multilingual model XLMR$_{large}$ and monolingual model PhoBERT$_{large}$ are the two most important models in Vietnamese NLP at the time of this writing and are expected to achieve impressive performance on VLUE benchmark tasks.

4.2 Result Benchmark

Table 3 presents the results of all experimented models on the VLUE tasks. We observed that the larger the model, the higher the performance, typically the XLM-Roberta$_{large}$ and PhoBERT$_{large}$ models with the most significant number of parameters have outstanding performance on all tasks. XLM-RoBERTa$_{large}$ is the model with the best performance on 4 over 5 VLUE tasks including UIT-ViQuAD, ViNLI, ViHOS, and NIIVTB POS. This results agree with multiple previous work as XLM-Roberta$_{large}$ also achieves SOTA results other Vietnamese tasks other than the VLUE benchmark (Do et al., 2021; Van Nguyen et al., 2023; Tran et al., 2021). PhoBERT$_{large}$ is the model with the best performance on VSMEC tasks with F1-score achieved is 65.44%. Especially for the NIIVTB POS task, the pre-trained multilingual models have higher performance than the pre-trained monolingual models. XLM-Roberta$_{large}$ has the highest performance on NIIVTB POS, with an 83.62% F1-score.

According to the results, models pre-trained on multilingual data perform better than monolingual pre-trained models. The XLM-Roberta$_{large}$ performed better than the PhoBERT$_{large}$, in 4 tasks of the VLUE benchmark. For the base version of the two models above, PhoBERT is stronger than XLM-Roberta with a ratio of 3: 2. The number of attention heads of XLM-Roberta is eight, smaller than PhoBERT's 12, which contributes to the result of the base version of XLM-Roberta losing to PhoBERT. Models with more attention heads allow the model to pay attention to more parts (Michel et al., 2019; Ma et al., 2021). For example, one head focuses on the next word, the other head focuses on subject-verb agreement, and so on. In addition, the XLM-Roberta model has to learn many languages, with a limited amount of attention, it is impossible to deeply learn a specific language like PhoBERT.

We then compare WikiBERT (monolingual pre-trained model) and mBERT (multilingual pre-trained model), the two models with the same number of attention heads and the number of layers (transformers block). We observe that mBERT outperforms WikiBERT on three tasks (UIT-ViQuAD 2.0, ViNLI, NIIVTB POS), similar to results from work in other languages (Pikuliak et al., 2022; Armengol-Estapé et al., 2022).

The monolingual pre-training models perform better than the multilingual pre-training models in the social network domain (Quoc Tran et al., 2023; Nguyen et al., 2022). In the VLUE benchmark, there are two models with a social network domain, VSMEC, and ViHOS. For VSMEC, the PhoBERT large model achieve the SOTA results. With the ViHOS dataset, the XLM-RoBERTa model achieve the best performance. However, the difference in results between XLM-RoBERTa and PhoBERT is minor (only 0.54%) compared to the difference between the two models in other tasks ranging from 3% to 6%. Vietnamese Wikipedia data is quite formal and unlike the language frequently used in society and on social networks. Additionally, Vietnamese is unlike English and other languages, the space in Vietnamese only separate syllables, not words. This means that multilingual models like mBERT do not unaware this. We experiment with several Vietnamese data sets on social networking domains such as VSMEC, ViHOS (in VLUE benchmark), ViCTSD (Nguyen et al., 2021b), ViOCD (Nguyen et al., 2021c), and ViHSD (Luu et al., 2021). Table 4 shows the results of the experiment, the PhoBERT model achieved better results than multilingual models on most tasks of the social network data domain. This results suggest that training NLU models with monolingual textual data is necessary for tasks whose domain is social networks (Wilie et al., 2020; Müller et al., 2020). On the other hand, models trained with multilingual data can comprehend multiple languages and tackle tasks that involve corpora with a significant presence of foreign words (non-Vietnamese), such as news articles and Wikipedia.

5 CafeBERT

The results from our analysis on current progress of Vietnamese NLU show that the XLM-RoBERTa$_{large}$ achieves the best performance on most tasks of VLUE. However, PhoBERT also show a comparable performance on tasks with corpus from social networks, such as VSMEC and ViHOS. This observation drives us to a hypothesis that further adapting multilingual model XLM-RoBERTa$_{large}$ into Vietnamese can help improve its performance on VLUE. We then propose a new model that is expected to combine the existing knowledge from XLM-RoBERTa and the newly trained knowledge from Vietnamese corpus. We continue pre-training XLM-RoBERTa with a Vietnamese dataset similar to the data used to train the PhoBERT model. We refer to our proposed model as CafeBERT.

5.1 Dataset and Training New Language Model

In this section, we describes the dataset, architecture, and training setting that we used to develop the new pre-training model.

Pre-training data: We use a corpus of 18GB of textual data as the pre-training dataset. The dataset has two corpora: 1GB of text from the Vietnamese Wikipedia and 17GB of text which is de-duplicated and preprocessed data from a 27.5GB corpus of text sourced from online Vietnamese news articles[8]. Our dataset contains about 180 million sentences and more than 2.8 billion word tokens.

Architecture: Our model is built upon the XLM-Roberta model (Conneau et al., 2020b) by continue pre-training it on the large Vietnamese text corpus. The training process uses the objective of the mask language model (MLM) task. Our model has a hidden state of 1024, 24 layers, and 16 attention heads.

Fine-tuning: We create the CafeBERT pre-training model by fine-tuning the XLM-Roberta model with the transformers library[9]. The optimizer for training is Adam (Kingma and Ba, 2014) with weight decay (Loshchilov and Hutter, 2019). We fine-tuned the model on an A100 40GB GPU with a peak learning rate of 2e-5. For the MLM task, we do masking for 15% of the words of the data.

5.2 Results of CafeBERT

5.2.1 Results of CafeBERT on VLUE

Table 3 shows that our new pre-trained model achieves best performance on all the tasks of the VLUE benchmark. On UIT-ViQuAD 2.0 dataset, CafeBERT has the best improvement in F1-score with a 1% increase on the test set. On the other hand, this model has a minor performance increase with 0.06% F1-score and 0.12% accuracy on the test set of ViNLI. On the VSMEC dataset, our pre-trained model CafeBERT outperforms

XLM-Roberta	62.24	**77.70**	80.51	94.35	63.68

Table 4: Performance of models on several Vietnamese tasks on social network data domain. For all tasks, we report F1-score.

PhoBERT$_{large}$ by 0.68% F1-score and 3.88% F1-score over XLM-Roberta$_{large}$. On ViHOS and NIIVTB POS datasets, CafeBERT achieves the new SOTA results with F1-scores on the test set of 78.56% (+0.86%) and 84.04% (+0.42%), respectively. Besides, CafeBERT also performs well on all corpus domains in VLUE, including Wikipedia, news, and social networks. So our model sets a new SOTA performance on the VLUE benchmark and establishes a strong baseline for future proposed Vietnamese NLU model.

5.2.2 Results of CafeBERT on other tasks

In addition to the tasks in VLUE, we implement the CafeBERT model on other tasks in Vietnamese including: ViNewsQA, UIT-ViFSD, and UIT-VSFC. In which:

- **ViNewsQA** (Nguyen et al., 2021a) is an machine reading comprehension task on the health domain. The dataset contains 22,057 question-answer pairs extracted from health news.
- **UIT-ViFSD** (Luc Phan et al., 2021) is the customer comments classification on e-commerce platforms. The data set includes 11,122 comments about phones classified into three sentiments: positive, negative, and neutral.
- **UIT-VSFC** (Nguyen et al., 2018a) is a dataset including 16,000 student feedback sentences. Sentences are human-annotated with two tasks: sentiment-based classification and topic-based classification.

Table 5 shows our experimental results on the three datasets described above with several pretrained models that support Vietnamese. On all three tasks, the CafeBERT model has better results than other models. In tasks C and D, the CafeBERT model has higher performance than the model with the second best results (XLM-Roberta$_{large}$) by just under 1% in evaluation metrics. The CafeBERT model shows the highest superiority in the ViNewsQA task with F1 and accuracy 1.95% and 6.04% higher, respectively, when compared to the XLM-Roberta$_{large}$ model. The CafeBERT model is enhanced by training on corpus text mainly in news domains similar to ViNewsQA's data source, so the CafeBERT model shows its best power on this task.

Models	**ViNewsQA**		**UIT-ViSFD**	**UIT-VSFC**			
				Sentiment Classification		**Topic Classification**	
	EM	F1	F1	Accuracy	F1	Accuracy	F1

Table 5: Performance of models on tasks outside VLUE. We evaluate the results on the test data set.

6 Conclusion and Future Works

We proposed **VLUE** - the first Vietnamese language understanding evaluation benchmark. VLUE is used to evaluate pre-trained models in Vietnamese with various tasks such as reading comprehension, text classification, natural language inference, hate speech detection, and part-of-speech tagging. We also publicize a pre-trained model, **CafeBERT**, which is trained based on the XLM-Roberta model with a vast Vietnamese text dataset. We show that CafeBERT achieves SOTA performance on all VLUE benchmark tasks and all VLUE domains, such as social networks, Wikipedia, and news.

We expect VLUE to be widely used to evaluate Vietnamese-supported pre-trained models. The pre-trained models will be evaluated comprehensively on multiple tasks with different domains. The CafeBERT model will be applied to many tasks for Vietnamese to improve performance and get many applications in the field of natural language processing in Vietnamese. In addition, resource-poor languages can monitor and work our way up to creating great pre-training models that can enhance performance and have many real-world applications.

Limitations

We have shown that the CafeBERT model achieves SOTA results on the VLUE benchmark. However, more experiments and analysis are still needed to clarify and better understand the impact of our model on tasks of the VLUE benchmark. In addition, more tests are needed for tasks other than the VLUE benchmark to clarify and understand the new model across domains and different types of tasks in Vietnamese. We leave these as motivation for future studies. In addition, we choose a large data set available instead of taking advantage of a large amount of Vietnamese data from more sources because it requires a large amount of computing power and requires hardware resources.

Ethics Statement

The authors introduced the first Vietnamese language understanding evaluation (VLUE) benchmark to evaluate the power of pre-trained language models in Vietnamese. The VLUE benchmark uses five datasets for five tasks, including UIT-ViQuAD 2.0, ViNLI, VSMEC, ViHOS, and NIIVTB POS, published previously. In addition, the authors introduce the CafeBERT pre-trained model. The new model is trained based on the XLM-Roberta model with a large Vietnamese dataset, including Wikipedia and electronic news articles.

Abstract

Fine-tuning pre-trained language models (LMs) is essential for enhancing their capabilities. Existing techniques commonly fine-tune on input-output pairs (e.g., instruction tuning) or with numerical rewards that gauge the output quality (e.g., RLHF). We explore LMs' potential to **le**arn from **t**extual **i**nteractions (**LETI**) that not only check their correctness with *binary labels* but also pinpoint and explain errors in their outputs through *textual feedback*. Our focus is the code generation task, where the model produces code based on natural language instructions. This setting invites a natural and scalable way to acquire textual feedback: the error messages and stack traces from code execution using a Python interpreter. LETI iteratively fine-tunes the model, using the LM objective, on a concatenation of natural language instructions, LM-generated programs, and textual feedback. Prepended to this fine-tuning text, a binary reward token is used to differentiate correct and buggy solutions. LETI requires *no* ground-truth outputs for training and even outperforms a fine-tuned baseline that does. LETI not only improves the performance of LMs on a code generation dataset MBPP, but also generalizes to other datasets. Trained on MBPP, it achieves comparable or better performance than the base LMs on unseen problems in HumanEval. Furthermore, compared to binary feedback, we observe that textual feedback leads to improved generation quality and sample efficiency, achieving the same performance with fewer than half of the gradient steps. LETI is equally applicable in natural language tasks when they can be formulated as code generation, which we empirically verified on event argument extraction. [1]

1 Introduction

Large-scale language models have fundamentally shifted the paradigms of natural language processing (NLP). Based on LMs pre-trained on raw text, subsequent fine-tuning stages have proven crucial to enhance their capabilities in solving benchmark NLP tasks and generating texts that align with human preferences. Success has been achieved by fine-tuning with direct training signals that measure whether the model, e.g., classifies the input into the right category (Devlin et al., 2019), answers a question correctly (Li et al., 2017; Ramamurthy et al., 2022), summarizes documents well (Stiennon et al., 2020; Wu et al., 2021), and generates outputs that align with human preferences (Ouyang et al., 2022; Korbak et al., 2023). We hypothesize that LMs can harness the much richer training signals from textual interactions with the environment (e.g., a human or a Python interpreter) that not only *check the correctness* of LM's outputs but also *pinpoint the errors and explain why*.

We propose LETI, a new LM fine-tuning paradigm that aims to explore LMs' potential to **le**arn from nuanced **t**extual **i**nteractions. We evaluate LETI on code generation tasks, where the LM is supposed to generate code pieces to solve tasks described in natural language. This setting invites a natural and scalable way to acquire *automatic* interactive textual feedback: the stack traces and error message outputs by established programming language (PL) tools such as a Python interpreter. LETI's improvement process naturally mirrors a typical software development cycle: a human developer writes an initial program, executes it, and improves the program based on feedback obtained from the programming environment until a satisfying solution is found (e.g., successfully executed with no error); Furthermore, the human developer learns from mistakes in this process and becomes a (slightly) better developer who can avoid similar mistakes in the future. Similarly to the human development process, we provide empirical evidence that LETI can learn from past mistakes and avoid similar errors in §3.2.

Figure 1: Qualitative example of LETI improving an LM on code generation by leveraging feedback from a solution evaluator (e.g., a Python interpreter). At each LETI iteration, the LM is first asked to generate candidate solutions. As a case study, we obtain binary and textual feedback by executing the solution against test cases using a Python interpreter. Feedback and the generated solutions are used to improve the LM generator for the next LETI iteration through feedback-conditioned fine-tuning (§2.3). This is a code generation (MBPP; Austin et al., 2021) test set example generated by a 2B model optimized with LETI. We omit a few iterations and repetitive code for clarity.

In LETI, a base LM pre-trained on both natural language and code[2] is asked to generate a piece of program conditioning on the natural language instruction, which is then tested on a suite of test cases. LETI fine-tunes the model on a concatenation of natural language instruction, LM-generated program, and the textual feedback (e.g., stack traces and error messages) that pinpoints the bug, which is only provided when the generated program fails to solve the task. In addition to textual feedback, we prepend the fine-tuning sequences with a reward token (i.e., binary feedback), which differs for correct (`<|good|>`) and buggy solutions (`<|bad|>`), to encourage the LM to generate correct solutions when conditioning on `<|good|>`. LETI repeats this procedure for multiple rounds. During this iterative process, LETI assumes *no* instruction-code paired data.

We find that LETI improves LM's performance on code generation tasks in MBPP (Austin et al., 2021) *without* using any ground-truth code. Specifically, it generates 63.2% more syntactically correct and executable code (on the 2B LM) compared to the pre-trained model without any commonly employed post-processing heuristics[3]. When post-processing is applied, LETI (2B) improves performance and eliminates most NameError issues that occur when a variable or function is not defined (from 10% to 1% on the 2B LM) in two iterations. The optimized LM also shows generalized performance improvement on another code generation dataset HumanEval (Chen et al., 2021b) (§3.2). Such improvement in in-domain tasks does *not* come at the cost of the capability of the original LM (e.g., reasoning and chain-of-thought capability Wei et al. 2022) due to LETI's auxiliary objective that continuing pre-train (§3.4).

---

[2] Almost all modern large language models train on both natural language and code (Brown et al., 2020; OpenAI, 2023; Chowdhery et al., 2022; Touvron et al., 2023a).

[3] Stop-word-based post-processing heuristics (Fig. A.11) are commonly used by Code-LM (Chen et al., 2021b) to remove irrelevant code (e.g., only keep the first block of generated code).

We observe that textual feedback is advantageous in terms of improving the LM compared to baselines that only use binary feedback, as it offers enhanced performance and greater sample efficiency that only requires about half of the gradient steps to reach the same performance for the 2B-scale model (§3.3). Furthermore, we find LETI is equally applicable to NLP tasks (e.g., event argument extraction Wang et al. 2023a) when they can be formulated as code generation problems (§3.5).

2 LETI: Learning from Textual Interactions

Each iteration, LETI prompts the LM (§2.1) with the natural language problem description to generate a set of n solutions. The solutions are then evaluated on a suite of test cases by a **solution evaluator** (§2.2) to generate textual feedback (i.e., stack traces and error messages). This work uses a Python interpreter as the solution evaluator to assess LM-generated solutions. The textual feedback is used to fine-tune the LM with **feedback-conditioned fine-tuning** (FCFT, §2.3).

We assume no ground-truth solutions while fine-tuning the LM, as LETI directly learns from solution evaluator's feedback. Intuitively, FCFT leverages textual feedback to associate various types of errors (e.g., `SyntaxError`) and solutions that commit them. Furthermore, with binary feedback, FCFT aligns correct or wrong solutions with corresponding pre-pended reward tokens <|good|> or <|bad|>, so that better solutions can be sampled from a trained LM by conditioning it on <|good|>. The workflow (one iteration) is described in Algorithm 1 and Fig. A.6.

2.1 Language Model

The base LM can be any generative language model p_θ, pre-trained on both natural and programming languages. For a given problem $x_i \in \mathcal{P}$, we sample n solutions $\mathcal{S}_i = \{\hat{y}_{i,1}, \ldots, \hat{y}_{i,n}\}$ from $p_\theta(\cdot \mid x_i)$ (conditioned on reward token <|good|> when p_θ is fine-tuned for at least one iteration using FCFT), where each solution $\hat{y}_{i,j}$ is a sequence of tokens. We analyze the importance of problem set size $|\mathcal{P}|$ and the number of sampled solutions n in §A.2 and §A.1. Since p_θ is trained on code, we assume that it can generate programs reasonably well in the training problem set, and at least some of the n solutions are correct when an arbitrarily large n is chosen. We use $n = 128$ for code generation experiments on MBPP (§3.2) and $n = 64$ for event argument extraction (§3.5).

2.2 Solution Evaluator

Given a problem x_i, its test cases $\mathcal{T}_i$, and any generated solution $\hat{y}_{i,j}$, the Solution Evaluator ϕ (a Python interpreter) provides feedback $F_{i,j}$, which consists of binary f_{binary} and textual feedback f_{text} (i.e., $f_{\text{binary}}, f_{\text{text}} = \phi(x_i, \hat{y}_{i,j}, \mathcal{T}_i)$). $f_{\text{binary}} \in \{0, 1\}$ reflects the correctness of a solution, where $f_{\text{binary}} = 1$ means the given solution $\hat{y}_{i,j}$ can successfully solve the given problem x_i, and vice versa. f_{text} is a concatenation of stack traces and a textual error message provided by the Python interpreter only when the generated solution commits an error on a test case. Examples of f_{text} can be found in Fig. 1 and A.6. Generally speaking, we can implement ϕ differently for different types of problems; In §3.5, we show that it is possible to implement a ϕ that works for an NLP task.

2.3 Feedback-conditioned Fine-tuning

Each LETI iteration samples solutions from LM p_θ, evaluates generated solutions to obtain feedback using ϕ, and improves the generator LM with feedback-conditioned fine-tuning (FCFT). FCFT fine-tunes p_θ on each problem x_i and generated solution $\hat{y}_{i,j}$ conditioned on feedback $F_{i,j}$ (a sequence of tokens comprised of binary f_{binary} and textual feedback f_{text}). This resembles on-policy reinforcement learning, where p_θ is the policy and the solution evaluator ϕ plays the role of a reward function.

Feedback $F_{i,j}$ concatenates one initial reward token that denotes the binary feedback f_{binary} indicating whether the solution is correct, and textual feedback f_{text}, if provided. If the solution evaluator ϕ finds solution $\hat{y}_{i,j}$ correct, we use a reward token <|good|>, and <|bad|> otherwise. Following the initial reward token, we include the textual feedback f_{text}, if provided, enclosed by two special tokens denoting the beginning and end of textual feedback (i.e., `<|text_feedback|>`, `<|/text_feedback|>`). That is, both feedback for the problem x_i and solution $\hat{y}_{i,j}$ are a concatenated sequence of tokens: $F_{i,j} = f_{\text{binary}} \oplus$ `<|text_feedback|>` $\oplus f_{\text{text}} \oplus$ `<|/text_feedback|>`. In the case when f_{text} is not provided (e.g., when $f_{\text{binary}} = 1$), only the initial reward token is included as feedback: $F_{i,j} = f_{\text{binary}}$. We expand the vocabulary of the initial pre-trained LM p_θ to include these additional tokens.

LETI optimizes p_θ with the language modeling objective on sequence $s = F_{i,j} \oplus x_i \oplus \hat{y}_{i,j}$ (i.e., a concatenation of instruction and generated solution conditioned on the feedback) as shown in part (1) of Eq. 1. A concrete example of a data instance can be found in Fig. A.6.

2.4 Regularization with Continued Pre-training

To alleviate distribution shifts that may be caused by fine-tuning on generated solutions, we interleave FCFT optimization (§2.3) with LM objective optimization on the pre-training data. Eq. 1 puts the entire LETI's training loss together. Our ablation study shows that the regularization by continued pre-training is essential to maintain LM's original capability on tasks that it was not trained on (§3.4).

$$\mathcal{L}(\theta) = \overbrace{\frac{1}{|D_{\texttt{FCFT}}|} \sum_{s=F\oplus x\oplus\hat{y}\in D_{\texttt{FCFT}}}}^{\text{(1) Feedback-conditioned Fine-tuning}} \mathcal{L}_{\text{LM}}(s,\theta) + \underbrace{\frac{1}{|D_{\texttt{pre-train}}|} \sum_{s'\in D_{\texttt{pre-train}}}}_{\text{(2) Continued Pre-training}} \mathcal{L}_{\text{LM}}(s',\theta) \tag{1}$$

where $\mathcal{L}_{\text{LM}}(x,\theta) = -\sum_t \log p_\theta(x_t \mid x_{<t})$.

3 Experimental Results

3.1 Experiment Setup

Base model. We experiment with `CodeGen-mono` LMs (Nijkamp et al., 2022), a series of open-sourced LMs pre-trained with both natural language and code with a range of model sizes. The NL and PL mixture of pre-training data makes it possible to evaluate LETI on both NL and PL tasks. Due to limited computational resources, we choose to experiment with `350M` and `2B` sized models.

Dataset for continued pre-training. We use the `Python` subset of `TheStack v1.1` dataset (Kocetkov et al., 2022) as the continued pre-training dataset for the mixture pre-train objective (§2.4)[4].

3.2 LETI Makes LMs Better Code Generators

3.2.1 Mostly Basic Python Problems (MBPP)

Setup. We use the **Mostly Basic Python Problems (MBPP)** dataset (Austin et al., 2021) for training and evaluation. It contains 974 short Python problems described in natural language targeting entry-level programmers. LETI requires *no* ground-truth code but assumes a test suite for each problem that MBPP provides to check solutions' correctness. Additional details (e.g., hyper-parameters) can be found in §B. We allow the model to generate 512 tokens at max for each problem and evaluate the generated solutions by executing them against a test suite.

Post-Processing. Stop-word-based post-processing heuristics (Fig. A.11) are commonly employed by Code-LM (Chen et al., 2021b) to remove irrelevant code (e.g., only keep the first block of generated code) and improve performance. However, such post-processing heuristics require manual effort and are less scalable to extend to different tasks. Whether or not LMs can improve code generation without postprocessing is a great testbed to evaluate their capabilities of learning from textual feedback and is central to answering our research question. Therefore, we test the general applicability of LETI both with and without postprocessing. Unless otherwise noted, we default to without post-processing setting in the following experiments.

Evaluation metrics. We use the `pass@k` metric. The model generates k solutions for each problem; it is considered successfully solving the problem if

---

[4] The pre-training dataset BIGPYTHON of `CodeGen-mono` is not publicly available at the time of writing.

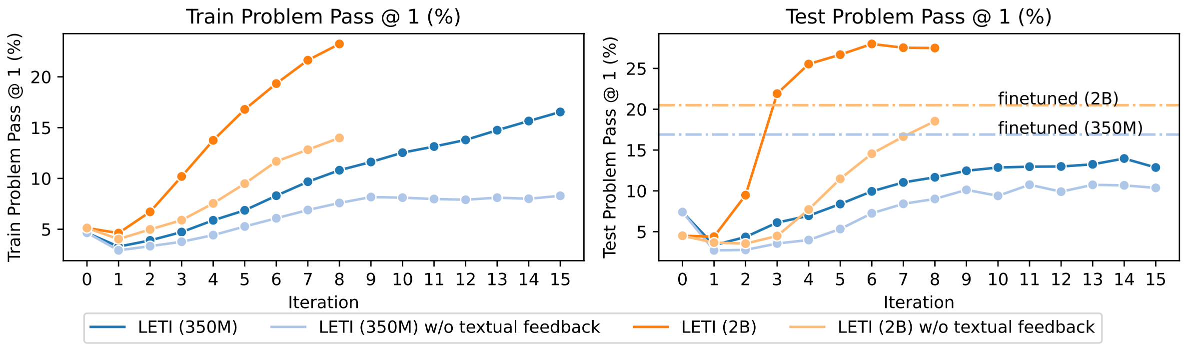

Figure 2: LETI (w/o post-processing) improves the base LMs performance on a code generation dataset MBPP. (left) LETI can iteratively improve the success rate of the LMs' generated solutions on training set problems; (right) LETI reaches performance close to (350M) or surpasses (2B) fine-tuned performance on the test set after a few iterations, despite not using any ground truth solutions.

at least one of the k solutions passes all test cases. With higher k values, the chance of observing a correct output for a problem increases. To reduce variances, we sample more than k solutions to estimate `pass@k`, see §B.1 for details.

Results. As shown in Fig. 2, LETI (w/o post-processing) learns from interactions with MBPP training set problems (i.e., iteratively generate, evaluate solutions, and learn from textual feedback) to generate better solutions for both *training* and *testing* problems. Despite not being fine-tuned on any ground truth solutions, LETI improves test set Pass@1 with increasing iterations and outperforms a supervised fine-tuned baseline (for the 2B model). LETI is also helpful when the post-processing heuristic is applied to the LM's output: 2B LM improves from 26.89% to 29.53% within two iterations (Tab. 1). We include a qualitative example for the 2B model in Fig. 1.

Error analysis. On MBPP test set with 8,000 instances (500 test examples, 16 generations per example), we show how the distribution of error types changes for LETI (2B) in Tab. 1. These error types are concrete exceptions[5] of Python3 programming language. On LETI (2B, w/o post-processing), we initially observed that most errors are SyntaxError (5179, 64.7%) due to no post-processing. We find that LETI can gradually reduce the proportion of generated code that causes SyntaxError by 56.5% (5179 → 652) and produce 63.2% more executable code (pass test + AssertionError). Most of the remaining errors (54.5% out of 71.8%) are due to the generated code being functionally incorrect as validated by the test suite (AssertionError), which can be hard to fix using the error message and stack traces alone (Jones et al., 2002), even for humans. Similarly, on LETI (2B, w/ post-processing), we observe NameError, which can be fixed using the error message alone, is mostly eliminated (810 → 94) within two iterations, demonstrating the effectiveness of LETI. These results also expose the limitation of automated textual feedback from Python interpreter (i.e., automated textual feedback is less informative for harder error types like AssertionError), which can be mitigated by (1) increasing exploration in the hope of finding better code by sampling more per problem (§A.1, Li et al. 2022), (2) leveraging more powerful sources of feedback (Wang et al., 2023b), or (3) keeping pre-training base LM on more relevant solutions.

3.2.2 HumanEval

Setup. We evaluate LM trained on MBPP on another code generation dataset HumanEval (Chen et al., 2021b), which contains 164 handwritten problems to assess language comprehension, reasoning, algorithms, and simple math capabilities. We use the same `pass@k` metric (estimated follow Chen et al. 2021b and §B.1) as described in §3.2.1 and *apply post-processing* for the generated solution.

Results. Despite being trained on a problem set MBPP that contains the most basic Python problems, as shown in Tab. 2, LETI can improve LM's capability in other code generation problems in the HumanEval dataset. Compared to pre-trained LM, we observe consistent Pass@10 and Pass@100 improvement across both 350M and 2B LMs, while the 2B LM has a degraded Pass@1 performance. We observe larger improvements for LETI (2B) trained with post-processing as it allows LETI to

LETI (2B, trained w/ post-processing)	21.60	**39.51**	**61.46**

focus on improving common error (e.g., NameError) in evaluation that applies post-processing.

3.3 Learning from Textual Feedback is More Sample-efficient

To study the effect of learning from textual feedback, Fig. 2 compares LETI against a baseline that only uses binary feedback. Regardless of model sizes, LMs trained with textual feedback obtain better final performance and improve faster (up to 2.2x for 2B; Tab. 3).

LM's ability to leverage textual feedback increases with scale. A larger model is more effective in learning from textual feedback and can obtain a larger (average) improvement per iteration than a baseline that only uses binary feedback (Tab. 3): 2B model that uses textual feedback improves 2.24x faster than binary feedback, while 350M is only 1.57x faster. Similar to Kaplan et al. 2020, we also find that a larger LM (2B) optimized using LETI obtains larger improvements per iteration (approx. 8x more compared to 350M LM) for both training and testing problems when both are given textual feedback. In other words, a larger model requires fewer gradient updates to achieve similar performance in a smaller model. These observations suggest that we might see more significant gains by applying LETI on LMs of a larger scale (e.g., 6B, 16B), which we leave for future work.

LMs trained with textual feedback can use samples more efficiently. As shown in Fig. A.5, compared to a baseline that only uses binary feedback, LETI (2B) yields better accuracy and sample efficiency: 2.74x and 2.24x higher improvement rate for $|\mathcal{P}| = 128$ and $|\mathcal{P}| = 374$ (Tab. 4). Interestingly, we observe a different trend for the smaller LM (350M). When decreasing the number of training problems from 374 to 128, LETI actually *underperforms* the baseline that only uses binary feedback. We conjecture that this is because (1) a smaller LM may lack the capacity to learn from textural feedback, and (2) LMs can benefit from a larger $|\mathcal{P}|$ by seeing a more diverse set of problems.

Table 3: On MBPP, LETI improves the LMs' code generation performance by up to 2.24x more per iteration when textual feedback is provided.

		Test Problem Pass@1 (%)			
Model Size	Textual Feedback	Initial Pass@1	Max Pass@1	#Iter to Max	Avg. improvement per iteration
2B	✓	4.50	**28.00**	6	**3.92** (2.24x)
	×	4.50	18.54	8	1.75
350M	✓	7.40	**13.96**	14	**0.47** (1.57x)
	×	7.40	10.75	11	0.30

Table 4: LETI's average improvement per iterations for different numbers of training problems $|\mathcal{P}| \in \{128, 374\}$.

Avg. improvement per iteration			
Model Size	Textual Feedback	# Train Problems $\|\mathcal{P}\|$ 128	 374 (full dataset)
2B	✓	**2.60** (2.74x)	**3.92** (2.24x)
	×	0.95	1.75
350M	✓	0.17 (0.63x)	**0.47** (1.57x)
	×	**0.27**	0.30

3.4 LETI Retains Reasoning and Chain-of-Thought Performance

Setup. We evaluate LETI-optimized LM (w/o post-processing) on additional reasoning tasks, including GSM8K (Grade School Math) (Cobbe et al., 2021), a mathematical reasoning dataset that includes grade school math problems, and Big-Bench-Hard (BBH) (Suzgun et al., 2022) that includes 26 challenging and diverse tasks (e.g.,

Table 5: Performance on additional reasoning tasks, including math reasoning benchmark GSM8K (Cobbe et al., 2021) and Big-Bench-Hard (i.e., BBH) (Suzgun et al., 2022). *250 out of 6,511 $\text{BBH}_{\texttt{CoT}}$ prompts have more than 2048 tokens, which exceed `CodeGen` models' context window. Scores are set to 0 for these prompts.

	GSM8K	**Big-Bench-Hard**		
	`PaL`	`direct`	`CoT*`	$\Delta_{\texttt{CoT}-\texttt{direct}}$
Pre-trained (2B)	40.03	29.67	36.81	7.14
LETI (2B)	38.97	29.41	**37.46**	**8.05**
LETI (2B, w/ post-processing)	**42.99**	**29.81**	36.72	6.91
LETI (2B) w/o textual feedback	41.93	29.23	36.71	7.48
LETI (2B) w/o regularization	32.15	30.06	35.82	5.76
Pre-trained (350M)	13.04	**29.10**	**30.53**	**1.43**
LETI (350M)	**16.68**	28.89	28.86	-0.03
LETI (350M) w/o textual feedback	16.07	28.81	28.72	-0.09
LETI (350M) w/o regularization	7.88	28.00	28.31	0.31

date understanding, sport understanding) testing model's generic reasoning capability. For GSM8K, we evaluate on `PaL`-style prompting (Gao et al., 2022) settings that ask LM to generate code and execute them to solve the given reasoning problem. Solutions for these reasoning tasks are generated without being conditioned on any reward token (e.g., `<|good|>`). We evaluate Big-Bench-Hard on two prompt settings: direct prompting that asks the model to generate an answer directly and chain-of-thought (CoT) prompting (Wei et al., 2022) that elicits a series of intermediate reasoning steps from the LM before generating the answer. We calculate the performance gain $\Delta_{\texttt{CoT}-\texttt{direct}}$ from doing chain-of-thought by calculating the performance difference between CoT and direct prompting.

Results. As shown in Tab. 5, we observe no significant degradation in out-of-domain reasoning performance (i.e., GSM8K and BBH) after LETI fine-tuning. Moreover, as shown on BBH, applying LETI on a 2B LM improves its chain-of-thought capability compared to its pre-trained checkpoint (i.e., higher `CoT` and $\Delta_{\texttt{CoT}-\texttt{direct}}$). In a smaller 350M model, we observe some degradation in BBH's CoT performance despite also applying regularization via continued pre-training (§2.4).

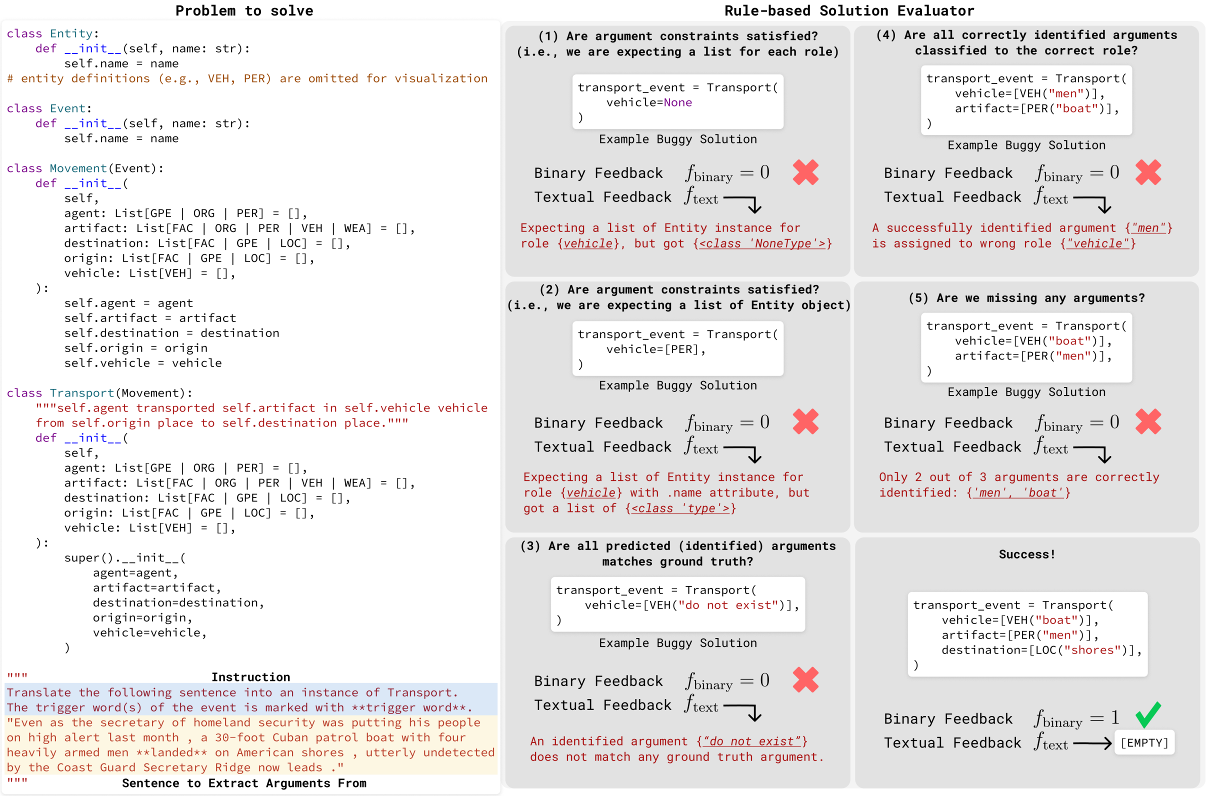
Removing regularization degrades performance outside MBPP. We compare LMs (350M) trained with and without the continued pre-training regularization (§2.4). We observe no significant difference between in-domain task performance (MBPP) shown in Fig. A.9. However, as shown in Tab. 5, removing regularization significantly degrades LM's capability on `PaL`-prompted GSM-8K, similar to findings from Fu et al. 2023b, it also degrades BBH's chain-of-thought performance.

3.5 LETI is applicable to NLP tasks like Event Argument Extraction (EAE)

When an NLP task can be formulated into a code generation problem, LETI is equally applicable. We experiment with event argument extraction (EAE), cast as a code generation problem by Wang et al. (2023a). Given an event ontology (Fig. 3 upper left) and a natural language sentence (Fig. 3 bottom left), we ask the LM to generate code to instantiate an event class using correct argument roles extracted from the sentence. Then we can examine the instantiated event object to validate the correctness of the solution (Fig. 3, right).

Solution evaluator implementation. We build a rule-based solution evaluator for the EAE task that checks the instantiated event object in Python (Fig. 3). Specifically, we first check whether the generation satisfies argument constraints by providing a list of Entity objects for each event argument role (1, 2 in Fig. 3); Then we check whether all the predicted arguments match any of the ground truths (3, Fig. 3) and whether all the correctly identified arguments are classified to the correct event role (4, Fig. 3); Finally, we check if the prediction is complete by identifying all arguments in the ground truth solution (5, Fig. 3). We say the solution is correct with $f_{\text{binary}} = 1$ when the it meets all of the above criteria. Note that the design decision of the solution evaluator (e.g., which error to check first) can influence what type of error LETI-optimized LM will prioritize to avoid.

Results. LETI's performance on EAE task is summarized in Fig. 4. In Fig. 4 (left), We find that LETI is capable of improving the train and test pass rate of generated solutions (i.e., a larger proportion of $f_{\text{binary}} = 1$ for both training and testing test). We also observe increased test performance on task-specific metrics: Argument Identification



```
class Entity:
    def __init__(self, name: str):
        self.name = name
# entity definitions (e.g., VEH, PER) are omitted for visualization

```
transport_event = Transport(
    vehicle=[VEH("do not exist")],
)
```

An identified argument {"do not exist"} does not match any ground truth argument.

(4)

```
transport_event = Transport(
    vehicle=[VEH("men")],
    artifact=[PER("boat")],
)
```

A successfully identified argument {"men"} is assigned to wrong role {"vehicle"}

(5)

```
transport_event = Transport(
    vehicle=[VEH("boat")],
    artifact=[PER("men")],
)
```

Only 2 out of 3 arguments are correctly identified: {'men', 'boat'}

Success!

```
transport_event = Transport(
    vehicle=[VEH("boat")],
    artifact=[PER("men")],
    destination=[LOC("shores")],
)
```

Figure 3: Rule-based Solution Evaluator for Event Argument Extraction (EAE) formulated as code generation task (Wang et al., 2023a). Content enclosed by `{. . . }` in f_{text} is automatically populated by a Python implementation of Evaluator for any given solution.

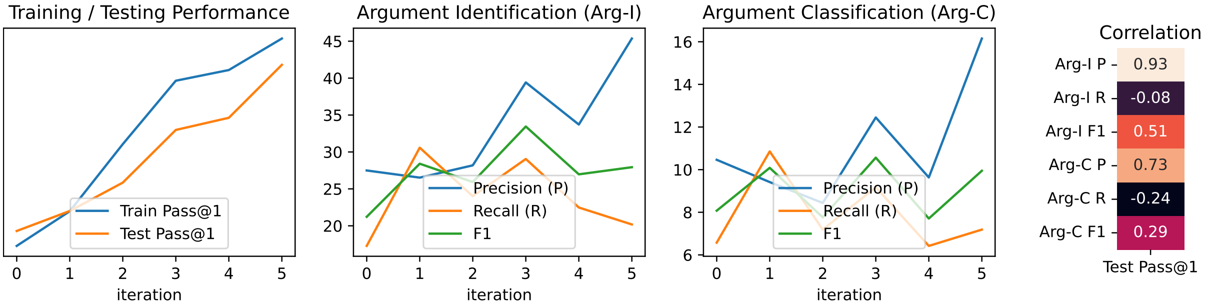

Figure 4: Event Argument Extraction performance and their correlation with Test Pass@1 when using LETI to optimize towards success rate. We found that the rule-based solution evaluator (Fig. 3) can be designed to biased towards optimizing precision as discussed in §3.5.

(Arg-I) F1 increases by 12.3% (21.2% → 33.5%), and Argument Classification (Arg-C) F1 increases 2.6% (8% → 10.6%) with three iterations.

Implementation of solution verifier could influence the target metric of optimization. Interestingly, we find that improving f_{binary} using our solution evaluator results in better performance in some task-specific metrics (e.g., Arg-I and Arg-C precision) but not others (e.g., Arg-I and Arg-C F1). As shown in Fig. 4, Arg-I and Arg-C precision, among other task-specific metrics, has the highest Pearson correlation of 0.93 and 0.73 with test Pass@1, while Arg-I F1 and Arg-C F1 only moderately (0.51) or weakly (0.29) correlate with test Pass@1. One possible reason is that LETI forces the model to be correct on *every* argument it identified in the evaluator implementation (Fig. 3 step 3). This could inhibit the model from generating arguments very close to the ground truth solutions, reflected in the degrading recall (correlation with Test Pass@1 of -0.08 and -0.24 for Arg-I and Arg-C recall) and improved precision in Fig. 4. This is similar to the reward-shaping problem (Wiewiora, 2003) in reinforcement learning. One can implement solution evaluators (i.e., reward fucntion) that suit better certain metrics.

4 Related Work

Using feedback to improve code generation. Leveraging non-textual feedback from an interpreter, prior work can generate solutions following natural language instructions by sampling and filtering large amounts of programs (Li et al., 2022; Chen et al., 2022), training a model to rank generated solutions (Inala et al., 2022), fine-tuning a Code-LM on generated solutions verified by test cases (Haluptzok et al., 2022), or training a reward model and using reinforcement learning (RL) to improve Code-LMs (Le et al., 2022). Recent work has explored textual feedback (e.g., error messages, human language feedback) to improve LMs (Fu et al., 2023a). (Chen et al., 2023a) improves code generation by fine-tuning the original LM on code refinement generated by conditioning on human language feedback; Different from our work, their fine-tuned LM uses more expensive human feedback and is not trained directly on the provided textual feedback. Chen et al. 2023b; Madaan et al. 2023 improve code generation by allowing LM to look at self-generated (and/or interpreter) feedback; however, the generator LM was frozen and couldn't generate better code on the original problem without these methods, while LETI improves the underlying LM directly.

Improving LMs with reinforcement learning. Using PPO, Stiennon et al. 2020; Ouyang et al. 2022 align LMs with human preferences. CodeRL (Le et al., 2022) follows REINFORCE (Williams, 1992) and policy gradient (Sutton et al., 1999) to improve Code-LMs with a scalar reward from the interpreter. Different from LETI that directly leverages textual feedback, these algorithms require either manually crafting (Le et al., 2022) or training (Stiennon et al., 2020; Ouyang et al., 2022) reward/value functions, which could be less scalable for various tasks. Another strand of work leverages Transformer architecture (Vaswani et al., 2017) to perform RL with sequence modeling (Janner et al., 2021; Chen et al., 2021a). (Lu et al., 2022; Korbak et al., 2023; Zhang et al., 2023; Liu et al., 2023) improve LM by performing condition training, similar to conditioning LM on binary feedback f_{binary} in LETI. LETI goes beyond the aforementioned work conditioning on the coarse-grained label: we are asking the LM to comprehend and improve directly based on textual feedback (e.g., error messages) that generally contains richer information compared to binary feedback.

5 Conclusion

We proposed LETI, a new LM fine-tuning paradigm that explores LM's potential to learn from textual interactions. We focused on code generation tasks and showed that one can effectively leverage *automatic* textual feedback from a Python interpreter to improve LMs. Textual feedback outperforms baselines that only use binary feedback in both generation quality and sample efficiency. Furthermore, LETI is equally applicable in NLP tasks that can be formulated as code generation, which we empirically verified on Event Argument Extraction.

Limitations and Future Work

In this study, we only explored the automatic textual feedback from a Python interpreter and did not get the chance to investigate real-world human language feedback which may have higher linguistic diversity and helpfulness. Automatic textual feedback from a Python interpreter can be limited as they are not always useful: as shown in §3.2.1 that they are helpful in improving error types like SyntaxError and NameError. Generally, the stack trace for AssertError (functional correctness) is equivalent to binary feedback telling LM it is wrong but does not provide any additional information. A natural follow-up of LETI would be exploring ways to combine Python interpreter feedback with more helpful feedback (e.g., LLM-simulated feedback Wang et al., 2023b; Madaan et al., 2023), applying to stronger and larger backbone LM (Li et al., 2023; Touvron et al., 2023b), as well as extending to multi-turn setting (Nijkamp et al., 2022).

A Analysis and Ablation Study

A.1 Does the number of solutions generated per problem matter?

We generate different number $n = \{16, 64, 128\}$ of solutions for each given problem. We use $n = 128$ for all other experiments in this paper. In Fig. A.7, we observe that LETI consistently benefits from larger n for each problem (i.e., more exploration).

A.2 Does the number of training problems $|\mathcal{P}|$ matters?

In Fig. A.8, we compare an LM trained on a complete MBPP dataset of problems $|\mathcal{P}| = 374$ with LMs trained to iteratively improve on $|\mathcal{P}| = \{16, 64, 128\}$ problems, which corresponds to the first $|\mathcal{P}|$ problems on the MBPP training set.

We observe that the number of training problems impacts the performance of LMs on test sets: larger $|\mathcal{P}|$ generally leads to faster and more significant improvements. LETI can generally improve the 2B model, with a smaller rate of improvement for smaller $|\mathcal{P}|$. However, for the smaller 350M model, we observe net positive improvements on the test set only after the number of training problems exceeds a threshold of $|\mathcal{P}| \geq 128$.

A.3 How do reward tokens impact performance?

The LM is fine-tuned on two different reward tokens `<|good|>` and `<|bad|>`, which correspond to correct and incorrect solutions (§2.3). In Tab. **??**, we quantify the effect of reward tokens on solution quality by calculating the pairwise performance difference between `<|good|>`, `<|bad|>` and `none` (i.e., not conditioned on any reward token). We perform this analysis on two code synthesis datasets MBPP and HumanEval, as well as the math reasoning dataset GSM8K and Big-Bench-Hard, which measures generic reasoning capability.

We find that `<|good|>` generally outperforms `<|bad|>` (i.e., positive Δ`<|good|>` – `<|bad|>`) and both reward tokens outperform `none` on in-domain dataset MBPP. In LETI, the LM is optimized to partition its probability space to put good solutions as sequences that start with `<|good|>` and bad solutions to be sequences starting with `<|bad|>`. This naturally moves solutions that are related to the code synthesis problems away from `none` sequences (i.e., sequences that do not condition on any reward token) towards the space of sequences that start with either `<|good|>` or

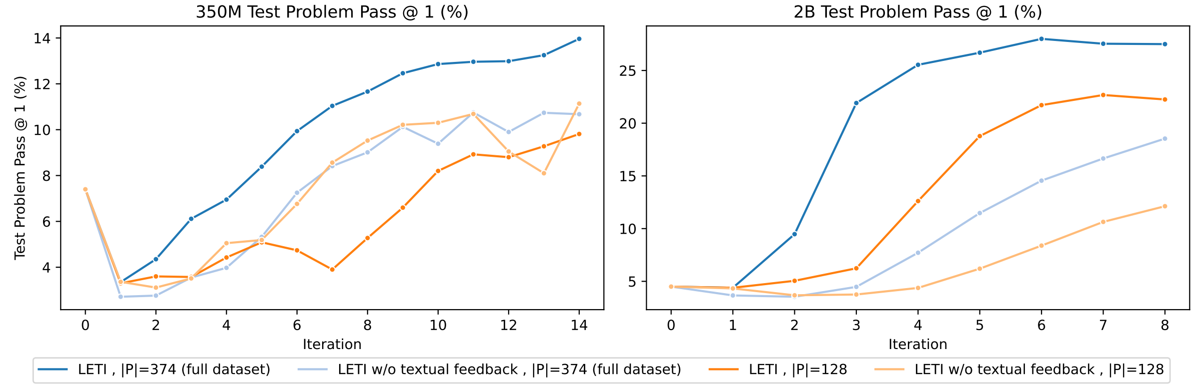

Figure A.5: LETI performance with different numbers of training problems $|\mathcal{P}| \in \{128, 374\}$. LETI (2B) with textual feedback can use samples more efficiently than a baseline that does not leverage textual feedback by always achieving higher performance and improvement rate (Tab. 4).

Figure A.6: An LETI Iteration. (1) An actor LM p_θ generates n solutions for every given problem (§2.1); (2) Each solution $\hat{y}_{i,j}$ for each problem x_i and corresponding test cases $\mathcal{T}_i$ is given to the solution evaluator to obtain binary and textual feedback $F_{i,j}$ on the correctness of $\hat{y}_{i,j}$ on problem x_i (§2.2); (3) The binary and textual feedback $F_{i,j}$ is used to perform feedback-conditioned fine-tuning to improve the actor LM p_θ (§2.3, Eq. 1).

<|bad|>, which could cause the sequences that start with any reward tokens to be better than none sequences as we observed.

On the HumanEval code synthesis dataset, we find that conditioning on both reward tokens does not improve performance. Instead, we observe a large gap between none and any of the reward tokens, while the performance difference between two reward tokens is minimal. This hints that the solutions for the HumanEval dataset are different compared to in-domain solutions for MBPP, therefore only sequences drawn from the original none sequences distribution (i.e., code that an LM has seen during its pre-training) achieves good performance.

We generally observe minimal differences between different reward tokens and none on GSM8K and Big-Bench-Hard. That is, performance is similar regardless of whether we are conditioned on any reward token. One notable exception is the PaL prompt on GSM8K which performs math reasoning through code generation, where it exhibits a similar pattern of condition on <|good|> is better than <|bad|> as seen in in-domain dataset MBPP. In fact, somes solutions to GSM8K with PaL prompt are very similar to solutions that solve MBPP problems. This suggests that the performance difference between reward tokens could be a way to measure the similarity between two different problems.

A.4 Does the performance gain come from more pre-training steps?

When training LETI, as described in §2.4, we regularize the model by alternating a batch of FCFT (§2.3) with a batch from a continued pre-training batch (§3.1). A natural question arises: Do all the improvements come from FCFT? Is it possible that

Iteration	2B Model		350M Model	
	w/ Textual Feedback	w/o Textual Feedback	w/ Textual Feedback	w/o Textual Feedback
0	26.89%	26.90%	15.29%	**15.29%**
1	29.18%	**28.51%**	14.90%	13.56%
2	**29.53%**	28.41%	15.47%	11.91%
3	28.94%	28.29%	**16.48%**	11.94%

Table A.6: LETI (w/ post-processing) `pass@1` performance of MBPP at different iteration, similar to Fig. 2.

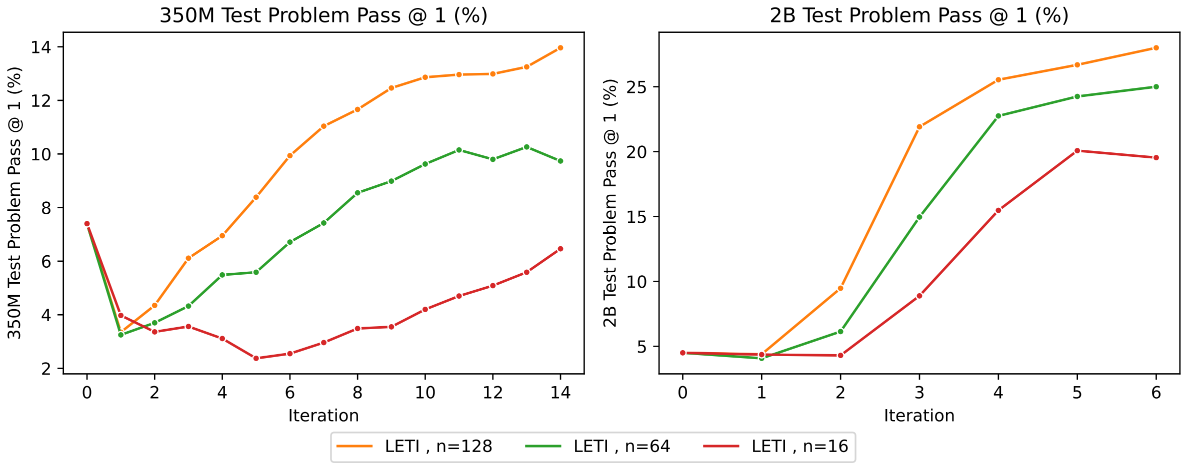

Figure A.7: Comparison of LETI (w/o post-processing) performance when given different numbers n of candidate solutions generated per problem. LETI consistently benefits from larger n for each problem (i.e., more exploration).

additional pre-training steps from regularization contribute to the improvements?

We perform an experiment to validate this claim on a 350M model. As shown in Fig. A.10, MBPP test performance cannot improve when only training the LM with more steps of pre-training data; That is, we can attribute LETI's performance improvements to FCFT instead of pre-training regularization.

B LETI Training Details

For each LETI iteration, we are doing feedback-conditioned fine-tuning for $k = 3$ epochs. We train the 350M model with a learning rate of 1e-5, weight decay of 0.01, and batch size of 128. For the 2B model, we use the same hyperparameter except we change the learning rate to 5e-6 due to instability during training (i.e., spiking loss). Training for 350M and 2B were completed on TPU-v3-8 VM instances. Each iteration (with $k = 3$ epochs) takes approximately 22 hours for 2B model and 4 hours for 350M model.

Applying LETI to MBPP Out of 974 total problems in MBPP, it contains 374 training problems, 500 testing problems, and the rest being validation set which we did not use. In every LETI iteration, we generate $n = 128$ solutions for each of the 374 training problems with a sampling temperature of 1.0 to construct our training data for FCFT (§2.3). For test set evaluation, we sample $n = 16$ solutions for each test problem with a sampling temperature of 0.1.

Applying LETI to Event Argument Extraction (EAE) (§3.5) We use the ACE-05 dataset following pre-processing as described in (Wang et al., 2023a). For each training example, we sample $n = 64$ solutions due to computation capacity limitation. We did not do continued pre-training regularization as described in Fig. 2.4 for more efficient computation since regularization mainly helps maintain out-of-domain performance, which is not the main focus of the EAE experiment.

B.1 Metrics Details

Pass@k We follow the unbiased estimator from (Chen et al., 2021b) to estimate `pass@k` that samples n solutions ($n > k$) to more accurately estimate pass@k.

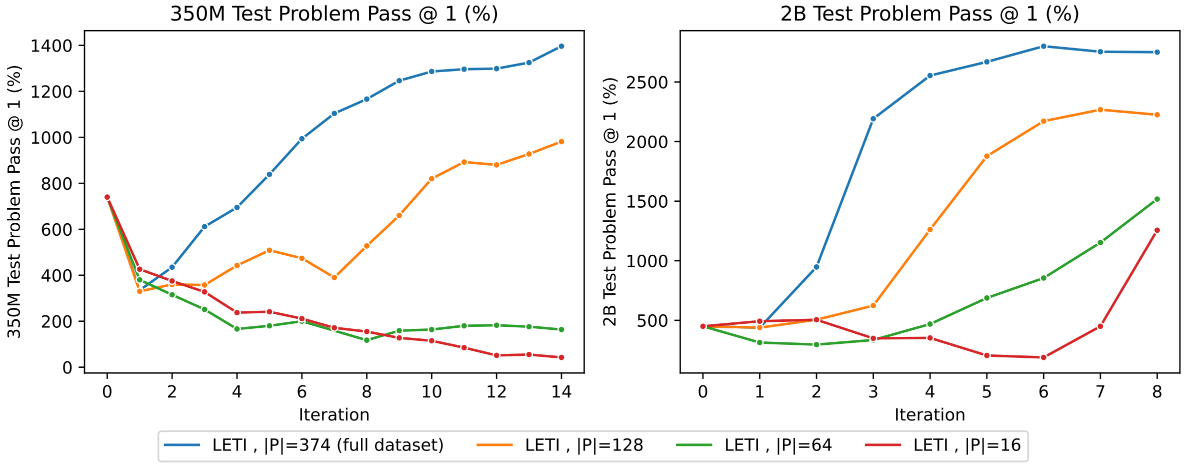

Figure A.8: Comparison of LETI (w/o post-processing) performance when given different numbers $|\mathcal{P}|$ of training problems. Larger $|\mathcal{P}|$ leads to faster and more significant improvements.

Table A.7: Iteration number of reported LETI-optimized performance in the main paper.

	i-th Iteration
LETI (350M)	14
LETI (2B)	6
LETI (2B, w/ post-processing)	3

Table A.8: MBPP Fine-tuned performance. See §B.3 for details.

	pass@1
Fine-tuned (`CodeGen-Mono`, 350M)	16.9
Fine-tuned (`CodeGen-Mono`, 2B)	20.5

B.2 Evaluation Details

We do not condition the generation on any reward token (e.g., `<|good|>`, `<|bad|>`) when generating solutions for the following evaluation datasets.

GSM-8K Following (Gao et al., 2022), we use a sampling temperature of 0.7, `top-p` of 0.95, and the number of samples $n = 40$. We generate up to 1,536 tokens for each problem.

Big-Bench-Hard We sample $n = 1$ example for each prompt using a `top-p` of 1 and sampling temperature of 0.0 (deterministic). We generate up to 1,536 tokens for direct prompts and 2,048 tokens for chain-of-thought (CoT) prompts[6]. 250 out of 6,511 CoT prompts have more than 2048 tokens, exceeding the context window of the `CodeGen` models. Scores are set to 0 for these prompts.

HumanEval We follow (Nijkamp et al., 2022) to sample $n = 256$ solutions for each problem using `top-p` of 0.95, and temperature of $\{0.2, 0.6, 0.8\}$. The final performance is obtained by taking the max across different temperatures. We generate up to 768 tokens for each problem, which is large enough to include all prompts along with their ground truth solutions.

B.3 Fine-tuned Baseline Details

MBPP Fine-tuned Baseline (in Fig. 2) We fine-tune 350M and 2B `CodeGen-Mono` LM on MBPP training set with 374 examples[7] for 30 epochs with AdamW optimizer of learning rate of 1e-4 and weight decay of 0.01. We evaluate checkpoints (every 6 epochs) on the MBPP test set and report the best pass@1 performance without post-processing. Note that we append `<eos>` token to the end of each ground truth solution for fine-tuning, which encourages the use of `<eos>` to stop the generation when deemed necessary by the LM. The fine-tuned performance is reported in Tab. A.8.

```

Figure A.11: Examples of code that requires post-processing, generated by pre-trained 2B `CodeGen-mono` on MBPP test set. The LM is asked to generate a fixed number of tokens (up to 512 tokens). It generates a function `frequency`, followed by a print statement. Then it begins to repeat the same prompt and code repeatedly for the rest number of the tokens. Existing implementation typically uses a post-processing heuristic that only keeps the first block of the code (i.e., green block in this figure) for the execution and evaluation. (`https://github.com/bigcode-project/bigcode-evaluation-harness/blob/3ad3b8de11605e74db369450a7ee6704874a4aa7/lm_eval/tasks/mbpp.py#L68`)

Abstract

The pre-trained language model (PLM) has achieved significant success in the field of knowledge graph completion (KGC) by effectively modeling entity and relation descriptions. In recent studies, the research in this field has been categorized into methods based on word matching and sentence matching, with the former significantly lags behind. However, there is a critical issue in word matching methods, which is that these methods fail to obtain satisfactory single embedding representations for entities.To address this issue and enhance entity representation, we propose the Bilateral Masking with prompt for Knowledge Graph Completion (BMKGC) approach.Our methodology employs prompts to narrow the distance between the predicted entity and the known entity. Additionally, the BMKGC model incorporates a bi-encoder architecture, enabling simultaneous predictions at both the head and tail. Furthermore, we propose a straightforward technique to augment positive samples, mitigating the problem of degree bias present in knowledge graphs and thereby improving the model's robustness. Experimental results conclusively demonstrate that BMKGC achieves state-of-the-art performance on the WN18RR dataset.

1 Introduction

Knowledge graphs (KGs) are graph-structured knowledge bases, typically consisting of triples, denoted as (h, r, t), where h represents the head entity, r represents the relation, and t represents the tail entity. Prominent examples of KGs include Freebase , Wikidata(Vrandečić and Krötzsch, 2014), YAGO(Suchanek et al., 2007),ConceptNet(Speer et al., 2017), and WordNet(Miller, 1992). KGs find applications in various domains, including information retrieval(Xiong et al., 2017), recommendation systems(Huang et al., 2018), and question answering(Sun et al., 2019a). However, KGs encounter the challenge of incompleteness as real-world information continuously evolves Figure1. Hence, the tasks of knowledge graph completion (KGC)(Galárraga et al., 2017) hold significant importance. In recent years, to enhance KG completion and utilization, significant research efforts have been devoted to the field of knowledge embedding (KE), which aims to map KGs into low-dimensional vector spaces. Existing knowledge embedding methods fall into two categories: structure-based methods and description-based methods. Structure-based methods, such as TransE(Bordes et al., 2013), RotatE(Sun et al., 2019b) and TuckER(Balazevic et al., 2019), leverage the topological information within the knowledge graph to represent entities and relations. Description-based methods can be further categorized into sentence matching and word matching approaches.The methods utilized in this paper draw inspiration from sentence matching techniques while falling under the category of word matching methods. These methods enrich entity representations by incorporating descriptive information related to entities and relations. They transform entity-relation pairs and their descriptions into natural language-style sequences and uti-

lize pre-trained language models (PLM) such as BERT(Devlin et al., 2019)) to encode them. This encoding process generates comprehensive representations of entities and relations.

The distinction between the two approaches lies in their treatment of triplets.Sentence matching transforms KGC into a text matching task, as seen in SimKGC(Wang et al., 2022a), enabling description-based methods to surpass structure-based methods for the first time.In contrast, word matching involves predicting the masked positions in the input data and matching them with all candidate entities. Prior word matching techniques, like C-LMKE(Wang et al., 2022b), have commonly employed a specific token, frequently denoted as 'ent_id', as a replacement for the original entity while handling candidate entities. As a consequence, the suboptimal representation of candidate entities significantly affects the overall performance.Furthermore, they position the description of the known entity immediately following the entity, inevitably widening the gap between the predicted entity and the known entity. Consequently, this introduces additional challenges for the model in predicting unknown entities.These two factors have led to a significant disparity between word matching methods and sentence matching methods.

In this paper, inspired by SimKGC(Wang et al., 2022a), we introduce a new fuzzy operation to handle relations of candidate entities. We achieve this operation by simultaneously making predictions in both the head and tail encoders. Moreover,we design prompts to narrow the distance between the known entity and the predicted entity, with the aim of strengthening their association. The objective of this fuzzy operation is to improve the word matching method based on descriptive embedding, resulting in enhanced single entity embedding representations. Furthermore, graph-related tasks commonly encounter the issue of degree bias(Kojaku et al., 2021), where nodes with lower degrees tend to exhibit weaker representations and poorer downstream performance.We take inspiration from SimCSE(Gao et al., 2021) and utilize the dropout mechanism of pre-trained language models to acquire additional positive samples, addressing the degree bias issue in knowledge graphs. We conduct experiments on three popular benchmark datasets, including WN18RR and FB15k-237. According to automated evaluation metrics MRR and Hits@k ($k \in \{1, 3, 10\}$), our Bilateral Masking with prompt for Knowledge Graph Completion (BMKGC) method achieves state-of-the-art performance on the WN18RR dataset and competitive results on the FB15k-237 dataset.

2 Related Work

The knowledge graph is composed of triples, denoted as (h, r, t), where each triple consists of a head entity, $h \in \mathcal{E}$, connected to a tail entity, $t \in \mathcal{E}$, through a relationship, $r \in \mathcal{R}$. Presently, knowledge graph completion approaches involve representing entities and relationships as vectors in a lower-dimensional space, known as knowledge graph embedding. These knowledge graph embedding are further categorized into structure-based and description-based embedding.

Structure-Based Knowledge Embedding We categorize structural-based knowledge embedding into three types. Firstly, the first type relies on translation-based techniques, such as TransE(Bordes et al., 2013), TransH(Wang et al., 2014), and TransR(Lin et al., 2015), which employ distance-based scoring functions. These methods generate embeddings for the head entity (h), relationship (r), and tail entity (t) based on specific translations, allowing assessment of the plausibility of triples (h, r, t) using distance scoring functions.Secondly, the ComplEx(Trouillon et al., 2016) model utilizes factorization and complex embeddings to enhance the representation of entities and relationships. TuckER(Balazevic et al., 2019) considers knowledge graph completion as a 3-D binary tensor decomposition problem and explores the effectiveness of various factorization techniques.Thirdly, knowledge graph embedding is approached as a deep learning task, utilizing various neural network architectures. ConvE(Dettmers et al., 2018) adopts convolutional neural networks (CNNs) to capture interactions between entities and relations, while CompGCN(Vashishth et al., 2020) improves knowledge graph representations by incorporating multi-layered information through graph convolutional networks (GCNs)(Schlichtkrull et al., 2018). Simultaneously, HittER(Chen et al., 2021) and CoKE(Wang et al., 2019) leverage Transformers to process information within the knowledge graph. These models demonstrate innovative methodologies based on different neural network architectures aimed at advancing the performance and precision of knowledge graph completion.

Description-Based Knowledge Embedding Recent studies have utilized pre-trained language models (PLM) such as BERT(Devlin et al., 2019) to improve the completion of knowledge graphs (KGs) by converting incomplete triples into natural language inputs. In this paper, we categorize descriptive-based embedding into two types: sentence matching and word matching. Sentence matching involves dividing the triple (h, r, t) into the head entity h, connected by a relationship r, and the tail entity t. The goal is to determine the most plausible triple by evaluating the similarity of the semantic meanings between these two components. SimKGC(Wang et al., 2022a) significantly enhances performance by introducing efficient contrastive learning. On the other hand, word matching methods such as MEM-KGC(Choi et al., 2021) mask the tail entity and consider the head entity and relationship as context for predicting the masked entity. C-LMKE(Wang et al., 2022b) utilizes predictions for unknown tail entities from the input, together with representations of all entities within the same batch, to obtain the most probable tail entity.

Degree Bias The C-LMKE(Wang et al., 2022b) enhances the representations of long-tail entities in KGs by incorporating degrees and leveraging text information, effectively improving the performance of PLM on KGs. While KG-Mixup(Shomer et al., 2023) validates the presence of degree bias in embedding-based Knowledge Graph Completion (KGC) and identifies its main factors, it is worth noting that KG-Mixup only focuses on enhancing structural-based embedding methods. Consequently, there is a lack of data augmentation techniques for descriptive-based embedding methods to enhance KG completion performance for long-tail entities. Our proposed BMKGC model aims to address this gap.

3 Methods

This section provides a comprehensive introduction to BMKGC, as depicted in Figure2. Firstly, we present a concise definition of knowledge graphs and their relevance to link prediction. Subsequently, we elucidate the principles and implementation specifics of our Bidirectional masking technique. Finally, a succinct overview of degree compensation is provided.

3.1 Definitions and Notation

A knowledge graph is a directed graph consisting of entities and relationships, denoted as $\mathcal{G} = \{\mathcal{E},\ \mathcal{R},\ \mathcal{T}\}$, where $\mathcal{E}$ represents the set of entities, $\mathcal{R}$ denotes the set of relationships, and $\mathcal{T}$ stands for the set of triples, defined as $T = \{(h, r, t) \subseteq \mathcal{E} \times \mathcal{R} \times \mathcal{E}\}$. BMKGC maximizes the utilization of descriptive information related to entities and relationships, denoted as d_h, d_r, d_t for h, r, and t, respectively. This additional information serves as input to PLM, enabling them to understand entities and relationships and acquire their embedding representations. Link prediction tasks aim to predict missing parts of triples within existing knowledge graphs. Using the widely adopted entity ranking evaluation protocol, predicting the tail entity (h,r,?) involves ranking all entities given h and r, and similarly, for predicting the head entity (?,r,t). In this study, we reverse the relationship by transforming (h, r, t) into (t, r^{-1}, h). This reversal allows us to solely focus on predicting the tail entity.

3.2 Bidirectional Masking

Knowledge Graph Completion (KGC) tasks initially aimed to predict missing entities given specific entities and relationships, similar to Masked Language Modeling (MLM)(Devlin et al., 2019) where certain words within input text sequences are randomly masked, and the model predicts these masked words. Motivated by MLM, our proposed BMKGC model adopts a similar approach, employing a bi-encoder architecture . We initialize two encoders, named $BERT_{head}$ and $BERT_{tail}$, with the same pre-trained language model but operate independently without parameter sharing.

Given a specific triplet $T = (h, r, t)$ along with corresponding descriptions d_h, d_r, and d_t, the first encoder, $BERT_{head}$, is utilized to predict the missing tail entity based on the provided head entity h, its description d_h, and relationship r along with its description d_r. To closely align with the triplet structure, we utilize a prompt format input as follows:

$$x_{base} = [CLS](h, r, [MASK]), d_h[SEP] \quad (1)$$

Our objective with this prompt is to strengthen the connection between the predicted entity and the known entity relationship. Unlike previous methods that placed [MASK] at the end and interleaved the description of the head entity within it, resulting in the predicted entity being too distant from

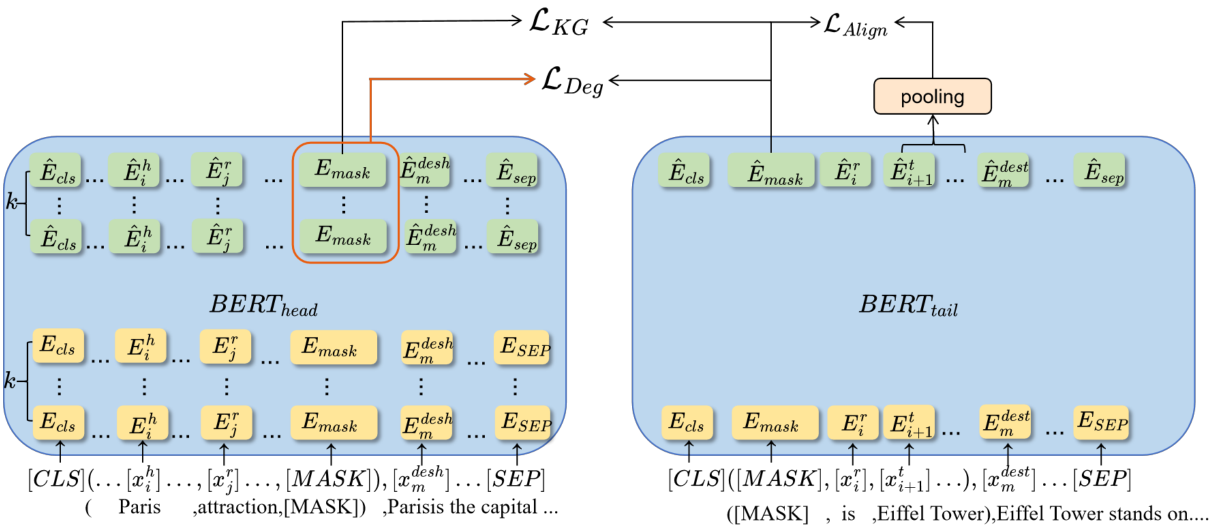

Figure 2: The architecture of BMKGC.We will illustrate the usage of a triplet (Paris, attraction, Eiffel Tower) as an example. The prompt input is depicted at the bottom of the figure, where the input in $BERT_{head}$ is duplicated k times to mitigate the inherent bias in the knowledge graph (KG). $BERT_{tail}$ input incorporates [MASK], enabling the implementation of the proposed bilateral masking technique.

the head entity within the sentence, we place our prompt in a more coherent position. x_{base} is then fed into $BERT_{head}$, yielding the representation of the [MASK] token e_p as follows:

$$e_p = BERT_{head}(x_{base})_{mask} \tag{2}$$

The second encoder, $BERT_{tail}$, performs a similar operation on candidate tail entities and their descriptions for entity representation. Similar to $BERT_{head}$, we adopt a prompt format and introduce a new relation "is". The input format is as follows:

$$x_{tail} = [CLS]([MASK], is, t), d_t[SEP] \tag{3}$$

This relation "is" signifies an equivalence relationship, allowing $BERT_{tail}$ to predict the tail entity based on entity t and its description d_t, aiming to obtain a robust single embedding representation for the tail entity through self-prediction.We refer to it as a fuzzy operation. x_{tail} is then fed into $BERT_{tail}$, generating the representation of the MASK token as follows:

$$e_t = BERT_{tail}(x_{tail})_{mask} \tag{4}$$

Finally, we calculate the similarity between e_p and e_t using cosine similarity. Additionally, to employ contrastive learning, we utilize an InfoNCE loss function(Chen et al., 2020), where the $\mathcal{L}_{KG}$ loss is defined as follows:

$$score = cos(e_p, e_t) = \frac{e_p \cdot e_t}{||e_p||\,||e_t||} \tag{5}$$

$$\mathcal{L}_{KG} = InfoNCE(score, L) \tag{6}$$

where L represents the true label of the training dataset. In order to prevent the embeddings obtained from the fuzzy operation from excessively deviating from the original word meanings, we apply an $\mathcal{L}_{align}$ loss to minimize the distance between e_t and the original word representation, given by:

$$\mathcal{L}_{Align} = InfoNCE(cos(e_t, e_w), L) \tag{7}$$

Here, e_w denotes the embedded representation obtained by averaging the original tail entity, and L is the true label of the training dataset.

3.3 Degree compensation

Based on the research conducted in KG-Mixup(Shomer et al., 2023), it has been observed that the performance of the KGC task is influenced by the in-degree of tail entities. Taking inspiration from Mixup(Zhang et al., 2018), they generated supplementary positive samples, which were previously absent from the training dataset, to augment entities with lower degrees. This approach effectively mitigated the degree bias issue in structure-based methods. However, there is currently a lack of methods to generate similar additional positive samples in description-based approaches.Drawing inspiration from SimCSE(Gao et al., 2021), a method utilizing the dropout mechanism in BERT to generate similar yet distinct sentences as positive samples, we propose a similar approach. By incorporating a contrastive learning framework, we effectively capture textual representations, resulting in a significant enhancement of performance in text matching tasks. In our method, we calculate the degrees of all entities within the training dataset, establish a threshold value η and repeatedly pass the corresponding head entities and relationships of tail entities with degrees below this threshold to $BERT_{head}$ k times.

$$\tilde{\mathcal{T}} = \begin{cases} \mathcal{T}_{train} \cup \left\{(\tilde{h}, \tilde{r}, t)\right\}_{i=1}^{k} & d_{tail} < \eta, \\ \mathcal{T}_{train} & else, \end{cases} \tag{8}$$

where d_{tail} represents the in-degree of the entity with t as the tail, $(h, r, t) \in \mathcal{T}_{train}$ represents the original training triples, $(\tilde{h}, \tilde{r}, t)$ is a synthetic sample, and $\tilde{\mathcal{T}}_{v,r}$ denotes the new set of triples used during training.

It is important to note that tail entities are included only once, consistent with the KG-Mixup research. Here, k represents the difference between the tail entity's degree and the threshold value η. These repeated input-output samples are considered additional positive samples, providing some mitigation for the issue of degree bias. The loss term $\mathcal{L}_{Deg}$ aligns with the previous KG loss (6). The final loss of BMKGC is the weighted sum of the losses from each task. We experimentally determine the weight λ for $\mathcal{L}_{Align}$ as demonstrated below:

$$\mathcal{L} = \mathcal{L}_{KG} + \lambda \mathcal{L}_{Align} + \mathcal{L}_{Deg} \tag{9}$$

4 Experiments

4.1 Experimental Setup

Dataset	N_e	N_r	N_{Train}	N_{Valid}	N_{Test}
WN18RR	40943	11	86835	3034	3134
FB15K-237	14541	237	272115	17535	20466

Table 1: Statistics of the datasets.

Datasets Our experiments were conducted on two datasets, namely WN18RR and FB15k-237. Both FB15k-237 and WN18RR datasets are knowledge graph datasets utilized for relation prediction tasks. FB15k-237 was extracted from Facebook's Freebase data and comprises a comprehensive collection of entities and relations. In contrast, WN18RR is based on the WordNet knowledge graph, encompassing entities such as nouns and verbs, and their corresponding relations. The primary distinctions between these two datasets lie in their data sources and the quantity of relations. FB15k-237 is derived from the real-world Freebase knowledge graph, encompassing a wide array of entities and relations. Conversely, WN18RR is specifically oriented towards the domain of natural language processing, encompassing more precise and restricted entities and relations. Additionally, FB15k-237 has undergone a reduction in redundant and inconsistent relations to enhance the overall data quality. The statistical data is shown in Table1. In our experiments, the state-of-the-art SimKGC(Wang et al., 2022a) model is adopted as the baseline. We compare our method with a set of structure-based methods, namely TransE(Bordes et al., 2013) , RotatE(Sun et al., 2019b), ,ConvE(Dettmers et al., 2018), and CompGCN(Vashishth et al., 2020). Additionally, we compare our method with description-based approaches, including KG-BERT(Yao et al., 2019), MTL-KGC(Kim et al., 2020), C-LMKE(Wang et al., 2022b),KGLM(Youn and Tagkopoulos, 2022),LP-BERT(Li et al., 2022) and StAR(Wang et al., 2021).

Evaluation Metrics The evaluation metrics for the link prediction task involve adopting an entity ranking approach based on previous research. For each tested triple (h, r, t), the prediction of the tail entity t entails ranking all entities using the provided head entity h and relationship r. A similar process is employed for predicting the head entity. Four automatic evaluation metrics are utilized, namely Mean Reciprocal Rank (MRR) and Hits@k (k $\in \{1, 3, 10\}$). MRR represents the average reciprocal rank of all tested triples, while Hits@k calculates the proportion of correctly ranked entities within the top k positions. The reported MRR and Hits@k values are obtained using the filtered setting(Bordes et al., 2013), which involves the common practice of excluding other correct entities (that also form triples in the knowledge graph) from the list. The measurements are calculated by averaging in both directions: head entity prediction and tail entity prediction. In general, a good model is expected to achieve higher MRR and Hits@k values, as well as a lower MR.

Hyperparameters To enhance the performance of pre-trained language models, we employ bert-base-uncased (English) to initialize our encoder. During training, we conduct training sessions on WN18RR and FB15k-237 datasets using a batch size of 512 on A800 GPU for 50 and 5 epochs,

respectively.In our study, we solely considered the samples within each batch as negative samples. The learning rates are set to 9×10^{-5} and 1×10^{-5}. Moreover, we initialize the temperature τ to 0.05 and set the margin value to 0.02. In optimizing our model, we utilize the AdamW optimizer with linear learning rate decay.The weight λ in the loss function is assigned a value of 0.5.

4.2 Main Results

We utilized the experimental results from StAR(Wang et al., 2021) for embedding-based methods, and we obtained the results of SimKGC(Wang et al., 2022a) through its corresponding code. The optimal outcomes for other models were extracted from the experimental data presented in their respective papers. In Table2, our proposed BMKGC demonstrated significant advancements in all metrics for the WN18RR dataset, reaching a state-of-the-art level. The Hits@10 metric has demonstrated a notable enhancement to 80.7, surpassing the robustness of all prior models. This improvement can be credited to the utilization of a fuzzy operation that effectively portrays entities and acquires superior individual embedding representations. Consequently, it empowers the model to achieve a more comprehensive comprehension of entities with lengthier names, thereby augmenting the overall robustness of the model.Moreover, the Hits@1 metric has also increased to 59.0, indicating enhanced precision. This improvement can be ascribed to our prompt design, which leverages the closer proximity between known entities and predicted entities, resulting in more accurate predictions made by the model.

When comparing BMKGC to the baseline SimKGC on the FB15k-237 dataset, it performs better in Hits@3 and Hits@10 but exhibits a decrease in other metrics. However, our performance in FB15k-237 is better than other description-based methods.We believe this is primarily attributed to two factors. Firstly, unlike other datasets, FB15k-237 contains a lower number of entities (14,541) and relations (237), resulting in a denser graph structure with an average degree of approximately 37 for each entity. This suggests the presence of multiple relationships per entity, which are more intricate and cannot be simply explained by a single word but require the combination of multiple words. This complexity poses a challenge for the encoder as it struggles to comprehend and process such multilayered relationships. Furthermore, (Cao et al., 2021) remarked that numerous connections in the FB15k-237 dataset cannot be predicted based on the available information.

5 Analysis

Prompt In contrast to previous methods that rely on descriptions, our prompt aims to reduce the distance between the predicted tail entity, the head entity, and their relationship. We hypothesize that this approach strengthens the association between the entities, thereby improving the model's ability to make description-based predictions. To vali-

w/ prompt	(Paris,Attraction,[MASK])Paris:the enchanting capital of France,known for its rich history... ([MASK],is,Eiffel Tower)Eiffel Tower: an iconic symbol of Paris,stands tall as a testament to architectural...)

date this hypothesis, we designed a control groups with specific inputs $(h, d_h, r, [MASK])$. Table 3 illustrates the input formats for the prompts we proposed in the $BERT_{head}$ and $BERT_{tail}$ models in the first row, while the second row shows the input format without prompts.Keeping all other parameters consistent, we conducted experiments on the WN18RR dataset. In Table4,the results clearly demonstrate that the performance on each metric is significantly lower when compared to our proposed prompt. This provides substantial evidence supporting the effectiveness of BMKGC.Designing prompts in this manner offers an additional advantage by effectively addressing the max_length constraint of the tokenizer. In the absence of prompts, there would be a necessity to predefine the length of entity descriptions. However, this approach presents a risk of potentially excluding the [MASK] token when the descriptions exceed the maximum input length defined by the tokenizer. Moreover, establishing a predetermined description length in advance is deemed as detrimental to the model's performance.

	MRR	Hits@1	Hits@3	Hits@10
w/ prompt	66.9	59.0	72.0	80.7
w/o prompt	62.3	54.9	66.3	75.9

Table 4: Analysis of prompt on the WN18RR dataset.

Bilateral Masking We have implemented a novel methodology for representing candidate entities, which distinguishes itself from previous descriptive-based methods by introducing a fuzzy operation to manipulate the predicted forms of the candidate tail entities. Table 3 presents the application of average pooling for entities in the third row, while the last row showcases the substitution of the original entities with special token_id. In this instance, i and j correspond to the entity id of Paris and Eiffel Tower, respectively, in the dataset. Table 5 reveals that our proposed BMKGC method outperforms the other two approaches across all metrics, exhibiting particularly substantial enhancements in Hits@1. These findings indisputably establish the effectiveness of our BMKGC model. Additionally, we observe that Average Pooling underperforms, suggesting its inability to replicate the pooling technique employed in sentence-based matching methods within word-based matching approaches. This limitation negatively impacts the representation of words, directly diminishing the model's performance.

Method	MRR	Hits@1	Hits@3	Hits@10
MASK	66.9	59.0	72.0	80.7
Pooling	62.3	53.0	68.0	79.1
token_id	64.7	55.9	70.2	80.3

Table 5: Analysis of approach for handling entities on the WN18RR dataset. MASK is the bilateral masking method proposed by us. Pooling is the average pooling applied to candidate entities. Token_id is used to replace the original entity name with the entity reference ID

Degree bias In Figure3, we analyze the performance of BMKGC and BMKGC without additional positive samples on WN18RR. The x-axis represents the degree of the tail entities that require completion, which is derived from the training set. We categorize them into four groups since entities with a degree exceeding one hundred are not within the scope of the degree bias problem in our research. The y-axis represents the mean reciprocal rank (MRR) of each group. By conducting a comparison, it is evident that the inclusion of extra positive samples enhances the MRR for entities with lower degrees, corroborating the effectiveness

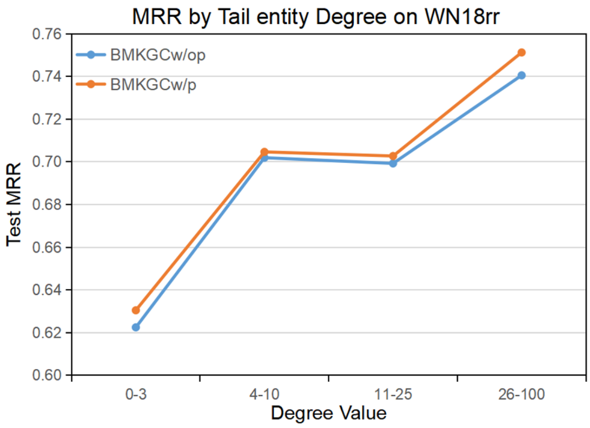

Figure 3: Analysis of using degree compensation different degree groups in terms of MRR on the WN18RR dataset.

of our proposed method in mitigating the degree bias issue to some extent.

Alignment loss ration We conducted an investigation into the potential constraining effect of alignment loss on the prediction of $BERT_{tail}$. In Table6, we employed an annotation scale λ with values ranging from 0 to 1, including 0, 0.25, 0.5, 0.75, and 1. It was observed that both excessively small and large values of λ adversely impacted the model's prediction accuracy. In the case of a small λ, the predictions made by $BERT_{tail}$ deviated from the true meaning of the word and exhibited an undue bias towards the expected answer. Conversely, a large λ value weakened the representation of entities. As a result of our analysis, we selected λ=0.5 as it yielded the best overall performance.

Loss Ration	MRR	Hits@1	Hits@10
$\lambda = 0$	65.8	57.8	80.3
$\lambda = 0.25$	66.4	58.3	80.5
$\lambda = 0.5$	66.9	59.0	80.7
$\lambda = 0.75$	66.4	58.4	80.1
$\lambda = 1$	66.1	57.8	80.3

Table 6: Performance comparison on the WN18RR dataset across the different loss ratio .

6 Conclusion

This paper proposes BMKGC, a method that effectively enhances entity representation by predicting candidate entities during training to obtain improved single embedding representations. Furthermore, we propose a simple method to increase positive samples, thus alleviating the issue of degree bias in the knowledge graph. Extensive experimental results convincingly demonstrate that our approach achieves state-of-the-art performance. In future research, we will concentrate on exploring entity-related information within the PLM, reducing the impact of noise generated during pretraining, and further advancing entity representation.

Limitations

Our proposed method optimizes the representation of entities by using bilateral masking and prompts to enhance the model's prediction. Furthermore, we introduce dropout as a means to mitigate the degree bias issue in the knowledge graph. Our method demonstrates significant performance improvements; however, it comes with associated costs in terms of time and computational resources. In the $BERT_{head}$ section, the positions of [MASK] in the input are stored and later retrieved during output processing due to varying entity lengths. Moreover, the inclusion of additional positive samples slightly increases the computational resources requirement of our model compared to the one without them. Nonetheless, these costs are deemed acceptable in practice. Moreover, our research did not explore hrad negative samples beyond those within the batch. We consider this as a potential future research direction, aiming to delve into more challenging negative samples and enhance entity representation.

Abstract

Generative language models are usually pretrained on large text corpus via predicting the next token (i.e., sub-word/word/phrase) given the previous ones. Recent works have demonstrated the impressive performance of large generative language models on downstream tasks. However, existing generative language models generally neglect an inherent challenge in text corpus during training, i.e., the imbalance between frequent tokens and infrequent ones. It can lead a language model to be dominated by common and easy-to-learn tokens, thereby overlooking the infrequent and difficult-to-learn ones. To alleviate that, we propose a **MiLe Loss** function for **mi**tigating the bias of **le**arning difficulties with tokens. During training, it can dynamically assess the learning difficulty of a to-be-learned token, according to the information entropy of the corresponding predicted probability distribution over the vocabulary. Then it scales the training loss adaptively, trying to lead the model to focus more on the difficult-to-learn tokens. On the Pile dataset, we train generative language models at different scales of 468M, 1.2B, and 6.7B parameters. Experiments reveal that models incorporating the proposed MiLe Loss can gain consistent performance improvement on downstream benchmarks.

1 Introduction

Generative language models like GPT-3 (Brown et al., 2020) are generally pretrained on extensive textual data, in the manner of predicting the next token given the previous ones for each training text. Recently, large generative language models have been exhibiting impressive performance on various downstream natural language tasks, like dialogue system, classification, sequence labeling, etc. (Touvron et al., 2023; Brown et al., 2020; Chowdhery et al., 2022), and attracting much attention from both academia and industry.

Frequency Bucket	high	medium	low
PPL	4.323	13.541	15.517

Table 1: The average perplexity (PPL) for tokens in different frequency buckets.

However, previous works have overlooked an inherent issue in natural language corpus that might affect the pretraining of a language model, i.e., frequent tokens far outnumber infrequent ones. Actually, Zipf's law (Piantadosi, 2014) highlights the inherent imbalance of tokens in natural language datasets, i.e., a few frequent tokens would dominate a dataset while many infrequent ones only form a minor portion. For instance, 50% of the Brown Corpus (Francis and Kucera, 1979), which comprises over a million tokens, is covered by only the top 135 most frequent tokens.

The imbalance of tokens is essentially a class imbalance problem. We argue that infrequent tokens are difficult to learn due to their fewer occurrences, in contrast to the frequent ones that can be learned adequately (Lin et al., 2017). To confirm that, we utilize the remarkable language model LLaMA (Touvron et al., 2023) with 6.7B parameters on the Pile (Gao et al., 2021a) validation set and perform a detailed perplexity (PPL) analysis at the token level. It's worth noting that a higher perplexity is indicative of a token's higher learning difficulty. In our analysis, all tokens are grouped into three frequency buckets: high, medium, and low, based on their counts in the whole Pile dataset[1]. Here, we calculate the frequency of each token and sort them in descending order of frequency. Then, we categorize the top tokens that cover 80% of the

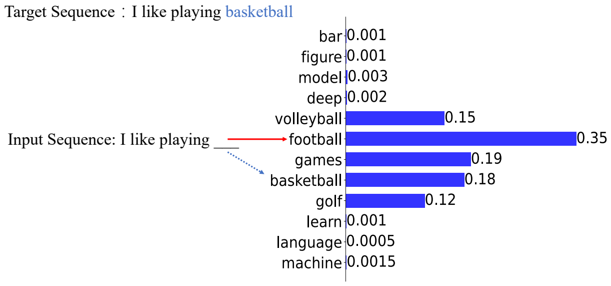

Figure 1: An example where predicting the next token is more like a multi-label classification problem.

dataset as tokens of high frequency, those that cover the extra 15% (i.e., $80\% - 95\%$) of the dataset as tokens of medium frequency, and the remaining 5% as tokens of low frequency. As shown in Table 1, for the tokens of high frequency, LLaMA derives a much lower average perplexity (4.394) than those of medium (13.891) or low (15.814) frequency. That confirms our assumption: token imbalance can lead to the bias of learning difficulties. More explicitly, those frequent and easy-to-learn tokens (i.e., classes) might overwhelm the model and make it neglect the infrequent and difficult-to-learn ones during training (Lin et al., 2017). Therefore, we emphasize that the latter kinds of tokens should be given more attention during language model pretraining.

It is a straightforward idea to use the notable Focal Loss (Lin et al., 2017) from the field of object detection as an alternative to the prevalent Cross-Entropy Loss for the next token prediction. This modification aims to intensify the language model's focus on the infrequent and difficult-to-learn tokens. Focal Loss is a dynamically scaled version of the Cross-Entropy Loss, where the scaling factor decreases as the predicted probability w.r.t the ground-truth token increases. Specifically, Focal Loss decreases the weights of the easy-to-learn tokens, as their predicted probabilities are higher, and meanwhile increases the weights of the difficult-to-learn ones, as their predicted probabilities are lower. In that way, it compels the language model to pay more attention to difficult-to-learn tokens.

Nevertheless, Focal Loss (Lin et al., 2017) only takes into account the probability w.r.t the ground-truth token when assessing its learning difficulty, and is intuitively designed for the multi-class classification problem where an object is only associated with a single class label. Indeed, in language model pretraining, when predicting the next token given the previous ones, there might exist multiple valid tokens besides the ground-truth one. This makes predicting the next token more like a multi-label classification problem, where an object can be associated with multiple class labels (Tsoumakas and Katakis, 2007; Chen et al., 2018). For example, as shown in Figure 1, given the previous tokens "I like playing ", there are multiple valid next tokens, like "basketball", "football", "golf", etc. Suppose the target training token sequence is "I like playing basketball". As the valid tokens would divide up almost the total probability (i.e., 1.0), the ground-truth token "basketball" would be given a smaller probability (e.g., 0.18). Then Focal Loss would treat "basketball" for the position as a difficult-to-learn token. However, as all the other valid tokens are also correct for the position in the view of language modeling, only allowing "basketball" to be predicted is unsuitable. Thus, the learning difficulty assessed by Focal Loss for "basketball" is imperfect in such a multi-label classification case.

In this paper, we propose a new loss function termed MiLe Loss to better enable a language model to pay more attention to the difficult-to-learn tokens in such multi-label classification cases. We observe that when a next target token is easy-to-learn, the minor valid tokens would divide up almost the total probability while others are associated with very low probabilities, resulting in a low information entropy of the predicted probability distribution over the vocabulary. On the contrary, if a next token is difficult-to-learn, the predicted probability distribution would be more uniform, resulting in a higher information entropy. Therefore, instead of relying on the single probability of the ground-truth token as Focal Loss, the proposed MiLe Loss uses the information entropy of the predicted probability distribution for assessing learning difficulties, which can better handle cases with multiple valid tokens. Then, tokens exhibiting high-entropy, possibly being difficult-to-learn, will be assigned increased weights during language model pretraining.

To validate the effectiveness of the proposed MiLe Loss, we train three different-sized models on the Pile dataset (Gao et al., 2021a). Experimental results indicate that MiLe Loss steadily outperforms Focal Loss and Cross-Entropy Loss on downstream benchmarks.

Our contributions can be summarized as follows.

- We highlight the bias of learning difficulties in generative language models, which is mainly caused by the inherent token imbalance in textual training data.

- We propose a new loss function termed MiLe Loss to enhance Focal Loss for mitigating the bias of learning difficulties.
- We validate the effectiveness of the proposed MiLe Loss with extensive experiments. Experimental results show that it consistently outperforms Focal Loss and Cross-Entropy Loss.

2 Related Works

2.1 Language Models

Language Models are statistical models that aim to maximize the likelihood of the training sequences of tokens (Touvron et al., 2023). Early language models are based on the statistics of n-grams (Bahl et al., 1983; Katz, 1987; Kneser and Ney, 1995). Then the focus has shifted toward neural-network-based models. Recurrent Neural Networks (Mikolov et al., 2010) and their variants, e.g., LSTMs (Graves, 2013), have been successful in this regard. Those models are capable of learning complex patterns in textual data and have achieved remarkable results in various language modeling tasks.

Recently, Transformers are commonly used as the backbone network for language models. Representative works include BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), GPT-2 (Radford et al., 2019), UniLM (Dong et al., 2019a), and T5 (Raffel et al., 2020), etc. Since the advent of GPT-3 (Brown et al., 2020) with 175 billion parameters, which achieves outstanding performance in various downstream tasks, the research landscape has increasingly pivoted towards large generative language models. Notable works like Gopher (Rae et al., 2021), Pythia (Biderman et al., 2023), PaLM (Chowdhery et al., 2022), GaLM (Du et al., 2022), OPT (Zhang et al., 2022) and LLaMA (Touvron et al., 2023), have also been proposed.

However, previous works do not consider the bias of learning difficulties among tokens, which is mainly caused by the inherent token imbalance in the textual training data. They probably overlook some difficult-to-learn but informative tokens during model training. To tackle that, in this paper we introduce MiLe Loss, aiming to lead generative language models to pay more attention to those tokens.

2.2 Class Imbalance

Class Imbalance refers to a highly skewed distribution of classes in the training data, which means that the number of instances in some classes is significantly higher than those in the other classes (Yang and Xu, 2020). A commonly used solution is to perform data re-sampling, where the minority classes are up-sampled (Chawla et al., 2002; Ando and Huang, 2017; Pouyanfar et al., 2018; Shen et al., 2016), and the majority classes are down-sampled (Lee et al., 2016; Buda et al., 2018). Other works (Cui et al., 2019; Dong et al., 2019b; Lin et al., 2017) have also proposed enhanced loss functions to mitigate issues caused by class imbalance, e.g., Focal Loss.

In language modeling, to mitigate the mentioned bias of learning difficulties caused by the inherent token imbalance, one may simply refer to the data re-sampling method. However, data re-sampling at the `token` level, i.e., up-sampling infrequent tokens and down-sampling frequent ones, will probably break the semantics of training texts. Meanwhile, re-sampling at the coarse-grained `sentence/paragraph/document/domain` level will equally increase/decrease the number of both kinds of tokens, and thus cannot well tackle the token imbalance.

Therefore, we consider enhancing the loss function to alleviate the bias of learning difficulties among tokens for generative language models, enabling them to pay more attention to those difficult-to-learn but informative tokens. Firstly, we attempted to use the notable Focal Loss. However, since predicting the next token in generative language models is more like a multi-label classification problem as analyzed before, Focal Loss struggles to give suitable scaling factors for cases with multiple valid next tokens. To tackle that, we introduce the MiLe Loss.

3 Method

3.1 Preliminaries

Language Model Pretraining As mentioned before, a generative language model is generally trained via predicting the next token (i.e., subword/word/phrase), one by one, based on the previous ones for each training text, aiming to maximize the likelihood. Formally, given a training text T consisting of n tokens, i.e., $T = [t_1, \ldots, t_{i-1}, t_i, \ldots, t_n]$, when predicting a target token t_i, the generative language model takes the previous ones $\mathbf{t} = [t_1, t_2, ..., t_{i-1}]$ as input, and then generates a probability distribution $\mathbf{p}$ over the vocabulary as output. In nearly all implementations, the Cross-Entropy loss is employed as the loss function, to maximize the predicted probability $\mathbf{p}_{t_i}$ w.r.t the ground-truth token t_i. Considering that the recent state-of-the-art deep language models (LM) predominantly leverage the Transformer architecture (Vaswani et al., 2017), the training loss $\mathcal{L}_{CE}$ of the generative language model can be formulated as follows.

$$\mathcal{L}_{CE} = -\log(\mathbf{p}_{t_i}) \tag{1}$$

$$s.t., \quad \mathbf{p} = \text{softmax}(W\mathbf{H}_{i-1}^{last}) \tag{2}$$

$$\mathbf{H}^{last} = \text{Transformer}(\text{Embedding}(\mathbf{t})) \tag{3}$$

Here, $\mathbf{H}^{last}$ denotes the hidden states of the last layer of the Transformer architecture, which consists of the hidden states w.r.t the previous tokens $\mathbf{t} = [t_1, t_2, ..., t_{i-1}]$, i.e., $\mathbf{H}^{last} = [\mathbf{H}_1^{last}, \mathbf{H}_2^{last}, \ldots, \mathbf{H}_{i-1}^{last}]$. With $\mathbf{H}_{i-1}^{last}$, a linear projection layer W is introduced to derive the predicted probability distribution $\mathbf{p}$ over the vocabulary, with a `softmax` operation.

Focal Loss for Classification Focal Loss is originally proposed for object detection to address the issue of extreme foreground-background class imbalance encountered during the training of one-stage object detectors (Lin et al., 2017). Focal Loss can lead a classification model to concentrate more on a sparse set of difficult-to-learn classes and prevent the abundance of easy-to-learn classes from overwhelming the model during training. Actually, Focal Loss is an extension of Cross-Entropy Loss, with an extra dynamic scaling factor, as formulated below.

$$\mathcal{L}_{FL}^{0} = -(1-p)^{\gamma}\log(p) \tag{4}$$

Here, p is the predicted probability w.r.t the ground-truth class, and γ is a hyperparameter with $\gamma \geq 0$. It can be seen that when $\gamma = 0$, Focal Loss would degenerate to Cross-Entropy Loss. As p decreases, i.e., getting more-difficult-to-learn, the dynamic scaling factor $(1-p)^{\gamma}$ increases, thus giving more attention (i.e., higher weights) to the difficult-to-learn classes.

3.2 Focal Loss for Language Models

Generative language models are commonly trained on the massive textual corpus, which exhibits inherent token imbalance as revealed by Zipf's law (Piantadosi, 2014). Such an imbalance of tokens can lead to two primary challenges: 1) Training efficiency becomes sub-optimal. A large number of easy-to-learn tokens (i.e., classes) provide marginal gains in learning signals. (Lin et al., 2017). 2) The training process can be overwhelmed by a large proportion of the frequent and easy-to-learn tokens, and thus pay insufficient attention to the other infrequent, difficult-to-learn but informative tokens, which might lead to performance degradation.

As revealed in Equation (1), training a generative language model is essentially a classification problem. Therefore to mitigate the bias of learning difficulties caused by the inherent token imbalance, Focal Loss can be applied. Specifically, we can use the Focal Loss as a substitute for the Cross-Entropy Loss in Equation (1) to train a generative language model as follows.

$$\mathcal{L}_{FL} = -(1-\mathbf{p}_{t_i})^{\gamma}\log(\mathbf{p}_{t_i}) \tag{5}$$

Here, the dynamic scaling factor $(1-\mathbf{p}_{t_i})^{\gamma}$ is derived based on the predicted probability $\mathbf{p}_{t_i}$ of the to-be-learned token t_i. Similarly, as the probability $\mathbf{p}_{t_i}$ decreases (i.e., being more difficult to learn), the scaling factor $(1-\mathbf{p}_{t_i})^{\gamma}$ increases correspondingly. Therefore, more-difficult-to-learn tokens will receive higher loss weights.

3.3 Proposed MiLe Loss

However, as illustrated in Figure 1 and analyzed before, in language model pretraining, predicting the next token is more like a multi-label classification problem. When there are multiple valid next tokens for a given sequence of previous tokens, the learning difficulty assessed by Focal Loss is imperfect.

To tackle that, we propose MiLe Loss, which leverages the information entropy of the predicted probability distribution $\mathbf{p}$ over the vocabulary, instead of the single probability $\mathbf{p}_{t_i}$ as Focal Loss, to derive a dynamic scaling factor. MiLe Loss is naturally designed for cases with multiple valid tokens. It is inspired by the following observations: 1) when a next token is easy-to-learn, the minor valid tokens would divide up almost the total probability (i.e., 1.0) while others are associated with very low probabilities (i.e., $\mathbf{p}$ is more focused), resulting in a low information entropy; 2) when a next token is difficult-to-learn, the predicted probability distribution would be more uniform, resulting in a higher information entropy.

Specifically, MiLe Loss can be formulated as

model size	dimension	n heads	n layers	learning rate	batch size	seq length
468M	1024	16	24	$3.0e^{-4}$	1024	1024
1.2B	2048	8	16	$3.0e^{-4}$	1024	1024
6.7B	4096	32	32	$3.0e^{-4}$	2048	2048

Table 2: Model sizes, architectures, and optimization hyper-parameters.

follows in language model pretraining.

$$\mathcal{L}_{IL} = -(1 - \sum_{j} \mathbf{p}_j \log(\mathbf{p}_j))^{\gamma} \log(\mathbf{p}_{t_i}) \tag{6}$$

Here, $-\sum_j \mathbf{p}_j \log(\mathbf{p}_j) \geq 0$ is the information entropy of the predicted probability distribution $\mathbf{p}$ over the vocabulary. Note that when $\mathbf{p}$ is a uniform distribution, i.e., $p_j = \frac{1}{N}$ with N being the vocabulary size for all j, the information entropy reaches its upper bound $\log(N)$. Therefore, the dynamic scaling factor $(1 - \sum_j \mathbf{p}_j \log(\mathbf{p}_j))$ is bounded in $[1, 1 + \log(N)]$. When a next token is difficult to learn, the corresponding higher information entropy results in a higher scaling factor, and thus MiLe Loss increases the loss weights for such tokens. Conversely, MiLe Loss decreases the loss weights for easy-to-learn tokens, according to their lower information entropies.

4 Experiments

We train three generative language models of different capacities, i.e., 468M, 1.2B, and 6.7B parameters, on the open-source Pile dataset (Gao et al., 2021a) as (Biderman et al., 2023; Xie et al., 2023; Carlini et al., 2023), and make comparisons among different loss functions.

4.1 The Pile dataset

The Pile dataset is a public large-scale corpus for language model pretraining, which has over 825GB English texts across 22 domains. For experiments, we tokenize it using the remarkable LLaMA tokenizer (Touvron et al., 2023) with a 32k-sized vocabulary. As the number of tokens changes with a new tokenizer, we follow (Xie et al., 2023) to re-calculate the sampling weight for each domain. Specifically, we chunk the dataset into sequences of 1,024 tokens, and then for each domain, we multiply its corresponding number of sequences with its domain-specific epochs reported in (Gao et al., 2021a). Finally, we normalize all the multiplication results to obtain the sampling weights listed in Table 3.

Table 3: Sampling weights on the Pile dataset.

4.2 Experimental setup

We train three generative language models with 468M, 1.2B, and 6.7B parameters, respectively. Specifically, the architectures of the 468M-parameter and the 1.2B-parameter models, including the dimensionality of hidden states, the number of layers, etc., are identical to those of the 410M-parameter and the 1.0B-parameter models outlined in (Biderman et al., 2023). The minor differences in parameter sizes are attributed to the variations of vocabulary size in the embedding layer. As for the 6.7B-parameter model, its architecture is identical to LLaMA-7B (Touvron et al., 2023). The corresponding hyperparameters for each model can be found in Table 2. Following LLaMA (Touvron et al., 2023), we use the AdamW optimizer (Loshchilov and Hutter, 2019) with a learning rate of $3.0e^{-4}$, $2k$ warmup steps, and a cosine learning rate decay schedule. Following (Lin et al., 2017), the hyperparameter γ is set as 1.0 for both Focal Loss and the proposed MiLe Loss, unless explicitly stated otherwise. Due to the computational budget and following the pretraining settings of (Xie et al., 2023), all models are pretrained with 100B tokens.

Following (Touvron et al., 2023; Brown et al., 2020; Rae et al., 2021; Hoffmann et al., 2022), we primarily evaluate all models on tasks of commonsense reasoning, closed-book question answering, and massive multitask language understanding. For fair comparisons, we utilize the open-

Table 4: Zero-shot and few-shot performance (i.e., accuracy) of models at different scales on common sense reasoning benchmarks.

source pipeline `lm-evaluation-harness`[2] (Gao et al., 2021b) for evaluation, as (Biderman et al., 2023; Dettmers and Zettlemoyer, 2023).

4.3 Experimental Results

Common Sense Reasoning Following (Touvron et al., 2023; Brown et al., 2020; Rae et al., 2021; Hoffmann et al., 2022), we employ 8 widely used benchmark datasets for the evaluation of common sense reasoning, including BoolQ (Clark et al., 2019), HellaSwag (Zellers et al., 2019), LAMBADA (Paperno et al., 2016), OpenBookQA (Mihaylov et al., 2018), PIQA (Bisk et al., 2020), SIQA (Sap et al., 2019), StoryCloze (Mostafazadeh et al., 2016),Winogrande (Sakaguchi et al., 2020). We report the model performance in terms of accuracy for zero-shot and few-shot settings in Table 4, like (Touvron et al., 2023; Brown et al., 2020).

We can observe that the proposed MiLe Loss substantially outperforms both Cross-Entropy Loss and Focal Loss on different setups with different model capacities. Specifically, for models with 468M and 6.7B parameters on 0/1/5-shot settings, MiLe Loss consistently achieves superior performance to both compared baselines. As for the 1.2B-parameter model, although MiLe Loss yields slightly lower average performance than Focal Loss, it still delivers the highest performance on 6 out of the 8 datasets and steadily outperforms Cross-Entropy Loss on most datasets.

These results clearly demonstrate the effectiveness of the proposed MiLe Loss. We attribute it to that MiLe Loss compels language models to allocate more attention to those difficult-to-learn yet informative tokens during pretraining, which mitigates the bias of learning difficulties among tokens. Moreover, the consistent performance superiority of MiLe Loss over Focal Loss also validates that, relying on the information entropy of the predicted probability distribution over the vocabulary to assess the learning difficulties of tokens is more reasonable.

MiLe Loss	5.02	**9.89**	14.57

Table 5: Zero-shot and few-shot exact match performance of 6.7B-parameter models on closed-book question-answering benchmarks.

Closed Book Question Answering Following (Brown et al., 2020; Touvron et al., 2023), for the task of closed book question answering, we evaluate the performance of the largest 6.7B-parameter models with different loss functions on two benchmark datasets, i.e., TriviaQA (Joshi et al., 2017) and WebQuestions (Berant et al., 2013). We report the exact match performance for the zero-shot and few-shot settings in Table 5.

It can be seen that language models trained with the proposed MiLe Loss achieve superior performance across most settings. Compared with Cross-Entropy Loss, MiLe Loss achieves substantial performance improvement in 5 out of 6 settings. Particularly, on TriviaQA, MiLe Loss achieves a maximum performance improvement of 3.55% (0-shot) over Cross-Entropy Loss. Compared with Focal Loss, MiLe Loss also exhibits consistent superiority. Notably, in the 0-shot setting on TriviaQA, MiLe Loss outperforms Focal Loss by 4.17%.

Massive Multitask Language Understanding We further validate the effectiveness of the proposed MiLe Loss on the MMLU (Massive Multitask Language Understanding) benchmark (Hendrycks et al., 2021). MMLU consists of multiple-choice questions covering 57 subjects, including STEM, social sciences, humanities, etc. It has been serving as a benchmark for evaluating the multitasking capability of pretrained language models. Following LLaMA (Touvron et al., 2023), we evaluate the 6.7B-parameter models in the 5-shot setting. Among multiple choices, we choose the one with the highest probability normalized by the number of tokens.

	Cross-Entropy Loss	Focal Loss	MiLe Loss
STEM	29.59	**29.99**	29.91
Social Sciences	**29.64**	27.57	28.07
Humanities	27.00	27.35	**28.28**
Other	29.94	29.34	**30.85**
Avg	29.38	28.90	**29.68**

Table 6: The 5-shot learning performance of 6.7B-parameter models on MMLU.

As shown in Table 6, MiLe loss exhibits superior performance on average. Compared with Cross-Entropy loss, MiLe loss obtains performance improvement of 0.32%, 1.28%, and 0.91% for the field of `STEM`, `Humanities`, and `Other`, respectively. For the field of `Social Sciences`, the performance decline may be attributed to that MiLe Loss tends to consider `Social Sciences` samples as easier-to-learn ones. We intend to study it in depth in our future work. Compared with Focal Loss, MiLe Loss also yields superior performance on all fields except `STEM`. All the results above further demonstrate the proposed MiLe Loss's effectiveness and reasonableness.

5 Analyses

We conduct further experiments to provide more insightful analyses on the proposed MiLe Loss.

5.1 Impact of γ

We aim to discern the performance change of the proposed MiLe Loss on language models with different values of γ, i.e., the hyperparameter in Equation (6). It's worth noting that when γ is set to 0, MiLe Loss is functionally equivalent to Cross-Entropy Loss. As γ increases, the language model becomes more focused on the difficult-to-learn tokens, i.e., those with higher information entropy. Here we conduct a grid search for γ on language models of various scales (i.e., 468M, 1.2B, and 6.7B parameters), and use the average performance in 5-shot learning for the Common Sense Reasoning task that covers the most benchmarks as the evaluation metric.

As shown in Figure 2, when γ increases from 0 to 5 for the 468M-parameter model or increases from 0 to 2 for the 1.2B-parameter/6.7B-parameter models, the performances of MiLe Loss consistently surpass those of Cross-Entropy Loss. The results clearly demonstrate that the performance of MiLe Loss is not very sensitive to the setting of

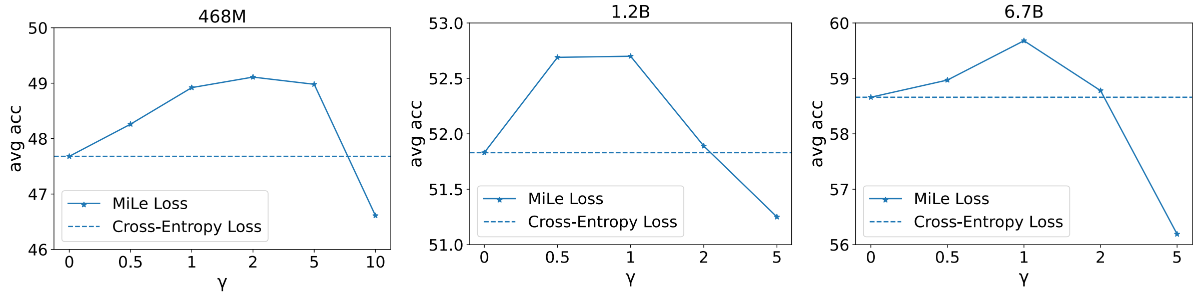

Figure 2: The performance of MiLe Loss and Cross-Entropy Loss in 5-shot learning with different γ values.

the hyperparameter γ, which shows practical applicability. As expected, when γ increases to a relatively large value, the performance of MiLe Loss declines, because too much attention is given to the difficult-to-learn tokens, and the easy-to-learn ones get overlooked as a result.

γ	0	0.5	1	2	5
PPL	5.473	5.467	5.492	5.608	6.317

Table 7: The perplexity (PPL) on the Pile validation set under different γ values for MiLe Loss. Among them, $\gamma = 0$ equals Cross-Entropy Loss.

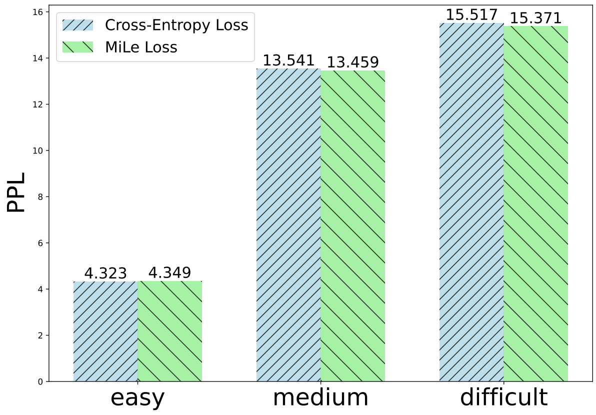

Figure 3: The average perplexity (i.e., PPL) for tokens in different learning-difficulty levels.

5.2 Perplexity on the Pile Validation Set

Here we further discuss how the proposed MiLe Loss affects the perplexity of pretrained language models on the Pile validation set.

Table 7 reports the perplexity of the largest 6.7B-parameter models trained with γ increasing from 0 to 5 for MiLe Loss. Among them, $\gamma = 0$ is equivalent to Cross-Entropy Loss. Notably, when $\gamma = 0.5$, the perplexity obtained by MiLe Loss is lower than that by Cross-Entropy Loss (i.e., $\gamma = 0$). However, as we increase γ, the perplexity of MiLe Loss also increases and becomes higher than that of Cross-Entropy Loss. The increase of perplexity can be attributed to: 1) the measurement of perplexity is directly related to the exponentiation of Cross-Entropy Loss, and thus optimizing Cross-Entropy Loss during training is consistent with optimizing the perplexity; 2) the objective function of MiLe Loss somewhat diverges from that of perplexity due to the dynamic scaling factor, and thus optimizing it may lead to an increase of perplexity.

To thoroughly inspect how the perplexity increases, we conduct a fine-grained analysis of perplexity at the token level. Similar to the perplexity analysis before, we group all tokens into three learning-difficulty levels based on their corresponding frequencies, i.e., `easy`, `medium`, and `difficult`. Specifically, we categorize the top tokens that cover 80% of the Pile dataset as `easy`, those that cover the extra 15% (i.e., $80\% - 95\%$) of the Pile dataset as `medium`, and the remaining 5% as `difficult`. The average perplexity for tokens in each learning-difficulty level, obtained by Cross-Entropy Loss and the proposed MiLe Loss with $\gamma = 1$, is shown in Figure 3. It can be seen that, compared with Cross-Entropy Loss, MiLe Loss results in an unnoticeable increase in perplexity for the `easy` tokens, while for the `medium` or the `difficult` tokens, MiLe Loss substantially reduces their perplexity with a noticeable decline. Given that `easy` tokens dominate the dataset, the overall increase in perplexity is expected. However, the substantial decline of perplexity for the `medium` or the `difficult` tokens further demonstrates the effectiveness of MiLe Loss in guiding language models to focus more on infrequent, difficult-to-learn but informative tokens and thereby mitigating the bias of learning difficulties during training.

Table 8: The performance of the 6.7B models trained with 200B tokens in zero/few-shot settings across various benchmarks.

5.3 Performance of Training with More Tokens

MiLe Loss assesses the learning difficulty of each token through information entropy. Intuitively, the more tokens used in model training, the more powerful the Language Model becomes, and the output word distribution becomes more reasonable. Consequently, the assessment of the learning difficulties of tokens becomes more accurate, and thus the MiLe Loss can probably better lead the LM to tackle the bias. To validate that, with limited computational resources, we continue to pretrain the 6.7B model from 100B tokens to 200B tokens, with both Cross-Entropy Loss and MiLe Loss. Their corresponding evaluation results on all benchmarks are reported in Table 8. We can see that, when the number of training tokens for the 6.7B models increases to 200B, the models trained with MiLe Loss yield consistent and substantial performance improvements over those trained with Cross-Entropy Loss. Moreover, compared to training with 100B tokens, training with more tokens even helps MiLe Loss to yield **LARGER** performance improvements. For instance, in the 5-shot setting, with 100B training tokens, the performance improvements gained by MiLe Loss over Cross-Entropy Loss on the 6.7B models is 1.02%. Then by continuing pre-training with more training tokens, the gained improvements increase to 1.33%. The experimental results above demonstrate well that using more tokens increases the benefits of MiLe Loss.

6 Conclusions

In this paper, we present our observation of the bias of learning difficulties among tokens during language model pretraining, mainly caused by the inherent token imbalance in textual training data. We initially introduce Focal Loss as an attempt to mitigate the bias of learning difficulties. However, we find that considering the single probability of the ground-truth next token for assessing its learning difficulty is unreasonable, especially in cases with multiple valid next tokens. To tackle that, we propose MiLe Loss, which assesses the learning difficulty of a token by taking into account the global information entropy of the predicted probability distribution over the vocabulary. Extensive experiments demonstrate that, compared with both Cross-Entropy Loss and Focal Loss, the proposed MiLe Loss achieves superior performance for various downstream tasks in zero-shot and few-shot learning settings.

7 Limitations

In the proposed MiLe Loss, we scale the Cross-Entropy Loss based on information entropy to lead a generative language model to allocate more attention to difficult-to-learn tokens, which yields superior performance. Yet the effectiveness of MiLe Loss may be influenced by the quality of the training data. Specifically, as noisy data samples are generally outliers, the predicted probability distributions on them would typically exhibit high information entropy. Thus, too many noisy samples may make MiLe Loss amplify their corresponding loss weights too much, causing negative impacts on the model performance. We leave the investigation of how noisy data samples affect MiLe Loss to our future research.

Abstract

Addressing the challenge of automated geometry math problem-solving in artificial intelligence (AI) involves understanding multi-modal information and mathematics. Current methods struggle with accurately interpreting geometry diagrams, which hinders effective problem-solving. To tackle this issue, we present the **G**eometry problem s**O**lver with natural **L**anguage **D**escription (GOLD) model. GOLD enhances the extraction of geometric relations by separately processing symbols and geometric primitives within the diagram. Subsequently, it converts the extracted relations into natural language descriptions, efficiently utilizing large language models to solve geometry math problems. Experiments show that the GOLD model outperforms the Geoformer model, the previous best method on the UniGeo dataset, by achieving accuracy improvements of 12.7% and 42.1% in calculation and proving subsets. Additionally, it surpasses the former best model on the PGPS9K and Geometry3K datasets, PGPSNet, by obtaining accuracy enhancements of 1.8% and 3.2%, respectively.[1]

1 Introduction

Automated solving of geometry math problems has gained considerable attention in the AI community recently (Chen et al., 2021; Lu et al., 2021; Cao and Xiao, 2022; Chen et al., 2022; Zhang et al., 2023; Peng et al., 2023; Ning et al., 2023). Unlike math word problems, geometry math problems involve additional geometry diagrams, necessitating comprehensive reasoning capabilities for understanding multi-modal information (refer to Figure 1 for an example of a geometry math problem). As a result, research on automated geometry math problem solving is still in its infancy (Chen et al., 2022).

Existing approaches for solving geometry math problems utilize neural networks to embed the diagram and problem text separately or jointly, resulting in highly generalized models (Chen et al., 2021, 2022). However, these methods struggle with accurately capturing the complex relationships within geometry diagrams (Lu et al., 2023b). Additionally, their vector-based representation of geometric relations is not easily interpretable by humans, posing challenges in identifying whether performance issues are from the relation extraction or the problem-solving component. In a different approach, some studies have successfully translated geometry diagrams into formal languages, enhancing precision and interpretability (Sachan et al., 2017; Seo et al., 2015; Lu et al., 2021; Zhang et al., 2023). However, these methods do not separately process relations among geometric primitives and relations between symbols and geometric primitives, which adds difficulty in solving the geometry math problem correctly. Moreover, these approaches necessitate specifically designed solvers that take formal languages as input, making them incompatible with prevalent large language models (LLMs).

To address the limitations of existing methods in solving geometry math problems, we introduce the GOLD model. The GOLD model converts geometry diagrams into natural language descriptions, aiding in the generation of solution programs for the problems. Particularly, the GOLD model's relation-construction head extracts two types of geometric relations: *sym2geo* (relations between symbols and geometric primitives) and *geo2geo* (relations among geometric primitives). This process involves two specialized heads that separately model symbols and geometric primitives within diagrams as distinct vectors. These extracted geometric relations are then converted into natural language descriptions. This not only improves the model's interpretability but also connects geometry diagrams with problem texts. Furthermore, since these natural language descriptions meet the input requirements of LLMs, the GOLD model is able to

---

Findings of the Association for Computational Linguistics: NAACL 2024, pages 263–278
June 16-21, 2024 ©2024 Association for Computational Linguistics

utilize the advanced LLMs as the problem-solving module, efficiently generating solution programs used to solve geometry math problems.

To evaluate the effectiveness of the GOLD model, we conduct experiments on the three latest released datasets: UniGeo (comprising calculation and proving subsets) (Chen et al., 2022), PGPS9K (Zhang et al., 2023), and Geometry3K (Lu et al., 2021). The experimental results show the significant performance gains of our GOLD model compared to state-of-the-art (SOTA) models. It surpasses the Geoformer model, which is the SOTA model on the UniGeo dataset, by 12.7% and 42.1% in accuracy on the UniGeo calculation and proving subsets, respectively. Additionally, our GOLD model outperforms the PGPSNet model, the SOTA model on the PGPS9K and Geometry3K datasets by 1.8% and 3.2% in accuracy, respectively. These results highlight the superior performance and effectiveness of our proposed GOLD model compared to existing approaches.

The contributions of this work are: (1) We propose the GOLD model to extract geometric relations from geometry diagrams and subsequently convert these relations into natural languages, which are then utilized for solving geometry math problems. Its compatibility with LLMs is a significant advantage, enabling the GOLD model to utilize the capabilities of LLMs to generate solution programs. (2) The GOLD model separately processes symbols and geometric primitives from the diagrams. This separation design simplifies the extraction of the geometric relations. (3) Our GOLD model demonstrates significant improvements over previous methods across all evaluated datasets, validating the effectiveness of our approach.

2 Related Work

Early works have explored solving geometry math problems through rule-based approaches (Gelernter et al., 1960; Wen-Tsün, 1986; Chou and Gao, 1996a,b). Recently, with the success of deep learning methods, several works have explored using neural network architectures for automated geometry math problem-solving. Approaches such as NGS (Chen et al., 2021) utilizing LSTM (Hochreiter and Schmidhuber, 1997) and ResNet-101 (He et al., 2016) encoded problem texts and geometry diagrams separately. Later, methods like DPE-NGS (Cao and Xiao, 2022) replaced the text encoder with transformer models. However, these methods struggle to effectively integrate problem texts and geometry diagrams. In response, Geoformer (Chen et al., 2022) emerged, embedding both diagram and problem text jointly using the VL-T5 (Cho et al., 2021) model, treating visuals as additional tokens. Despite these advancements, they still struggle to provide precise descriptions of slender, overlapped geometric primitives with complex spatial relationships (Zhang et al., 2022), resulting in sub-optimal performance when solving geometry math problems.

Other approaches typically involve parsing the diagram into formal language and utilizing specific solvers to generate solution programs. Recent works like Inter-GPS (Lu et al., 2021) and PGPSNet (Zhang et al., 2023) employed their parsers to describe the diagram using carefully crafted rules. However, these methods based on predefined rules often lack extensibility, resulting in limited generalization capabilities. To address this issue, our proposed GOLD model generates natural language descriptions of the diagrams, ensuring compatibility of adopting LLMs to generate solution programs.

3 Model

Our GOLD model is illustrated in Figure 1.

3.1 Task Description and Pre-parsing

The objective is to generate the correct solution program $\mathcal{P}$ to solve the problem by analyzing a geometry math problem text $\mathcal{T}$ and its corresponding diagram $\mathcal{D}$. Specifically, the solution program represents intermediate steps in the domain-specific language generating the output for the question (see an example of solution program in Figure 1).

In our approach, we initially preprocess geometry diagrams to extract geometric primitives $\mathcal{G}$ (including *Point* **P**, *Line* **L**, and *Circle* **C**) and symbols $\mathcal{S}$ from the diagram $\mathcal{D}$ for subsequent task. Specifically, we utilize a standard Feature Pyramid Network (FPN) (Lin et al., 2017) integrated with a MobileNetV2 (Sandler et al., 2018) backbone for this task. For the detection of symbols, we apply the anchor-free detection model FCOS (Tian et al., 2022), and for the extraction of geometric primitives, we use the GSM model (Zhang et al., 2022). The FCOS model employs feature maps P3 to P7, generated by the FPN layer, to detect symbols within the diagram. This detection step produces bounding box coordinates (box_s) and class type (cls_s) for each symbol ($s \in \mathcal{S}$). For the

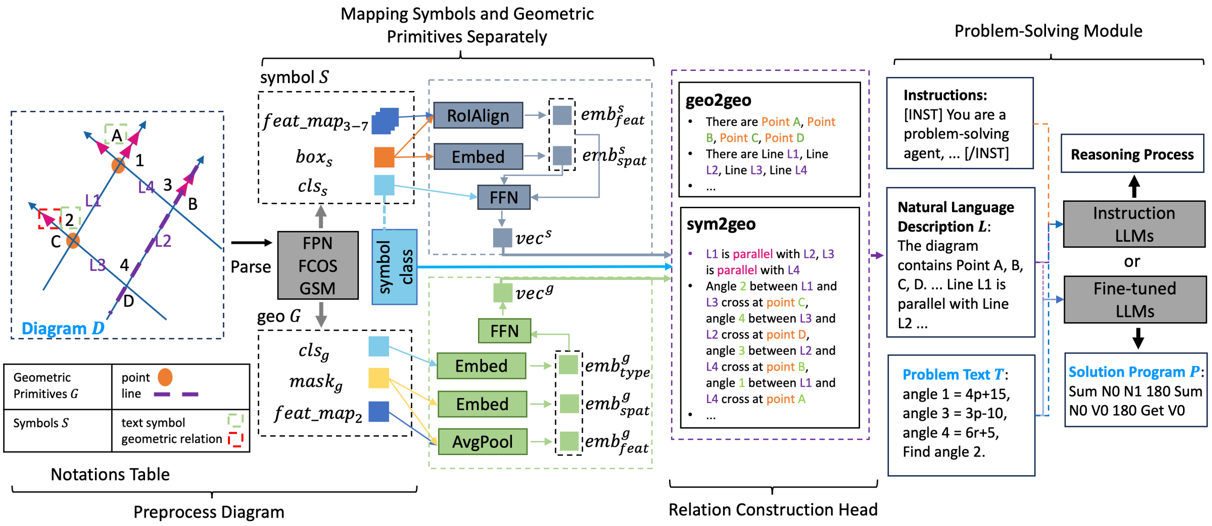

Figure 1: The illustration of the GOLD Model. The diagram $\mathcal{D}$, problem text $\mathcal{T}$, and solution program $\mathcal{P}$ used in this illustration are sourced from the PGPS9K dataset (Zhang et al., 2023). The symbols and geometric primitives in the diagram are annotated using the notations from the Notation Table, which are consistent with the colours of extracted relations of sym2geo and geo2geo.

extraction of geometric primitives, we prefer using the feature map P2 instead of P1, as P2 is more memory-efficient due to its lower resolution. This process results in the identification of segmentation masks (mask_g) and class type (cls_g) for each geometric primitive ($g \in \mathcal{G}$).

3.2 Mapping Symbols and Geometric Primitives Separately

Before constructing the geometric relations, we map the symbols and geometric primitives into vectors. To achieve this, we introduce two heads: symbol vector head and geometric primitive vector head. Specifically, each head functions as extracting the *feature_embedding* (emb_{feat}) and *spatial_embedding* (emb_{spat}). The *feature_embedding* is computed from the cropped feature map, which is determined by either the bounding box or the segmentation mask. Moreover, where symbols and geometric primitives are placed significantly shapes how they relate. For instance, only points lying on a line can hold the geometric relation with that particular line. Thus, we hypothesize that incorporating spatial information of $\mathcal{S}$ and $\mathcal{G}$ can enhance the accuracy of predictions about geometric relations. Consequently, we embed the bounding boxes of symbols and the coordinates of the geometric primitives into the *spatial_embedding*.

3.2.1 Constructing the *feature_embedding*

To obtain the *feature_embedding* ($\text{emb}^{s,g}_{feat}$) and *spatial_embedding* ($\text{emb}^{s,g}_{spat}$) for symbol s or geometric primitive g, we conduct the below calculation:

$$\text{emb}^{s,g}_{feat} = \text{ReLU}(\mathbf{W}^{s,g}_{feat}\mathbf{V}^{s,g}) \tag{1}$$

where $\mathbf{W}^{s,g}_{feat} \in \mathbb{R}^{h\times h}$ are trainable parameters for either symbols or geometric primitives. Next, we elaborate the calculation process of $\mathbf{V}^{s,g}$ for symbols and geometric primitives separately.

To obtain the $\mathbf{V}^s$ for symbol s, we utilize RoIAlign (He et al., 2017) on its feature map, based on the bounding box of symbol s:

$$\mathbf{V}^s = \mathbb{F}(\text{ReLU}(\text{BN}(\text{Conv}(\text{RoIAlign}(\text{box}_s, \text{feat\_map}_i))))) \tag{2}$$

where i refers to the i-th layer of feature maps where the bounding box (box_s) is calculated from. The Conv is the convolution layer with 64 channels, BN is the BatchNorm layer, and ReLU is the ReLU activation layer. The $\mathbb{F}$ means flatten operation, indicating that the $\mathbf{V}^s$ is further flatten into a vector and used for obtaining the *feature_embedding* emb^s_{feat} for symbol s through Eq 1.

To obtain the $\mathbf{V}^g$ for geometric primitive g, we perform an element-wise multiplication between the segmentation mask (mask_g) of g and the P2 layer of feature map (feat_map_2). Next, we flatten the resulting vector along the height and width dimensions and apply global average pooling to obtain the $\mathbf{V}^g$:

$$\mathbf{V}^g = \text{AvgPool}(\mathbb{F}(\text{mask}_g \times \text{feat\_map}_2)) \tag{3}$$

The $\mathbf{V}^g$ is used for calculating the *feature_embedding* emb^g_{feat} for geometric primitive g

through Eq 1.

3.2.2 Constructing the *spatial_embedding*

The *spatial_embedding* is obtained by mapping the spatial information of symbols and geometric primitives into embeddings. Specifically, for symbol s, we map the coordinates of its bounding box into an embedding using the trainable parameters $\mathbf{W}^{s}_{spat} \in \mathbb{R}^{h\times 4}$. Specifically, $\text{emb}^{s}_{spat} = \mathbf{W}^{s}_{spat}[x_t, y_t, x_b, y_b]^{\top}$, where (x_t, y_t) represent the coordinates of the top-left corner of the bounding box, and (x_b, y_b) is the coordinates of the bottom-right corner of the bounding box.

Next, to obtain the *spatial_embedding* of a geometric primitive g, we start by representing coordinates of g using loc_g. The format of loc_g depends on the class type (cls_g) of the geometric primitive: for a point, it contains two numbers ($n_g = 2$) representing its coordinates; for a line, it contains four numbers ($n_g = 4$) representing the coordinates of its start and end points; and for a circle, it contains three numbers ($n_g = 3$) representing the coordinates of its centre point and the radius length. We then map loc_g into *spatial_embedding* by calculating $\text{emb}^{g}_{spat} = \text{ReLU}(\mathbf{W}^{g}_{spat}(\mathbf{W}^{g}_{loc} loc_g))$, where $\mathbf{W}^{g}_{loc} \in \mathbb{R}^{h\times n_g}$ are different trainable parameters for different cls_g, and $\mathbf{W}^{g}_{spat} \in \mathbb{R}^{h\times h}$ are trainable parameters.

To help the model differentiate between different types of geometric primitives, we introduce the *geo_type_embedding* (emb^{g}_{type}) to capture the semantic information of the geometric primitive. The emb^{g}_{type} is obtained by performing a lookup operation on the embeddings using the class type (cls_g) of g from the list of geometric primitive types $[\mathbf{P}, \mathbf{L}, \mathbf{C}]$. Specifically, $\text{emb}^{g}_{type} = \text{embedding}(\text{cls}_g)$, where cls_g is the class type ID of g.

3.2.3 Symbol Vector and Geometric Primitive Vector

The vector representation $\text{vec}^{s\in\mathcal{S}}$ of symbol s is obtained by passing concatenated emb^{s}_{feat} and emb^{s}_{spat} through a specific feed-forward neural network:

$$\text{vec}^{s\in\mathcal{S}} = \text{ReLU}(\mathbf{W}^{s}_{vec}[\text{emb}^{s}_{feat} : \text{emb}^{s}_{spat}]^{\top}) \qquad (4)$$

where $\mathbf{W}^{s}_{vec} \in \mathbb{R}^{h\times 2h}$ are the trainable parameters depending on the class type (cls_s) of symbol s, and [:] refers to concatenation operation.

The vector representation of the geometric primitive $\text{vec}^{g\in\mathcal{G}}$ is obtained by summing up three embeddings relevant to the geometric primitive g, emb^{g}_{feat}, emb^{g}_{spat}, and emb^{g}_{type}:

$$\text{vec}^{g\in\mathcal{G}} = \text{ReLU}(\mathbf{W}^{g}_{vec}(\text{emb}^{g}_{feat} + \text{emb}^{g}_{spat} + \text{emb}^{g}_{type})) \quad (5)$$

where $\mathbf{W}^{g}_{vec} \in \mathbb{R}^{h\times h}$ are the trainable parameters.

3.3 Relation Construction Head

The relation-construction head aims to establish *sym2geo* relations among symbols and geometric primitives and *geo2geo* relations among geometric primitives themselves.

3.3.1 sym2geo relation

The *sym2geo* relation can be further divided into *text2geo* and *other2geo* relations. The *text2geo* relation explains the association between text symbols and geometric primitives, where the text symbols are used to be the reference to a geometric primitive or to display degree, length, etc. To distinguish the role of a text symbol, we introduce the *text_class* for the text symbol. Specifically, when *text_class* is category *0*, the *text2geo* signifies point (or line, or circle) names; when *text_class* is category *1*, the *text2geo* corresponds to angle degrees; when *text_class* is category *2*, the *text2geo* signifies line lengths; when *text_class* is category *3*, the *text2geo* denotes the degree of an angle within a circle. The probabilities of the category ($P(\textit{text\_class}|s)$) of text symbol ($s \in \{\mathcal{S}|\text{cls}_s = \text{"text"}\}$) is defined as:

$$P = \text{softmax}(\mathbf{W}^{sym2geo}_{text\_class}\text{ReLU}(\mathbf{W}^{sym2geo}_{1}\text{vec}^{s})) \qquad (6)$$

where $\mathbf{W}^{sym2geo}_{1} \in \mathbb{R}^{h\times h}$ and $\mathbf{W}^{sym2geo}_{text\_class} \in \mathbb{R}^{4\times h}$, both are the trainable parameters.

The *other2geo* relation captures relations between non-text symbols ($s \in \{\mathcal{S}|\text{cls}_s \neq \text{"text"}\}$) and geometric primitives. The non-text symbols are used to find out the relations among geometric primitives, such as *angles of same degree*, *lines of same length*, *parallel lines*, and *perpendicular lines*. For instance, in Figure 1, the symbol enclosed in a red rectangle signifies the parallel relation.

To establish the *sym2geo* relation between symbol s and geometric primitive g, we begin by utilizing the corresponding symbol head to transform the vector of the geometric primitive: $\widehat{\text{vec}}^{g} = \text{ReLU}(\mathbf{W}^{sym2geo}_{s1}\text{vec}^{g})$, where $\mathbf{W}^{sym2geo}_{s1} \in \mathbb{R}^{h\times h}$ are trainable parameters that vary depending on different class types (cls_s) of symbols. Finally, we calculate the probabilities of the existence of the relation between symbol s and geometric primitive g as follows:

$$\begin{aligned} O_1 &= \mathrm{ReLU}(\mathbf{W}_2^{sym2geo}[\mathrm{vec}^s : \widehat{\mathrm{vec}}^{g \in \{sub\}}]) \\ P(\mathrm{rel}_{s,g}^{sym2geo}|s, g) &= \mathrm{sigmoid}(\mathbf{W}_{rel}^{sym2geo} O_1) \end{aligned} \quad (7)$$

where $\mathbf{W}_2^{sym2geo} \in \mathbb{R}^{h \times 2h}$ and $\mathbf{W}_{rel}^{sym2geo} \in \mathbb{R}^{1 \times h}$ are the trainable parameters. Worth mentioning, that each type of symbol, including the additional four categories of the text symbol, has its own $\mathbf{W}_2^{sym2geo}$. Additionally, $\{sub\}$ refers to the subset of geometric primitives, as certain symbols can only have relations with specific geometric primitives. Please refer to Appendix A.1 for details on how to predict *text2geo* and *other2geo* relations during the inference stage.

3.3.2 geo2geo relation

Previous work tend to provide only *sym2geo* relations. However, despite the *sym2geo* relation can provide geometric relations among geometric primitives like parallel, perpendicular, etc. We hypothesize that providing additional information that describes all the geometric primitives from the diagrams is beneficial for the task. Moreover, we tackle the issue concerning the absence of references to geometric primitives in the diagram. For example, in Figure 1, the original diagram lacks a reference to the line, where *sym2geo* relation cannot address. To overcome this limitation, we have devised an automated approach that assigns appropriate references to the geometric primitives using the format "cls$_g$ + num" (e.g., "L1, L2, L3, L4" in purple in Figure 1). This enables the relation-construction module to (1) present a detailed depiction of the diagram by describing the *geo2geo* relations, even in the absence of a single reference, and (2) generate all *sym2geo* relations, even when some geometric primitives lack references. The *geo2geo* relations are categorized according to the involved geometric primitives: (1) Point and Line: "on-a-line" and "end-point". The "on-a-line" relation occurs when a point lies between the tail and the head of the line. Specifically, a point lying at either the head or the tail of the line is the "end-point", which is the special case of "on-a-line". (2) Point and Circle: "centre-point" and "on-a-circle." The "centre-point" relation refers to a point being the centre point of the circle. The "on-a-circle" relation occurs when a point lies on the arc of the circle. Finally, the probabilities ($P(\mathrm{rel}_{g_i,g_j}^{geo2geo}|g_i, g_j)$) of the relations between geometric primitives g_i and g_j can be calculated as follows:

$$P = \mathrm{softmax}(\mathbf{W}_{rel}^{geo2geo}\mathrm{ReLU}(\mathbf{W}_1^{geo2geo}(\mathrm{vec}^{g_i} + \mathrm{vec}^{g_j}))) \quad (8)$$

where $\mathbf{W}_1^{geo2geo} \in \mathbb{R}^{h \times h}$ and $\mathbf{W}_{rel}^{geo2geo} \in \mathbb{R}^{3 \times h}$ are the trainable parameters (the number 3 refers to "no relation" and two relations from either Point and Line or Point and Circle). Please refer to Appendix A.2 for details on how to predict *geo2geo* relations during the inference stage.

3.4 Problem-Solving Module

Both the *sym2geo* and *geo2geo* relations are expressed in natural languages by the GOLD model, following the same format as the problem text $\mathcal{T}$ (please refer to Appendix B for the paradigm of converting *sym2geo* and *geo2geo* relations to natural language descriptions). Therefore, it is convenient to utilize the LLMs as the problem-solving module. Specifically, the problem text $\mathcal{T}$ and the natural language descriptions $\mathcal{L}$ are concatenated for the LLMs to generate the solution program $\mathcal{P}$. To illustrate the compatibility of our methods with LLMs, we employ three well-known models for problem-solving: T5-base (Raffel et al., 2020), Llama2-13b-chat (Touvron et al., 2023), and CodeLlama-13b (Rozière et al., 2023). The T5-base model is fine-tuned for the target solution programs. Conversely, for Llama2-13b-chat and CodeLlama-13b, we employ directive instructions to guide their solution generation process (please refer to Appendix C for the choice of instructions).

3.5 Training Objective

Given a dataset of geometry math problems. The training process begins with training the pre-parsing module to extract necessary features from the geometry diagrams. Following this, we focus on training three components: the symbol vector head, the geometric primitive vector head, and the relation-construction head. This training is guided by minimizing a joint loss function, which is defined as $L_{cons} = L_{g2g} + L_{t\_cls} + L_{s2g}$. The L_{g2g} loss represents the negative log-likelihood loss for accurately identifying the ground truth *geo2geo* relations. Meanwhile, the L_{t_cls} constitutes the negative log-likelihood loss for correctly categorizing the text symbols. Lastly, the L_{s2g} loss is the binary cross-entropy loss associated with the ground truth *sym2geo* relations. Once they are trained, and their parameters are fixed, we advance to the final stage of fine-tuning the problem-solving module.[2] During this stage, our objective is to minimize the L_{prog} loss, which is the negative log-likelihood loss for correct solution programs (please refer to Appendix D for more details of loss functions).

4 Experiments and Results

4.1 Experimental Setup

Our method was implemented using the PyTorch (Paszke et al., 2019) and HuggingFace (Wolf et al., 2020) libraries. For the pre-parsing module, we followed the training and parameter settings of the previous work (Zhang et al., 2022). We evaluated the dimensions of the embeddings over a range of {32, 64, 128}, and based on the model's performance in the validation set, we experimentally determined 64 as the optimal dimension size for the embeddings. We utilized the Adam optimizer with a learning rate of $1e^{-4}$ and weight decay of $1e^{-4}$ for training all modules. The symbol vector head, geometric primitive vector head, and relation-construction head were trained end-to-end for 50 epochs with a batch size of 20, while the problem-solving module (using T5-base) was fine-tuned for 30 epochs with a batch size of 10. All experiments were conducted on one NVIDIA A100 80GB GPU.

4.2 Datasets

Our experiments are conducted on three datasets: UniGeo (Chen et al., 2022), PGPS9K (Zhang et al., 2023), and Geometry3K (Lu et al., 2021). The UniGeo dataset comprises 14,541 problems, categorized into 4,998 calculation problems (CAL) and 9,543 proving problems (PRV), which are split into train, validate, and test subsets in a ratio of 7.0: 1.5: 1.5. The Geometry3K includes 3,002 problems, divided into train, validate, and test subsets following a 7.0: 1.0: 2.0 ratio. Since PGPS9K contains a partial Geometry3K dataset, we keep an exclusive set of 6,131 problems, of which 1000 problems are a test subset. Due to the absence of a validation subset in PGPS9K, we divide its training set to create a train-validation split in a 9.0: 1.0 ratio.

4.3 Evaluation Metrics

To compare against existing works, we adhere to the evaluation criteria from the original datasets for both our model and the baselines. For the UniGeo dataset, we utilize the top-10 accuracy metric, which measures the ratio of correct solution programs among the top ten predictions, aligning with the metric used by the authors of the UniGeo dataset. For the PGPS9K and Geometry3K datasets, we adopt a stricter metric, the top-3 accuracy, as recommended by the authors of the PGPS9K dataset. Note that our comparison involves matching the predicted solution program with the ground truth, which is more rigorous than merely comparing the numerical output derived from the solution program.[3]

4.4 Comparison with State-of-the-art Models

We evaluate the performance of our GOLD model (*using T5-base as its problem-solving module*) against state-of-the-art (SOTA) methods in solving geometry math problems. The selected baselines for this comparison include: 1. **PGSPNet** (Zhang et al., 2023): it integrates a combination of CNN and GRU encoders, which generate an encoded vector of the diagram that serves as the input aligning with the logic form to the solver module. 2. **Inter-GPS** (Lu et al., 2021): it parses both the problem text and the diagram into a formal language, subsequently feeding this into the solver. 3. **Geoformer** (Chen et al., 2022): it utilizes the VL-T5 model for the purpose of diagram encoding, then servers encoded embeddings to the transformer. 4. **NGS** (Chen et al., 2021): it uses the ResNet-101 for its encoding process, showcasing a different approach in handling the diagram encoding. 5. **Bert2Prog** (Chen et al., 2021): it leverages BERT and ResNet as encoders and an LSTM network for generating.

The results presented in Table 1 demonstrate that our GOLD model outperforms baselines across test subsets of all datasets. Specifically, when compared to Geoformer, the SOTA on the UniGeo dataset, our model exhibits a remarkable increase in accuracy: 12.7% on the UniGeo CAL and 42.1% on the UniGeo PRV. Compared to the SOTA model on PGPS9K and Geometry3K datasets, PGPSNet, the GOLD model surpasses it by 1.8% and 3.2% in accuracy, respectively. When using ground truth diagram annotations, the GOLD (GT) shows a significant improvement in accuracy on the PGPS9K

---

[2] Note that the fine-tuning step is only implemented when T5-base is used as the problem-solving module.

[3] This is grounded in the principle that a correct output can sometimes be produced by an incorrect solution program, indicating a failure in the model's understanding of the problem. For example, consider a problem where the correct answer is "5" and the correct program is "2 × 3 - 1". An incorrect program like "2 + 3" could still yield the correct output. Thus, generating the correct program is a more reliable indicator of the model's accurate problem comprehension.

Models	UniGeo CAL Test (%)	UniGeo Prv Test (%)	PGPS9K Test (%)	Geometry3K Test (%)
BERT2Prog	54.7†	48.0†	-	-
NGS	56.9†	53.2†	34.1‡	35.3‡
Geoformer	62.5†	56.4†	35.6‡	36.8‡
InterGPS	56.8	47.2	38.3	48.6
InterGPS (GT)	n/a	n/a	59.8‡	64.2‡
PGPSNet	53.2	42.3	58.8	59.5
PGPSNet (GT)	n/a	n/a	62.7‡	65.0‡
GOLD	**75.2**	**98.5**	**60.6**	**62.7**
GOLD (GT)	n/a	n/a	65.8	69.1

Table 1: Comparison results on the test subsets of chosen datasets. PGPSNet reported models' performances using the ground truth diagram annotations, where these models have "(GT)" behind them. We re-implemented these methods to get performances without GT annotations. Note that UniGeo lacks GT diagram annotations, so relevant cells are "n/a". "†" and "‡" indicates the results are from Chen et al., 2022 and Zhang et al., 2023, respectively.

and Geometry3K, with gains of 3.1% and 4.1% over PGPSNet (GT). Against InterGPS (GT), the improvements are at 6.0% and 4.9%, respectively. These results underline the effectiveness of the GOLD model in solving geometry math problems.

Moreover, our GOLD model distinguishes itself from approaches like InterGPS and PGPSNet, which rely on logic-form representations to describe diagrams. In contrast, GOLD inputs natural language descriptions to LLMs to generate solution programs. Using natural language leads to significant improvements across all datasets compared to InterGPS and PGPSNet, as evidenced in Table 1. Furthermore, models like Geoformer and NGS primarily encode diagrams into vectors. These approaches fall short in providing precise descriptions of the diagrams and limit the adoption of LLMs, thus leading to worse performances compared to our GOLD model. This highlights the importance of detailed and accurate diagram representations for tackling geometry math problems, where our GOLD model excels.

Worth mentioning is that the training for the symbol vector head, geometric primitive vector head, and relation-construction head of the GOLD model was exclusively conducted on the PGPS9K and Geometry datasets due to the lack of annotations in the UniGeo dataset. Despite this, the outstanding performance of the GOLD model on the test subset of UniGeo, as shown in Table 1, demonstrates its exceptional generalization capability.

4.5 Ablation Study on Natural Language Description

We assess our model's efficacy using three distinct diagram description formats: absence of diagram description, logic forms, and natural language descriptions. The comparative results are detailed in Table 2. When fine-tuning T5-base as the problem-solving module, Table 2 indicates that descriptions in natural language outperform those in logic-form, with 3.1% and 3.4% improvements on the test subsets of PGPS9K and Geometry3K, respectively.

	PGPS9K			Geometry3K		
	n/a	LF	NLD	n/a	LF	NLD
T5-base	22.3 ± *0.0*	57.5 ± *0.3*	**60.6** ± *0.3*	12.3 ± *0.0*	59.3 ± *0.5*	**62.7** ± *0.2*
Llama2-13b-chat	5.2 ± *0.0*	33.5 ± *0.4*	39.6 ± *0.2*	2.3 ± *0.0*	31.8 ± *0.3*	40.1 ± *0.4*
CodeLlama-13b	3.2 ± *0.0*	15.8 ± *0.0*	16.2 ± *0.0*	2.0 ± *0.0*	14.6 ± *0.0*	15.1 ± *0.0*

Table 2: Evaluation of the GOLD model on two datasets with no description (n/a), logic-forms (LF), and natural language descriptions (NLD). Both the mean and standard errors of the accuracy metrics are presented.

Conversely, when using Llama2-13b-chat (Llama2) and CodeLlama-13b (CodeLlama) as the problem-solving module, we implement instructions to guide the generation of answers. Since their generations differ from the ground truth, we opt to calculate the accuracy of choosing the correct option from given candidates. According to Table 2, using natural language descriptions significantly enhances the accuracy of the Llama2 model compared to using logic forms, demonstrating the greater compatibility of our natural language descriptions with models like Llama2. However, neither natural language descriptions nor logic forms yield satisfactory outcomes with CodeLlama, possibly due to a mismatch between the training corpus of CodeLlama and the description formats.

Lastly, we conduct experiments by excluding relevant modules used to generate the natural language descriptions and solely inputting the problem text $\mathcal{T}$ into the problem-solving module. The results in Table 2 show a substantial decline in the performance of the GOLD model across all selected LLMs, highlighting the importance of diagram descriptions provided by relevant modules of the GOLD model in solving geometry math problems.

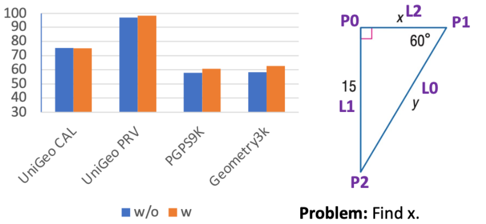
4.6 Accuracy of the Extraction of geo2geo and sym2geo Relations

Our analysis in Table 3 and measured by F1 metric, evaluates the accuracy of extracting geometric relations with and without emb_{feat} and emb_{spat} on PGPS9K test subset. We note that the pre-parsing stage achieves a high F1-score of 98.9%, ensuring accurate identification of symbols and geometric primitives for *sym2geo* and *geo2geo* relations extraction. However, when directly using $\mathbf{V}^{s,g}$ as vectors of symbols and geometric primitives (only using feature outputs from the pre-parsing step), the absence of emb_{feat} and emb_{spat} leads to a notable decrease in performance for both relations extraction. Conversely, the inclusion of either emb_{feat} and emb_{spat} results in improved performance. Table 3 further reveals that the extraction of both relation types reaches its highest F1-score when both embeddings are utilized. These results highlight the advantages of our approach in separately modelling symbols and geometric primitives, which proves to be more efficient in addressing the relation extraction of geometry math problems (please see Appendix G for the impact of emb_{feat} and emb_{spat} on problem-solving accuracy, and Appendix H for the ablation analysis for the emb^{g}_{type}).

emb_{feat}	emb_{spat}	pre-parsing	geo2geo	sym2geo
		98.9	65.2 ± *0.1*	58.6 ± *0.1*
✔		98.9	79.8 ± *0.3*	75.6 ± *0.5*
	✔	98.9	80.6 ± *0.4*	71.1 ± *0.2*
✔	✔	98.9	**93.7** ± *0.2*	**77.3** ± *0.1*

Table 3: The check mark (✔) indicates that the corresponding embedding is enabled. Note that "pre-parsing" is not influenced by emb_{feat} and emb_{spat}. Both the mean and standard errors of the accuracy metrics are presented. See Appendix E and F for the accuracy of fine-grained relations.

Table 3 shows that the GOLD model accurately captures *geo2geo* relation, prompting us to investigate its impact on solving geometry math problems. The bar chart in Figure 2 indicates a notable decline in model performance on the PGPS9K and Geometry3K datasets when *geo2geo* relations are omitted. However, this trend is less pronounced on the UniGeo datasets. This is likely because the PGPS9K and Geometry3K datasets often lack descriptions of geometric primitives in their problem texts. An example from the Geometry3K dataset, illustrated in Figure 2, demonstrates this issue: the problem text typically poses a question (e.g., "Find X") without extra information. Consequently, relying only on *sym2geo* relations leads to insufficient representation of essential diagram details.



Problem: Find x.

w/o: Line L2 and Line L0 cross at Point P1 has degree of 60. The length of Line L1 between Point P0 and Point P2 is 15. The length of Line L0 between Point P2 and Point P1 is y. The length of Line L2 between Point P0 and Point P1 is X. Line L2 is perpendicular with Line L1 at Point P0.

w: The diagram contains Line L0, which has endpoints: Point P1 and Point P2, the diagram contains Line L1, which has endpoints: Point P0 and Point P2, the diagram contains Line L2, which has endpoints: Point P0 and Point P1, …

Figure 2: Top-left: the performance of the GOLD (using T5-base) with (**w**) and without (**w/o**) the *geo2geo*. Top-right: Geometry math problem. Bottom: Predicted diagram description with and without the *geo2geo*. The same text between (**w**) and (**w/o**) is omitted for space consideration, where the red text is *geo2geo* relations.

5 Conclusion

In this work, we have introduced the GOLD model for automated geometry math problem-solving. GOLD uniquely converts geometry diagrams into natural language descriptions, facilitating direct integration with LLMs for problem-solving. A key feature of the GOLD model is that it separately handles symbols and geometric primitives, simplifying the process of establishing relations between symbols and geometric primitives and relations among geometric primitives themselves. Our experiments show that the GOLD model outperforms the Geoformer, the previous SOTA on the UniGeo dataset, with accuracy improvements of 12.7% and 42.1% on the UniGeo calculation and proving datasets, respectively. Additionally, compared to PGPSNet, the SOTA for the PGPS9K and Geometry3K datasets, the GOLD model shows notable accuracy improvements of 1.8% and 3.2%, respectively, showing our method's effectiveness.

6 Limitations

While our GOLD model marks a significant advancement in solving geometry math problems, areas remain for future improvement. For example, the GOLD model has not yet reached the level of human performance in solving geometry math problems. This gap is possibly due to the limitations in fully extracting geometric relations from diagrams. While GOLD accurately identifies symbols, geometric primitives, and *geo2geo* relations, the extraction of *sym2geo* relations still requires enhancement. Moreover, this study evaluated three popular large language models (LLMs): T5-bases, Llama2-13b-chat, and CodeLlama-13b. To deepen our understanding and leverage the full potential of LLMs in solving geometry math problems, it would be beneficial to assess more LLMs. This broader evaluation could provide more comprehensive insights into optimizing LLMs for this specific task.

A Inference

During the inference stage, we employ Eq 4 and Eq 5 to map symbols $s \in \mathcal{S}$ and geometric primitives $g \in \mathcal{G}$ to corresponding vectors $\mathrm{vec}^{s\in\mathcal{S}}$ and $\mathrm{vec}^{g\in\mathcal{G}}$, respectively. Following this, we proceed with the inference of *sym2geo* and *geo2geo* relations.

A.1 Predict sym2geo Relation

For a text symbol $s \in \{\mathcal{S}|\mathrm{cls}_s = \text{"text"}\}$, it is necessary to determine its meaning based on its *text_class*. To accomplish this, we assign the category of text symbol $s \in \{\mathcal{S}|\mathrm{cls}_s = \text{"text"}\}$ as the one with the highest probability among the $P(\textit{text\_class}|s)$ values, as specified in Eq 6:

$$\textit{text\_class}_s = \textit{argmax}P(\textit{text\_class}|s) \tag{9}$$

- if $\textit{text\_class}_s$ is 0 (i.e., category *0*), it indicates that the symbol s corresponds to the reference name of a point, or a line, or a circle. In this case, we assign the symbol s to the geometric primitive g that has the highest probability of $P(\mathrm{rel}^{sym2geo}_{s\in\{\mathcal{S}|\mathrm{cls}_s=\text{"text"}\},g\in\{\mathbf{P},\mathbf{L},\mathbf{C}\}}|s,g)$, where $g \in \{\mathbf{P},\mathbf{L},\mathbf{C}\}$ specifies that the geometric primitive g belongs to the set of points, lines, and circles:

$$g = \textit{argmax}P(\mathrm{rel}^{sym2geo}_{s\in\{\mathcal{S}|\mathrm{cls}_s=\text{"text"}\},g\in\{\mathbf{P},\mathbf{L},\mathbf{C}\}}|s,g) \tag{10}$$

- if $\textit{text\_class}_s$ is 1 (i.e., category *1*), it indicates that the symbol s represents the degree of an angle. Since an angle consists of two lines and one point, we select the point with the highest probability $P(\mathrm{rel}^{sym2geo}_{s\in\{\mathcal{S}|\mathrm{cls}_s=\text{"text"}\},g\in\{\mathbf{P}\}}|s,g)$, and we select the two lines with the top two highest probabilities $P(\mathrm{rel}^{sym2geo}_{s\in\{\mathcal{S}|\mathrm{cls}_s=\text{"text"}\},g\in\{\mathbf{L}\}}|s,g)$. It is worth mentioning these two lines must have *geo2geo* relations of "end-point" or "on-a-line" with the selected point.

$$\begin{aligned}
&p = \textit{argmax}P(\mathrm{rel}^{sym2geo}_{s\in\{\mathcal{S}|\mathrm{cls}_s=\text{"text"}\},g\in\{\mathbf{P}\}}|s,g)\\
&l_1,l_2 = \textit{argmax}_{two}P(\mathrm{rel}^{sym2geo}_{s\in\{\mathcal{S}|\mathrm{cls}_s=\text{"text"}\},g\in\{\mathbf{L}\}}|s,g),\\
&\text{where } rel_{l_1,p} \in \{\text{"end-point"‘, "on-a-line"}\} \text{ and}\\
&rel_{l_2,p} \in \{\text{"end-point"‘, "on-a-line"}\}
\end{aligned} \tag{11}$$

- if $\textit{text\_class}_s$ is 2 (i.e., category *2*), it indicates that the symbol s represents the length of a line. Since a line consists of two points, we select the points with the top two highest probabilities $P(\mathrm{rel}^{sym2geo}_{s\in\{\mathcal{S}|\mathrm{cls}_s=\text{"text"}\},g\in\{\mathbf{P}\}}|s,g)$:

$$p_1,p_2 = \textit{argmax}_{two}P(\mathrm{rel}^{sym2geo}_{s\in\{\mathcal{S}|\mathrm{cls}_s=\text{"text"}\},g\in\{\mathbf{P}\}}|s,g) \tag{12}$$

- if $\textit{text\_class}_s$ is 3 (i.e., category *3*), it indicates that the symbol s represents the degree of an angle on the circle. In this case, the angle is formed by the centre point of a circle and two points lying on the arc of a circle. Therefore, we first select the circle with the highest probability of $P(\mathrm{rel}^{sym2geo}_{s\in\{\mathcal{S}|\mathrm{cls}_s=\text{"text"}\},g\in\{\mathbf{C}\}}|s,g)$. Subsequently, we select two points with the top two highest probabilities $P(\mathrm{rel}^{sym2geo}_{s\in\{\mathcal{S}|\mathrm{cls}_s=\text{"text"}\},g\in\{\mathbf{P}\}}|s,g)$. Worth mentioning, these two points must be on the arc of the selected circle:

$$\begin{aligned}
&c = \textit{argmax}P(\mathrm{rel}^{sym2geo}_{s\in\{\mathcal{S}|\mathrm{cls}_s=\text{"text"}\},g\in\{\mathbf{C}\}}|s,g)\\
&p_1,p_2 = \textit{argmax}_{two}P(\mathrm{rel}^{sym2geo}_{s\in\{\mathcal{S}|\mathrm{cls}_s=\text{"text"}\},g\in\{\mathbf{P}\}}|s,g),\\
&\text{where } rel_{p_1,c} = rel_{p_2,c} = \text{"on-a-circle"}
\end{aligned} \tag{13}$$

For the geometric relations among geometric primitives, such as parallel. It is determined by the *other2geo* relation. For the *other2geo* relation involving other symbols, it is required that the relation holds with at least two geometric primitives. This means that there should be at least two geometric primitives with probabilities $P(\mathrm{rel}^{sym2geo}_{s,g}|s,g)$ larger than a threshold θ. In this case, the geometric primitives are selected based on this criterion.

$$\begin{aligned}
&\{g_{\text{indices}}\} = \text{sorted}(P(\mathrm{rel}^{sym2geo}_{s\in\{\mathcal{S}|\mathrm{cls}_s\neq\text{"text"}\},g\in\{\mathbf{P},\mathbf{L},\mathbf{C}}\}|s,g)) > \theta\\
&g_{\text{selected}} = \mathcal{G}[\{g_{\text{indices}}\}]
\end{aligned} \tag{14}$$

where "sorted" indicates that values are sorted in descending order, and [] refers to the selection from the geometric primitives group $\mathcal{G}$ according to the indices $\{g_{\text{indices}}\}$. The threshold θ is set as 0.5 experimentally.

A.2 Predict geo2geo Relation

The *geo2geo* relation between geometric primitives g_i and g_j is determined based on Eq 8, where it is assigned as the relation with the highest probability:

$$rel_{g_i, g_j \in \mathcal{G}} = argmaxP(\mathrm{rel}_{g_i, g_j}^{geo2geo} | g_i, g_j) \tag{15}$$

In an ideal scenario, the OCR results would accurately provide references to the points, lines, and circles, allowing us to extract precise information about the geometric primitives. However, the open-source OCR tool[4] we have adopted is not accurate. As a result, some primitives may lack reference names. To address this issue, we automatically label the primitives in sequential order (e.g., "P1, P2, L1, L2") if their reference names are missing.

A.3 Generate Solution Program

Once the *geo2geo* and *sym2geo* relations are constructed, we proceed to convert them into natural language descriptions $\mathcal{L}$ (See Appendix B for details). We then concatenate the natural language descriptions $\mathcal{L}$ with the problem text $\mathcal{T}$. This combined text is passed to the problem-solving module, which employs BeamSearch with a beam size of 10 to generate the solution program $\mathcal{P}$. Moreover, when using larger LLMs, such as Llama2, we add instructions in front of the concatenation of $\mathcal{L}$ and $\mathcal{T}$, which is further sent to LLMs to generate reasoning process.

B Convert Relations to Natural Language Descriptions

Once the *geo2geo* relations and *sym2geo* relations have been established, we proceed to convert these relations into natural language descriptions denoted as $\mathcal{L}$ following the guidelines specified in Table 4.

To begin, we initiate the process by representing the existing geometric primitives in the diagram by enumerating points, lines, and circles within the description of the *geo2geo* relation. In detail, we sequentially enumerate all existing points, providing their reference names as described in the "Point" entry of Table 4. We describe the associated points for each line by mentioning their reference names. Additionally, we include a list of points that have "end-point" and "on-a-line" relations with the line, as specified in the "Line" entry of Table 4. Similarly, for each circle, we mention its reference name and proceed to list the points that exhibit "center-point" and "on-a-circle" relations with the circle, following the guidelines provided in the "Circle" entry of Table 4.

Next, we proceed to describe the *text2geo* relation within the *sym2geo* relation based on the predicted *text_class*. Here are the guidelines for each case:

- If the *text_class* indicates that the symbol refers to the reference name of a point (or a line, or a circle), we modify the name of the corresponding point (or line, or circle) accordingly.
- If the *text_class* indicates that the symbol refers to the degree of an angle, we describe it following the guidelines specified in the "Degree" entry of Table 4.
- If the *text_class* indicates that the symbol refers to the length of a line, we describe it according to the instructions provided in the "Length" entry of Table 4.
- If the *text_class* indicates that the symbol refers to the degree of an angle on the circle, we describe it based on the guidelines outlined in the "Circle Degree" entry of Table 4.

Furthermore, when dealing with the *other2geo* relations, we describe them based on the specific type of geometric relation as indicated in Table 4.

C Instruction Choice

Instructions serve as direct and explicit commands that clearly communicate to the model the specific task it is required to perform. For our experiments, we initially selected two distinct instruction templates for Llama2-13b-chat (Touvron et al., 2023) and CodeLlama-13b (Rozière et al., 2023), as detailed in Table 5. Upon experimental evaluation, it was observed that the instruction template modified from the one used to train the Llama2 model (displayed at the upper row in Table 5) demonstrated superior performance. Consequently, we opted for this template in our work.

D Loss Function Details

The L_{g2g} is defined as the negative log-likelihood loss, where we aim to minimize the negative log-likelihood of the ground truth relations among geometric primitives:

$$L_{g2g} = - \sum_{g_i \in \mathbf{P}} \sum_{g_j \in \mathbf{L}, \mathbf{C}} \log(P(\mathrm{rel}_{g_i, g_j}^{geo2geo} | g_i, g_j)) \tag{16}$$

where g_i is a geometric primitive belonging to points, and g_j is a geometric primitive belonging to

---

	Relations	Paradigm	Example
geo2geo	Point	The diagram contains ${}.	The diagram contains **Point A**, **B**, **C**.
	Line	The diagram contains ${}, which has endpoints: ${} and ${}, In addition, there is/are ${} on the line.	The diagram contains **Line L1**, which has endpoints: **Point P0** and **Point P1**, In addition, there is/are **Point P2** on the line.
	Circle	The diagram contains ${}, whose center point is ${}, which has ${} on its arc.	The diagram contains **Circle M**, whose center point is **Point E**, which has **Point F**, **Point G** on its arc.
text2geo	Degree	1. Angle ${} has degree of ${}. 2. Line ${} and Line ${} cross at Point ${} has degree of ${}.	1. Angle **1** has degree of **100**. 2. Line **L1** and Line **L2** cross at Point **C** has degree of **50**.
	Length	The length of Line ${} between Point ${} and Point $ is ${}.	The length of Line **L3** between Point **A** and Point **B** is **10**.
	Circle Degree	Line ${} and Line ${} cross at the center point ${} of Circle ${} has degree of ${}.	Line **L1** and Line **L2** cross at the center point **C** of Circle **C0** has degree of **20**.
other2geo	same degree	Angle ${} has the same degree with Angle ${} ...	Angle **1** has the same degree with Angle **2**, Angle **3**.
	same length	Line ${} has the same length with Line ${} ...	Line **L1** has the same length with Line **L2**, Line **L3**.
	parallel	Line ${} is parallel with Line ${}...	Line **a** is parallel with Line **b**.
	perpendicular	Line ${} is perpendicular with Line ${} at Point ${}.	Line **L1** is perpendicular with Line **L2** at Point **C**.

Table 4: The defined paradigm used to convert *geo2geo* and *sym2geo* relations to natural language descriptions $\mathcal{L}$. "${}" is the placeholder. The placeholder is filled in as demonstrated in the "Example" column, and the filled content is highlighted in bold type.

lines and circles. The $\text{rel}^{geo2geo}_{g_i,g_j}$ refers to the ground truth relation between g_i and g_j.

The L_{t_cls} is defined as the negative log-likelihood loss, where we aim to minimize the negative log-likelihood of the ground truth *text_class* of the text symbol:

$$L_{t\_cls} = -\sum_{S} \log(P(\textit{text\_class}_s|s)) \tag{17}$$

where text_class$_s$ is the ground truth $text\_class$ of the symbol s.

The L_{s2g} is the binary cross-entropy loss:

$$L_{s2g}=-\sum_{s\in\mathcal{S}}\sum_{g\in\mathcal{G}}\{\mathbb{I}(s,g)\times\log(P(\text{rel}^{sym2geo}_{s,g}|s,g)) + (1-\mathbb{I}(s,g))\times(1-\log(P(\text{rel}^{sym2geo}_{s,g}|s,g))\} \tag{18}$$

where $\mathbb{I}(s,g)$ is 1 if there is relation between symbol s and geometric primitive g, otherwise it is 0.

The L_{prog} is defined as the negative log-likelihood loss, where we aim to minimize the negative log-likelihood of the tokens of the ground truth solution programs:

$$L_{prog} = -\sum_{i} \log(P(t_i|t_{<i})) \tag{19}$$

where i is the i-th token in the ground truth solution program.

E Image Parsing Accuracy

Table 6 presents the performance of the image-parsing module, measured using the F1 metric. For geometric primitives, we employ the parsing position evaluation method, utilizing the Hough transform with a distance threshold of 15. For symbols, we use an Intersection over Union (IoU) threshold of 0.5. The results in Table 6 demonstrate that the image-parsing module delivers accurate parsing results for diagrams, providing the model with precise information.

F Relation Prediction Accuracy

Table 7 displays the F1 metric for the performance of relation parsing. The results show that our GOLD model accurately predicts *geo2geo* relations. However, for *sym2geo* relations, except for the "parallel" relation, there is considerable room for improvement in the prediction performance.

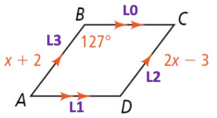
G Influence of feature_embedding and spatial_embedding on Geometry Problem Solving

We conduct ablation study on *feature_embedding* and *spatial_embedding* in Table 8. To discard the use of (emb_{feat} and emb_{spat}), we directly use feature outputs from the pre-parsing step as vectors of symbols and geometric primitives, i.e., $\mathbf{V}^{s,g}$, to construct the *sym2geo* and *geo2geo* relations. We can observe that the GOLD model without any embedding performs the worst on all test subsets. However, when either one of embeddings (emb_{feat} or emb_{spat}) is added, the model's performance improves. Notably, the model equipped with both embeddings achieves the best performance.

emb_{feat}	emb_{spat}	CAL	PRV	PGPS9K	Geometry3K
		66.2 ± *0.3*	90.2 ± *0.2*	48.2 ± *0.5*	50.2 ± *0.3*
✔		71.5 ± *0.3*	93.2 ± *0.4*	55.0 ± *0.1*	58.1 ± *0.1*
	✔	72.8 ± *0.2*	93.0 ± *0.3*	56.3 ± *0.1*	58.0 ± *0.2*
✔	✔	**75.2** ± *0.3*	**98.5** ± *0.5*	**60.6** ± *0.3*	**62.7** ± *0.2*

Table 8: Program accuracy with or without *feature_embedding* and *spatial_embedding*. The check mark (✔) indicates that the corresponding embedding is enabled. T5-base is used as the problem-solving module for the GOLD model. Both the mean and standard errors of the accuracy metrics are presented.



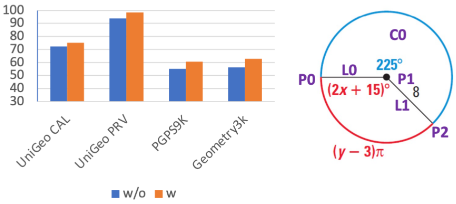
Problem: Use the diagram of parallelogram ABCD to find angle A?

w/o solution program: sum (x + 2) 127
w solution program: subtract 180 127

w/o: The diagram contains Point B, C, D, A, the diagram contains Line L0, which has endpoints: Point B and Point C, the diagram contains Line L1, which has endpoints: Point D and Point A, the diagram contains Line L2, which has endpoints: Point C and Point D, the diagram contains Line L3, which has endpoints: Point B and Point A, Line L0 and Line L3 cross at Point B has degree of 127. The length of L3 between Point A and Point B is x + 2. The length of L2 between Point C and Point D is 2x - 3. Line L3 is parallel with Line L2 , Line L0, Line L1.

w: The diagram contains Point B, C, D, A, the diagram contains Line L0, which has endpoints: Point B and Point C, the diagram contains Line L1, which has endpoints: Point D and Point A, the diagram contains Line L2, which has endpoints: Point C and Point D, the diagram contains Line L3, which has endpoints: Point B and Point A, Line L0 and Line L3 cross at Point B has degree of 127. The length of L3 between Point A and Point B is x + 2. The length of L2 between Point C and Point D is 2x - 3. Line L3 is parallel with Line L2, Line L1 is parallel with Line L0.

Figure 3: An example from the *111*-th problem in the PGPS9K dataset. This case shows that models' natural language descriptions and solution programs outputs with and without *spatial_embedding*. The purple notations in the diagram are added by us. Note that the different parts of diagram descriptions between **w/o** and **w** are coloured red.



w/o: the diagram contains Point P0, P1, P2, the diagram contains Line L0, which has endpoints: P0 and P1, the diagram contains Line L1, which has endpoints: P1 and P2.

w: ..., the diagram contains Circle C0, whose center point is Point P1, which has Point P0, Point P2 on its arc.

Figure 4: The top-left bar chart compares GOLD (T5-base as the problem-solving module) accuracy in solving geometry math problems, with (**w**) and without (**w/o**) the use of *geo_type_embedding*. The top-right diagram is from the 375th problem in the PGPS9K dataset, while the bottom part shows the predicted diagram descriptions for two different cases. Purple notations in the diagram are added for better visual comprehension. The differences between the two diagram description texts are highlighted in red. It should be noted that the same texts in the **w** to the **w/o** section are omitted, which are represented by "...".

In Figure 3, we conduct a case study on the GOLD model with and without the use of *spatial_embedding*. It is evident that the model without *spatial_embedding* incorrectly generates the "parallel" relation between lines, resulting in an erroneous solution program. This highlights the importance of *spatial_embedding* in capturing accurate spatial relations and improving the model's performance.

H Importance of the geo_type_embedding

We conducted experiments to assess the impact of *geo_type_embedding* (emb^{g}_{type}). The top-left bar chart in Figure 4 demonstrates that the model's performance declines when emb^{g}_{type} is not utilized. Notably, the performance gaps between the model with emb^{g}_{type} and without it are more pronounced on the PGPS9K and Geometry3K datasets compared to the UniGeo datasets. We believe this is because the problem text in the UniGeo dataset explicitly mentions the geometric primitives, providing valuable information that helps the GOLD model understand the geometric primitives more effectively. Furthermore, as shown in Figure 4, the GOLD model without emb^{g}_{type} fails to generate accurate circle information, impeding its ability to further generate correct solution programs.

RoDia: A New Dataset for Romanian Dialect Identification from Speech

Codruţ Rotaru[1] and **Nicolae Cătălin Ristea**[1,2] and **Radu Tudor Ionescu**[1]
[1]University of Bucharest, Romania
[2]National University of Science and Technology Politehnica Bucharest, Romania
Corresponding author: `raducu.ionescu@gmail.com`

Abstract

We introduce RoDia, the first dataset for Romanian dialect identification from speech. The RoDia dataset includes a varied compilation of speech samples from five distinct regions of Romania, covering both urban and rural environments, totaling 2 hours of manually annotated speech data. Along with our dataset, we introduce a set of competitive models to be used as baselines for future research. The top scoring model achieves a macro F_1 score of 59.83% and a micro F_1 score of 62.08%, indicating that the task is challenging. We thus believe that RoDia is a valuable resource that will stimulate research aiming to address the challenges of Romanian dialect identification. We release our dataset at `https://github.com/codrut2/RoDia`.

1 Introduction

Spoken dialect identification emerged as a challenging task aiming to achieve a fine-grained distinction between varieties of a certain language, having similar implications to spoken language identification (Barnard et al., 2014; Kimanuka et al., 2024; Ma et al., 2007). Despite being a more delicate task, spoken dialect identification received comparatively lower attention, most of it being devoted to dialect identification for widely spoken languages, such as English (Weinberger and Kunath, 2011), Chinese (Zhang et al., 2022), and Arabic (Ali et al., 2017, 2019; Shon et al., 2020). Spoken dialect identification for low-resource languages, such as Swiss German (Dogan-Schönberger et al., 2021; Plüss et al., 2023) and Finnish (Hämäläinen et al., 2021), has remained relatively underexplored (Ranathunga et al., 2023; Barnard et al., 2014; Hämäläinen et al., 2021). Different from prior studies, we focus on spoken language identification in Romanian, a low-resource language characterized by its intricate dialectal variations within the country of Romania. Romanian, a Romance language with Latin roots, boasts a rich linguistic landscape shaped by historical, geographical, and sociocultural factors (Barbu-Mititelu et al., 2018). However, despite its linguistic complexity, Romanian remains a low-resource language, with limited studies dedicated to understanding its regional linguistic diversity. This scarcity of resources is not unique to Romanian, numerous other languages around the world having similar challenges due to their lower visibility on the global linguistic stage (Ranathunga et al., 2023; Barnard et al., 2014; Hämäläinen et al., 2021). Notably, the VarDial workshop is one of the main drivers for growing the interest around language variety and dialect identification, through the organization of multiple shared tasks each year (Aepli et al., 2022; Chakravarthi et al., 2021; Gaman et al., 2020; Zampieri et al., 2019).

Due to the success of deep learning frameworks in speech processing (Mehrish et al., 2023), researchers started to employ such methods in the area of low-resource languages (Chan and Lane, 2015; Al-Ghezi et al., 2023). This has led to a growing need for resources on low-resource languages. Considering dialect identification datasets across different languages, we can distinguish between two types of resources: text-based datasets (Bouamor et al., 2018; Butnaru and Ionescu, 2019; Francom et al., 2014; Găman et al., 2023; Găman and Ionescu, 2022) and speech-based datasets (Ali et al., 2017, 2019; Shon et al., 2020; Dogan-Schönberger et al., 2021; Plüss et al., 2023; Hämäläinen et al., 2021). While various languages have benefited from text-based resources that leverage written materials capturing linguistic variations, the auditory dimension of dialects adds an intricate layer of complexity. Text data, although valuable, might not fully encapsulate the nuanced phonetic and prosodic characteristics that are pivotal in dialect differentiation. In contrast to text datasets, audio datasets (Ali et al., 2017, 2019; Shon et al.,

Findings of the Association for Computational Linguistics: NAACL 2024, pages 279–286
June 16-21, 2024

Figure 1: The administrative regions of Romania and the dominant dialect spoken within each region. RoDia is the first benchmark to contain samples representing these five Romanian dialects.

2020; Dogan-Schönberger et al., 2021; Plüss et al., 2023) offer a more holistic representation, capturing not only the lexical disparities, but also the subtle intonations and accents inherent in speech.

To the best of our knowledge, RoDia is the first dataset to tackle spoken dialect identification in the Romanian landscape in accordance with historical, geographical, and sociocultural factors, encouraging the research in this low-resource language. Although there are two text datasets addressing Romanian dialect identification, MOROCO (Butnaru and Ionescu, 2019) and MOROCO-Tweets (Găman and Ionescu, 2022), these cover only two dialects: Romanian (equivalent to the *Muntenesc* dialect) and Moldavian (*Moldovenesc*). In contrast, our dataset is focused on speech and covers five Romanian dialects, as shown in Figure 1. We underline that the extra dialects, namely *Ardelenesc*, *Bănăţean*, and *Oltenesc*, are very well characterized by phonetic differences captured only in speech. This explains why MOROCO (Butnaru and Ionescu, 2019) and MOROCO-Tweets (Găman and Ionescu, 2022) only contain text samples from the other two dialects.

The number of audio datasets available in Romanian is rather low (Avram et al., 2022; Georgescu et al., 2020), confirming that Romanian is indeed a low-resource language. We underline that existing datasets comprising Romanian speech samples are mainly focused on automatic speech recognition, ignoring the diversity of dialects within the region. In contrast, our dataset is specifically designed to represent five distinct dialects spoken in Romania: *Muntenesc* (accepted as the official language of Romania), *Ardelenesc*, *Moldovenesc*, *Oltenesc*, and *Bănăţean*[1].

2 Dataset

Data collection and annotation. We collected the vast majority of the audio samples by gathering interviews and shows from local TV channels from all five regions considered in the dataset (see Figure 1). To obtain a clean dataset, we employed a rigorous selection process. First, we manually cropped the gathered audio files with respect to each speaker, e.g. we split an interview into multiple samples, such that each sample contains a single speaker. Next, we discard samples with interfering speakers and with a low perceived intelligibility. To make sure the label assignment is robust, we submitted all samples gathered from the TV channels to local annotators to validate the assigned labels. The manual validation process eliminates samples with a questionable dialect. In addition, a small proportion of data was acquired by recording citizens native to the five regions, who were asked to read some random texts from the Romanian Wikipedia, in their own dialect. We cropped the recorded samples to minimize the amount of silence at the start and the end of each audio sample. Upon curating the gathered data, we are left with a clean dataset containing $2{,}768$ audio samples, each having between 2.5 and 5.0 seconds of speech. The sample rate of all samples is 44.1 kHz.

We divide the dataset into $2{,}164$ samples for training and 604 samples for testing, such that there is no overlap between speakers in training and test. Without separating the speakers between training and test, a model that overfits to certain speaker-specific features that are not related to dialect (e.g. pitch, loudness, rate, etc.) will reach high scores on the test set. However, these scores are unlikely to represent the actual performance of the model in a real-world scenario, where the audio samples come from unknown speakers. We thus consider that a more realistic evaluation is to separate the speakers. In the proposed setting, models that learn patterns related to speakers will not be able to capitalize on features unrelated to dialect identification.

There are five local annotators (one per region), who annotated all samples. The inter-rater Quadratic Weighted Kappa score is 0.83, indicating that the collected labels exhibit a substantial

---

[1] We refer to the original (untranslated) dialect names, since most of them have no translation in English.

Class	#speakers	Train			Test		
		#samples	SNR	SRR	#samples	SNR	SRR
Ardelenesc	47	427	28.8	36.4	119	30.5	38.5
Bănăţean	67	424	23.1	34.6	99	25.0	37.7
Moldovenesc	47	384	25.6	32.4	206	25.7	27.8
Muntenesc	64	603	29.0	35.3	106	26.7	37.8
Oltenesc	31	326	26.6	31.2	74	26.5	33.7
Overall	256	2164	26.9	34.2	604	26.8	34.0

Table 1: The number of training and test samples for each class in our dataset. For reference, we include the average SNR and SRR values for each category. The number of speakers per dialect is also provided.

agreement among human evaluators. The average accuracy of our raters is 86%, indicating that the task is fairly easy for humans. Note that all raters are native Romanian speakers who speak the literary language, as well as at least one of the five dialects.

The collected samples comprise interviews and read speech found on YouTube. The read speech is actually gathered from videos where various speakers read from different books (without any influence or preparation from our side). The percentage of read speech is 21%.

Aside from dialect labels, our annotators also labeled each audio sample with the gender and age of each speaker. More precisely, the age and gender of each speaker is estimated by two annotators who had to analyze both video and audio modalities. The age annotation consists in classifying each speaker into a 10-year age group, after watching the video available for the respective speaker. In summary, our audio samples come with dialect, age and gender labels, enabling the study of additional tasks such as gender prediction or age estimation from speech.

Dataset statistics. For a more comprehensive view, we present both demographic information and audio quality statistics for our new dataset. In Table 1, we report the number of samples for each dialect in both train and test splits, as well as the signal-to-noise ratio (SNR) and signal-to-reverberation ratio (SRR). Regarding data quality, we note that the SNR and SRR values are consistently higher than 23 dB, highlighting that the audio samples have relatively low noise and reverberation. The *Muntenesc* dialect has the largest number of audio samples. This dialect was easy to collect, since it represents the literary language, which is often borrowed by speakers native to other regions. On the opposite side, the *Oltenesc* dialect is least represented, having only 400 audio samples. However, the distribution gap between the five classes is not high enough to pose significant challenges to machine learning models.

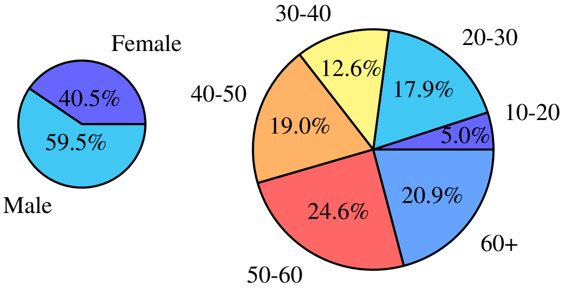


Figure 2: Age and gender statistics for the RoDia dataset.

We present demographic information in Figure 2. In terms of demographic insights, RoDia exhibits a relatively balanced gender distribution, having 59.5% male and 40.5% female speakers. Aside from separating the speakers between training and test, we also made sure to have similar demographics for the train and test splits, reducing unnecessary distribution gaps. In summary, we consider that RoDia is a suitable resource for spoken dialect identification.

3 Experiments

Baseline methods. We compile a lineup of four state-of-the-art neural architectures for speech processing to form a set of competitive dialect identification baselines for our novel dataset. We consider both convolutional (He et al., 2016) and transformer-based neural networks (Gong et al., 2021; Ristea et al., 2022), as well as a hybrid architecture (Baevski et al., 2020). We employ the ResNet-18 (He et al., 2016) convolutional network, as it was previously used for audio classification tasks (Ristea and Ionescu, 2020). Additionally, we explore two transformer-based architectures, namely the Audio Spectrogram Transformer (AST) (Gong et al., 2021) and the Separable Transformer (SepTr) (Ristea et al., 2022), due to their high performance in audio classification. We also employ the wav2vec 2.0 model (Baevski et al., 2020),

Model	Ardelenesc			Bănăţean			Moldovenesc			Muntenesc			Oltenesc			Overall F_1	
	P	R	F_1	P	R	F_1	P	R	F_1	P	R	F_1	P	R	F_1	Micro	Macro
ResNet-18	59.45	73.94	65.91	47.54	58.58	52.48	73.98	62.13	67.54	44.11	56.60	49.58	88.00	29.72	44.44	58.94	55.99
AST	66.92	73.10	69.87	43.62	65.65	52.41	77.92	58.25	66.66	48.96	66.98	56.57	92.30	32.43	48.00	60.76	58.70
SepTr	67.71	72.26	69.91	41.31	69.69	51.87	81.75	58.73	68.36	53.33	67.92	59.75	85.18	31.08	45.54	61.42	59.08
wav2vec 2.0	68.00	71.42	69.67	43.13	66.66	52.38	77.63	60.67	68.10	54.34	70.75	61.47	88.88	32.24	47.52	62.08	59.83

Table 2: Spoken dialect identification results of ResNet-18 (He et al., 2016), AST (Gong et al., 2021), SepTr (Ristea et al., 2022) and wav2vec 2.0 (Baevski et al., 2020) on the RoDia test set. For a comprehensive evaluation, we report both per dialect and overall results. The best score on each column is highlighted in blue.

which uses a hybrid architecture combining the advantages of both convolutional and transformer blocks. All models are trained in the multi-class setting, since the ground-truth labels are constructed in a similar manner: one audio sample belongs to only one dialect.

Preprocessing. For models operating in the time-frequency domain (He et al., 2016; Gong et al., 2021; Ristea et al., 2022), we apply the Short-Time Fourier Transform with a window size of 512 and a hop size of 256. Then, we compute the square root of the magnitude, obtaining the spectrogram map. The other steps and parameters are exactly as described in the original papers. For wav2vec 2.0 (Baevski et al., 2020), we apply the preprocessing steps described by the authors, which are mainly used for normalization. In all our experiments, we use the following data augmentation methods: noise perturbation, time shifting, speed perturbation, mix-up and SpecAugment (Park et al., 2019).

Evaluation metrics. We report the precision (P), recall (R), and F_1 scores computed for each dialect. These metrics provide insights into the ability of models to correctly classify instances within each class. To quantify the overall performance, we aggregate the individual scores via the micro and macro F_1 measures. The micro F_1 score combines the performance metrics across all examples, while the macro F_1 score offers a balanced average of the F_1 scores across all classes.

Training environment. All models are optimized on an Nvidia GeForce GTX 3090 GPU with 24 GB of VRAM.

Hyperparameter tuning. For each model, we employed grid search to find the optimal learning rate (between 10^{-2} and 10^{-6}) and the optimal batch size (between 8 and 128 samples). We take the wav2vec 2.0 (Baevski et al., 2020) model, which is pretrained on English data, and fine-tune it for 10 epochs on RoDia using a learning rate of 10^{-5} and mini-batches of 16 samples. We train ResNet-18, AST (Gong et al., 2021) and SepTr (Ristea et al., 2022) from scratch. The models are trained for 50 epochs with early stopping, using a learning rate of 10^{-4} and mini-batches of 32 samples. All models are optimized with the Adam optimizer (Kingma and Ba, 2015).

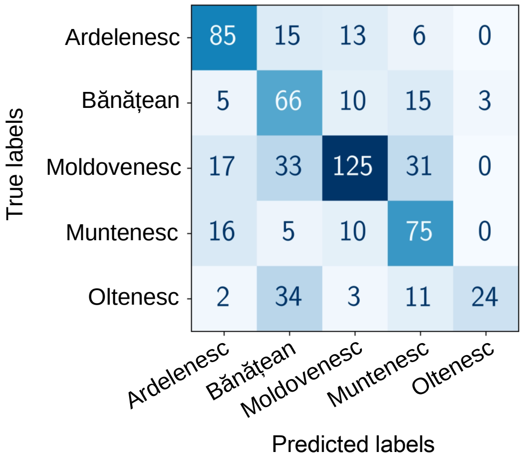

Figure 3: Confusion matrix on the test set for the wav2vec 2.0 (Baevski et al., 2020) model.

Dialect identification results. In Table 2, we present the spoken dialect identification results of the baseline models on the RoDia test set. The convolutional network, ResNet-18, obtains the lowest overall performance. Still, ResNet-18 reaches competitive F_1 scores for the *Bănăţean* and *Moldovenesc* dialects. Unlike the other baselines, the ResNet-18 model struggles with the *Muntenesc* and *Ardelenesc* dialects, which explains its low overall performance. The transformer-based models, AST (Gong et al., 2021) and SepTr (Ristea et al., 2022), yield superior results, with a slight upper hand from the SepTr model. In terms of the overall F_1 scores, the best model appears to be wav2vec 2.0 (Baevski et al., 2020). However, the F_1 scores per dialect seem to tell a slightly different story, since the wav2vec 2.0 is outperformed by at least one of the other models on four dialects: *Ardelenesc*, *Bănăţean*, *Moldovenesc* and *Oltenesc*. The competitive edge of wav2vec 2.0 lies in its ability to better identify the *Muntenesc* dialect. We underline that the audio samples were recorded in uncontrolled scenarios, so the reported results directly reflect the capability of systems in the real-world case.

To further assess the behavior of the best baseline model, namely wav2vec 2.0, we consider its confusion matrix illustrated in Figure 3. The confusion matrix reveals some interesting patterns. While the model tends to mislabel samples from the *Oltenesc* dialect, we observe that most of these mistakes are caused by a high confusion with the *Bănăţean* dialect. Since Banat and Oltenia are neighboring regions, there are several similarities between these two dialects. For instance, both dialects are characterized by the frequent use of the perfect simple tense, which is hardly encountered in the other Romanian dialects. Another noticeable problem is with the *Moldovenesc* dialect, which is often wrongly identified as *Bănăţean* and *Muntenesc*. The confusion between the *Moldovenesc* and *Bănăţean* dialects is caused by the fact these two dialects kept the form of words such as *câne* (dog), *pâne* (bread) and *mâne* (tomorrow), from the old Romanian. In the literary language, as well as the other dialects, these words are pronounced with an 'i' before the consonant 'n', as follows: *câine*, *pâine* and *mâine*. The confusion with the *Muntenesc* dialect can be attributed to the fact that some residents of the southern part of Moldavia lost some of the dialectal features, e.g. they prefer to use the word *pantofi* to refer to shoes, and the word *papuci* to refer to slippers, just as the residents of Muntenia. In contrast, the residents of the northern side of Moldavia regularly use *papuci* to refer to shoes, and *şlapi* to refer to slippers. In summary, the confusion matrix shows that Romanian dialect identification is not an easy task, requiring researchers to address specific issues in order to come up with more accurate models in the future.

The confusion matrix illustrated in Figure 3 also shows that the training data distribution does not affect wav2vec 2.0. For example, the Moldovenesc dialect is the second-least popular dialect in our dataset, but wav2vec places many of the test samples into the Moldovenesc class. Overall, the confusion matrix of wav2vec reflects the test data distribution, although the model was trained on a slightly different class distribution. This confirms that the imbalance is not high enough to bias models.

Speech recognition results. We manually transcribed our data samples to test the performance of a state-of-the-art automatic speech recognition (ASR) system on RoDia. Then, we applied the open source Whisper-Large model (Radford et al., 2023) on our test set and obtained the word error rates reported in Table 3. The *Muntenesc* dialect is almost identical to the literary language, explaining why it exhibits the lowest WER. The WER obtained by the Whisper-Large model for the Romanian language on the Common Voice dataset is 19.8%. The difference between the WER for the Muntenesc dialect and the WER reported on Common Voice can be attributed to the distribution gap between the RoDia and the Common Voice datasets. Considering the generally higher error rates for the other Romanian dialects shown in Table 3, we conclude that ASR for dialectal speech is more difficult. This justifies the utility of our novel dataset for ASR.

Dialect	WER
Ardelenesc	31.5%
Bănăţean	30.2%
Moldovenesc	32.8%
Muntenesc	24.1%
Oltenesc	29.7%

Table 3: Word error rates (WER) of the Whisper-Large model (Radford et al., 2023) on the five dialects from the RoDia dataset. The Whisper-Large model is trained on the literary Romanian language. The ASR transcripts are compared with manual transcripts to establish the performance of the Whisper-Large model.

4 Conclusion

In this paper, we introduced RoDia, the first dataset for Romanian dialect identification from speech. Our dataset contains 2,768 speech samples representing five Romanian dialects. The audio samples were manually annotated with dialect, age and gender labels, enabling the study of spoken dialect identification in a realistic scenario, where the speakers in the training and test splits are disjoint. We conducted experiments with four state-of-the-art speech processing models, establishing a range of baseline performance levels for future research.

5 Limitations

This work is focused on spoken Romanian dialect identification, but the performance levels of the considered approaches might be different on other languages. Due to our specific focus on the Romanian language, we did not evaluate the performance of the considered models across other languages.

However, we consider that the evaluation on other languages is beyond the scope of the current study.

Another limitation of our work is the slightly limited number of samples with manual labels included in our corpus. This limitation is caused by scarcity of resources available online. Most of the Romanian video or audio samples available online use the literary language. Local news and content creators commonly use the literary language taught in schools. Hence, dialects are mostly used by rural residents, which often have no Internet access. This situation significantly limits the dialectal resources that are publicly available.

6 Ethics Statement

The manual labeling was carried out by volunteers who agreed to annotate the audio samples for free. Prior to the annotation, they also agreed to let us publish their labels along with the dataset. Our data is collected from YouTube, which resides in the public web domain. We note that the European regulations[2] allow researchers to use data in the public web domain for non-commercial research purposes. Thus, we release our data and code under the CC BY-NC-SA 4.0 license[3].

During data collection, we made sure the audio samples do not contain information that names or uniquely identifies individual people.

A Appendix

Peculiarities of Romanian dialects. As per Wikipedia[4], the Romanian dialects are not easy to classify, and their classification is still highly debated by experts, who proposed various classifications, ranging from 2 to even 20 dialects. Since there is no standard classification, we underline that the dialects from RoDia are not unanimously considered as dialects by experts. In Romanian, these are called "grai", which is translated (perhaps abusively) as "idiom" or "dialect" in English. Aside from phonetic differences, we note that there are a few hundred words that are specific to each such "grai". For example, lists of such words, called regionalisms, are available online[5]. The dialects included in our dataset have lists comprising between 300 and 800 regionalisms. In summary, the Romanian dialects have several distinctive features, such as:

- Phonetic differences, e.g. the word "ce" (what) is pronounced "ci" in the Moldovenesc dialect and "ce" in other dialects.
- Regionalisms, e.g. the word "melon" is translated as "pepene" in the Muntenesc dialect, "harbuz" in the Moldovenesc dialect, "lubeniţă" in the Bănăţean and Oltenesc dialects, and "curcubete" or "lebeniţă" in the Ardelenesc dialect.
- The addition of unnecessary dialect-specific words, e.g. "What time is it?" is normally translated as "Cât este ceasul?", but in the Ardelenesc dialect, people commonly use "Oare cât este ceasul?" (which can be translated as "I wonder what time is it"). In general, it is common to use "Oare" when addressing a question to another person in the Ardelenesc dialect.
- Preference for using a different past tense in the Oltenesc and Bănăţean dialects than in other Romanian dialects, e.g. for the phrase "I was", speakers of the Oltenesc and Bănăţean dialects dialects say "fusei", but the speakers of other Romanian dialects use "am fost".

Criteria for choosing the five dialects. To establish the set of dialects for RoDia, we used two criteria. On the one hand, we aimed to include as many dialects as possible. On the other hand, we were limited by the low number of audio samples available for dialects spoken in small regions (by low populations). We thus selected the top five most popular dialects, which are representative for the regions depicted in Figure 1 from our paper. In Table 4, we provide the size of the population in each region of Romania corresponding to one of the top seven Romanian dialects. Dialects that are not included in RoDia correspond to smaller subregions, e.g. Crişana and Maramureş, for which it is even harder to collect sufficient audio samples.

Dialect	Population
Ardeal (without Banat)	5.5M
Moldova	4.2M
Muntenia	3.3M
Oltenia	2M
Banat	1.25M
Crişana	1.2M
Maramureş	0.46M

Table 4: Population size for seven of the largest regions in Romania. Our dataset includes representative dialects for the top five regions.

Abstract

Recent work has proposed explicitly inducing language-wise modularity in multilingual LMs via sparse fine-tuning (SFT) on per-language subnetworks as a means of better guiding cross-lingual sharing. In this paper, we investigate (1) the degree to which language-wise modularity *naturally* arises within models with no special modularity interventions, and (2) how cross-lingual sharing and interference differ between such models and those with explicit SFT-guided subnetwork modularity. In order to do so, we use XLM-R as our multilingual LM. Moreover, to quantify language specialization and cross-lingual interaction, we use a Training Data Attribution method that estimates the degree to which a model's predictions are influenced by in-language or cross-language training examples. Our results show that language-specialized subnetworks do naturally arise, and that SFT, rather than always increasing modularity, can decrease language specialization of subnetworks in favor of more cross-lingual sharing.

1 Introduction

Multilingual language models (LMs) can achieve remarkable performance across many languages thanks to phenomena like cross-lingual sharing (Pires et al., 2019), but they still suffer from the "curse of multilinguality" (Conneau et al., 2020) as performance can be hindered by negative cross-language interference (Wang et al., 2020). Recently, new methods have been proposed for mitigating these negative effects by training specialized model components for processing individual languages (Pfeiffer et al., 2022). These approaches, which add explicit **modularity** to the model, are also effective in promoting positive transfer and increasing interpretability (Pfeiffer et al., 2023).

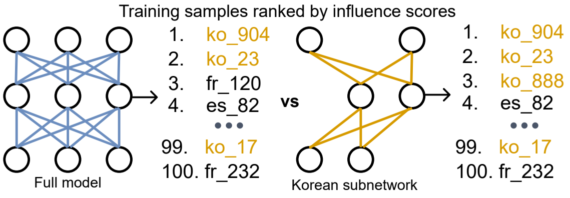

Figure 1: We study how in-language training data reliance changes for individual test languages when using a subnetwork compared to the full model at test time. For instance, will a Korean subnetwork rely more on Korean training samples when making a prediction for a Korean test sample? Note that each training example is denoted by its language and a training sample ID (`lang_ID`).

While previous work has focused on developing techniques for explicitly adding modularity to models, we take a step back and ask: To what degree does language-wise modularity *naturally* arise within a model with no targeted modularity interventions? To investigate this question, we make use of a method inspired by the Lottery Ticket Hypothesis (Frankle and Carbin, 2018; Chen et al., 2020): for each language, we identify a **subnetwork**—a subset of model parameters—such that when fine-tuned on in-language data, it performs on par with the full model on that language (Wang et al., 2020; Nooralahzadeh et al., 2020). We then use these subnetworks to quantify language-wise modularity in a model by measuring the degree to which the subnetworks depend solely on in-language training examples when making predictions, which we refer to as *language specialization*. Subnetworks are an appealing method for our study because they do not require the introduction of additional model parameters, which means that we are able to use this approach on a model that has not been explicitly modified to add modularity.

Moreover, subnetworks have also proven to be a popular modularization technique because when used to restrict parameter updates as a form of sparse fine-tuning (**SFT**), they are able to guide cross-lingual sharing toward positive transfer and away from negative interference (Lin et al., 2021; Lu et al., 2022; Xu et al., 2022; Choenni et al.,

Findings of the Association for Computational Linguistics: NAACL 2024, pages 287–301
June 16-21, 2024 ©2024 Association for Computational Linguistics

2023a; Hendy et al., 2022). However, less is known about precisely what effects SFT has on the underlying model behavior. Thus, we investigate the following set of questions for XLM-R (Conneau et al., 2020): (1) To what extent does language-wise modularity naturally arise within the model, when it is not explicitly enforced by restricting gradient updates? (2) How do cross-lingual sharing and interference differ between models without modularity interventions versus models with SFT-guided language-wise modularity? (3) How does the degree of language specialization affect model performance? and (4) To what extent does the similarity of language-specific subnetworks dictate cross-language influence?

To quantify cross-language interaction, we follow Choenni et al. (2023b) in using a Training Data Attribution (TDA) method, TracIn (Pruthi et al., 2020), which measures the degree of influence each training example has on a particular model prediction. By examining the influence each language's training set has on the test predictions for individual languages, we can estimate how much influence languages on average exert cross-lingually.

We conduct experiments on three text classification tasks—natural language inference, paraphrasing, and sentiment analysis. For each task, even without special modularity interventions, we are able to identify subnetworks that rely more heavily on in-language data than the full model does. Additionally, we find that SFT does not always increase this modularity, but instead can decrease language specialization within the subnetworks and boost cross-lingual sharing to improve performance. Finally, we provide additional analysis on factors that affect cross-language influence, and find interesting correlations between subnetwork similarity and the amount of positive influence across languages.

2 Background and Related work

2.1 Modular deep learning

Modular approaches existed before the rise of pre-trained LMs (Shazeer et al., 2016; Andreas et al., 2016), but have recently regained popularity in NLP. The idea is that modular systems will allow us to improve performance in an interpretable way as modularity provides a more intuitive path to compositionality. Various methods have been proposed to implement specialized modules, for instance, by inserting adapter layers into the model (Rebuffi et al., 2017, 2018; Houlsby et al., 2019; Pfeiffer et al., 2022), replacing fine-tuning by prefix-tuning (Li and Liang, 2021), or by SFT with subnetworks (Sun et al., 2020). While the former two aim to create modularity *post-hoc* by injecting task-specific parameters into the existing model, the latter approach aims to induce it into the model as an inductive bias during fine-tuning. In this work, we delve deeper into the effects of SFT to understand whether it is able to produce more modular systems. While some work studies modularity in both vision and language models (Csordás et al., 2020; Zhang et al., 2023; Lepori et al., 2023; Dobs et al., 2022), we are the first to explicitly examine the degree of modularity in multilingual LMs, and to study subnetwork interaction by directly looking at the training data.

2.2 Subnetworks and SFT

Frankle and Carbin (2018) showed that subnetworks can be found through pruning methods (Han et al., 2015; Li et al., 2016) that match the performance of the full model. Since then, it has been shown that such subnetworks exist within BERT models (Prasanna et al., 2020; Budhraja et al., 2021; Li et al., 2022), and that both language-neutral and language-specific subnetworks can be found in multilingual LMs (Foroutan et al., 2022). Hence, sparse training gained popularity in multilingual NLP: Nooralahzadeh and Sennrich (2023) show that training *task-specific* subnetworks can help in cross-lingual transfer, Lin et al. (2021) use *language-pair-specific* subnetworks for neural machine translation, and Hendy et al. (2022) use *domain-specific* subnetworks. Finally, Wang et al. (2020); Lu et al. (2022); Choenni et al. (2023a); Xu et al. (2022) use language-specific subnetworks to improve cross-lingual performance on a range of tasks, e.g. speech recognition, dependency parsing and natural language understanding, suggesting that sparse training can reduce negative interference and/or stimulate positive knowledge transfer. While Choenni et al. (2023a) found evidence of the former through fewer gradient conflicts during training (Yu et al., 2020), we are the first to study the effect of SFT on cross-lingual data sharing.

2.3 Training Data Attribution

TDA methods aim to identify a set of training examples that most informed a particular test prediction. Typically, the influence of training point z_{train} on test point z_{test} is formalized as the change in the loss that would be observed for z_{test} if sample z_{train} was omitted during training (Koh and Liang, 2017). Thus, we can use it as a measure of how important z_{train} is for making a prediction for z_{test}. TDA methods have been used in NLP for unveiling data artifacts (Han and Tsvetkov, 2022), e.g., to detect outlier data (Han et al., 2020), enable instance-specific data filtering (Lam et al., 2022), or to correct erroneous model predictions (Meng et al., 2020; Guo et al., 2021). Following Choenni et al. (2023b), we instead employ it to study cross-lingual data sharing in LMs. To understand how much influence languages exert cross-lingually, Choenni et al. (2023b) quantify cross-language influence during multilingual fine-tuning by the percentage that each language's training data contributes to the most influential training samples for each test language. While they study the effects of full model fine-tuning, we employ their framework to study modularity in LMs by testing the data reliance behavior of language-specific subnetworks and the effect that SFT has on this.

3 Methods

3.1 Identifying Subnetworks

Subnetworks are represented by masks that can be applied to the model to ensure that only a subset of the model's parameters are activated (or updated during training). We follow Prasanna et al. (2020) in using *structured* masks, treating entire attention heads as units which are always fully enabled or disabled. Thus, for a language ℓ, its subnetwork is implemented as a binary mask $\xi_\ell \in \{0,1\}^{H \times L}$, where H and L correspond to the number of attention heads and layers. We aim to find masks for languages that prune away as many heads as possible without harming model performance on a given language (i.e., by pruning away heads that are only used by other languages, or that are unrelated to the task). For this, we apply the procedure introduced by Michel et al. (2019). Starting from a model that is fine-tuned for a task in language ℓ, we iterate by repeatedly removing the 10% of heads with the lowest importance scores $\mathrm{HI}_\ell^{(i,j)}$ (i=head, j=layer), which is estimated based on the expected sensitivity of the model to the mask variable $\xi_\ell^{(i,j)}$:

$$\mathrm{HI}_\ell^{(i,j)} = \mathbb{E}_{x_\ell \sim X_\ell} \left| \frac{\partial \mathcal{L}(x_\ell)}{\partial \xi_\ell^{(i,j)}} \right| \tag{1}$$

where X_ℓ is ℓ's data distribution, x_ℓ is a sample from that distribution, and $\mathcal{L}(x_\ell)$ is the loss with respect to the sample. Pruning stops when we reach 95% of the original model performance.

3.2 TracIn: Tracing Influence

Pruthi et al. (2020) propose TracIn, a simple TDA method to approximate influence of a training sample over training. They do this by computing the influence of a training sample z_i on the prediction for a test sample z_{test} as follows:

$$\mathcal{I}(z_i, z_{test}) = \sum_{e=1}^{E} \nabla_\theta \mathcal{L}(z_i, \theta_e) \cdot \nabla_\theta \mathcal{L}(z_{test}, \theta_e) \tag{2}$$

where θ_e is the checkpoint of the model at each training epoch. The intuition behind this method is to approximate the total reduction in the test loss $\mathcal{L}(z_{test}, \theta)$ during the training process when the training sample z_i is used. This gradient product method reduces the problem to the dot product between the gradient of the training loss and the gradient of the test loss. As dominating gradients are a known problem in multilingual NLP (Wang et al., 2020), we also adopt the simple normalization trick from Barshan et al. (2020), i.e., substituting the dot product operation with cosine similarity, thus normalizing by the norm of the training gradients. Lastly, following Pruthi et al. (2020), we reduce computational costs by pre-computing low-memory sketches of the loss gradients of the training points using random projections, and reuse them to compute randomized unbiased estimators of the influence on different test points (Woodruff et al., 2014). See Appendix A for more details.

4 Experimental setup

4.1 Tasks and datasets

Natural language inference The Cross-Lingual Natural Language Inference (XNLI) dataset (Conneau et al., 2018) contains premise-hypothesis pairs labeled with their relationship: 'entailment', 'neutral' or 'contradiction'. The dataset contains parallel data of which the original pairs come from English and were translated to other languages. We use English, French, German, Russian and Spanish portions of the dataset.

Paraphrasing Cross-Lingual Paraphrase Adversaries from Word Scrambling (PAWS-X) (Yang et al., 2019) requires the model to decide if two sentences are paraphrases of one another. PAWS-X contains translated data from PAWS (Zhang et al., 2019). Part of the development and test sets was translated from English by professionals and the training data was translated automatically. We experiment with English, French, German, Korean and Spanish.

Sentiment analysis The Multilingual Amazon Review Corpus (MARC) (Keung et al., 2020) contains Amazon reviews written by users in various languages. Each record in the dataset contains the review text and title, and a star rating. The corpus is balanced across 5 star rating, so that each star rating constitutes 20% of the reviews in each language. Note that this is a non-parallel dataset. We experiment with Chinese, English, French, German and Spanish.

4.2 Training techniques

Full model fine-tuning We fine-tune the full XLM-R model (Conneau et al., 2020) on the concatenation of 2K samples from 5 languages, i.e. 10K samples for each task. As computational costs of TracIn increase with training size, we use a minimal required number of training examples to obtaining reasonably high performance. Thus, we simplify the task to get a better trade-off between the number of training examples and performance. For XNLI, we follow Han et al. (2020) by performing binary classification "entailment or not" ; for MARC, we collapse 1 and 2 stars into a negative and 4 and 5 stars into a positive review category. Training converges at epoch 4 for XNLI, and at epoch 5 for PAWS-X and MARC, obtaining 78%, 83%, and 90% accuracy on their development sets respectively, for more details see Appendix B.

Sparse fine-tuning (SFT) We sample language-specific batches in random order, and each time restrict parameter updates to only those parameters that are enabled within the respective language's identified subnetwork. We use the subnetworks during fine-tuning by restricting the model both in the forward and backward pass.[1] We ensure that we sample each language equally often. All other fine-tuning details remain the same as for full model fine-tuning.

4.3 Evaluation

Computing influence scores We use 500 random test samples from each language and compute influence scores between each test sample and all 10K training instances. For each test sample, we retrieve the top m=100 training instances with the largest *positive* and the largest *negative* influence scores and refer to them as the set of most positively and negatively influential samples respectively. Note that we use m=100 as it was previously found to be optimal on the exact same tasks (Choenni et al., 2023b).[2] Moreover, negative cosine similarity between gradients have been referred to as gradient conflicts (Yu et al., 2020), and were shown to be indicative of negative interference in the multilingual setting (Wang et al., 2020)[3]. In addition, we ensure that the model was able to predict the correct label for all test instances that we compute influence scores for such that we only study the training samples that influenced the model to make a correct prediction. Also, as we train on parallel data for XNLI and PAWS-X, the content in our training data is identical across languages, giving each language an equal opportunity to be retrieved amongst the most influential samples.

Quantifying cross-language influence After obtaining an influence score ranking over our training set for each test sample, we compute how much each training language contributed to the prediction for the test samples in other languages. We then compare the resulting rankings produced using the full model and an identified subnetwork, see Figure 1. As there can be small differences in performance between the subnetworks and the full model, throughout all experiments, we compare cross-language influence for test samples that both models were able to correctly classify.

5 Naturally arising modularity

In this section, we study whether modularity has naturally arisen within a model after multilingual full model fine-tuning. As such, the subnetworks are only applied at test time.

5.1 How specialized are subnetworks?

To study the degree to which modularity has naturally arisen after full model fine-tuning, we look for subnetworks that naturally specialize in their

---

[1] We implement this during backpropagation by multiplying the gradients by the binary subnetwork mask, and passing the masked gradients to the optimizer. In the forward pass, we simply disable the attention heads.

[2] Note that we carefully follow the experimental set-up from Choenni et al. (2023b), i.e., we use the same tasks, data and model for our experiments.

[3] When gradients point in opposite directions, the model will update in a suboptimal direction for both examples, hence resulting in negative interference.

Figure 2: (After full model fine-tuning) The effect of using the identified language-specific subnetwork for each test language compared to the full model at test time. On the x-axis we have the training language and on the y-axis the test language. The values denote the change (%) in influence from the training on the test language. Results are averaged over all 500 test samples per language.

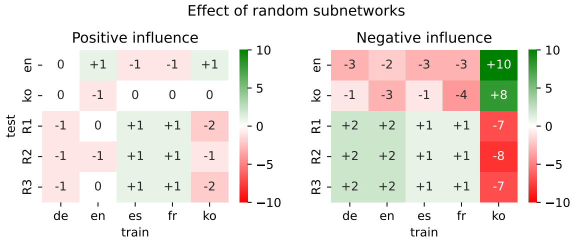

Figure 3: (After full model fine-tuning) The effect on cross-language influence when using random (R) and suboptimal (English and Korean) subnetworks on German as a test language for PAWS-X.

respective languages. We quantify language specialization as the extent to which the subnetworks rely solely on in-language training data when making test-time predictions. Thus, for each test language, we use the pruning procedure explained in Section 3.1 to identify a subnetwork within the fine-tuned model. We then compute influence scores on the fine-tuned model, applying the subnetwork mask corresponding to the language of the test example. Finally, we compare the model's reliance on in-language data when using these subnetworks against its reliance when no subnetwork mask is applied (i.e. when predicting with the full model).

Results In Figure 2 we show, per task and test language, the change in contribution (%) to the top 100 most positively and negatively influential samples when using the subnetworks compared to the full model. On the diagonals, we clearly see that for all languages across all tasks, using the subnetwork does mostly result in more positive influence from the respective language (from +1 to +8%). This indicates that we are able to identify language-specialized subnetworks that are more biased toward relying on in-language data, and thus suggests that some form of modularity naturally exists within the model. For baseline results from the full model and more details on the subnetworks, see Appendices C and D respectively. Also, importantly, our results using 500 test samples per language on the full model are similar to those on the same tasks from Choenni et al. (2023b), who performed extensive analysis on the quality of the influence scores.

The effects are less clear when looking at negative influence; here we see that using a language's subnetwork can also decrease negative influence coming from in-language data (e.g. Chinese for MARC). Finally, results from XNLI are overall weaker than for the other tasks. This is in line with results from the full model that showed that, for XNLI, the model relies to the least extent on in-language data, hence we can expect language-specificity to be less strong for these subnetworks. Moreover, for English, we find no difference in language specialization. This can be explained by the fact that the German and Russian subnetworks share 100% of their capacity with English, making its subnetwork less distinct (see Appendix D).

Cross-language influence We have shown that language-specialized subnetworks rise. We now analyze how cross-language influence differs within such subnetworks compared to the full model. For MARC, we see that the increase in positive self-influence (diagonal) can be smaller than the increase in positive influence from related languages. In particular, we see that using a German subnetwork strongly increases positive influence from the most typologically similar training language, i.e., English (+7%), and vice versa (+5%). While the change in positive influence from related languages is stronger than that of the respective subnetwork's language, the subnetwork still relies more on in-

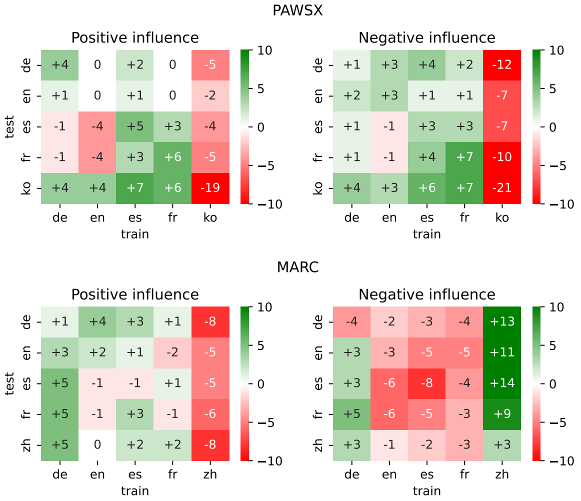

Figure 4: (After SFT) The effect of using the identified language-specific subnetwork for each test language compared to using the full model at test time. On the x-axis we have the training language and on the y-axis the test language. The values denote the change (%) in influence from the training on the test language. Results are averaged over all 500 test samples per language

language data when looking at absolute numbers. For German, the full model was relying for 33% on in-language data, which using its subnetwork increased to 35% (+2%). Yet, English initially only contributed 17% to German, which after using its subnetwork increased to 24% (+7%) (see Appendix C for the full model results). We suspect that we observe the effect of positive knowledge transfer through cross-lingual sharing here. Similar to the full model, when subnetworks have exploited most useful in-language data, they start benefitting more from exploiting other languages' data instead.

5.2 Random and suboptimal subnetworks

As baselines to our identified subnetworks, we study whether evidence for language specialization can also be found within random and suboptimal subnetworks for PAWS-X. *Random*: we shuffle the binary subnetwork masks with 3 random seeds, and recompute scores from them. Note that we do this only for German—we saw the weakest increase in language-specificity for German (+2%, see Figure 2), thus it should be the easiest to get similar results from a random subnetwork. *Suboptimal*: we pick the subnetwork from the most similar and distant language to German, i.e., English and Korean, and recompute influence scores for German (i.e., testing the effect of applying the subnetwork from a language A to a language's B's input.).

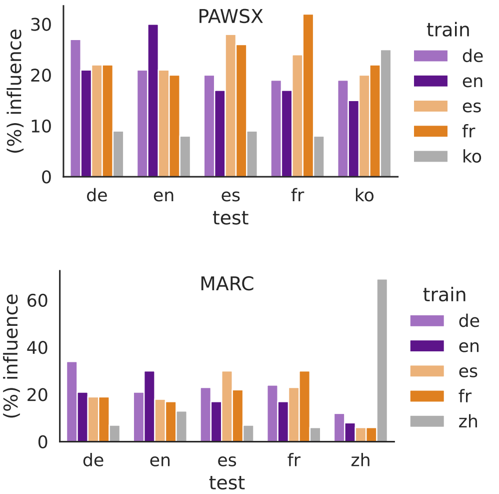

Figure 5: The positive influence (%) from each training language on each test language in absolute numbers. The values are retrieved from the subnetworks after SFT. Note that the y-axes are not on the same scale.

Results In Figure 3, we find that using random subnetworks overall causes little change to the score distributions as compared to the full model. In particular, we find that in none of the cases the influence of German increases. Also, it is evident that the behavior from the suboptimal subnetworks is different from the random subnetworks. For instance, we find that using either the correct English or Korean subnetworks result in a strong increase of negative interference from Korean (+10 and 8%). Yet, when we use the random subnetworks we instead observe a strong tendency for Korean to decrease in negative influence. These results show that our identified subnetworks encode meaningful differences compared to randomly selected ones.

6 How does SFT affect modularity?

In Section 5, we studied whether modularity had naturally arisen in the model in the form of language-specialized subnetworks. We now study the effect that SFT has on these subnetworks, i.e., does it further encourage modularity within the model? Thus, instead of only applying the subnetworks at test time, as was done in the previous section, we now use the same identified subnetworks, but apply them both during SFT and at test time. We then recompute influence scores between test and training samples, and observe the change in language specialization compared to full model fine-tuning. This way, we test whether SFT, compared to full model fine-tuning, causes the subnetworks to further specialize on in-language data.

Given that the subnetworks found for XNLI had the smallest effect on cross-language data reliance, and we did not find a distinct English subnetwork, we conduct further experiments on PAWS-X and MARC (that contain parallel and non-parallel data respectively) to reduce computational costs. Also, we confirm that SFT improves performance on both tasks (see Appendix E). For PAWS-X, we obtain an average test accuracy of 74.8% when using subnetworks after full model fine-tuning and 78.4% after SFT (+3.6%). For MARC we see an average improvement of +1.2% when using SFT.

Results In Figure 4, we see the change in language influence compared to using the full model. We find that the in-language data reliance of some subnetworks tends to decrease after SFT (i.e., Korean for PAWS-X and Chinese, French, and Spanish for MARC). This is surprising given that SFT is generally seen as a modularization technique. Whilst it is important to note that all subnetworks still mostly rely on in-language data as shown by the absolute numbers reported in Figure 5, our results suggest that the benefit of SFT cannot fully be attributed to language specialization of the subnetworks. Instead, cross-lingual sharing, guided through subnetwork interaction, is likely a contributing factor as well. Finally, as our results suggest that SFT does not necessarily strengthen language specialization, it sheds doubt on SFT as a method for creating more modular systems.

6.1 SFT with random subnetworks

As a baseline to our previous findings, we now test whether any randomly found subnetwork could in principle be taught to specialize in a language when we use SFT as a training method. Thus, for each language, we shuffle the language-specific subnetworks to obtain a random subnetworks with the same sparsity level. We then use these random subnetworks, both during SFT and at test time, and repeat the procedure from Section 6.

Results Surprisingly, in Figure 6, we see that random subnetworks to a much larger extent rely on in-language data than the identified subnetworks used in Section 6. In particular, we see that the model barely relies on cross-lingual sharing for English (+64% compared to the full model, which results in 97% reliance on English data when using the subnetwork). Yet, we also find that these highly specialized subnetworks perform considerably worse, on average only obtaining ±56% across languages. Given that random subnetworks do not contain the necessary information to process the language, we hypothesize that (1) during SFT they need to learn both the task and language, which causes them to focus on in-language data first, and (2) cross-lingual sharing will only happen once the in-language data has been fully exploited. Our results show that any subnetwork can in principle learn to specialize in one language, but that this might be suboptimal.

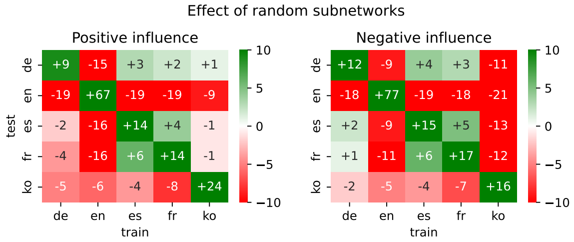

Figure 6: (After SFT) The effect that SFT with *random* subnetworks has for PAWS-X on the amount of language specialization that the subnetworks acquire compared to full model fine-tuning.

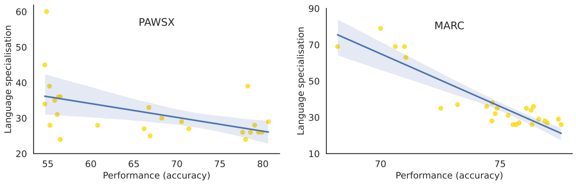

Figure 7: The correlation between language specialization and performance accuracy for PAWS-X and MARC. We compute scores for all languages and model checkpoints.

7 Further analysis

In Section 6, we show that SFT only sometimes causes our identified subnetworks to rely more on in-language data, yet unlike random subnetworks, do seem to encode meaningful information. To understand where the performance improvements from SFT come from, we perform further analysis on how language specialization correlates with performance, and how subnetwork similarity affects cross-language influence.

7.1 Correlation between language specialization and performance

We find that SFT only decreases performance on French for PAWS-X (Table 2, Appendix E), which happens to also be the subnetwork that showed the strongest increase in language specialization after SFT (+6%) in Section 6. To test to what degree subnetwork performance benefits from language

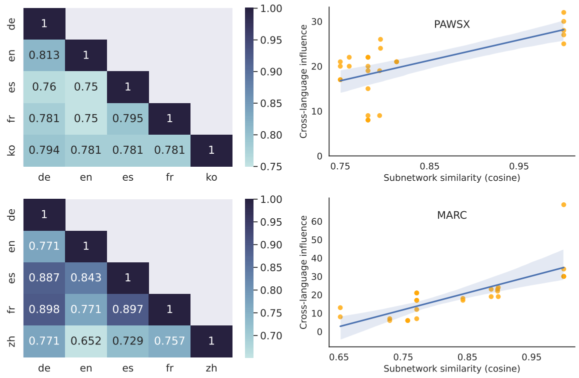

Figure 8: (**Left**) The cosine similarity between the flattened binary subnetwork masks for each language pair. (**Right**) Positive cross-language influence as a function of structural (cosine) similarity between subnetworks.

specialization, we study the correlation between the two using data from all model checkpoints.

Results In Figure 7, we see that, for both tasks, stronger language specialization is negatively correlated with model performance. This finding further supports our hypothesis that the strength of SFT really comes from cross-lingual sharing that happens between the subnetworks rather than from the language specialization of the subnetworks themselves. Intuitively, this makes sense as SFT forces the model to squeeze information into the smaller subsets of model parameters, which has to improve performance on a set of training languages, and as such, requires better cross-lingual sharing.

7.2 Correlation between subnetwork similarity and cross-language influence

SFT allows for cross-lingual interaction through subnetwork overlap in which the model parameters are shared between languages. This sharing mechanism is motivated by the idea that similar languages are encoded by similar subnetworks (and thus naturally dictating cross-lingual sharing by their overlap). To test this hypothesis we study the correlation between subnetwork similarity and cross-language influence between language pairs. We measure similarity by the cosine similarity between the flattened binary subnetwork masks.

Results In Figure 8 (Left) we report the cosine similarity between the subnetworks of each language pair and (Right) the correlation between such subnetwork similarity and positive cross-language influence (in absolute numbers). From this, we find that for both tasks, subnetwork similarity is positively correlated with positive cross-language influence. Yet, we did not find a strong correlation between negative cross-language influence and subnetwork overlap. This is a promising finding, as it suggests that positive and negative influence do not necessarily have to go hand-in-hand. Thus, future work should investigate how we can further exploit subnetwork overlap to increase positive influence without increasing negative influence as well. Moreover, it is evident that for MARC the subnetworks show on average more overlap than for PAWS-X. Thus as the capacity within subnetworks from MARC have to be shared with more languages, it can explain why their language specialization is less strong as seen in Figure 4. Future work should test whether SFT is still effective when using many more training languages (in which case subnetwork overlap will inevitably be higher).

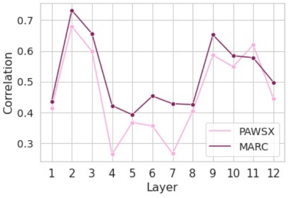

Figure 9: The correlation between positive cross-language influence and the subnetwork similarity computed based on individual model layers.

Layer-wise analysis To further analyze how subnetwork similarity affects cross-language influence, we now test how layer-wise subnetwork similarity correlates with performance. In Figure 9, we see that similarity between certain layers is much more indicative of cross-language influence, and moreover, that both tasks follow very similar patterns despite ending up with vastly different subnetworks. This suggests that while language-specific subnetworks are also task-specific, there may be general language-specific properties across task-specific subnetworks that we can identify and exploit to better guide cross-lingual sharing.

8 Conclusion

We studied to what degree modularity, in the form of language-specialized subnetworks, naturally arises within multilingual LMs. We demonstrate the existence of such subnetworks using TracIn to monitor the change in reliance on in-language data at test time when using subnetworks compared to the full model. Moreover, we studied the effects that SFT has on modularization, and find that it does not cause all subnetworks to become more specialized. Yet, in all cases, our identified subnetworks show vastly different behavior from random ones, indicating that we are able to uncover meaningful language-specific model behavior. Finally, we find that subnetwork similarity, particularly in specific model layers, correlates with positive, but not negative, cross-language influence. Future work should focus on further exploiting subnetworks and their interaction to better control cross-lingual sharing.

9 Limitations

One limitation of TDA methods in general is that the experiments are computationally expensive to run. While using the random projection method, explained in Appendix A, somewhat mitigates the problem, it still prevents us from studying a wider range of LMs and/or larger models. Similarly, due to the computational costs, we are restricted to relatively easy tasks as (1) we can not use a large fine-tuning dataset and (2) TracIn operates on the sequence-level, i.e., it estimates how much a full training instance contributed to a prediction, making this method mostly suitable for classification and regression tasks. Given that the tasks are relatively simple, this might also limit the benefit of SFT over full model fine-tuning, hence the subnetwork behavior we see after SFT might be weaker than if we had studied more complicated tasks and/or tasks that generally require more language-specific information (e.g., masked language modelling or dependency parsing).

A Low-memory sketches using random projections

LMs have a large number of parameters which makes the inner product computations in the first-order approximation of the influence expensive, especially when computing influence scores for a large number of test points. Thus, following Pruthi et al. (2020), we speed up the computations by using random projections, a method that allows us to pre-compute low-memory sketches of the loss gradients of the training points (Woodruff et al., 2014) which can be stored and re-used to compute randomized unbiased estimators of the influence on different test points. To do so, we choose a random matrix $G \in \mathcal{R}^{d \times p}$, where $d \ll p$ is a user-defined dimension for the random projections, whose entries are sampled i.i.d. from $\mathcal{N}(0, \frac{1}{d})$ such that $E[G^T G] = \mathcal{I}$. Similarly, for the fully connected layers with a weight matrix $W \in \mathcal{R}^{m \times n}$, it is also possible to obtain a random projection of the gradient with respect to W into d dimensions. To do so, we use two independently chosen random projection matrices $G1 \in \mathcal{R}^{\sqrt{d} \times m}$ and $G2 \in \mathcal{R}^{\sqrt{d} \times n}$, where $E[G_1 G_1^T] = E[G_2 G_2^T] = I$, and compute:

$$G_1 \nabla_y f(y) x^T G_2^T \in \mathcal{R}^{\sqrt{d} \times \sqrt{d}} \qquad (3)$$

, which can be flattened into a d-dimensional vector. See Appendix E and F from Pruthi et al. (2020) for more details. Note that throughout our experiments we set $d = 256$.

B Fine-tuning details

For each task, we add a simple classifier on top of the pretrained XLM-R base model (Conneau et al., 2020). The classifier consists of one hidden layer and uses `tanh` activation. We then feed the hidden representation corresponding to the `<S>` token for each input sequence to the classifier for prediction. Moreover, following Choenni et al. (2023b), we use AdamW (Loshchilov and Hutter, 2017) as an optimizer, and use learning rates of 2e-5, 9e-6, and 2e-5 for XNLI, PAWS-X and MARC respectively.

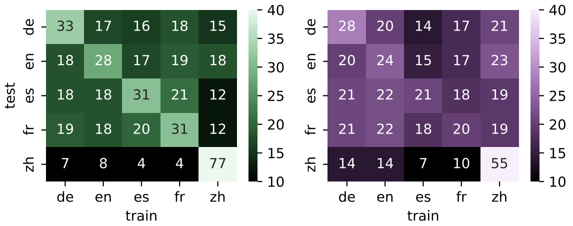
(b) PAWS-X



(c) MARC

Figure 10: Percentage that each training language contributes to the top 100 training samples for each test language when using the full model. Results are averaged over all 500 test samples per language.

D Details on the identified subnetworks

In Figure 11, we show the overlap in attention heads of the identified subnetworks that we found for each of our 5 training languages. While we find that all subnetworks have similar sparsity levels (see Table 1 for the absolute number of disabled attention heads per task and language), we also see that across all tasks, some heads are not used by any of the languages (indicated by 0). This finding suggests that the model capacity does not have to be a limiting factor within this model, as more language-specific parameters could be assigned if needed. In contrast, many heads, especially in the lower layers of the models for PAWS-X and in the higher layers for XNLI, are fully shared across all languages. Given that paraphrasing relies more on lower-level syntactic information than NLI, this is in line with previous findings that suggest that syntax is processed in lower layers while semantics in processed in the higher ones (Tenney et al., 2019). Moreover, in Figures 12, 13 and 14, we see for XNLI, PAWSX-X and MARC the amount of subnetwork overlap between each language pair both in absolute values and as a percentage of the language's full subnetwork capacity.

Table 2: The performance effect of SFT compared to full model fine-tuning. We report the performance of the language-specific subnetworks when used on the test samples from the respective languages when using either one of the fine-tuning techniques. Note that we do not optimize for obtaining SOTA performance in this study e.g., we train on relatively little data to make our TracIN experiments computationally feasible.

F Additional experiments

F.1 What happens within subnetworks during full model fine-tuning versus SFT?

In Sections 5 and 6 we used the sum of influence scores over model checkpoints to compute influence scores. We now conduct the same experiments, but instead study how cross-language influence changes over time while using the different fine-tuning strategies. To do so, we now analyze the influence scores (and their corresponding rankings) from each checkpoint separately.

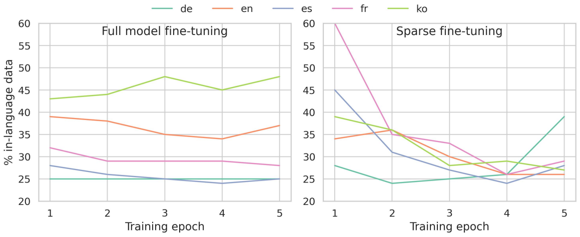

Figure 16: The change in language specialization of subnetworks over training epochs for PAWS-X.

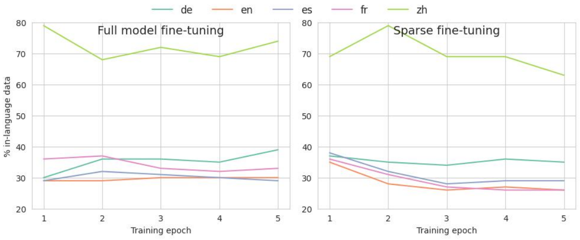

Figure 17: The change in language specialization for each test language over training epochs for MARC. We see that the patterns for full model fine-tuning are similar to PAWS-X, yet for sparse fine-tuning they differ considerably.

Figure 18: The language specialization effect of SFT with random subnetworks on PAWS-X over training epochs.

Results In Figure 16 we see that while both fine-tuning techniques converge to similar maximum levels of cross-lingual sharing (∼25% reliance on in-language data) for PAWS-X, SFT allows for *all* training languages to start sharing more data. Whereas for full model fine-tuning, we instead see that Korean and English are left behind. The same trend was found for MARC, see Figure 17. Also, in Figure 18, we find that using random subnetworks for SFT on PAWS-X, similarly to full model fine-tuning, results in Korean and English staying more isolated from the other three languages. This suggests that when we use random subnetworks for SFT, the model can not benefit from better cross-lingual sharing in the same way as when we identify the subnetworks via pruning. In line with results in Sections 6.1 and 7.2, we conclude that the subnetworks meaningfully overlap to enable better cross-lingual interaction during SFT.

F.2 Composing subnetworks at test time

As an additional analysis, we study whether we can compose two languages' identified subnetworks into a language-pair specific subnetwork that, when applied at test time, will enforce more cross-lingual reliance on each other's training data. For merging two subnetworks we both tried taking the union and the intersect of the respective binary subnetwork masks. Note that we apply the composed subnetwork only at test time to a model that was trained with SFT (using the initial identified subnetworks).

Results We find that we can only successfully enforce cross-lingual sharing through subnetwork composition for two languages, if those individual language's subnetworks already stimulated cross-lingual sharing between the pair. For instance, in Figure 4, we saw that both the Spanish and French subnetworks (PAWS-X) and the German and English ones (MARC) resulted in more sharing between the pairs. In Figure 19, we show that taking the intersections of those language pairs' subnetworks can further strengthen this behavior (taking their union resulted in sharing to a lesser extent)

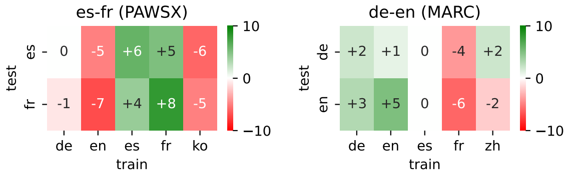

Figure 19: The effect on the contribution of positive influence from each training language when composing two language's subnetworks by their intersect and applying them at test time (compared to full model fine-tuning).

Trying to control sharing behavior by composing two language-specific subnetworks that individually did not lead to more sharing between the pair did not yield any clear positive results. This shows that while SFT can better cross-lingual sharing, there is still much room for improvement when it comes to creating a truly modular system that enables compositionality.

Reverse Chain: A Generic-Rule for LLMs to Master Multi-API Planning

Abstract

While enabling large language models to implement function calling (known as APIs) can greatly enhance the performance of Large Language Models (LLMs), function calling is still a challenging task due to the complicated relations between different APIs, especially in a context-learning setting without fine-tuning. This paper introduces "Reverse Chain", a controllable, target-driven approach designed to empower LLMs with the capability to operate external APIs only via prompts. Recognizing that most LLMs have limited tool-use capabilities, Reverse Chain limits LLMs to executing simple tasks, e.g., API Selection and Argument Completion. Furthermore, to manage a controllable multi-function calling, Reverse Chain adopts a generic rule-based on a backward reasoning process. This rule determines when to do API selection or Argument completion. To evaluate the multi-tool-use capability of LLMs, we have released a compositional multi-tool task dataset, available at `https://github.com/zhangyingerjelly/reverse-chain`. Extensive numerical experiments validate the remarkable proficiency of Reverse Chain in managing multiple API calls.

1 Introduction

Recently, there has been an impressive wave in the progress made in Large Language Models (LLMs), due to their excellent performance in a variety of tasks (Chowdhery et al., 2022; Brown et al., 2020; Scao et al., 2022; Wei et al., 2022a; Bubeck et al., 2023). However, LLMs still face difficulties with some specialized tasks due to their fundamental limitation on the information they stored and learned, which can become outdated and may not be suitable for all applications. A practical solution is to augment LLMs with external tools (known as APIs). In this setup, LLMs act as controllers, not only to understand user intents but crucially to select and orchestrate the appropriate tools to complete tasks.

Unfortunately, LLMs still lack the sophistication to fully understand human instructions and effectively implement function calling. Many works are dedicated to enhancing the function calling abilities of LLMs through fine-tuning or in-context learning methods (Patil et al., 2023; Qin et al., 2023; Schick et al., 2023; Tang et al., 2023; Parisi et al., 2022; Li et al., 2023; Liang et al., 2023; Song et al., 2023; Xu et al., 2023). Compared to fine-tuning, in-context learning approaches offer a more straightforward and scalable solution, as they eliminate the need to train an entirely new model for each new API. Consequently, the primary goal of this paper is to enhance the API planning capabilities of LLMs within the in-context learning setting.

Different from the aforementioned studies which focus on simpler tasks, such as single-tool task or independent multi-tool task (detailed in Table 1), this paper targets at enhancing LLMs' ability to handle more complicated **compositional multi-tool task** (detailed in Table 1). Implementations of this task requires to employ multiple, potentially interdependent APIs, which is common in real-world scenarios but poses a greater challenge in API planning for LLMs. It's worth noting that single-tool task and independent multi-tool task can be seen as subsets of compositional multi-tool task, and the proposed approach can also manage them with minimal modifications. The generalizability of the proposed method to different task types will be discussed in the Section 5.

In the realm of tool-use, various prompting techniques have been explored. **One-step planning** algorithms are introduced in (Shen et al., 2023; Liang et al., 2023), but its accuracy is often low in complex, ambiguous scenarios. The Chain of Thought (CoT) approach (Wei et al., 2022b) counters this by

Task Type	Example	API planning
Single-tool	What's the weather in New York ?	*getWearther*(city='New York')
Independent multi-tool	What's the weather in New York? When's my next meeting?	*getWearther*(city='New York') *showCalendar*(event='next meeting')
Compositional multi-tool	I'm Lucas, Could you find a flight and book it to my destination ?	*BookFlight*(flight_ID=*FindFlight*(destination =*GetUserDestination*(userName='Lucas'))

Table 1: Different task types, classified by the number of required tools and their dependencies for task execution.

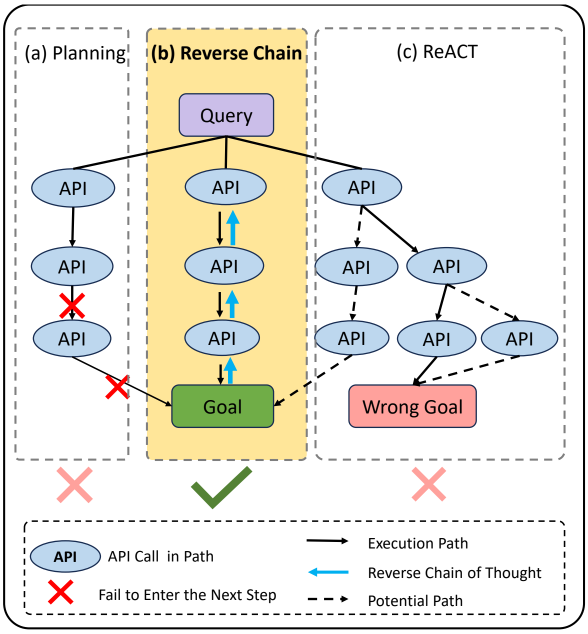

Figure 1: A comparison of our Reverse Chain with the one-step/CoT Planning and ReAct for multi-API planning.

step-by-step planning with intermediate reasoning. Known as **CoT planning**, this technique decomposes tasks into several simpler sub-tasks, thereby boosting reasoning and accuracy. Nevertheless, as illustrated in Figure 1 (a), a limitation of these planning methods is their potential for errors in the intermediate stages. While the final step of the plan is intended to achieve the ultimate goal, errors in the intermediate planning steps can lead to execution failures. For instance, as illustrated in the compositional multi-tool case of Table 1, if the value of 'destination' parameter is parsed incorrectly, e.g., destination = 'None', it is obvious that *BookFlight* could not be executed successfully. To bridge this gap, **ReAct**, as described by (Yao et al., 2022), refines reasoning by combining actions and observations for deeper insights. Expanding on this, tool-learning projects (Song et al., 2023; Ruan et al., 2023) utilize the output from each step to inform the next decision. However, as depicted in Figure 1(c), in the multi-function call scenarios, ReAct, despite successfully executing each step, may not adhere to the correct reasoning path towards the final goal, as a result, it deviates to the wrong destination and may end up early. For instance, in the previously mentioned scenario, the ReAct execution flow would be: *GetUserDestination* (userName='Lucas') -> destination, flight_ID = *FindFlight* (destination) -> Final Answer, which is not completed since the last API *BookFlight* has not been executed.

In summary, both one-step/CoT planning and ReAct are forward reasoning solutions, so they encounter similar control challenges: each step exhibits a high level of **unpredictability** and **uncertainty**, especially at the beginning when the search space is large. Errors can propagate from a wrong thought or action, leading to incorrect solution paths or final goals. This issue arises because these methods start from scratch and progress forward towards the final target, with the LLM bearing the entire burden of planning.

To address these issues, we propose a controllable yet general framework called **Reverse Chain**. This framework consists of a generic rule and two key modules: API Selection and Argument Completion, both centered on prompting an LLM. Specifically, the generic rule in Reverse Chain performs a multi-API planning task in a **backward manner**: it starts by selecting the final API for a task, and then completes the required arguments, drawing values from the query and context, or by outputs of other APIs. When a new API is selected during the argument completion stage, this process repeats. The procedure continues iteratively until all arguments of all APIs are filled. Reverse Chain distinguishes itself from previous work with the following three main advantages: 1. **Backward reasoning**, starting from the final goal, preventing planning from deviating into a wrong direction, thus ensuring the correctness of the final goal. 2. The **step-by-step decomposition** dominated by the rule makes the process controllable, with each stage being forward-executable, effectively avoiding errors such as incorrect intermediate stage. 3. The **tasks of LLMs are simplified** to just selecting APIs and filling arguments, avoiding complex planning. This strategy effectively utilizes the strengths and capabilities of the existing LLMs without depending on extensive reasoning abilities.

In summary, the **contributions** of this paper are:

1. This paper presents Reverse Chain, a straightforward framework to improve the API planning capabilities of LLMs in an in-context-learning setting. By employing a backward reasoning scheme and a step-by-step problem-solving methodology, the process becomes more manageable and controllable.

2. This paper focuses on API planning for compositional multi-tool task. To assess the capabilities of LLMs in handling such tasks, we build a high-quality dataset containing 825 APIs and 1550 instances for that task, constructed automatically using GPT-4 (OpenAI, 2023). Additionally, an automatic evaluator powered by GPT-4 is also developed for efficient evaluation purpose.

3. Extensive experiments are conducted to demonstrate the superiority of the Reverse Chain approach in multi-API calling tasks, surpassing the state-of-the-art in-context learning approaches, e.g., CoT and ReAct.

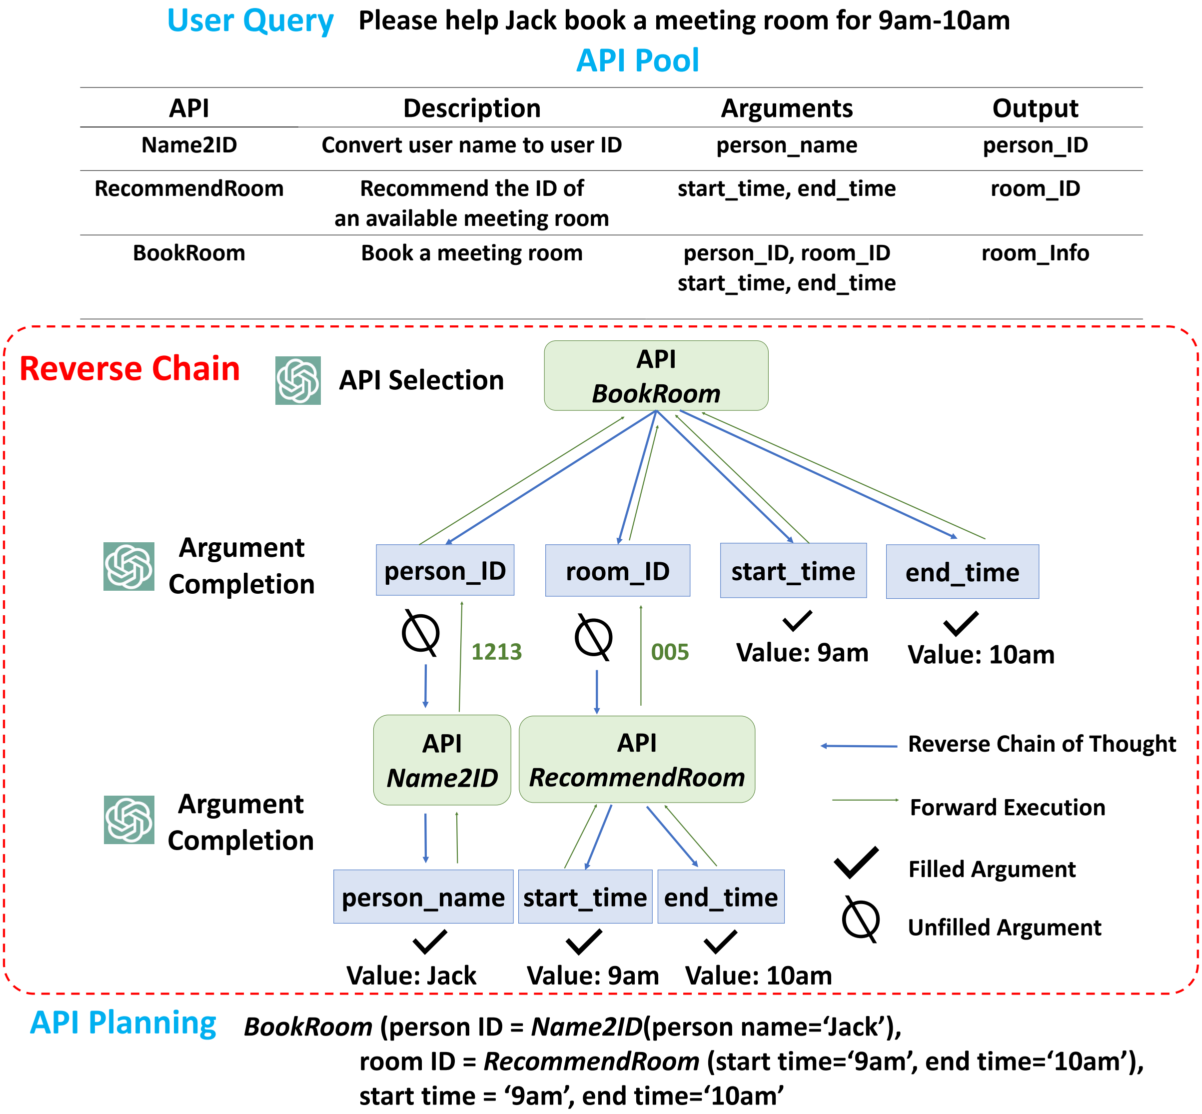
2 Related Work

Tool Learning The discussion of tool usage in LLMs has grown significantly, with models like Toolformer leading the way (Schick et al., 2023; Nakano et al., 2021). Current approaches can be divided into two categories. The first category focuses on enhancing the tool-specific capabilities of language models through fine-tuning with specialized datasets (Patil et al., 2023; Qin et al., 2023; Schick et al., 2023; Tang et al., 2023; Parisi et al., 2022; Yang et al., 2023; Qian et al., 2023). The second category directly leverages the capabilities of LLMs, prompting them to interact with various tools, ranging from AI models (Shen et al., 2023; Wu et al., 2023) to more versatile tool sets (Li et al., 2023; Liang et al., 2023; Song et al., 2023; Xu et al., 2023). Generally, the prompting approach is simpler and more scalable, but it still has a significant gap compared to fine-tuning method, so this work is proposed to enhance the API planning capability of prompting methods. It is notable that while the previously mentioned studies introduced numerous tool-learning datasets, they primarily encompass relatively simple tasks, focusing on single-tool task or independent multi-tool task. In contrast, this paper targets a more complex task called compositional task, where multiple dependent APIs are needed.

Prompting LLMs Various methods, like CoT (Wei et al., 2022b) for task decomposition and ReAct (Yao et al., 2022) for melding reasoning with action, enhance general prompting capabilities. Additionally, numerous planning methods are tailored for tool-use. (Shen et al., 2023; Liang et al., 2023) start by generating a direct solution outline, followed by selecting and executing relevant APIs. DFSDT (Qin et al., 2023) can be seen as an improved version of ReAct, enables LLMs to evaluate different reasoning paths and select the most promising one. RestGPT's (Song et al., 2023) workflow involves an iterative "plan and execute" cycle. Meanwhile, (Ruan et al., 2023) employs a sequential planning approach, feeding the outcome of each step into the subsequent one. All these works require an LLM to perform either full or step-by-step planning based on the task. However, the Reverse Chain proposed in this work simplifies this by having the LLM focus on just two tasks: API selection and argument completion, thereby greatly simplifying the task complexity. Furthermore, Unlike previous methods that progress from scratch to the final goal, Reverse Chain starts from the end goal and reasons backwards, enhancing controllability.

3 Reverse Chain: A Multi-API Planning Approach

The objective of this work is to generate effective API planning based on user queries and API candidates. Figure 2 provides a detailed example: A user query could be a natural language request like "Please help Jack book a meeting room from 9:00 am to 10:00 am". Each API in the API pool is characterized by its description, arguments, and output. e.g., the API *RecommendRoom* has a functionality description of "Recommend the ID of an available meeting room", arguments "start_time" and "end_time", and an output of "room_ID". A successful API planning consists of two parts: selecting the proper API and filling in all the argu-



API	Description	Arguments	Output
Name2ID	Convert user name to user ID	person_name	person_ID
RecommendRoom	Recommend the ID of an available meeting room	start_time, end_time	room_ID
BookRoom	Book a meeting room	person_ID, room_ID start_time, end_time	room_Info

BookRoom (person ID = *Name2ID*(person name='Jack'),
room ID = *RecommendRoom* (start time='9am', end time='10am'),
start time = '9am', end time='10am'

Figure 2: Workflow of Reverse Chain on an example.

ments correctly, where the argument values can come from the query or context, or from the output of another API.

Section 3.1 outlines the Reverse Chain process, while Section 3.2 specifically discusses the two modules that interact with LLM: **API Selection** and **Argument Completion**.

3.1 Reverse Chaining

Different from CoT and ReAct, Reverse Chain performs a task decomposition in a reverse manner, and its step-by-step problem-solving path is predefined by a generic rule. It is notable that this generic rule is not restricted with a certain type of tasks.

Figure 2 shows an example of Reverse Chain applied to API planning for a query. Initially, Reverse Chain selects the final API for a given task, this step is referred to as **API Selection**. In this example, LLM selects an API named *BookRoom* to match the task "booking a meeting room". Next, the required arguments of the selected API are identified through engineering guidance, e.g. API *BookRoom* has four required arguments, that is, person_ID, room_ID, start_time, and end_time. There are three possible approaches for arguments filling, and we define this process as **Argument Completion**:

Case 1. The argument value extracted directly from the context and user query, e.g., start_time = 9:00 am;

Case 2. When the argument value could not be obtained directly, Reverse Chain searches for another possible API whose output could complete the missing argument, e.g., the argument person_ID could be obtained from API *Name2ID*;

Case 3. If it is unable to obtain the argument value from the above two cases, the generic rule will request the argument value directly from the user.

For the selected internal APIs in **Case 2**, Reverse Chain makes recursive calls to complete the required arguments of these APIs, e.g., the required argument of *Name2ID* is person_name, and the value 'Jack' could be obtained through **Case 1** in Argument Completion. The algorithm continues until the termination condition is met, i.e., all of the required arguments are completed. Finally, when all required arguments of an API are filled, the API is ready to be executed forward to complete the given task.

3.2 LLM Modules in Reverse Chain

3.2.1 API Selection

In this module, the LLM effectively determines the relevant API by analyzing the task descriptions and API candidates. The specific prompt used in this module is depicted in Figure 3.(a). Within the Reverse Chain, the API Selection module is employed in two different scenarios, separated with regard to different task description and API candidates. The first scenario occurs when selecting the ultimate API. In this case, the task descriptions correspond to the user query and the API candidates refers to all APIs in the API Pool. The second scenario occurs as a sub-module of Argument Completion. When the value of an argument cannot be obtained from the user query or context, the Reverse Chain selects an appropriate API whose output can fulfill the missing argument. In such cases, the task descriptions refers to the description of the unfilled argument. The scope of API candidates can be narrowed down through variable type matching, which encompasses Time, Date, String, etc. This capability facilitates a more refined selection process, leading to a improved accuracy.

3.2.2 Argument Completion

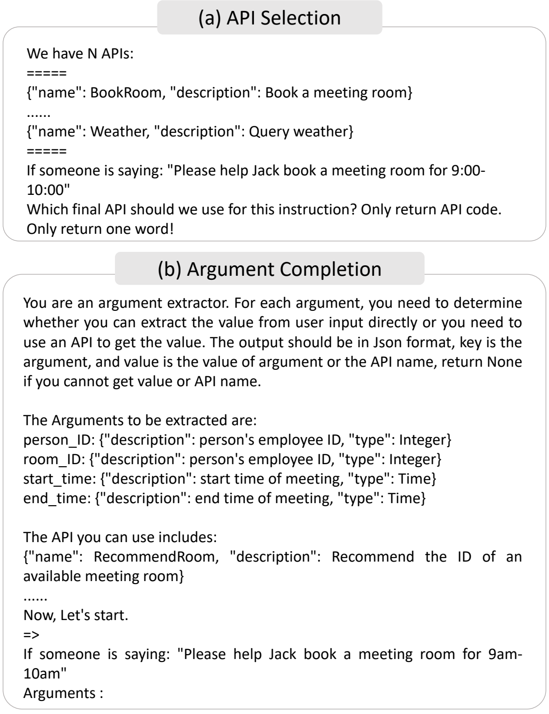
After API Selection, the required arguments for the selected API are determined with the help of engineering guidance. In this module, the LLM is leveraged to complete these arguments using information from the query, context and API candidates. The execution follows three possible outcomes:

Case 1 The argument value is directly extracted from the context or user query.

Case 2 Another API is used to complete the missing argument value, indicating that the LLM is unable to obtain the argument value directly. It should be noted that the arguments of this new internal API must be completed before execution.

Case 3 None, indicating the inability to obtain the argument value from the context, user query, and potential API output. In this case, the generic rule will request the argument value directly from the user.

Specific optimizations have been applied to the aforementioned approach, which are further explored in Section 4.2.2. The optimized prompt used in this module is illustrated in Figure 3.(b).



(a) API Selection

```
We have N APIs:
=====
{"name": BookRoom, "description": Book a meeting room}
......
{"name": Weather, "description": Query weather}
=====
If someone is saying: "Please help Jack book a meeting room for 9:00-10:00"
Which final API should we use for this instruction? Only return API code. Only return one word!
```

(b) Argument Completion

```
You are an argument extractor. For each argument, you need to determine whether you can extract the value from user input directly or you need to use an API to get the value. The output should be in Json format, key is the argument, and value is the value of argument or the API name, return None if you cannot get value or API name.

The Arguments to be extracted are:
person_ID: {"description": person's employee ID, "type": Integer}
room_ID: {"description": person's employee ID, "type": Integer}
start_time: {"description": start time of meeting, "type": Time}
end_time: {"description": end time of meeting, "type": Time}

The API you can use includes:
{"name": RecommendRoom, "description": Recommend the ID of an available meeting room}
......
Now, Let's start.
=>
If someone is saying: "Please help Jack book a meeting room for 9am-10am"
Arguments :
```

Figure 3: The details of prompts used in Reverse Chain for API Selection and Argument Completion (when LLM is chatgpt).

4 Experiments

In this section, extensive experiments are conducted to investigate the performance of Reverse Chain. We start with generating an evaluation dataset automatically, benchmarking different in-context learning methods on function calling and defining the evaluation metrics. In Section 4.1, to benchmark Reverse Chain, we compare its API planning capabilities with the current state-of-the-art in-context learning solutions on ChatGPT. Section 4.2, details a set of ablation experiments designed to elucidate the underlying principles of Reverse Chain. Finally, Section 4.3 analyzes the factors contributing to the effectiveness of Reverse Chain.

Dataset We construct a dataset for evaluating compositional multi-tool tasks. Guided by the self-instruct paradigm (Wang et al., 2022), this dataset is generated automatically based on GPT-4 and ChatGPT (gpt-3.5-turbo), involving the following steps:

1. Initially, APIs are selected from public repositories, including API-Bank (Li et al., 2023) and public-apis. We then manually create 20 diverse seed examples for compositional multi-tool task, each comprising three components: {API and its description, User query, System response}. A specific seed example is detailed in Figure 4 in Appendix A.1 .
2. These seed instances serve as in-context examples for GPT-4, so as to generating more complex new samples. The prompts for GPT-4 are detailed in Figure 6 in Appendix A.2, include a general description of the task, a randomly chosen seed example, and a prescribed response format. Then we conduct manual quality checks to filter out erroneous samples, achieving a 50% filtration rate. The high-quality samples produced are used as new seed examples for further data collection, repeating the process multiple times. To enhance dataset diversity, GPT-4's temperature is set at 0.8.
3. Additionally, we employ ChatGPT to enhance API information and uniformly standardize the samples into a JSON format. A detailed example is in the Figure 5 in Appendix A.1. Each sample includes fields: {APIs, Query, Label}, with each API in APIs represented as a JSON object with fields: {name, description, arguments, output, format}. Notably, the fields {arguments, output, and format} are generated by leveraging existing information. The prompt for this is outlined in Figure 7 Appendix A.2.

It's worth mentioning that the dataset comprises 825 unique APIs across 20 categories, totaling 1550 labeled instances, with the categories detailed in Table 7 in Appendix A.1. Focused on compositional multi-tool tasks, the samples are classified into three levels based on API nesting complexity: Level-1, two levels of API nesting, containing 798 instances; Level-2, three levels of API nesting, containing 693 instances; and Level-3, more than four levels of API nesting, containing 59 instances. Each Instance has an average of 2.93 function calls.

It is clear that this synthetic dataset is suitable for evaluation since: 1. Automated data generation guarantees unbiased data; 2. The APIs are spread across diverse domains, accurately reflecting real-world situations; 3. The inclusion of various nesting levels in compositional multi-tool tasks ensures a rich diversity.

Baseline To benchmark Reverse Chain, we measure its performance against five other in-context learning methods: **Zero-Shot**, **Few-Shot**, **Zero-Shot-CoT**, **Few-Shot-CoT**, and **ReAct**, using ChatGPT as the underlying LLM. Each method integrates API data into the prompt, utilizing the LLM's in-context learning for API planning. The Zero-Shot approach uses API information and user queries in the prompt, Few-Shot adds extra examples to prompt. Zero-Shot-CoT includes step-by-step instructions, while Few-Shot-CoT adds explanations to these steps in the examples. ReAct, implemented via the langchain framework, uses a (thought, action, observation) format for task execution. Examples of prompts for these methods can be found in the Appendix A.3. Experiments are conducted on GPT-3.5-turbo at the gpt-3.5-turbo-0301 checkpoint with the temperature set to 0.1.

Metrics We use accuracy as a metric to evaluate API planning, which consists of two aspects: API name and API arguments. The value of argument consists of direct value filling or another API calling.

Given the diversity of output formats across solutions, we rule out simple string matching due to its inefficiency and manual annotation for its time-consuming nature. Instead, we craft an efficient automated evaluator using GPT-4. Tailored prompts are designed for each baseline method to match its output characteristics. The prompts are presented in Appendix A.4. We manually test 200 samples, comparing human annotations with GPT-4 evaluations, and discover that the GPT-4 evaluator exhibits a strong 89% correlation with human assessments.

4.1 Main Results

Throughout the experiments, the given API candidates set in prompt only includes the needed APIs for a given task since the focus of this paper is primarily on evaluating the capability of LLMs on generating a proper API calling rather than the retrieval

---

https://github.com/public-apis/public-apis

Method	level 1	level 2	level 3	Overall
Zero-Shot	72.06	67.68	42.37	68.97
Few-Shot	86.46	77.48	71.18	81.87
Zero-Shot-CoT	82.45	81.38	57.62	81.29
Few-Shot-CoT	89.72	85.71	66.10	87.16
ReAct	72.68	69.11	45.76	70.06
Reverse Chain	**93.99**	**90.33**	**86.44**	**92.06**

Table 2: Evaluation results on various in-context learning methods. We can observe that the proposed Reverse Chain outperforms all other approaches.

of API. Table 2 compares the accuracy of different in-context learning methods. Under a **Zero-Shot** setting, the LLM's API planning accuracy stands at approximately 68.97%. Although **Few-Shot** methods raises this to 81.87%, the addition of Chains of Thought (CoT) further elevates performance to 87.16% in **Few-Shot-CoT**, which indicates the benefit of decomposing complex tasks. The **ReAct** strategy, with its reasoning-action-observation approach, also improves upon the zero-shot method. However, the standout performer is the **Reverse Chain** method, which surpasses all others by simplifying the multi-API calling problem into two easier tasks (API Selection and Argument Completion) and adopting a target-driven approach, thereby minimizing uncertainty. Impressively, **Reverse Chain** achieves superior results even in a zero-shot context surpassing both the **Few-Shot-CoT** and **Few-Shot** methods. Additionally, Table 2 displays results across different levels of API planning where higher levels indicates greater difficulty. As expected, all methods exhibit increased error rates as the complexity of API planning escalates. In these more challenging scenarios, the Reverse Chain approach demonstrates a more pronounced improvement compared to other methods. This significant gap underscores its robustness and effectiveness in handling complex multi-API calling tasks.

4.2 Ablation Study

In this section, we mainly focus on exploring the impact of creativity of LLMs and different argument completion strategies on the performance of Reverse Chain. The experiments are conducted on GPT-3.5-turbo.

4.2.1 Creativity and imagination of LLMs on Reverse Chain

We first investigate the impact of LLM's temperature on Reverse Chain. Temperature controls the randomness of the LLM's output. A lower temperature results in more focused and deterministic responses, while a higher temperature generates more diverse and creative answers. Table 3 shows that Reverse Chain performs better at lower temperatures, with accuracy decreasing when it seeks more creative responses. It makes sense as we require LLM to make rational and accurate decisions.

Method	level 1	level 2	level 3	Overall
T=0.1	**93.99**	**90.33**	**86.44**	**92.06**
T=0.5	78.45	59.88	59.32	69.42
T=1	69.80	50.50	49.15	60.39

Table 3: The impact of different temperatures of LLMs on the performance of Reverse Chain. T represents the temperature of ChatGPT

4.2.2 Argument Completion Optimization

Reverse Chain	**92.06**
Reverse Chain_one-by-one	74.19
Reverse Chain_three-step	38.71

Table 4: Ablation study for the design of Argument Completion in Reverse Chain.

In this part, a series of ablation studies are performed to examine various optimizations during the development of the Reverse Chain Algorithm. The optimizations discussed there primarily concentrate on the stage Argument Completion.

Reverse Chain_one-by-one In the existing Reverse Chain method, LLMs simultaneously extracts all argument results. An alternative strategy involves processing each argument completion sequentially, a method we term Reverse Chain_one-by-one. For instance, the API *FlightBooking* has two arguments: departure_point and destination. While the standard Reverse Chain completes both departure_point and destination arguments concurrently, Reverse Chain_one-by-one first fills the argument departure_point, followed by the destination.

Table 4 shows that Reverse Chain achieves a 92.06% accuracy, surpassing Reverse Chain_one-by-one's 74.19%. The performance disparity arises because the LLM in Reverse Chain can access all information about unfilled arguments during the argument completion process. This comprehensive insight enables more precise and accurate argument filling. Consider the API example *FlightBooking* with the user query: "help me book a flight from

London to Los Angeles", Table 5 demonstrates that in Reverse Chain_one-by-one, both arguments mistakenly extract the value 'London', as the LLM interprets the query's location as the destination. Conversely, Reverse Chain, recognizing two separate arguments for departure_point and destination, accurately distinguishes between the two locations in the query.

In addition to its superior performance, Reverse Chain is also more efficient in terms of time and computational resources since it only requires one interaction with the LLM.

	departure	destination
One-by-one	London	**London (wrong)**
Reverse Chain	London	Los Angeles

Table 5: Examples of Reverse Chain_one-by-one and Reverse Chain

Reverse Chain_three-step Here is an example: user query is "help Jack book a meeting room", requiring the filling of the person_ID argument for the API *BookRoom*. In the Argument Completion step of standard Reverse Chain, both the query and API candidate sets are available to the LLM, enabling direct value extraction from the query or API selection. However, in the Reverse Chain_three-step setting, argument completion is further split into two steps: initially, the LLM is given only the query for value extraction, potentially returning the extracted value or 'None'. If 'None' is returned, then it will move to API selection, choosing from the API candidate set.

Table 4 reveals that Reverse Chain_three-step attains just a 38.71% accuracy rate. This is mainly due to the absence of API information during the value extraction step, often leading to forced extraction of incorrect values even when certainty is low. In the given example, the LLM mistakenly identifies 'Jack' as the person_ID value. This confusion is not surprising given the vague nature of the person_id concept. However, with API information, the LLM can discern between using APIs or forcibly extracting values, thus enhancing accuracy. For instance, the LLM might find that person_ID is retrievable through the API PersonName2ID, and consequently, it disregards the erroneously extracted 'Jack'.

	Wrong Final Tool	Wrong Argument
Zero-Shot	33	132
Few-Shot	29	75
Zero-Shot-CoT	36	68
Few-Shot-CoT	22	58
ReAct	91	70
Reverse Chain	**20**	**40**

Table 6: Error cause statistics all methods.

4.3 Why Reverse Chain works?

In this section, we dissect common errors in API planning and illustrate how the Reverse Chain method mitigates them for improved results. We categorize the errors, identify through manual review, into two primary types, **Wrong Final Tool** and **Wrong Argument**, detailed in Table 6. This statistics is done on 500 randomly sampled instances.

Wrong Final Tool arises when the final API is missing, leading to incorrect API termination and incomplete instructions. This error is prevalent across all comparison methods due to their tendency to plan from the scratch, increases the likelihood of deviating from the final goal. Particularly, ReAct is more susceptible to this mistake because of its thought-action-observation approach that lacks global planning. Reverse Chain, by planning based on the final goal, minimizes this error, except when the query's ultimate intention is ambiguous.

The second error, **Wrong Argument**, predominates in planning methods, can be further categorized into **Wrong Argument_API** and **Wrong Argument_Value**. Wrong Argument_API error occurs when a required argument is the output of another API, but the predicted result bypasses this API, filling in an incorrect value. For instance, the correct argument is person_ID = *PersonName2ID* (name='Jack'), but the prediction inaccurately inputs person_ID='Jack'. This error often results from mistakes in the intermediate planning steps. In Reverse Chain's argument completion phase, using the optimization approach from Section 4.2.2, these errors can be greatly reduced, which allows the LLM to choose between using the API or extracting the argument value. **Wrong Argument_Value** involves extracting incorrect values for the argument. Specific cases and optimization strategies for Reverse Chain are discussed discussed in Section 4.2.2.

5 Conclusion

This paper proposed Reverse Chain, a concise, target-driven approach developed to empower LLMs with the capability to interact with external APIs in an in-context learning setting. By implementing a backward reasoning strategy and a generic rule, Reverse Chain effectively broke down complex function-calling challenges into two fundamental tasks for LLMs: API selection and argument completion. Additionally, we collected a compositional multi-tool dataset for evaluation. Extensive experiments revealed that Reverse Chain markably enhances the tool-use proficiency of the existing LLM ChatGPT, achieving superior performance compared to methods like CoT and ReAct.

Although the current work concentrates on compositional multi-tool tasks, it can also be easily extended to other types of tasks. For instance, in the case of independent multi-tool tasks, after identifying sub-intents at the beginning of the task (known as Intent Detection, a well-established problem in NLP with numerous robust solutions), we could employ the reverse chain process for each identified sub-task separately.

6 Limitations

We identify some limitations with our current work that can be addressed in future work.

- The tasks/datasets in this work assume a sequential execution of APIs, Reverse chain cannot deal with branching ("if ... then ... else ...") or looping ("while ... do/check ...") situation, both of which are important cases in multi-API planning.

- The in-context learning approach generally struggles with handling a large number of API candidates due to length limitations. A solution similar to the one in (Qin et al., 2023), which involves adding a retrieval module at the beginning of the pipeline, can be adopted.

- While our demonstration shows that Reverse Chain surpasses other in-context learning methods in performance, it does require more calls to the LLM. This highlights a trade-off between performance enhancement and increased computational resource use.

- The API in the dataset is fake and it is supposed the function is called successfully. However, in reality, API calls often fail, thus multiple calls are required, so there is a gap between the simulation and the real world.

A Appendix

A.1 Sample in dataset

In this section, we show the details of the dataset. Figure 4 is an example among the 20 diverse seed examples designed by human. Figure 5 is an example in the dataset of final version. The category and examples of APIs are listed Table 7.

A.2 Prompts for dataset construction

In this section, we show the details of prompt templates in data construction. Figure 6 is the prompt of new sample generation for GPT-4. Figure 7 is the prompt of format conversion for ChatGPT.

A.3 Prompts for baseline methods

The prompt for baseline methods are listed in Figure 8, Figure 9, Figure 10 and Figure 11.

A.4 Prompts for evaluation

Following the evaluation method used by (Tang et al., 2023), We use GPT-4 as our evaluator. The evaluation prompts for different methods are shown in Figure 12, 13, 14, 15,16,17. It should be noted that prior to conducting the ReAct evaluation, it is necessary to preprocess the answer to extract the function callings.

Dataset - Seed example

[API and API description]:

PersonName2ID(person_name) -> person_ID. This API is to convert user name to user ID.

CampusName2ID(campus_name) -> campus_ID. This API is to convert campus name to campus_name ID.

BookRoom(person_ID,room_ID,start_time,end_time) -> a list of meeting rooms. This API is to book a meeting room.

[User query]:

Please help Jack book a meeting room at TowerCenter from 9:00 to 10:00 this morning

[System response]:

BookRoom(person_ID=PersonName2ID(person_name='Jack’),
campus_ID=CampusName2ID(campus_name='TowerCenter'),
start_time='9am',end_time='10am')

Figure 4: An example of seed example.

Category	example APIs
Geocoding	GetDirections,GetUserDietaryRestrictions, DistanceCalculator
Weather	GPS2Weather,WeatherVerification
Book	AddBookToReadingList,BooksByAuthor
Transportation	FlightBooking,FindFlightByDestination
Music	AddSongToPlaylist,MusicConcert
Food & Drink	SearchRestaurant,TableReservation,RestaurantReviews
Entertainment	CinemaShowtimes,MovieReview, TheatrePlay
Shopping	FindProductId,NearestStore, ComparePrices
Health	GetExerciseRoutine,NearbyHospitalQuery,GetHealthInformation
Travel	SearchHotel,CheckBaggageAllowance,PlanTrip
Database	CheckInventory,DateConversion
Calculator	TaxCostCalculator,CalculateCalorie
Email	UserEmail2UserId,SendReview
Finance	InvestmentSuggestion,CountryTaxRate,
Convertor	User2Age,HotelName2ID
Clothes	SelectOutfit,OutfitSuggestion,FindClothingType
Time	ConvertTime,GetEventCalendar
Activity	ActivityBook,PlanDayOut
Currency Exchange	CurrencyConversion,GetExchangeRate
Search	GetCurrentFuelPrice,ProductSearch

Table 7: Domain distribution and examples of APIs in our dataset.

Dataset – Sample

```
{
        "APIs": [
          {
            "name": "CheckWeather",
            "Description": "This API checks the weather of a specific location.",
            "input_params": {
              "location": {
                "description": "the specific location",
                "type": "String"
              }
            },
            "output_params": {
              "weather": {
                "description": "the weather at the specific location",
                "type": "String"
              }
            },
            "format": "CheckWeather(location) -> weather"
          },
          {
            "name": "SelectOutfit",
            "Description": "This API selects an appropriate outfit based on the weather and
occasion.",
            "input_params": {
              "weather": {
                "description": "the weather condition",
                "type": "String"
              },
              "occasion": {
                "description": "the occasion",
                "type": "String"
              }
            },
            "output_params": {
              "outfit": {
                "description": "the recommended outfit",
                "type": "String"
              }
            },
            "format": "SelectOutfit(weather, occasion) -> outfit"
          }
        ],
        "Query": "I'm attending a birthday party in San Francisco tomorrow, what should I
wear?",
        "Label": "SelectOutfit(weather=CheckWeather(location='San Francisco'),
occasion='birthday party’)”,
},
```

Figure 5: An example of sample in dataset.

Dataset Construction –
Sample Generation Prompt

Your task is to first generate multiple APIs with their descriptions, and then generate a pair of user query and the corresponding label only using the predefined APIs in a nested manner, which means the output of one API is the input of another API. Note that for each user query, system response had better employ at least three APIs. Here is an example:

Example:
[API and API descriptions]:
PersonName2ID(person_name) -> person_ID. This API is to convert user name to user ID.
CampusName2ID(campus_name) -> campus_ID. This API is to convert campus name to campus_name ID.
BookRoom(person_ID,room_ID,start_time,end_time) -> a list of meeting rooms. This API is to book a meeting room.
[User query]:
Please help Jack book a meeting room at TowerCenter from 9:00 to 10:00 this morning
[System response]:
BookRoom(person_ID=PersonName2ID(person_name='Jack'),
campus_ID=CampusName2ID(campus_name='TowerCenter'),
start_time='9am',end_time='10am')

Given above example, please assume you are a professional assistant who generate multiple reasonable APIs with their descriptions (not limited to above mentioned ones), User query and system response using at least three APIs in a nested manner. Let's take a deep breadth and start generating APIs with their descriptions, user query and the corresponding system response using APIs in a nested manner. please give 2 different answers.
your answer should strictly follow the format:
answer1:
[API and API descriptions]:
xxx
[User query]:
xxx
[System response]:
xxx

answer2:
[API and API descriptions]:
xxx
[User query]:
xxx
[System response]:
xxx

your answer:

Figure 6: Prompt for new sample generation.

**Dataset Construction –
Format Conversion Prompt**

There are some APIs, related query and system response below. Please follow the format in the example, add the detailed infomation of "input_params" and "output_params" to the APIs, the detailed information includes the description and the type of the parameter. please return in a Json format.

Example:
[input]:
[API and API descriptions]:
PersonName2ID(person_name) -> person_ID. This API is to convert user name to user ID.
RoomName2ID(room_name) -> room_ID. This API is to convert room name to room ID.
BookRoom(person_ID,room_ID,start_time,end_time) -> a list of meeting rooms. This API is to book a meeting room.
[User query]:
Please help Jack book a meeting room at TowerCenter room from 9:00 to 10:00 this morning
[System response]:
BookRoom(person_ID=PersonName2ID(person_name='Jack'),
room_ID=RoomName2ID(room_name='TowerCenter'), start_time='9am',end_time='10am')

[output]:
```
{      "APIs": [
          {"name": "PersonName2ID", "Description": "This API is to convert user name to user ID.",
         "input_params": {"person_name": {"description": "the name of the person", "type": "String"}},
          "output_params": {"person_ID": {"description": "the ID of the person","type": "Integer"}},
           "format": "PersonName2ID(person_name) -> person_ID"},
          {"name": "RoomName2ID","Description": "This API is to convert room name to room ID.",
           "input_params": {"room_name": {"description": "the name of the room","type": "String"}},
           "output_params": {"room_ID": {"description": "the ID of the room","type": "Integer"}},
           "format": "RoomName2ID(room_name) -> room_ID"},
          {"name": "BookRoom","Description": "This API is to book a meeting room.",
           "input_params": {"person_ID": {"description": "the ID of the person","type": "Integer"},
                           "room_ID": {"description": "the ID of the room","type": "Integer"},
                             "start_time": {"description": "the start time of the meet","type": "Time"},
                             "end_time": {"description": "the end time of the meet","type": "Time"}},
          "output_params": {"booking status": {"description": "the status of the booking","type":
"String"}},
          "format": "BookRoom(person_ID,room_ID,start_time,end_time)-> booking status."}
       ],
       "Query": "Please help Jack book a meeting room at TowerCenter from 9:00 to 10:00 this morning",
      "Label":"BookRoom(person_ID=PersonName2ID(person_name='Jack'),room_ID=RoomName2ID
                         (room_name='TowerCenter'), start_time='9am',end_time='10am')"
 }
```

Please note that parameter types include Strings, Integer, Floats, Time, Dates, etc., and can be determined based on actual meanings. If the output of API 1 is the input of API 2, the type of the output parameter of your API 1 and the type of the corresponding input parameter in API 2 are the same.

now let's start with new case:
[API and API descriptions]:
xxx
[User query]:
xxx
[System response]:
xxxx

your answer, only return json format, don't generate any other content:

Figure 7: Prompt for Json format conversion.

Zero-Shot Prompt

We have the following functions. Please return function calling according to user instruction with the following format.
APIs: {api info}
user instruction: {user instruction}
please generate the function calling:

Figure 8: Prompt for Zero-Shot method.

Few-Shot Prompt

We have a list of APIs. Please return function calling according to user instruction.

Here is an example :

APIs:
{"Name": "MakeAppointment", "Description": "This API is to make an appointment.", "input_params": {"hospital_name": {"description": "hospital name", "type": "String"}, "department_name": {"description": "department name", "type": "String"}}, "output_params": {"appointment_status": {"description": "the status of the appointment", "type": "String"}}, "format": "MakeAppointment(hospital_name, department_name) -> appointment status"}
{"Name": "GetDepartment", "Description": "This API is to find the corresponding department given user symptom.", "input_params": {"symptom": {"description": "patient's symptom", "type": "String"}}, "output_params": {"department_name": {"description": "department name", "type": "String"}}, "format": "GetDepartment(symptom) -> department_name"}

user instruction: I'm in zheyi hospital, I have a stomachache and want to make an appointment to see a doctor.
function calling: MakeAppointment (hospital_name='zheyi', department_name= GetDepartment (symptom = 'stomachache')) "

Given above example, Please generate function calling according to user instruction and the given apis.
APIs: {api info}
user instruction: {user instruction}
please generate the function calling,the format must be the same as example:

Figure 9: Prompt for Few-Shot method.

Zero-Shot-CoT Prompt

We have the following functions. Please return function calling according to user instruction with the following format.
APIs: {api info}
user instruction: {user instruction}
please generate the function calling, let's think step by step:

Figure 10: Prompt for Zero-Shot-CoT method.

Few-Shot-CoT Prompt

We have a list of APIs. Please return function calling according to user instruction.

Here is an example :

APIs:
{"Name": "MakeAppointment", "Description": "This API is to make an appointment.", "input_params": {"hospital_name": {"description": "hospital name", "type": "String"}, "department_name": {"description": "department name", "type": "String"}}, "output_params": {"appointment_status": {"description": "the status of the appointment", "type": "String"}}, "format": "MakeAppointment(hospital_name, department_name) -> appointment status"}
{"Name": "GetDepartment", "Description": "This API is to find the corresponding department given user symptom.", "input_params": {"symptom": {"description": "patient's symptom", "type": "String"}}, "output_params": {"department_name": {"description": "department name", "type": "String"}}, "format": "GetDepartment(symptom) -> department_name"}

user instruction: I'm in zheyi hospital, I have a stomachache and want to make an appointment to see a doctor.
thought:

1. you choose the API named 'GetDepartment', the value for reqiured parameter 'symptom' is 'stomachache', then you will get the output parameter department_name.
2. then you get hospital_name='zheyi'.
3. Finally, you choose the API named 'MakeAppointment'.

so the function calling:
MakeAppointment (hospital_name='zheyi', department_name= GetDepartment (symptom = 'stomachache')) "

Given above example, Please generate function calling according to user instruction and the given apis.
APIs: {api info}
user instruction: {user instruction}
please generate the function calling,the format must be the same as example:

Figure 11: Prompt for Few-Shot-CoT method.

Evaluation–
Prompt for Reverse Chain

Given the Query,Label and Answer, please check the correctness of the API planning in Answer with reference to the Label.
When comparing, pay attention to the relationships between APIs and the values of parameters. If they are the same as the Label, consider it correct; if different, consider it incorrect **(return 1 for correct, 0 for incorrect)**. Please follow these rules specifically:
1. Check if Answer contains all the APIs that appear in the Label. If any API is missing, the result is incorrect.
2. Verify if the relationships between APIs in answer are the same as in the label. If different, the result is incorrect.
3. Confirm if the input parameter values for APIs in answer are the same as in the label. If not the same, the result is incorrect. However, Please note that some minor differences, such as spaces, capitalization, different format but the same meaning, such as time 7am and 7:00:00,etc. can be ignored.

Query:
Xxx
Label:
xxx
Answer:
Xxx

Now give your reason and your answer in JSON format. Correspond them to the 'reason' and 'correctness' fields, respectively. If the answer is incorrect, then write the violated rule in the reason.

Figure 12: Prompt for evaluation for Reverse Chain.

Evaluation–
Prompt for Zero-Shot

Given the Query,Label and Answer, please check the correctness of the API planning in Answer with reference to the Label.
Please note that the format of answer is not fixed as that of label, so when comparing, only pay attention to the relationships between APIs and the values of parameters. If they are the same as the Label, consider it correct; if different, consider it incorrect **(return 1 for correct, 0 for incorrect)**.
Please follow these rules specifically:
1. The format of the answer is not a criterion for correctness. For instance, the following situations are considered correct:
 1.1 Missing the names of parameters, but not missing the parameter values, such as:
 [Label]
 AddSongToPlaylist(user_ID=UserName2ID(user_name='Emily'), playlist_ID=PlaylistName2ID(playlist_name='Classic Disco Hits'), song_name='Billie Jean')
 [Answer]
 AddSongToPlaylist(UserName2ID("Emily"), PlaylistName2ID("Classic Disco Hits"), "Billie Jean") -> playlist_songs

 In the Answer, it lacks the input parameter names user_ID, playlist_ID, playlist_name, but the parameter values are correct, thus it is considered correct.

 1.2 Splitting the execution of APIs, and the calling relationships between the APIs are correct
 [Label]
 AddSongToPlaylist(playlist_ID=PlaylistName2ID(playlist_name='Best Songs'), song_ID=SongName2ID(song_name='Imagine'))
 [Answer]
 PlaylistName2ID("Best Songs") -> playlist_ID
 SongName2ID("Imagine") -> song_ID
 AddSongToPlaylist(playlist_ID, song_ID) -> song_status

 First, execute API PlaylistName2ID to obtain playlist_ID, then execute API SongName2ID to obtain song_ID, and finally execute API AddSongToPlaylist. Since the parameter values of each API are correct, it is considered correct.

2. Check if Answer contains all the APIs that appear in the Label. If any API is missing, the result is incorrect.
3. Verify if the relationships between APIs in answer are the same as in the label. If different, the result is incorrect.
4. Confirm if the input parameter values for APIs in answer are the same as in the label. If not the same, the result is incorrect. However, Please note that some minor differences, such as spaces, capitalization, etc. can be ignored.

Query:
xxx
Label:
xxx
Answer:
Xxx

Now give your reason and your answer in JSON format. Correspond them to the 'reason' and 'correctness' fields, respectively. If the answer is incorrect, then write the violated rule in the reason.

Figure 13: Prompt for evaluation for Zero-Shot.

Evaluation–
Prompt for Few-Shot

Given the Query,Label and Answer, please check the correctness of the API planning in Answer with reference to the Label.
Please note that the format of answer is not fixed as that of label, so when comparing, only pay attention to the relationships between APIs and the values of parameters. If they are the same as the Label, consider it correct; if different, consider it incorrect **(return 1 for correct, 0 for incorrect)**.
Please follow these rules specifically:
1. The format of the answer is not a criterion for correctness. For instance, the following situations are considered correct:
   1.1 Missing the names of parameters, but not missing the parameter values, such as:
   [Label]
   AddSongToPlaylist(user_ID=UserName2ID(user_name='Emily'), playlist_ID=PlaylistName2ID(playlist_name='Classic Disco Hits'), song_name='Billie Jean')
   [Answer]
   AddSongToPlaylist(UserName2ID("Emily"), PlaylistName2ID("Classic Disco Hits"), "Billie Jean") -> playlist_songs

   In the Answer, it lacks the input parameter names user_ID, playlist_ID, playlist_name, but the parameter values are correct, thus it is considered correct.

   1.2 Splitting the execution of APIs, and the calling relationships between the APIs are correct
   [Label]
   BuyMovieTickets(show_time=MovieShowtimes(movie_name=FindMovie(genre='romantic'), city='San Francisco'), movie_name=FindMovie(genre='romantic'), seats=2)
   [Answer]
   FindMovie(genre='romantic'), MovieShowtimes(movie_name=FindMovie(genre='romantic'), city='San Francisco') -> show_time, BuyMovieTickets(show_time=MovieShowtimes(movie_name=FindMovie(genre='romantic'), city='San Francisco'), movie_name=FindMovie(genre='romantic'), seats=2) -> booking_status
   First, execute API FindMovie to obtain movie_name, then execute API MovieShowtimes to obtain show_time, and finally execute API BuyMovieTickets. Since the parameter values of each API are correct, it is considered correct.

2. Check if Answer contains all the APIs that appear in the Label. If any API is missing, the result is incorrect.
3. Verify if the relationships between APIs in answer are the same as in the label. If different, the result is incorrect.
4. Confirm if the input parameter values for APIs in answer are the same as in the label. If not the same, the result is incorrect. However, Please note that some minor differences, such as spaces, capitalization, different format but the same meaning, such as time 7am and 7:00:00, etc. can be ignored.

Query:
xxx
Label:
xxx
Answer:
Xxx

Now give your reason and your answer in JSON format. Correspond them to the 'reason' and 'correctness' fields, respectively. If the answer is incorrect, then write the violated rule in the reason.

Figure 14: Prompt for evaluation for Few-Shot.

Evaluation–
Prompt for Zero-Shot-CoT

Given the Query,Label and Answer, please check the correctness of the API planning in Answer with reference to the Label.
Please note that the format of answer is not fixed as that of label, answer may include step-by-step thoughts and final function calling, so when comparing, only pay attention to the relationships between APIs and the values of parameters. If they are the same as the Label, consider it correct; if different, consider it incorrect **(return 1 for correct, 0 for incorrect)**.
Please follow these rules specifically:
1. The format of the answer is not a criterion for correctness. For instance, the following situations are considered correct:
1.1 Missing the names of parameters, but not missing the parameter values, such as:
[Label]
AddSongToPlaylist(user_ID=UserName2ID(user_name='Emily'), playlist_ID=PlaylistName2ID(playlist_name='Classic Disco Hits'), song_name='Billie Jean')
[Answer]
AddSongToPlaylist(UserName2ID("Emily"), PlaylistName2ID("Classic Disco Hits"), "Billie Jean") -> playlist_songs
In the Answer, it lacks the input parameter names user_ID, playlist_ID, playlist_name, but the parameter values are correct, thus it is considered correct.
1.2 Splitting the execution of APIs, and the calling relationships between the APIs are correct, such as:
[Label] SetAlarm(timezone=GeoLocation2TimeZone(geolocation=GetUserGeolocation(user_name='Daniel')), time='5:30am')
[Answer]
Step 1: Get the user's geolocation
Function calling: GetUserGeolocation("Daniel") -> user_geolocation
Step 2: Convert the geolocation to timezone
Function calling: GeoLocation2TimeZone(user_geolocation) -> timezone
Step 3: Set the alarm in the specified timezone
Function calling: SetAlarm(timezone, "5:30am") -> alarm_status
In this case, first, execute API GetUserGeolocation to obtain user_geolocation, then execute API GeoLocation2TimeZone to obtain timezone, and finally execute API SetAlarm. Since the parameter values of each API are correct, it is considered correct.

2. Check if Answer contains all the API that appear in the Label. If any API is missing, the result is incorrect.
3. Function calling must include explicit API names and must match those in the label to be considered correct. answer in the following example lacks explicit API names, so it is considered incorrect：
[Label]
AddSongToPlaylist(user_ID=UserName2ID(user_name='Olivia'), playlist_ID=PlaylistName2ID(playlist_name='90s Nostalgia'), song_name='Smooth Criminal')
[Answer]:
1. Get the user ID of Olivia
2. Get the ID of the '90s Nostalgia' playlist
3. Add 'smooth Criminal' to the playlist
Please generate the function calling according to the user instruction.
Please note that the input and output parameters of the functions are just examples, and the actual parameters may vary depending on the specific implementation of the API.

4. Verify if the relationships between APIs in answer are the same as in the label. If different, the result is incorrect.
5. Verify whether each input parameter for API in answer has a value, if there is no value, consider it incorrect.
6. Confirm if the input parameter values for APIs in answer are the same as in the label. If not the same, the result is incorrect. However, Please note that some minor differences, such as spaces, capitalization, different format but the same meaning, such as time 7am and 7:00:00, etc. can be ignored.

Query:
XXX
Label:
XXX
Answer:
XXX

Now give your reason and your answer in JSON format. Correspond them to the 'reason' and 'correctness' fields, respectively. If the answer is incorrect, then write the violated rule in the reason.

Figure 15: Prompt for evaluation for Zero-Shot-CoT.

Evaluation–
Prompt for Few-Shot-CoT

Given the Query,Label and Answer, please check the correctness of the API planning in Answer with reference to the Label.
Please note that the format of answer is not fixed as that of label, In general, answer consists of two components: thought and function calling. You only need to focus on whether the function calling part is correct.
when comparing, only pay attention to the relationships between APIs and the values of parameters. If they are the same as the Label, consider it correct; if different, consider it incorrect **(return 1 for correct, 0 for incorrect)**.
Please follow these rules specifically:
1. The format of the answer is not a criterion for correctness. For instance, the following situations are considered correct:
   1.1 Missing the names of parameters, but not missing the parameter values, such as:
   [Label]
   AddSongToPlaylist(user_ID=UserName2ID(user_name='Emily'), playlist_ID=PlaylistName2ID(playlist_name='Classic Disco Hits'), song_name='Billie Jean')
   [Answer]
   AddSongToPlaylist(UserName2ID("Emily"), PlaylistName2ID("Classic Disco Hits"), "Billie Jean") -> playlist_songs

   In the Answer, it lacks the input parameter names user_ID, playlist_ID, playlist_name, but the parameter values are correct, thus it is considered correct.

   1.2 Splitting the execution of APIs, and the calling relationships between the APIs are correct, such as:
   [Label]
 SetAlarm(timezone=GeoLocation2TimeZone(geolocation=GetUserGeolocation(user_name='Daniel')), time='5:30am')
   [Answer]
   GetUserGeolocation(user_name='Daniel') ->geolocation
   GeoLocation2TimeZone(geolocation) ->timezone
   SetAlarm(timezone,time='5:30am') -> alarm_status
   In this case, first, execute API GetUserGeolocation to obtain geolocation, then execute API GeoLocation2TimeZone to obtain timezone, and finally execute API SetAlarm. Since the parameter values of each API are correct, it is considered correct.

2. Check if Answer contains all the API that appear in the Label. If any API is missing, the result is incorrect.
3. Verify if the relationships between APIs in answer are the same as in the label. If different, the result is incorrect.
4. Verify whether each input parameter for API in answer has a value, if there is no value, consider it incorrect.
5. Confirm if the input parameter values for APIs in answer are the same as in the label. If not the same, the result is incorrect. However, Please note that some minor differences, such as spaces, capitalization, different format but the same meaning, such as time 7am and 7:00:00, etc. can be ignored.

Query:
xxx
Label:
xxx
Answer:
xxx

Now give your reason and your answer in JSON format. Correspond them to the 'reason' and 'correctness' fields, respectively. If the answer is incorrect, then write the violated rule in the reason.

Figure 16: Prompt for evaluation for Few-Shot-CoT.

Evaluation–
Prompt for ReAct

Given the Query,Label and Answer, please check the correctness of the API planning in Answer with reference to the Label.
Please note that the format of answer is not fixed as that of label, and the format of the answer is not a criterion for correctness.when comparing, only pay attention to the relationships between APIs and the values of parameters. If they are the same as the Label, consider it correct; if different, consider it incorrect **(return 1 for correct, 0 for incorrect)**.
Typically, the format of the answer follows the execution of the split API, following is a correct case:
[Label]
AddSongToPlaylist(user_ID=UserName2ID(user_name='Jack'), playlist_ID=PlaylistName2ID(playlist_name='Party Mix'), song_name='Havana')
[Answer]
UserName2ID("user_name": "Jack")
PlaylistName2ID("playlist_name": "Party Mix")
AddSongToPlaylist("user_ID": "user_ID", "playlist_ID": "playlist_ID", "song_name": "Havana")

In this case, first, execute API UserName2ID to obtain user_ID, then execute API PlaylistName2ID to obtain playlist_ID, and finally execute API AddSongToPlaylist. Since the parameter values of each API are correct(from the other previous API or obatined directly), it is considered correct.

Please follow these rules specifically:

1. Check if Answer contains all the API that appear in the Label. If any API is missing, the result is incorrect.
2. Verify if the relationships between APIs in answer are the same as in the label. If different, the result is incorrect.
3. Check whether each input parameter for API in answer are mentioned, if some parameters is missed, consider it incorrect.
4. There are two possibilities for value of input parameter, both of them are considered as correct: one is a valid value directly extracted from the query (this case is judged according to rule 3.1), and the other is a placeholder or descriptive text (this case is judged according to rule 3.2).
4.1 For the former, confirm if the input parameter values for APIs in answer are the same as in the label. If not the same, the result is incorrect. However, Please note that some minor differences, such as spaces, capitalization, different format but the same meaning, such as time 7am and 7:00:00, etc. can be ignored.
4.2 For the latter case for placeholder, the answer is also correct. For example:
[Label]:
AddSongToPlaylist(user_ID=UserName2ID(user_name='Olivia'), playlist_ID=PlaylistName2ID(playlist_name='90s Nostalgia'), song_name='Smooth Criminal')
[Answer]:
UserName2ID("user_name": "Olivia")
PlaylistName2ID("playlist_name": "90s Nostalgia")
AddSongToPlaylist("user_ID": "Olivia's user ID", "playlist_ID": "90s Nostalgia playlist ID", "song_name": "smooth Criminal")

In this case, the values 'Olivia's user ID' and '90s Nostalgia playlist ID' in the AddSongToPlaylist API call are placeholders or descriptive texts, however, the value of these two placeholders can be obtained from the previously executed APIs, UserName2ID and PlaylistName2ID, therefore, it is considered correct.

5. When an API is repeatedly mentioned in the answer, it is considered correct as long as it is executed correctly at least once. For example:

[label]:
AddSongToPlaylist(user_ID=UserName2ID(user_name='Sophia'), playlist_ID=PlaylistName2ID(playlist_name='Jazz Legends'), song_name='Let It Be')

[answer]:
UserName2ID("user_name": "Sophia")
PlaylistName2ID("playlist_name": "Jazz Legends")
AddSongToPlaylist("user_ID": "user_ID", "playlist_ID": "playlist_ID", "song_name": "Let It Be")
AddSongToPlaylist("user_ID": "user_ID", "playlist_ID": "playlist_ID", "song_name": "Let It Be")

in this case, the API AddSongToPlaylist is executed twice, and it is recognized as correct since this API is executed correctly.

Query:
xxx
Label:
xxx
Answer:
xxx

Now give your reason and your answer in JSON format. Correspond them to the 'reason' and 'correctness' fields, respectively. If the answer is incorrect, then write the violated rule in the reason.

Incorporating Exponential Smoothing into MLP: A Simple but Effective Sequence Model

Jiqun Chu
Peking University
`chujiqun@pku.edu.cn`

Zuoquan Lin *
Peking University
`linzuoquan@pku.edu.cn`

Abstract

Modeling long-range dependencies in sequential data is a crucial step in sequence learning. A recently developed model, the Structured State Space (S4), demonstrated significant effectiveness in modeling long-range sequences. However, It is unclear whether the success of S4 can be attributed to its intricate parameterization and HiPPO initialization or simply due to State Space Models (SSMs). To further investigate the potential of the deep SSMs, we start with exponential smoothing (ETS), a simple SSM, and propose a stacked architecture by directly incorporating it into an element-wise MLP. We augment simple ETS with additional parameters and complex field to reduce the inductive bias. Despite increasing less than 1% of parameters of element-wise MLP, our models achieve comparable results to S4 on the LRA benchmark.[1]

1 Introduction

Transformer (Vaswani et al., 2017) and its variants have been the most successful architecture in various domains of deep learning. However, the self-attention layer, which plays a crucial role in contextualizing the input, poses a significant computational and memory burden with a complexity of $O(L^2)$. This limitation hinders the application of the transformers in modeling long sequences, particularly when operating under hardware constraints, which is a common scenario for large language models. To alleviate this issue, several models have been proposed to reduce the computational and memory requirements of the transformers (Beltagy et al., 2020; Choromanski et al., 2020; Kitaev et al., 2020; Wang et al., 2020; Guo et al., 2021; Kasai et al., 2021; Peng et al., 2021; Dao et al., 2022; Hua et al., 2022; Tay et al., 2022; Fournier et al., 2023; Zandieh et al., 2023). Despite these efforts, all the models are only partial modifications of the attention mechanism and struggle to perform well on long-range sequence benchmarks such as Long Range Arena (LRA) (Tay et al., 2020).

In a recent breakthrough result, (Gu et al., 2021) introduced a novel framework called the "structured state space sequence" (S4) that leveraged the State Space Models (SSMs). S4 builds upon continuous-time SSMs and addresses the computational bottleneck of previous approaches by introducing the Normal Plus Low-Rank (NPLR) decomposition of the state matrices. Additionally, the initialization of state matrices utilizes HiPPO matrices which have been demonstrated to be effective in sequence learning in (Gu et al., 2020). Notably, S4 exhibited exceptional performance across various sequential tasks, particularly in the LRA, where it outperformed the existing transformer variants by an impressive accuracy.

Despite the impressive performance of S4, its intricate parameterization and strict initialization schemes impede researchers from fully comprehending, implementing, and analyzing the model. Although there have been attempts to simplify the S4 framework by (Smith et al., 2022; Gupta et al., 2022), these models still required the HiPPO initialization process. Other studies have explored the relationship between SSMs and recurrent units or global convolutions and demonstrated strong performance on various tasks (Li et al., 2022; Orvieto et al., 2023). These works highlight the potential of SSMs and suggest that simpler yet effective SSM architectures may exist.

In our work, we deviate from the methodology proposed by S4, which begins with the continuous SSM and then simplifies the process. We initiate our approach with a discrete SSM, namely Exponential Smoothing (ETS), and introduce additional parameters to reduce the inductive bias. This alternative approach offers two notable advantages. Firstly, it circumvents the simplification of

Findings of the Association for Computational Linguistics: NAACL 2024, pages 326–337
June 16-21, 2024 ©2024 Association for Computational Linguistics

the continuous SSMs that need sophisticated mathematical derivations and thus enhances accessibility and comprehensibility. Secondly, it explores the possibility of random initialization departing from HiPPO initialization for continuous SSMs. For the streamlining of the model, our architecture directly integrates a parameterized ETS into an element-wise Multi-Layer Perceptron (MLP). By incorporating less than 3% of the total parameters after the initial linear layer of the MLP, we successfully transform a channel-only MLP into a sequence learner.

We conducted experiments on multiple datasets, including the LRA and several Natural Language Understanding (NLU) datasets. Despite its simplicity, surprisingly, our model performs comparably to S4. In all six tasks in the LRA, our results slightly surpass the performance of S4 and DSS by 2.61 points on average and significantly outperform the transformer variants by about 20 points. In addition, we evaluated our model on seven NLU datasets and consistently achieved comparable performance with the transformer encoders. The findings of our work shed light on the potential of SSMs from a unique standpoint, where simply incorporating an ETS into an MLP can achieve a similar effect as the transformer model. A thorough examination of the proposed model was undertaken through an ablation study on the hyperparameters and an evaluation of the initialization method. Additional experiments were conducted to compare our model with the transformer model for efficiency and memory utilization, especially in handling lengthy texts. The results of these experiments provide evidence of the advantages of our model over the transformer model in terms of time and memory complexity.

In summary, our main contributions are as follows:

- We introduce the Exponential Smoothing Multi-Layer Perceptron (ETSMLP) model. We integrate the enhanced ETS module into an element-wise MLP to create an effective sequence model.
- We evaluate ETSMLP on the LRA and conduct comparative experiments with transformer encoders on various NLU datasets. The empirical results demonstrate the effective capacity in long-range sequence modeling.
- We conduct ablation studies on the proposed parameters and initialization methods. Additionally, we emphasize the advantages of SSMs over the attention mechanism in speed and memory efficiency.

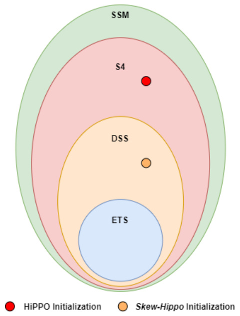

Figure 1: The relations among SSM, S4, DSS, and ETS. The HiPPO initialization is pointed out in red while the *Skew-Hippo* initialization is pointed out in orange.

2 Preliminaries

We introduce basic notations and briefly review SSMs and ETS in this section. Focusing on time-invariant sequence models, we aim to transform a sequence of inputs $X = \{x_1, \dots, x_n\} \in \mathbb{R}^{n \times d}$ into a corresponding sequence of outputs $Y = \{y_1, \dots, y_n\} \in \mathbb{R}^{n \times d}$ with each output y_i is exclusively based on historical data $x_1, \dots, x_i$.

2.1 State space models

The continuous-time SSM is characterized by the differential equation (1), which establishes the relationship between a continuous-time scalar input $x(t)$ to a scalar output $y(t)$ with the state matrix $A \in \mathbb{R}^{d \times d}$ and vectors $B \in \mathbb{R}^{d \times 1}$, $C \in \mathbb{R}^{1 \times N}$:

$$\frac{dh}{dt}(t) = Ah(x) + Bx(t) \quad , \quad y(t) = Ch(t). \tag{1}$$

If we set a sample time interval $\Delta > 0$, and assume that the duration of sampling remains constant Δ, we convert the continuous-time SSM into a discrete-time one using a recursive equation in the following:

$$h_k = \bar{A}h_{k-1} + \bar{B}x_k \quad , \quad y_k = \bar{C}h_k, \tag{2}$$

where $\bar{A} = e^{A\Delta}$,$\bar{B} = (\bar{A} - I)A^{-1}B$ and $\bar{C} = C$. With $x_0 = 0$, we unroll this recursion explicitly as the equation (3) which can be vectorized into a convolution in the equation (5) with the SSM convolution kernel defined in the equation (4) as follows:

$$y_k = \sum_{j=0}^{k} \bar{C}\bar{A}^j \bar{B} x_{k-j}, \tag{3}$$

$$\bar{K} \in \mathbb{R}^L = (\bar{C}\bar{B}, \dots, \bar{C}\bar{A}^{L-1}\bar{B}), \tag{4}$$

$$y = \bar{K} * x. \tag{5}$$

If we obtain the kernel $\bar{K}$, the convolution function aforementioned can be efficiently computed with Fast Fourier Transform (FFT) in $O(L\log(L))$ (Cormen et al., 2022). Nevertheless, the main challenge in the computation of SSMs is how to efficiently compute $\bar{K}$ from the matrices $\bar{A}, \bar{A}$ and $\bar{C}$. S4 proposes an effective parameterization through decomposing matrix $\bar{A}$ to the NPLR matrices (Gu et al., 2021), and diagonal state spaces (DSS) only consider the circumstances when A is diagonalizable over $\mathbb{C}$ (Gupta et al., 2022). Both methods involve intricate mathematics, sophisticated parameterization, and strict initialization, all of which are indispensable for achieving excellent performance. Our method will start from a special SSM, namely ETS, which gives a new insight into this problem, and requires fewer mathematical operations, fewer parameters, and more flexible initialization.

2.2 Exponential smoothing

ETS is a time series forecasting method that utilizes a weighted average of past observations to predict future values (Winters, 1960; Hunter, 1986; Hyndman et al., 2008). The fundamental idea behind ETS is to give more weight to recent observations and less to older ones, with the weights decreasing exponentially as the observations get older. The core recursive equation for this method is the equation (6) with the smoothing factor λ in the range $(0, 1)$:

$$y_t = \lambda x_t + (1-\lambda) y_{t-1}. \tag{6}$$

ETS is a special SSM, with the substitution $\bar{A} = 1-\lambda, \bar{B} = \lambda, \bar{C} = 1$. However, compared with SSMs, ETS cannot capture sequential information effectively. Figure 1 illustrates the relationship among SSMs, S4, DSS, and ETS. S4 and DSS are derived from the continuous-time SSMs with the difference that S4 decomposes the matrix A into an NPLR matrix, while DSS assumes A to be diagonalizable. As a result, the HiPPO initialization in S4 cannot directly adapt to DSS (Gu et al., 2020). The initialization in DSS is *skew-Hippo* initialization which is the normal part of the HiPPO matrix.

ETS serves as a special case within the realm of discrete-time SSM. In our approach, we incorporate parameters directly from ETS, distinguishing ours from S4 and DSS methods that simplify equations based on continuous-time SSMs.

3 Exponential Smoothing Multi-layer Perceptrons

In this section, we present our ETSMLP. We first introduce a complex exponential smoothing module which is the pivotal component of our architecture. We then describe the full architecture with two proposed versions, ESMLP and ESMLP-Gate.

3.1 Complex exponential smoothing module

Learnable damped factors. Damped factors are a commonly used technique of ETS for attenuating the influence of specific factors (Gardner Jr, 1985; McKenzie and Gardner Jr, 2010). We introduce two learnable damped factors α and β into simple ETS in equation (7). The factor α controls the learning of λ in an exponential scalar. A small α close to zero amplifies the impact of λ and results in λ^α approximating 1 while a large α diminishes its impact, driving the combination closer to 0. The factor β serves as a multiplicative factor that controls the influence of the current input x_t. The recursion can be unrolled in equation (8) with the kernel defined by the equation (9) as follows:

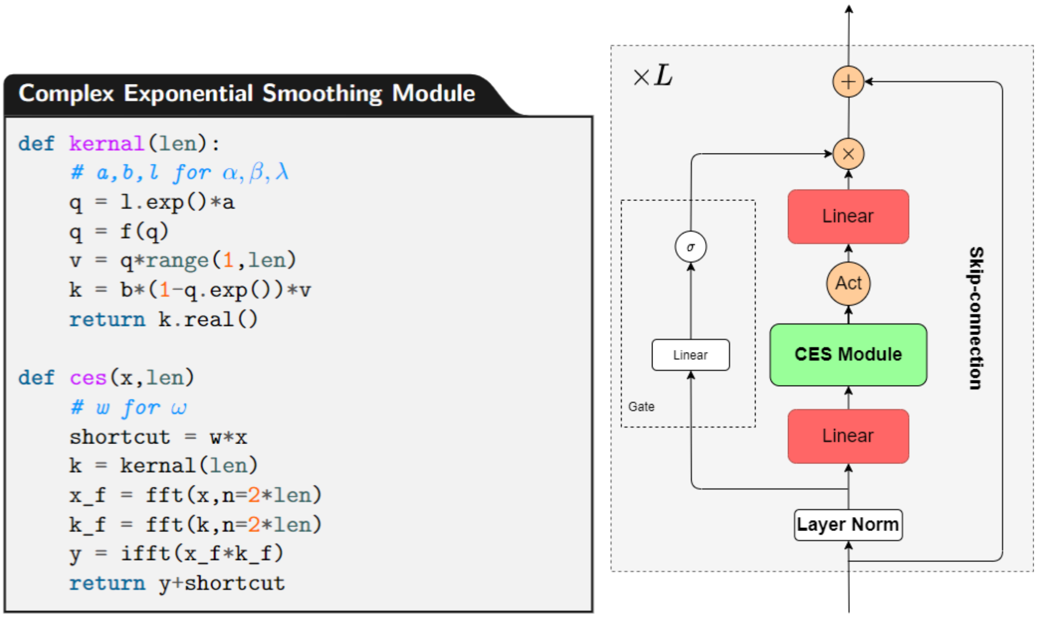
$$y_t = (1-\lambda^\alpha)\beta x_t + (\lambda^\alpha) y_{t-1}, \tag{7}$$

$$y_t = \sum_{i=0}^{t} (\lambda^\alpha)^i (1-\lambda^\alpha)\beta x_{t-i}, \tag{8}$$

$$K = ((1-\lambda^\alpha)\beta, \dots, (\lambda^\alpha)^{L-1}(1-\lambda^\alpha)\beta). \tag{9}$$

Complex parameters. Complex parameters in ETS have been demonstrated to capture both level and trend information in forecasting (Svetunkov et al., 2022). By extending the learning capacity and enlarging the parameter space, the transformation from real to complex numbers is beneficial. Therefore, we treat α, λ, β as complex numbers, and keep the input x_t and the output y_t real. Consequently, only the real part of the kernel coefficients is utilized, and the corresponding computation formula is as follows:

$$y_t = \sum_{i=0}^{t} \Re((\lambda^\alpha)^i (1-\lambda^\alpha)\beta) x_{t-i}. \tag{10}$$



Complex Exponential Smoothing Module

```
def kernal(len):
    # a,b,l for $\alpha,\beta,\lambda$
    q = l.exp()*a
    q = f(q)
    v = q*range(1,len)
    k = b*(1-q.exp())*v
    return k.real()

def ces(x,len):
    # w for $\omega$
    shortcut = w*x
    k = kernal(len)
    x_f = fft(x,n=2*len)
    k_f = fft(k,n=2*len)
    y = ifft(x_f*k_f)
    return y+shortcut
```

Figure 2: Overview of the ETSMLP architecture. The left is the pseudo-code of the complex exponential smoothing (CES) module. The right is the entire architecture with a gate mechanism.

Exponential parameterization. Directly training the parameters λ is infeasible, due to the rapid explosion of the gradient λ within a few steps. This challenge becomes evident upon inspecting the equation (6). Given the gradients of y_t $\frac{\mathrm{d}L}{\mathrm{d}y_t}$, the gradient of λ $\frac{\mathrm{d}L}{\mathrm{d}\lambda}$ could be derived from the formulas (11). This reveals that the gradients of λ are proportional to $\frac{1}{1-\lambda}$. Consequently, as λ approaches 1, the gradients of λ will explode.

$$\frac{\mathrm{d}L}{\mathrm{d}\lambda} = \sum_{t=1}^{N}\frac{\mathrm{d}L}{\mathrm{d}y_t}\sum_{j=1}^{t}\Big[\frac{(t-j)}{\lambda}-(t-j+1)\Big]\lambda^{t-j}x_j$$
$$\approx \sum_{t=1}^{N}\frac{\mathrm{d}L}{\mathrm{d}y_t}\sum_{j=1}^{t}(-1*\lambda^{t-j}x_j) = -\frac{\sum_{t=1}^{N}(\frac{\mathrm{d}L}{\mathrm{d}y_t}y_t)}{1-\lambda} \qquad (11)$$

To address this issue, we propose an exponential transformation of the parameters. We trains the parameter $\lambda' = \log\log\lambda$ instead of the λ. We prove that the stability of learning λ' constrains the gradients of λ' within a specified range, as described in Proposition 1.

Proposition 1. *Let $\lambda \in \mathbb{C}$ be within the interior of the hollow unit disc $D^\circ(0,1) = \{z||z| < 1\}/\{(0,0)\}$. We define $\lambda' = \log\log\lambda$ which substitutes λ in the equation (10). If the gradients of y_t satisfy $\sum_0^L \frac{\mathrm{d}L}{\mathrm{d}y_t}y_t < \infty$, the gradients of the real and imaginary parts of λ' are bounded for all $\lambda \in D^\circ(0,1)$.*

The proof of Proposition 1 is elementary and is provided in the appendix A. This proposition proves that the exponential parameterization λ' gradients are stable in the feasible region of λ.

Constraint function and shortcut. In addition to the settings as aforementioned, λ^α must lie within the feasible field $D^\circ(0,1)$. To address this, we introduce a constraint function to enforce the validity of these parameters, which can be formulated in equation (12):

$$f(\lambda) = \begin{cases} \lambda, & \text{if } |\lambda| < max_\lambda; \\ \frac{max_\lambda}{|\lambda|}\lambda, & \text{if } |\lambda| \geq max_\lambda. \end{cases} \qquad (12)$$

Although this solution is simple, it yields remarkably effective results. We also explored an alternative approach inspired by the separation of real and imaginary parts, as discussed in (Gu et al., 2022; Orvieto et al., 2023). Unfortunately, its performance is unsatisfactory, because the gradients of imaginary parts appear unstable and may explode in a few steps.

Moreover, we introduce a parameter ω to establish a shortcut from input to output, a commonly used technique in deep learning. This parameter serves as a gating unit that regulates the incoming input. The final output of our model can be described with the sigmoid function σ as follows:

$$o = \sigma(\omega)x + y. \qquad (13)$$

Bidirectional. We describe a bidirectional model incorporating backward recursion as $y_t = (1 -$

$\lambda_2)x_t + \lambda_2 y_{t+1}$. By employing a bidirectional model, the influence of tokens is determined by both preceding and succeeding tokens, resulting in a wide-ranging receptive field. The kernel function is formed by combining the forward and backward kernels in equation (14). We employ the circular convolution to compute the output with the input being zero-padded on the right side to twice its length.

$$\begin{aligned} K = (1-\lambda_1, \ldots, (1-\lambda_1)\lambda_1^{L-1}, \\ (1-\lambda_2)\lambda_2^{L-1}, \ldots, 1-\lambda_2). \end{aligned} \tag{14}$$

A sketch of the full computation is presented on the left of Figure 2. Initially, we calculate the kernel corresponding to the sequence length and subsequently apply FFT to compute the convolution of the inputs and the kernel. The Complex Exponential Smoothing (CES) module produces the final results by combining the shortcut and the convolution outputs. Although the current code is designed for a unidirectional kernel, a bidirectional kernel can be easily achieved by connecting two unidirectional kernels using the equations as aforementioned.

3.2 ETSMLP blocks

We incorporate the CES module into the element-wise MLP to learn token-level information. The CES module facilitates the mix of input information at the token level, resulting in a mixed output containing sequence information. We integrated the CES module just before the activation function into the MLP in the full architecture, depicted in Figure 2. The functions are described as follows:

$$\begin{aligned} X = \mathrm{LayerNorm}(X_i) \in \mathbb{R}^{L\times d}, \\ H = W_1 X \in \mathbb{R}^{L\times D}, \\ Y = \sigma(\mathrm{CES}(H)) \in \mathbb{R}^{L\times D}, \\ Z = W_2 Y \in \mathbb{R}^{L\times d}. \end{aligned}$$

Compared to standard MLP, the increased parameters constitute only $\frac{3}{d}$ of the original MLP, where d is the embedding dimension. For a typical model with $d = 512$, a modest increase 0.58% parameters enables channel-only MLP to learn sequence information, which is previously unattainable. Moreover, the computational and memory complexity is lower than that of the self-attention, as detailed in Section 4.3.3

Gated architecture. To further enhance the expressive capacity of our model, we add a gate mechanism like (Cho et al., 2014; Shazeer, 2020; Hua et al., 2022). This gate unit controls the output of each block. After obtaining the representation after layernorm, we pass it through a linear layer, derive the score using the sigmoid function, multiply it with the output from the preceding module, and obtain the output of our layer through a residual connection. As in Figure 2, we express these processes as follows:

$$\begin{aligned} G = \mathrm{sigmoid}(W_g X) \in \mathbb{R}^{L\times d}, \\ O = G \otimes Z \in \mathbb{R}^{L\times d}, \\ X_{i+1} = X_i + O \in \mathbb{R}^{L\times d}. \end{aligned}$$

4 Experiments

We present an empirical comparison between our ETSMLP and other baseline models. Our experiments encompass a set of sequence modeling tasks, including LRA, MNLI, IMDB, etc. The main experiment results are divided into two subsections: LRA and NLU benchmarks. Furthermore, we conduct an ablation study to examine the influence of hyperparameters. Additional information about the experimental details and datasets can be found in Appendix B.

4.1 LRA

The LRA benchmarks are a collection of long sequence modeling tasks ranging from 1024 to over 16000 (Tay et al., 2020). In Table 1, we compare our models to several variants of SSM and Transformer. We observe that our model outperforms all the Transformer variants and achieves the comparable performance of S4 on average which is 83.09 vs 80.48. Although we don't gain the highest average scores among all concurrent works, it still produces comparable results without relying on the attention in MEGA (Ma et al., 2022), or Hippo initialization in S5 (Smith et al., 2022). When comparing the individual tasks horizontally, we observe that our model performs significantly better in text tasks such as *ListOps* and *Text*, while slightly underperforming on image tasks like *Image*. This discrepancy may be attributed to the weight decaying exponentially with distance, which is unsuitable for flattened patches.

models	*ListOps*	*Text*	*Retrieval*	*Image*	*Pathfinder*	*Path-X*	Avg.
Transformer	36.37	64.27	57.46	42.44	71.40	-	53.66
Reformer	37.27	56.10	53.40	38.07	68.50	-	50.36
Linear Trans	16.13	65.90	53.09	42.34	75.30	-	50.46
Performer	18.01	65.40	53.82	42.77	77.05	-	51.18
S4	58.35	76.02	87.09	87.26	86.05	88.10	80.48
$DSS_{SOFTMAX}$	60.6	84.8	87.8	85.7	84.6	87.8	81.88
DSS_{EXP}	59.7	84.6	87.6	84.9	84.7	85.6	81.18
S5	62.15	89.02	91.4	88.0	95.33	98.58	87.46
Mega-chunk	58.76	90.19	90.97	85.80	94.41	93.81	85.66
ETSMLP	61.35	87.2	85.78	78.14	85.86	87.21	80.92
ETSMLP-Gate	**62.55**	**88.49**	86.72	75.34	**91.66**	**93.78**	83.09

Table 1: Performance on the LRA benchmark tasks. We follow the procedure reported in (Ma et al., 2022), and report means across three seeds for our methods. The Bold scores indicate the best performance between S4, DSS, and our models. We also include and underline the state-of-art results of concurrent methods such as Mega and S5.

Table 2: Performance on the several NLU tasks. We report accuracy scores averaged across three seeds for all the datasets. All models are trained from scratch and are of a fairly similar size. The bold scores indicate the highest performance of each dataset.

We provide the hyperparameters used in our experiments in Appendix B.

4.2 NLU

The LRA results demonstrate the benefits of our method in sequential text tasks. Furthermore, we conduct experiments on various NLU tasks and compare our models with a transformer encoder architecture trained from scratch. Our experimental evaluations were divided into three categories: sentence classification, including *CoLA* (Warstadt et al., 2019), *SST-2* (Socher et al., 2013), and *IMDB* (Maas et al., 2011); sentence similarity, including *QQP*, [2] and *MRPC* (Dolan and Brockett, 2005); and natural language inference, including *MNLI* (Williams et al., 2018) and *QNLI* (Rocktäschel et al., 2015). We present the experiment results in Table 2, which reveal that our architecture can achieve comparable or even superior performance to transformers on all the datasets. Considering the simple computation and slight increase in parameters on MLP, these results suggest that the ETS has tremendous potential in sequence learning tasks.

4.3 Analysis

4.3.1 Role of damped factors and fields

The experimental results presented above are encouraging and demonstrate the effectiveness of the ETS for sequence modeling tasks. It is proved empirically that even the simplest SSM like ETS can achieve a competitive result compared with other state space model variants. To further consider if we would simplify the ETS in fewer parameters, we conducted ablation studies on the damped factors and the number fields. Table 3 shows the accuracy results of *Listops* if we remove α, β, or ω or change all parameters from complex to real fields. We could observe that whether to remove the α or β or ω or the complex field, the performance of our method drops significantly, especially α, ω and complex field. These experiments illustrate the necessity of our architecture in sequence modeling tasks.

model	Arch	Acc
ETSMLP	Real	40.5
	No α	41.5
	No ω	40.75
	No β	56.05
	-	61.35

Table 3: Ablation analysis of the learnable parameters α, β, ω on *ListOps*. "-" means the keeping all the parameters of our methods.

model	Initialization	Acc
ETSMLP	Stable(0.3,0)	52.4
	Stable(0.7,0)	52.4
	Stable(0.5,0)	52.95
	Ring(0.1,0.6)	60.55
	Ring(0.6,0.9)	58.95
	Ring(0.1,0.9)	61.35

Table 4: Performance of *ListOps* with different initialization. "Ring" means uniform sampling on a ring $\{r_{min} \leq |z| \leq r_{max} | z \in \mathbb{C}\}$. "Stable" means initialization λ' on the same point.

4.3.2 Initialization of parameters

S4 and its variants conducted several experiments on $HiPPO$ initialization and concluded that random initialization may hurt performance (Gu et al., 2021, 2022). Because of the different computation processes, $HiPPO$ initialization doesn't work in our models. Therefore, we consider the ring initialization method, which involves uniform sampling on a ring defined by the range $\{r_{min} \leq |z| \leq r_{max} | z \in \mathbb{C}\}$. By predefining values for r_{min} and r_{max}, we uniformly sample λ along the ring, between circles with radii r_{min} and r_{max}. In addition to examining the effects of different initializations, we conducted experiments using fixed-value initialization operations. Our experimental results on *listops* are displayed in Figure 4. It can be observed that our model exhibits consistent performance across rings of varying sizes. However, when dealing with fixed points, the effectiveness diminishes significantly.

4.3.3 Efficiency and memory analysis

To assess the speed and memory efficiency across different lengths, we performed experiments using a synthetic dataset that combines multiple sentences to achieve sufficient length. Our chosen task is language modeling, as it allows us to segment sentences into desired lengths. The maximum length of our synthetic dataset is 8192. We adjusted the sample length within each batch to compare the words per second (WPS) and memory usage (in GB) between the transformer, S4, and our model at comparable sizes. The batch size was uniformly set to 1 to ensure accurate memory usage. All training procedures are carried out on an NVIDIA GeForce GTX 2080 GPU.

The comparison results are presented in Figure 3. Notice that our approach consistently achieves the highest WPS for all the sequence lengths. The slower performance of S4 can be attributed to its complex calculations on the NPLR. Both our model and S4 share a common characteristic: the WPS remains constant as the sequence length increases, while the transformer shows a decrease. Furthermore, the memory requirements of the transformer exhibit an almost quadratic growth, whereas our model and S4 demonstrate linear growth, with our model having a lower slope. For sequence lengths below 3072, there is minimal difference between our model and the transformer. However, as the training length increases, the undesirable quadratic growth in computation and memory complexity becomes apparent in the transformer, whereas our method avoids this issue.

5 Related Works

Since the Transformer was introduced, the quadratic time cost of the attention operation has been numerously researched. Optimizing this operation can improve the efficiency when training and inferencing long context for large language models (Xiao et al., 2023). Recently, many transformer variants have been introduced to reduce the complexity of attentions (Tay et al., 2022), including sparse attention (Beltagy et al., 2020; Kitaev et al., 2020; Guo et al., 2021), kernel-based methods (Choromanski et al., 2020; Kasai et al., 2021; Peng et al., 2021), chunked attention with gating (Hua et al., 2022; Ma et al., 2022) and other efficient methods (Wang et al., 2020; Dao et al., 2022). Another line of research tries to replace the attention mechanism with other modules for long sequences and avoid quadratic time costs. A dizzying number of attention-free models have emerged, where SSMs are becoming one of the most promising models among them.

SSMs. S4 first investigated the SSM for long sequence modeling (Gu et al., 2021). They showed

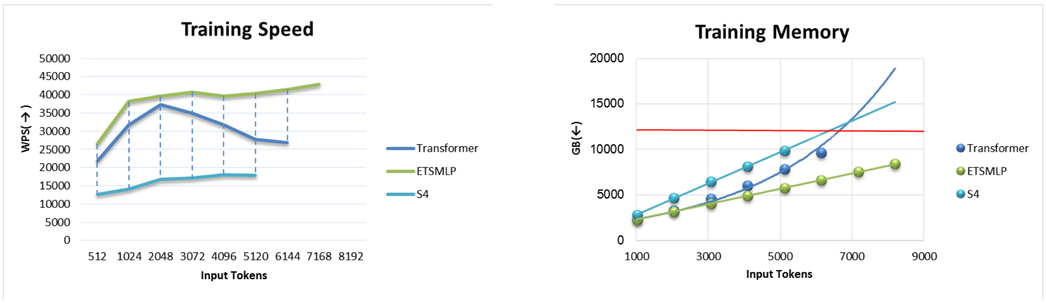

Figure 3: A training speed and memory comparison between the transformer and ETSMLP. Both models have approximately 30M parameters, and the batch size remains constant at 1 under all circumstances.

that naive instantiations of the SSM did not perform well but HiPPO-LegS matrix did (Gu et al., 2020), and hence introduced the DPLR that efficiently computed the complex diagonal plus low-rank matrix. DSS observed that a fully diagonal matrix could preserve the performance of the original S4 (Gupta et al., 2022), and S4D (Gu et al., 2022) then showed that the initialization is critical for DSS. Inspired by S4, many SSM variants emerged recently. S5 replaced single-input, single-output (SISO) SSMs in S4 with multi-input, multi-output (MIMO) (Smith et al., 2022). SGConv viewed the SSM as a global convolution model and suggested that the convolution kernel's sub-linear decay in sequence length is indispensable (Li et al., 2022). Linear Recurrent Unit (LRU) explored the relationship between the SSM and linear RNN and showed the importance of initialization, exponential parameterization, and normalization for SSMs (Orvieto et al., 2023). MEGA was the most similar approach to ours and plugged exponential moving average into the attention mechanism to improve position-wise local dependency (Ma et al., 2022). Our CES mechanism only considered a position-aware but representation-agnostic dependency which is completely different from the attention mechanism but matches the performance of the transformer.

Other attention free models. MLP-Mixer (Tolstikhin et al., 2021), and its variants proposed to replace the attention with MLPs in computer vision task (Touvron et al., 2022; Yu et al., 2022; Tatsunami and Taki, 2022). Another MLP-based model gMLP showed the potential of MLPs to model sequence dependency and achieved comparable results in pretraining and downstream NLP tasks (Liu et al., 2021). The Attention Free Transformer (AFT) replaced the attention mechanism with an element-wise multiplication and avoided the quadratic computation burden of the attention matrix (Zhai et al., 2021). Recurrent Memory Transformer (RMT) added a special cache token and utilized the recursive components to increase the context length in the transformer (Bulatov et al., 2022, 2023). Receptance Weighted Key Value (RWKV) leveraged token shift for parallel training a simple linear RNN (Peng et al., 2023). Our models do not conflict with those models in spirit. Our CES modules can be integrated into their models to improve their capabilities of sequence learning.

6 Conclusion

We proposed the ETSMLP model for long-range sequence modeling. Our approach began with a special SSM, namely ETS, and incorporated additional hyperparameters. Moreover, we proposed an exponential parameterization and a constraint function essential for stable training. The experimental results demonstrated the effectiveness of the ETSMLP in sequence learning. Our proposed module could become a plug-in module on other models to enhance their sequence learning capabilities. We hope our research could provide valuable insights into the application of SSMs and encourage further exploration in this area.

7 Limitations

Our approach focuses on evaluating datasets containing fewer than 100,000 samples, where the influence of prior knowledge on performance is substantial. In the next phase, we aim to conduct experiments on pretraining. The considerable disparity between pretraining and training from scratch requires meticulous adjustment of exponential smoothing and ingenious design of the architecture, something like Mamba (Gu and Dao, 2023).

Another limitation of our approach lies in the empirical design of the constraint function. This arises from the potential for lambda to surpass the precision of 32-bit floating point numbers if its training range is not restricted, and leads to NaN results during backpropagation. We believe that a low granularity parameterization can effectively mitigate this concern. Our future work will prioritize establishing a smooth training process on the parameter space.

A Proof of Proposition 1

We first restate Proposition 1 for the sake of convenience.

Proposition. *Let $\lambda \in \mathbb{C}$ be within the interior of the hollow unit disc $D^{\circ}(0,1) = \{z||z| < 1\}/\{(0,0)\}$. We define $\lambda' = \log\log\lambda$ which substitutes λ in the equation (10). If the gradients of y_t satisfy $\sum_0^L \frac{\mathrm{d}L}{\mathrm{d}y_t} y_t < \infty$, the gradients of the real and imaginary parts of λ' are bounded for all $\lambda \in D^{\circ}(0,1)$.*

Proof. Let the real and imaginary parts of λ' be a and b, thus $\lambda' = a + bi$.

We define intermediate variables $y'_t \in \mathbb{C}$ for t in range $\{0, 1, \ldots, L\}$ and

$$y'_t = \sum_{j=0}^{t-1} (\lambda^{\alpha})^j (1 - \lambda^{\alpha}) \beta x_{t-j}.$$

Compared with the equation (10), we find that $y_t = \Re(y'_t)$.

We have that if $\sum_0^L \frac{\mathrm{d}L}{\mathrm{d}y_t} y_t < \infty$, then $\sum_0^L \frac{\mathrm{d}L}{\mathrm{d}y_t} \Im(y'_t) < \infty$. This is proved by the following:

$$\begin{aligned}\frac{\Re(y'_t)}{\Im(y'_t)} &= \frac{\sum_{j=0}^t \Re(\beta(1-\lambda^{\alpha})\lambda^{\alpha * j})x_{t-i}}{\sum_{j=0}^t \Im(\beta(1-\lambda^{\alpha})\lambda^{\alpha * j})x_{t-i}} \\ &= \frac{\sum_{j=0}^t \Re((\beta_1 + i\beta_2)((\lambda^{\alpha})^j - (\lambda^{\alpha})^{j+1}))x_{t-i}}{\sum_{j=0}^t \Im((\beta_1 + i\beta_2)((\lambda^{\alpha})^j - (\lambda^{\alpha})^{j+1}))x_{t-i}} \\ &= \frac{\sum_{j=0}^t |\lambda^{\alpha}|^j (\beta_1(\cos(j\theta) - |\lambda^{\alpha}|\cos((j+1)\theta)) -}{\sum_{j=0}^t |\lambda^{\alpha}|^j (\beta_2(\cos(j\theta) - |\lambda^{\alpha}|\cos((j+1)\theta)) +} \\ &\quad \frac{\beta 2(\sin(j\theta) - |\lambda^{\alpha}|\sin((j+1)\theta)))x_{t-i}}{\beta 2(\sin(j\theta) - |\lambda^{\alpha}|\sin((j+1)\theta)))x_{t-i}}.\end{aligned}$$

It is obvious that the ratio $\frac{\Re(y'_t)}{\Im(y'_t)}$ is bounded for the finite summation $\sum_0^L \frac{\mathrm{d}L}{\mathrm{d}y_t} \Im(y'_t)$ is bounded too.

To compute the gradients of a and b, we consider the gradients of λ' for y'_t. The function of y'_t is holomorphic function for λ' thus the gradients is:

$$\begin{aligned}\frac{\mathrm{d}y'_t}{\mathrm{d}\lambda'} &= \sum_{j=0}^{t} \beta x_{t-j}(\alpha j \lambda^{\alpha j - 1} - \alpha(j+1)\lambda^{\alpha(j+1)-1}) e^{e^{\lambda'}} e^{\lambda'} \\ &= \sum_{j=0}^{t} \beta x_{t-j} \alpha \lambda^{\alpha j} (j - (j+1)\lambda^{\alpha}) \log(\lambda) \\ &= \sum_{j=0}^{t} \beta x_{t-j} \alpha \lambda^{\alpha j} (j - (j+1)\lambda^{\alpha}) \log(\lambda).\end{aligned}$$

As y'_t is a holomorphic function for λ' and $y_t = \Re(y'_t)$, we thus have:

$$\frac{\mathrm{d}y'_t}{\mathrm{d}\lambda'} = \frac{\mathrm{d}y_t}{\mathrm{d}a} - \frac{\mathrm{d}y_t}{\mathrm{d}b} i.$$

Thus, the gradients of a and b is computed by the chain rule in the following:

$$\begin{aligned}\frac{\mathrm{d}L}{\mathrm{d}a} &= \sum_{t=1}^{L} \frac{\mathrm{d}L}{\mathrm{d}y_t} \frac{\mathrm{d}y_t}{\mathrm{d}a} \\ &= \sum_{t=1}^{L} \frac{\mathrm{d}L}{\mathrm{d}y_t} \Re(\sum_{j=0}^{t} \beta x_{t-j} \alpha \lambda^{\alpha j} (j - (j+1)\lambda^{\alpha}) \log(\lambda));\end{aligned}$$

$$\begin{aligned}\frac{\mathrm{d}L}{\mathrm{d}b} &= \sum_{t=1}^{L} \frac{\mathrm{d}L}{\mathrm{d}y_t} \frac{\mathrm{d}y_t}{\mathrm{d}b} \\ &= -\sum_{t=1}^{L} \frac{\mathrm{d}L}{\mathrm{d}y_t} \Im(\sum_{j=0}^{t} \beta x_{t-j} \alpha \lambda^{\alpha j} (j - (j+1)\lambda^{\alpha}) \log(\lambda)).\end{aligned}$$

Obviously, $\frac{\mathrm{d}L}{\mathrm{d}a}$ and $\frac{\mathrm{d}L}{\mathrm{d}b}$ are continue on all $\lambda \in D^{\circ}(0,1)$.

We consider the boundary of $D^{\circ}(0,1)$. We first take a look at the zero point. For $\lim_{\lambda \to \infty} \lambda^{\alpha j} \log(\lambda) = 0$, we can easily compute the limitation :

$$\begin{aligned}\lim_{\lambda \to 0} \frac{\mathrm{d}L}{\mathrm{d}a} &= \sum_{t=1}^{L} \frac{\mathrm{d}L}{\mathrm{d}y_t} \Re(\sum_{j=0}^{t} \beta x_{t-j} \alpha j * (\lambda^{\alpha j} \log(\lambda))) \\ &= 0.\end{aligned}$$

For the point λ_0 on the unit cycle, we can find a constant $C(\lambda_0) \in D(0, 2L)$ which satisfies $\Re(\beta \alpha \lambda_0^{\alpha j}(j - (j+1)\lambda_0^{\alpha})) \leq \Re(\beta \alpha \lambda_0^{\alpha j} * C(\lambda_0))$ for all $j \in \{1, 2, \ldots, L\}$. Therefore,

$$\begin{aligned}\frac{\mathrm{d}L}{\mathrm{d}a} &= \sum_{t=1}^{L} \frac{\mathrm{d}L}{\mathrm{d}y_t} \frac{\mathrm{d}y_t}{\mathrm{d}a} \\ &\leq \sum_{t=1}^{L} \frac{\mathrm{d}L}{\mathrm{d}y_t} \Re(\sum_{j=0}^{t} \beta x_{t-j} \alpha \lambda^{\alpha j} C(\lambda_0) \log(\lambda)) \\ &= \sum_{t=1}^{L} \frac{\mathrm{d}L}{\mathrm{d}y_t} \Re(\frac{y'_t}{1 - \lambda^{\alpha}} \alpha C(\lambda_0) \log(\lambda)).\end{aligned}$$

Table 5: The hyperparameters of the ESMLP on LRA and NLU tasks. D is the embedding size, H is the hidden features, and L is the number of layers. LR is the learning rate, WD is weight decay and DP is dropout. BN and LN in the column $Norm$ refer to Batch Normalization and Layer Normalization. For NLU tasks, the small and base models have different model scales.

We know that $\frac{\log(\lambda)\alpha}{1-\lambda^\alpha}$ is finite on the unit cycle except for 1 and the $\lim_{\lambda\to 1}\frac{\log(\lambda)\alpha}{1-\lambda^\alpha} = -1$ is also finite. As a result, we can find a constant D which satisfies $\Re(y_t'\frac{\alpha\log(\lambda_0)}{1-\lambda_0^\alpha}C(\lambda_0)) \leq \Re(y_t')D$ for all $t = \{1,\dots,L\}$ and λ_0. Thus, for all λ_0 on the unit cycle we have:

$$\frac{\mathrm{d}L}{\mathrm{d}a} \leq \sum_{t=1}^{L}\frac{\mathrm{d}L}{\mathrm{d}y_t}\Re(y_t')D < \infty.$$

Similarly, we have:

$$\frac{\mathrm{d}L}{\mathrm{d}a} \leq \sum_{t=1}^{L}\frac{\mathrm{d}L}{\mathrm{d}y_t}\Im(y_t')D < \infty.$$

As the function $\frac{\mathrm{d}L}{\mathrm{d}a}$ and $\frac{\mathrm{d}L}{\mathrm{d}b}$ are continues and the boundaries are finite, by the boundedness theorem, we conclude that the gradients of a and b are bounded for all $\lambda \in D^\circ(0,1)$. $\square$

B Experimental setup

Architecture. We present an overview of our architecture in Figure 2. The ETSMLP architecture contains L blocks and each block contains a normalization, skip connection, and an MLP plus CES. We use the ReLU activation function in MLPs. For ETSMLP-Gate architecture, an extra gate mechanism is added parallel to the original architecture. For the sake of performance, we add extra normalization like LRU (Orvieto et al., 2023). We use bidirectional models for all datasets.

Experimental details. We use the Adam optimizer (Kingma and Ba, 2017), with the hyperparameter $\beta_1 = 0.9$, $\beta_2 = 0.98$. We use warmup for the learning rate LR that we start from a value of 10^{-7} and increase the learning rate linearly up a specified value for the first 10% of training. Then a linear annealing schedule is conducted for the rest of the training. All experiments except for Path-X were carried out on an NVIDIA GeForce GTX 2080 GPU, while Path-X requires 8 NVIDIA GeForce GTX 2080 GPUs.

Hyperparameters. We follow the general optimization approach used by Mega (Ma et al., 2022). Table 5 presents the main hyperparameters for each experiment. For all the experiments, we tune the embedding size D, the number of layers L, and the hidden features H. We also tune the learning rate LR and weight decay WD for all the datasets. Besides, the max_λ of the constraint function is all set to 0.9999.

OpenFMNav: Towards Open-Set Zero-Shot Object Navigation via Vision-Language Foundation Models

Abstract

Object navigation (ObjectNav) requires an agent to navigate through unseen environments to find queried objects. Many previous methods attempted to solve this task by relying on supervised or reinforcement learning, where they are trained on limited household datasets with close-set objects. However, two key challenges are unsolved: understanding free-form natural language instructions that demand open-set objects, and generalizing to new environments in a zero-shot manner. Aiming to solve the two challenges, in this paper, we propose **OpenFMNav**, an **Open**-set **F**oundation **M**odel based framework for zero-shot object **Nav**igation. We first unleash the reasoning abilities of large language models (LLMs) to extract proposed objects from natural language instructions that meet the user's demand. We then leverage the generalizability of large vision language models (VLMs) to actively discover and detect candidate objects from the scene, building a *Versatile Semantic Score Map (VSSM)*. Then, by conducting common sense reasoning on *VSSM*, our method can perform effective language-guided exploration and exploitation of the scene and finally reach the goal. By leveraging the reasoning and generalizing abilities of foundation models, our method can understand free-form human instructions and perform effective open-set zero-shot navigation in diverse environments. Extensive experiments on the HM3D ObjectNav benchmark show that our method surpasses all the strong baselines on all metrics, proving our method's effectiveness. Furthermore, we perform real robot demonstrations to validate our method's open-set-ness and generalizability to real-world environments.[1]

1 Introduction

As a fundamental task in robotics and embodied AI, object navigation requires an agent to navigate through unseen environments to find queried objects. Compared to other robotic tasks, it is particularly important because it is a prerequisite for robots to interact with objects. To address this issue, several household datasets and benchmarks, such as MP3D (Chang et al., 2017), Gibson (Xia et al., 2018) and HM3D (Ramakrishnan et al., 2021) are proposed. Many previous studies (Chaplot et al., 2020a; Ramrakhya et al., 2022; Zhang et al., 2023) have attempted to solve this problem through supervised or reinforcement learning, where they are trained on particular household datasets above with close-set objects and comparable environments.

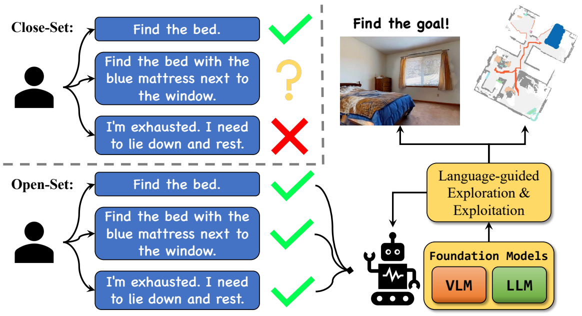

Figure 1: Leveraging foundation models, our proposed OpenFMNav can follow free-form natural language instructions with open-set objects and achieve effective zero-shot object navigation.

However, there are two significant challenges remaining unsolved. **First**, as shown in Fig 1, in many scenarios, instead of only mentioning an object category (e.g., *"Find the bed."*), humans often provide free-form instructions, either specifying objects with specific characteristics (e.g., *"Find the bed with the blue mattress next to the window."*), or expressing their demand without explicitly mentioning the object (e.g., *"I'm exhausted. I need to lie down and rest."*). These natural language instructions may demand open-set objects not included in the training vocabulary. In such cases, existing supervised or reinforcement learning-based

Findings of the Association for Computational Linguistics: NAACL 2024, pages 338–351
June 16-21, 2024 ©2024 Association for Computational Linguistics

methods fail to understand these natural language instructions since they require specific object categories and were trained to perform close-set object detection. **Second**, due to the data scarcity of embodied navigation (Gu et al., 2022), these methods are typically trained on limited datasets that only cover household environments, which causes severe overfitting issues and prevents them from generalizing to unseen and diverse environments, let alone performing zero-shot navigation.

To address the first challenge, some initial progress has been made in understanding free-form natural language instructions with open-set objects. For instance, demand-driven navigation (DDN) was proposed by Wang et al. (2023) to map human instructions to a demand-conditioned attribute space. However, it is still limited to household settings and cannot be generalized to various environments. Another approach was suggested by Majumdar et al. (2023), which involves finding objects with specific attributes and eliminating distractors. However, it needs 2D occupancy maps and pre-exploration of the scene in the beginning, which are unavailable in unseen environments.

On the second challenge, recent years have witnessed progress in Zero-Shot Object Navigation (ZSON) (Majumdar et al., 2022; Gadre et al., 2023; Yokoyama et al., 2023; Zhou et al., 2023; Dorbala et al., 2023; Yu et al., 2023; Shah et al., 2023; Cai et al., 2023; Liang et al., 2023). However, some of these works (Majumdar et al., 2022; Yu et al., 2023; Cai et al., 2023) require data to train specific modules such as locomotion planning, and hence are not real "Zero-Shot". More importantly, these methods cannot conduct explicit and comprehensive reasoning on free-form natural language instructions, leading to their low performance and preventing them from being applied to many downstream robotic tasks.

To better address the aforementioned two key challenges, in this paper, we propose OpenFMNav, a novel framework based on foundation models to achieve effective open-set zero-shot navigation. To this end, we utilize foundation models to leverage their reasoning abilities and generalizability to interpret human instructions and actively explore the environment. To be more specific, we first leverage large language models to extract initially proposed objects from natural language instructions and merge them with user-defined prior objects and objects discovered by vision language models. We then construct an object prompt to detect and segment objects from the observation image, leveraging large vision language models. By using depth images to project the segmentation masks to the space, we can build a 2D top-down *Versatile Semantic Score Map (VSSM)* of the whole scene, on which we sample frontiers with semantic information for a large language model to conduct common sense reasoning and wisely choose frontiers to guide navigation. This way, we can perform language-guided exploration and exploitation of the scene and achieve effective open-set zero-shot object navigation without prior training on any household datasets. Moreover, unlike previous map-based methods such as Zhou et al. (2023); Yu et al. (2023); Shah et al. (2023); Yokoyama et al. (2023), the *VSSM* produced by our method will keep updating during the navigation, which better adapts to changing environments and can be further used in downstream robotic tasks, such as multi-goal navigation and mobile manipulation.

We conduct extensive experiments on the HM3D ObjectNav benchmark (Yadav et al., 2022a). Results show that our method outperforms the State-of-the-Art open-set zero-shot object navigation method (Zhou et al., 2023) by over 15% on success rate and surpasses all the strong baselines on all metrics, validating the effectiveness and superiority of our framework. Additionally, our method has been proven to understand free-form natural language instructions with open-set objects and generalize well to real-world environments through real robot demonstrations.

2 Related Work

2.1 Embodied Navigation

Embodied navigation is a fundamental yet challenging task in robotics and embodied AI since it is the precursor to many downstream robotic tasks, such as object manipulation and teleoperation. In such scenarios, given a specific goal and egocentric observations, agents are required to move to a desired location within a maximum timestep.

Due to the importance of embodied navigation, recent years have witnessed several branches of navigation tasks with different goal specifications. For instance, point goal navigation (PointNav) (Wijmans et al., 2019; Savva et al., 2019) uses point coordinates in the space as the goal; image goal navigation (ImageNav) (Chaplot et al., 2020b; Savinov et al., 2018) requires the agent to move where the given image is taken; and vision-language nav-

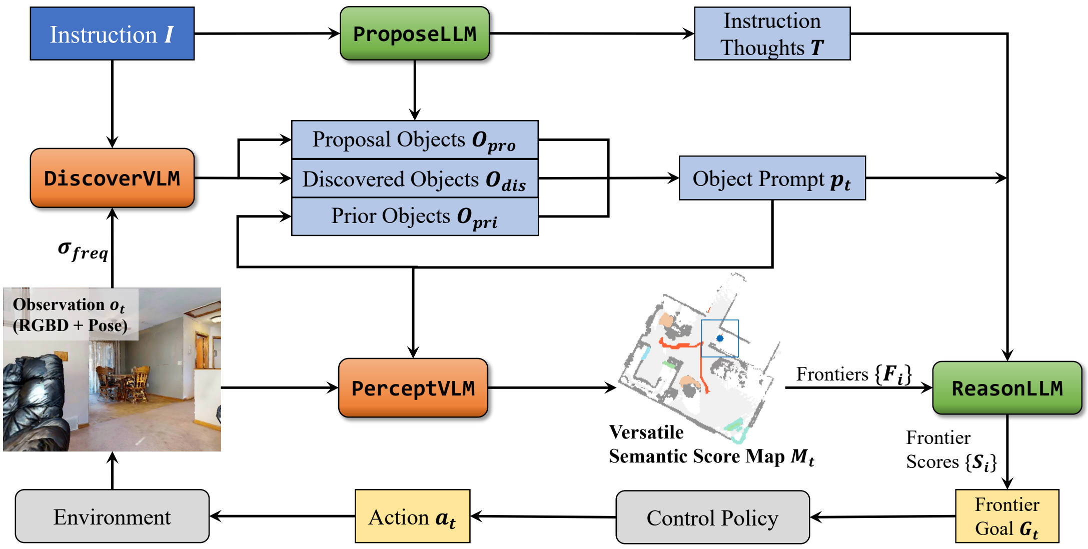

Figure 2: The framework of our proposed OpenFMNav. Based on the natural language instruction and observations, we utilize foundation models to interpret human instructions and construct a *Versatile Semantic Score Map (VSSM)*, on which we perform common sense reasoning and scoring to conduct language-guided frontier-based exploration.

igation (VLN) (Anderson et al., 2018; Ku et al., 2020) requires the agent to follow step-by-step instructions to reach the location; and in object navigation (ObjectNav) (Batra et al., 2020), the agent is required to find objects of specified categories.

Compared to vision-language navigation (VLN), which offers detailed and step-by-step instructions and requires an agent to strictly follow the trajectories conditioned by step-by-step instructions, object navigation (ObjectNav) is particularly challenging since the agent needs to do semantic recognition to find the goal and needs more efficient exploration than VLN since there are no step-by-step instructions (Chen et al., 2023). It is also more common in real life that humans will give ambiguous demands (Wang et al., 2023) rather than detailed instructions in VLN. Additionally, many VLN datasets (Anderson et al., 2018; Ku et al., 2020) are typically discretized into checker-like waypoint graphs, which makes it difficult to deploy algorithms in the real world. Compared to VLN, ObjectNav is **object-centric** and **continuous** so that it can be easily deployed and extended to many downstream robotic tasks like object manipulation.

To take a step further, in this paper, we propose a solution to the problem of open-set-ness in ObjectNav by introducing a framework that transforms the paradigm of ObjectNav from given close-set category names to free-form natural language instructions with open-set objects. This transformation will help bridge the interaction between humans and embodied agents, making it more useful in real-world applications. Compared to existing works (Majumdar et al., 2023; Wang et al., 2023), our method doesn't need prior occupancy maps and pre-exploration in the beginning and thus can navigate in unseen environments. Furthermore, our method addresses the overfitting issue in embodied navigation and easily generalizes to the real world in a zero-shot manner, enabling intelligent robot agents to navigate in more diverse environments.

2.2 Zero-Shot Object Navigation

As Gu et al. (2022) elaborates, embodied navigation faces a severe challenge of data scarcity, limiting the amount and distribution of available data for training. Methods directly supervised on these limited data cannot generalize to diverse real-world environments.

Therefore, recent years have witnessed great progress in Zero-Shot Object Navigation (ZSON). Methods proposed by Majumdar et al. (2022); Gadre et al. (2023); Yokoyama et al. (2023) leverage CLIP (Radford et al., 2021) or BLIP-2 (Li et al., 2023) embedded features to compute similarities between object goal and input image and construct an implicit map for certain goal objects to guide navigation. Other methods, such as those proposed by Zhou et al. (2023); Dorbala et al. (2023); Yu et al. (2023); Shah et al. (2023), leverage object detectors to construct metric maps and use large language models to conduct reasoning. Cai et al. (2023)

leverages foundation models to perform basic image processing and trains a locomotion module to navigate to certain chosen pixel points.

2.3 Foundation Models

Foundation models (Bommasani et al., 2022) are large-scale models that are pre-trained on vast amounts of data and can perform general tasks. The sheer volume of pretraining data endows them with exceptional generalizability, which allows them to perform zero-shot inference. Moreover, the extensive training data helps foundation models acquire common sense about our physical world, making them ideal for real-world applications.

Foundation models, particularly the large language models (LLMs), also have an intriguing feature — In-Context Learning (ICL) (Dong et al., 2023). This feature enables these models to follow pre-defined instructions to ground their output into certain patterns. By combining ICL with common sense learned from the large-scale data, foundation models can effectively perform semantic common sense reasoning and guesswork to provide intuitions of possible exploration directions like human beings, as illustrated in Zhou et al. (2023); Yu et al. (2023); Shah et al. (2023). For example, if the goal is a “toilet”, from common sense it is highly possible to find it around an area that contains a “bathtub”.

According to different modalities, foundation models can be mainly divided into Visual Foundation Models (VFM), such as SAM (Kirillov et al., 2023), Large Language Models (LLM), such as GPT-3.5/GPT-4 (Ouyang et al., 2022; OpenAI, 2023) and LLaMA/LLaMA-2 (Touvron et al., 2023a,b), and Vision Language Models (VLM), such as GPT-4V (Yang et al., 2023b), CLIP (Radford et al., 2021), Grounded-SAM (Liu et al., 2023), etc. There are also foundation models covering other modalities, such as audio (Yang et al., 2023a) and video (Xu et al., 2021). In this paper, we use VLMs and LLMs since our setting only involves vision and language modalities.

3 Method

3.1 Problem Statement and Method Overview

Problem Statement. As shown in Fig. 1, in an unfamiliar environment, given a natural language instruction I, an embodied agent needs to explore the environment in search of a certain queried object. At timestep t, the agent is provided with egocentric RGBD observation o_t and should output an action a_t such as `move_forward`, `turn_left`, `stop`, etc. A successful navigation is defined as finding the queried object within the maximum navigation timestep.

Method Overview. As shown in Fig. 2, given a starting point and human instruction I, the agent first utilizes the ProposeLLM to propose possible objects to meet the instruction. At timestep t, the agent can leverage the DiscoverVLM to discover new objects from the scene and check whether they can meet the instruction. Along with prior defined objects and proposal objects, the full object list is then converted into an object prompt p_t for foundation models to reason. Given current RGBD observation o_t, the PerceptVLM will detect and segment object masks based on p_t, constructing a *Versatile Semantic Score Map (VSSM)* M_t, on which possible exploration frontiers are sampled. Finally, the ReasonLLM will conduct common sense reasoning based on the semantic information of frontiers and give the next frontier goal G_t to explore, which will be executed by an underlying control policy to output low-level actions. The whole process is looped until the object is found or the agent fails.

3.2 Discovery and Perception

Discovery. Given a free-form human instruction I that may contain open-set objects, we first leverage a ProposeLLM to get all possible proposal objects O_{pro} that can satisfy the instruction. Each proposal object contains attributes such as color, location, etc., to satisfy fine-grained instructions. At timestep t, given egocentric RGBD and pose observations o_t, we propose a DiscoverVLM using GPT-4V (Yang et al., 2023b) that actively discovers novel objects O_{dis} from the RGB image. Meanwhile, the DiscoverVLM also conducts reasoning on the instruction, trying to discover objects that potentially meet the instruction and update O_{pro}. Extracting novel objects from the environment is essential for open-set navigation since they may contain scene-specific information that helps to find the goal. To save time and cost, the DiscoverVLM is randomly activated by a frequency parameter σ_{freq}.

Perception. After getting proposal objects O_{pro} and discovered objects O_{dis}, we merge them with prior objects O_{pri} to construct an object prompt p_t to feed into our PerceptVLM based on Grounded-SAM (Liu et al., 2023) to detect and segment all the appearing objects in p_t from the RGB image of o_t.

Note that due to the BERT encoder (Devlin et al., 2019) and powerful SAM backbone (Kirillov et al., 2023) in the PerceptVLM, it can achieve open-set object detection in high granularities. This process will output object masks with confidence scores for further mapping and reasoning.

3.3 Mapping and Reasoning

Mapping. At timestep t, based on the confidence scores of object masks produced by PerceptVLM and the depth image and pose in o_t, we project the masks to the top-down 2D space and construct a *Versatile Semantic Score Map (VSSM)* $M_t \in \mathbb{R}^{H \times W \times (C+2)}$, which contains C channels of object semantics, and two channels of the occupied area and explored area, with a resolution of $H \times W$. Each element in the map is a score in $[0, 1]$ instead of binary labels. Since we continuously discover novel objects from the environment, the C is versatile so that we can keep updating the map, enabling life-long learning and downstream robotic tasks. Also, instead of filling binary labels into semantic channels, we fill each semantic channel with confidence scores, with which we can easily update the map if there is a change in the environment.

Reasoning. Based on M_t, we can sample frontiers $\{F_i\}$ with semantic information in unexplored areas for further exploration. To choose the next frontier to explore, we leverage ReasonLLM by unleashing the power of LLM's common sense reasoning. Specifically, given the semantic information around each frontier, we construct a query template in the form of "`This area contains A, B and C.`". Combined with the thought T produced by Chain-of-Thought (Wei et al., 2022) prompting from ProposeLLM and the object prompt p_t, the ReasonLLM will conduct common sense reasoning as in Section 2.3 and rate these frontiers to pick one frontier goal G_t which is most likely to find the object goal. This frontier goal G_t will guide the agent for further exploration and produce low-level actions to control the agent.

Instead of directly asking the LLM which frontier to explore for once or multiple times (Shah et al., 2023), we leverage another reasoning process, which prompts the LLM to rate these frontiers $\{F_i\}$ to scores $\{S_i\}$, in which $S_i \in [0, 1]$, indicating the likelihood to find the goal. Then, the frontier with the highest score will be picked out for further exploration. By leveraging this rating process, ReasonLLM can map its common sense to concrete numbers that reflect the actual ranking, leading to better reasoning. We verified its effectiveness in Section 4.5. It's also worth mentioning that to balance exploration and exploitation, ReasonLLM is activated at regular timestep intervals δ to update G_t. At other timesteps, the frontier goal G_t remains unchanged to fully explore the previously chosen frontier $G_{t-\delta}$.

Algorithm 1: Pseudo-Code of the Overall Algorithm for OpenFMNav

```
Data: Natural Language Instruction $I$, Prior Objects
      $O_{pri}$, Discovery Frequency $\sigma_{freq}$, Frontier
      Goal Update Interval $\delta$
$t \leftarrow 0$;
$done \leftarrow False$;
$G_0,\ M_0,\ O_{dis} \leftarrow None$;
$O_{pro}, T \leftarrow$ ProposeLLM($I$);
while not done do
    $o_t \leftarrow$ getObservation();
    if toDiscover($\sigma_{freq}$) then
        $O_{dis},\ O_{pro} \leftarrow$ DiscoverVLM($o_t,\ I$);
    end
    $p_t \leftarrow$ getPrompt($O_{pro},\ O_{dis},\ O_{pri}$);
    $Masks \leftarrow$ PerceptVLM($o_t,\ p_t$);
    $M_t \leftarrow$ semanticMapping($M_{t-1},\ Masks,\ o_t$);
    if $O_{pro}$ in $M_t$ then
        $G_t \leftarrow$ getLocation($M_t,\ O_{pro}$);
    else
        if $t \,\%\, \delta == 0$ then
            $\{F_i\} \leftarrow$ sampleFrontiers($M_t$);
            $\{S_i\} \leftarrow$ ReasonLLM($\{F_i\},\ p_t,\ T$);
            $G_t \leftarrow$ getLocation($M_t$, argmax($\{S_i\}$));
        else
            $G_t \leftarrow G_{t-1}$;
        end
    end
    $O_{pri} \leftarrow$ updateObj($O_{pro},\ O_{dis},\ O_{pri}$);
    $a_t \leftarrow$ FMMPlanner($M_t,\ G_t$);
    $done \leftarrow$ stepAction($a_t,\ t$);
    $t \leftarrow t + 1$;
end
```

After obtaining the frontier goal and the occupancy channel in M_t, we utilize a control policy based on the Fast Marching Method (FMM) (Sethian, 1999) to output a low-level action a_t to control the agent. This closes the loop and goes to the next timestep $t + 1$.

We present the whole process of our OpenFMNav algorithm in Algorithm 1.

4 Experiments

In this section, we evaluate our method comprehensively in simulation to show our method's effectiveness compared to baseline methods. We also conducted ablation studies to validate the effectiveness of our framework design.

Method	Open-Set	Zero-Shot	SR (%) ↑	SPL ↑
FBE (Gervet et al., 2023)	×	✓	23.7	0.123
SemExp (Chaplot et al., 2020a)	×	×	37.9	0.188
ZSON (Majumdar et al., 2022)	✓	×	25.5	0.126
GoW (Gadre et al., 2023)	✓	✓	32.0	0.181
ESC (Zhou et al., 2023)	✓	✓	38.5	0.220
L3MVN (Yu et al., 2023)	×	✓	50.4	0.231
L3MVN + GPT-4 (Yu et al., 2023)	×	✓	51.8	0.234
PixNav (Cai et al., 2023)	✓	×	37.9	0.205
OpenFMNav (Ours)	✓	✓	**54.9**	**0.244**

Table 1: Comparison between different methods on the HM3D ObjectNav benchmark. Our method outperforms all the baseline methods on all metrics and achieves open-set zero-shot object navigation.

4.1 Experimental Setup

In the simulation, we evaluate on the HM3D ObjectNav benchmark based on the Habitat Matterport 3D Semantics Dataset (Yadav et al., 2022b), which contains 80 train scenes and 20 validation scenes. We utilize the validation scenes for evaluation. There are, in total, 2000 episodes and six goal classes (chair, couch, potted plant, bed, toilet, and tv) in the dataset. The action space of the robot agent is {`stop`, `move_forward`, `turn_left`, `turn_right`, `look_up`, `look_down`}. The forward distance is set to 0.25m, and the rotation angle is set to 30 degrees.

Following previous works (Zhou et al., 2023; Cai et al., 2023), we utilize **Success Rate (SR)** metric to measure whether an agent can find our desired objects. We also report results of **Success weighted by Path Length (SPL)** to measure the navigation efficiency.

4.2 Implementation Details

In our method, the foundation models we use are: GPT-4 (text-only) (OpenAI, 2023) for ProposeLLM and ReasonLLM, and GPT-4V (Yang et al., 2023b) for DiscoverVLM. For PerceptVLM, we utilize Grounded-SAM, which first leverages Grounding DINO (Liu et al., 2023) to produce bounding boxes given the RGB image in o_t and object prompt p_t, and then leverages Segment Anything Model (SAM) (Kirillov et al., 2023) for each bounding box to produce high-granularity object masks for semantic mapping.

Moreover, we utilize the Chain-of-Thought (CoT) (Wei et al., 2022) prompting technique to fully exploit the reasoning abilities of ProposeLLM, ReasonLLM and DiscoverVLM. The prompts we used can be found in Appendix C.

In the simulation, we set the update interval δ to 20 timesteps, discovery frequency σ_{freq} to 0.01, and the initial prior objects to a subset of HM3D object categories, which can be found in Appendix B.

4.3 Baseline Methods

We compare our method with several recent works, with a focus on open-set and zero-shot object navigation baselines to verify our framework's effectiveness. We classify these baseline methods into "Open-Set" and "Zero-Shot" or not. Here, we define "Open-Set" as that the method can find whatever object category we want, and define "Zero-Shot" as that the agent hasn't been trained or finetuned on ***any*** of the data previously, including images, episodes, and locomotion planning. The baseline methods are as follows:

- **FBE** (Gervet et al., 2023). This baseline method employs a classical robotics pipeline for mapping and a frontier-based exploration algorithm.
- **SemExp** (Chaplot et al., 2020a). A method that explores and searches for the target using close-set semantic maps and reinforcement learning.
- **ZSON** (Majumdar et al., 2022). An RGB-based zero-shot object navigation baseline using CLIP (Radford et al., 2021) to embed scene features. It is trained on ImageNav and directly transferred to ObjectNav.
- **GoW** (Gadre et al., 2023). A modification of CoW (Gadre et al., 2023) implemented by Zhou et al. (2023) that uses GLIP (Li* et al., 2022) for object detection and the vanilla fronter-based exploration method.

Method	SR (%) ↑	SPL ↑
w/o GPT-4	53.6	0.230
w/o CoT	51.8	0.208
w/o Discovery	50.0	0.222
w/o Scoring	50.0	0.208
Ours	**55.4**	**0.239**

Table 2: Ablation studies on different components of our method. Experiments are conducted under the same uniformly sampled episodes.

- **ESC** (Zhou et al., 2023). A map-based zero-shot object navigation baseline that uses GLIP (Li* et al., 2022) to detect objects and rooms, and combines LLM with soft commonsense constraints for planning.
- **L3MVN** (Yu et al., 2023). An LLM-based baseline that finetunes a close-set object detector (Jiang et al., 2018) and an LLM to conduct frontier-based exploration. We also conduct experiments that replace its LLM with GPT-4 for fairer comparisons.
- **PixNav** (Cai et al., 2023). A recent work that solely uses foundation models to pick out navigation pixels and trains a locomotion module to navigate to chosen pixels.

4.4 Results and Analysis

We report the main results in Table 1. Our method surpasses all the baselines on both Success Rate (SR) and Success weighted by Path Length (SPL), especially compared with open-set zero-shot methods. Our method surpasses the previous State-of-the-Art method on open-set zero-shot object navigation (Zhou et al., 2023) by over 15% on the success rate metric, suggesting that our framework is indeed effective.

First, we compare our method with previous semantic map based methods, such as SemExp (Chaplot et al., 2020a), ESC (Zhou et al., 2023) and L3MVN (Yu et al., 2023). The results show that our method performs better since we utilize DiscoverVLM to construct *VSSM* with versatile out-of-vocabulary class labels, such as "marble statue" and "range hood", which helps to alleviate the issue of limited categories and enriches the semantic information of the environment. Also, compared to these methods, our method achieves open-set navigation, which better adapts to complex situations and real-world applications.

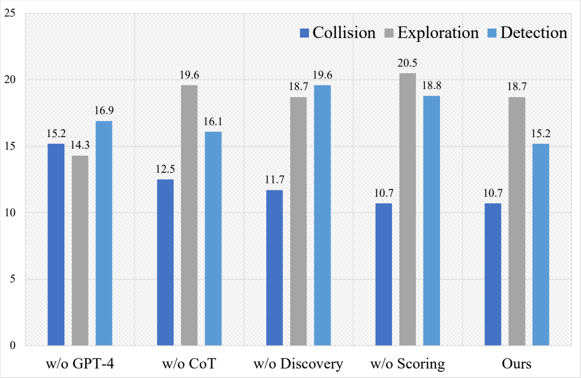

Figure 3: Types and percentages of failure cases in ablation methods.

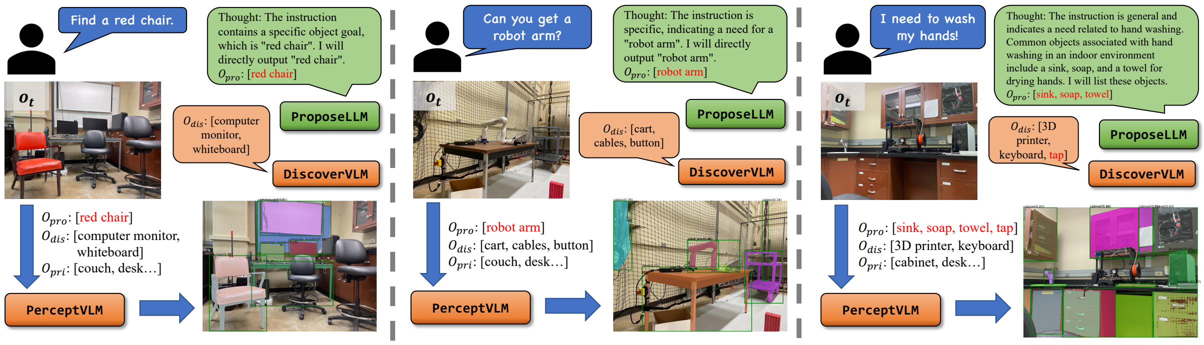
Compared with other open-set baselines, such as PixNav (Cai et al., 2023), ZSON (Majumdar et al., 2022) and GoW (Gadre et al., 2023), our method constructs an explicit map where all discovered objects are presented. Therefore, we can boost LLMs' reasoning abilities to balance between exploration and exploitation and make the agent move to where the goal is most likely to be. Also, the map constructed by our method is maintained and updated, which is perfect for life-long learning, enabling downstream robotic tasks with further natural language instructions, while methods like Gadre et al. (2023); Yokoyama et al. (2023) only construct implicit maps for a certain goal, which is useless after the navigation.

4.5 Ablation Studies

Probing deeper into our method design, we also performed ablation studies on various components of our pipeline. Note that to save time and cost, we test all the ablation methods on a subset of the full dataset under the same uniformly sampled episodes so that there can be slight differences in the result of our method. Table 2 shows that modifying multiple components of our framework leads to significantly worse performance. We also categorized the failure cases into different types and report their percentages in Fig. 3, in which **Collision** refers to the situation where the agent cannot avoid colliding with the environment, **Exploration** means the agent times out while trying to find the goal, and **Detection** means the agent mistakenly identifies a wrong object as the goal.

Effectiveness of using larger models. First, we analyze the usage of GPT-4 for LLMs. Compared to only using GPT-3.5, using larger GPT-4 achieves better performance (+1.8%), reducing failure cases



(a) Robust to distractors (b) Robust to open-set objects (c) Robust to free-form demands

Figure 4: Qualitative studies in the real world. Text marked in red indicates objects that potentially satisfy the instruction. Results show that our method is robust to natural language instructions, including distractors, open-set objects and free-form demands.

of Collision and Detection. However, the percentage of Exploration is slightly higher, showing that larger models have more diverse answers that encourage more exploration, which potentially causes more time out.

Effectiveness of our joint reasoning pipeline. Then, we analyze different foundation model components. We found that using CoT prompting ($+3.6\%$) and scoring prompting ($+5.4\%$) are essential to the strong performance of OpenFMNav since they generate more reasoning chains that elicit the common sense of large language models. Also, compared to restricting the object set, leveraging DiscoverVLM not only enables more free-form natural language instructions from users' input but also enriches the scene's semantics, which helps the reasoning for frontier-based exploration and improves performance ($+5.4\%$). These efforts reduce failure cases of all categories.

5 Navigation in the Real World

We further conduct real robot demonstrations to show our method's ability to understand free-form natural language instructions and perform open-set zero-shot navigation in the real world.

5.1 Real Robot Setup

For robots, we use a TurtleBot4 robot with scalable structures to navigate on the ground. We limit its action space to {`stop`, `move_forward`, `turn_left`, `turn_right`}. As in the simulation, we set the forward distance to 0.25m and the rotation angle to 30 degrees. For robotic perception, we use a Kinect RGBD camera to capture RGBD images.

For real-world environments, we select multiple rooms (including offices, labs, and meeting rooms) with sufficient space and various objects for the robot to navigate. These rooms contain not only common objects like "chair", "couch", "desk", "computer", "cabinet", etc., but also less common ones like "robot arm", "3D printer", "coffee machines", etc.

5.2 Qualitative Studies

We conduct qualitative studies on our OpenFMNav in the real world, as shown in Fig. 4. The results show that our method can perform effective zero-shot navigation in the real world given free-form natural language instructions. Especially, our method is robust to distractors, open-set objects and free-form demands.

For distractors, rather than object categories, our proposed ProposeLLM can extract the attributes in the instruction ("red chair"), which can be further detected and segmented by PerceptVLM. In Fig. 4(a), we can see that, among the three chairs in the observation, only the red chair is masked.

For open-set objects, due to the large-scale training data of foundation models, our method can also navigate to objects that are uncommon and out-of-vocabulary, such as the "robot arm" in Fig. 4(b).

Another intriguing feature of our method is that our method can adaptively add up goals in the navigation. This happens when the instruction is a free-form demand for ambiguous objects. For example, in Fig. 4(c), when the user needs to wash hands, the ProposeLLM first proposed "sink", "soap" and "towel", but they are not necessarily present in the scene. When the agent explores the environment, the DiscoverVLM can actively discover what's new in the environment and reason about whether they can potentially fulfill the user's demand. In this case, a "tap" is discovered and identified as a goal so that the agent can directly navigate to it without further exploration. This is extremely helpful when the humans are also unaware of the scene details.

6 Conclusions

In this paper, we presented a novel framework, OpenFMNav, for open-set zero-shot object navigation. By leveraging foundation models, our method could understand free-form natural language instructions, conduct reasoning, and perform effective zero-shot object navigation. Extensive experiments showed the superiority of our framework. Finally, we conducted real robot demonstrations to validate our method's open-set-ness and generalizability to real-world environments.

Ethics Statement

In this paper, we present a method for open-set zero-shot object navigation. This method can be used for zero-shot robotic navigation in diverse scenarios, such as home robots, warehouse robots, and so on. Our work further addresses the issue of ambiguous or free-form natural language instructions, benefitting the interaction between humans and robots. However, foundation models can have safety issues and risks such as privacy leaks and jailbreaking (Deng et al., 2023; Chao et al., 2023), which need to be further addressed.

Limitations

While extensive experiments validate the effectiveness of our method design, there exist a number of limitations in our work. First, our method requires relatively accurate depth sensors to build the 2D map, while the observed depths and camera poses may have much noise in reality, causing performance degradation. Moreover, we acknowledge that our method requires stable Internet connections to get responses from APIs of foundation models, limiting the potential of large-scale deployment in harsh environments. Another limitation is that the use of LLMs may not always be real-time, which can cause latency issues. We hope future works on depth sensing, LLM quantization, and edge computing can mitigate such limitations.

C Prompts and Examples

Below we show prompts and examples of LLM input/output.

C.1 Prompts for ProposeLLM

The prompts for ReasonLLM are shown in Fig. 6.

```
SYSTEM_PROMPT="""You are an intelligent embodied agent called
ProposeLLM that follows an instruction to navigate in a real indoor
environment. Your goal is to propose a list of objects that can
satisfy the user's need.

You are firstly given an instruction that indicates the user's need.

If the instruction contains a specific goal object, like "go to the
bed" or "find the red bottle", you should directly output the goal
object with its possible attributes, like "bed" or "red bottle".

Otherwise, if the instruction is more general, like "I'm so
thirsty", you should inference via common sense which objects are
feasible and output a list of objects that can satisfy the user's
need, like "bottle", "cup", "refrigerator", etc.

Notice that your output should be a list of objects with their
possible attributes, even if there is only one object in the
list."""

USER1="""go to the bed"""

ASSISTANT1="""Thought: The instruction contains a specific object
goal, so I will directly output "bed".

Answer: ["bed"]"""

USER2="""I have been standing for hours. I need some place to sit
down and rest."""

ASSISTANT2="""Thought: The instruction is quite general, so I will
use my common sense. The user needs some place to sit down, so
candidate objects in an indoor scene can be chair, couch, etc. I
will output a list of these objects.

Answer: ["chair", "couch"]"""
```

Figure 6: Prompts for ProposeLLM

C.2 Prompts for DiscoverVLM

The prompts for ReasonLLM are shown in Fig. 7.

```
SYSTEM_PROMPT="""You are an intelligent assistant called DiscoverVLM
that can understand natural language and scene images. Given a list
of objects and an image, your goal is to discover new objects in the
image that are not in the list.

You should consider the following rules when discovering new
objects:

(1) You should first consider, what's in the image? Note that you
should only include objects in the house, and avoid things that are
part of the house, like ceiling, wall, floor, window etc and avoid
room names, like bedroom, kitchen, etc.

(2) Considering the given object list, you should only output things
that are not in the list or are not similar to things in the list
because your duty is to discover new things. For example, if the
given object list contains "couch" or "tv", you should not output
"sofa" or "television" because they are similar.

(3) Confirm that the objects you output are in the image. For
example, if the image is a bedroom, you should not output "bathtub"
because it is impossible to find a bathtub in a bedroom. And also
confirm the objects you output don't violate rule (1).

(4) Avoid objects are common everywhere. For example, objects like
light switch and door are present in every room, so you should not
output them.

Your output should be in the form of "Answer: <list of objects>"
such as:

Answer: ["chair", "bed", "bottle"]
"""

USER="""What objects can you see in the image?"""
```

Figure 7: Prompts for DiscoverVLM

C.3 Prompts for PerceptVLM

For PerceptVLM, given the current object list, we use dots to separate each object as the object prompt p_t.

For example, if the object list is `[chair, bed, plant, toilet, tv, couch]`, the object prompt is “`chair.bed.plant.toilet.tv.couch`”.

C.4 Prompts for ReasonLLM

The prompts for ReasonLLM are shown in Fig. 8.

```
SYSTEM_PROMPT="""You are an intelligent embodied agent called ReasonLLM that follows an instruction to navigate in an indoor environment. You are firstly given
an object goal class for you to find, which is called the goal.

Then, at each step, your task is to take several descriptions of what an area contains to output scores for these areas to contain the goal. Each score is a
floating point number between 0 and 1.

Your output should be a list of scores.

At each step, you should consider:

(1) For each description, according to what the area contains, is it possible that the goal is also in this area? To better do reasoning, you can imagine what
kind of room the area is in, for example, a bedroom, a living room, a bathroom, etc. Based on the common sense, you can judge the possibility that the goal to
be in this area.

(2) If the goal class is already in the description, the score should be 1 without any hesitation.

(3) If one area contains nothing, it is still possible that the goal is in that area. Give a score of 0.4 to 0.6. Score the area higher in that case when other
areas are not likely to contain the goal.

(4) If there are no current frontiers, skip the thought and output 'No frontiers'."""

USER1="""Goal: toilet

- Description 0: The area contains a towel, a bathtub and a sink.

- Description 1: The area contains a bed and a plant.

- Description 2: The area contains a sofa, a TV and a table.

"""

ASSISTANT1="""Thought: Let's analyze each description.

- Description 0: this area contains a bathtub and a sink, so it is possibly a bathroom, and the goal is toilet, so it is possible that the goal is in this area,
I will give a score of 0.9

- Description 1: this area contains a bed and a plant, so it is possibly a bedroom, and the goal is toilet, so it is not likely that the goal is in this area. I
will give it a 0.2

- Description 2: this area contains a sofa, a TV and a table, so it is possibly a living room, and the goal is toilet, so it is also not likely that the goal is
in this area. I will give it a 0.3

Answer: [0.9, 0.2, 0.3]"""

USER2="""Goal: bed

- Description 0: The area contains a towel, a bathtub and a sink.

- Description 1: The area contains a bed and a plant.

- Description 2: The area contains a sofa, a TV and a table.

"""

ASSISTANT2="""Thought: Let's analyze each description.

- Description 0: this area contains a bathtub and a sink, so it is possibly a bathroom, and the goal is bed, so it is not possible that the goal is in this
area. My score is 0.1

- Description 1: this area contains a bed, which is the goal, so the score is 1

- Description 2: this area contains a sofa, a TV and a table, so it is possibly a living room. The goal is a bed, so it can be near this area. I will give it a
0.5

Answer: [0.1, 1, 0.5]"""
```

Comparing Two Model Designs for Clinical Note Generation; Is an LLM a Useful Evaluator of Consistency?

Nathan Brake and **Thomas Schaaf**
Solventum, Health Information Systems*
nbrake,tschaaf@solventum.com

Abstract

Following an interaction with a patient, physicians are responsible for the submission of clinical documentation, often organized as a SOAP note. A clinical note is not simply a summary of the conversation but requires the use of appropriate medical terminology. The relevant information can then be extracted and organized according to the structure of the SOAP note. In this paper we analyze two different approaches to generate the different sections of a SOAP note based on the audio recording of the conversation, and specifically examine them in terms of note consistency. The first approach generates the sections independently, while the second method generates them all together. In this work we make use of PEGASUS-X Transformer models and observe that both methods lead to similar ROUGE values (less than 1% difference) and have no difference in terms of the Factuality metric. We perform a human evaluation to measure aspects of consistency and demonstrate that LLMs like Llama2 can be used to perform the same tasks with roughly the same agreement as the human annotators. Between the Llama2 analysis and the human reviewers we observe a Cohen Kappa inter-rater reliability of 0.79, 1.00, and 0.32 for consistency of age, gender, and body part injury, respectively. With this we demonstrate the usefulness of leveraging an LLM to measure quality indicators that can be identified by humans but are not currently captured by automatic metrics. This allows scaling evaluation to larger data sets, and we find that clinical note consistency improves by generating each new section conditioned on the output of all previously generated sections.

1 Introduction

As a part of a physician's workload, the Electronic Health Record (EHR) has become an important tool for documenting patient information that is used for care and billing purposes. A SOAP note is a common framework for structuring a record of a Doctor Patient Conversation (DoPaCo) that consists of Subjective, Objective, Assessment, and Plan sections.

Two common components inside of the Subjective section are the "Chief Complaint" (CC) and "History of Present Illness" (HPI) sections. Chief Complaint is normally a brief one sentence statement about the reason for the patient's visit to the physician. For example: "Patient presents for evaluation of left foot pain". This information is mentioned in the DoPaCo, but may also be provided as a part of the patient's admission documentation. History of Present Illness is usually a multi-sentence or paragraph description of relevant patient information that was discussed in the DoPaCo. For example, it may contain snippets such as: "Patient is a 60-year-old male who reports left foot pain after having his foot run over by a tractor in 2021 . . . He had surgery on his foot in 2022 and is still experiencing pain . . . The patient reports a history of osteoporosis."

The Assessment section is normally a brief description or list of the doctor's assessment, e.g. "Assessment: Left Foot Pain" that may be mentioned during the DoPaCo or directly entered or dictated into an EHR system following the encounter. The Plan section is a description of a path forward and commonly has a more narrative style such as: "Plan: I have personally reviewed the findings with the patient today. He is scheduled for a left total knee arthroplasty soon. I anticipate that this procedure will also help with his left foot pain. At this time, we will hold off on a new orthotic prescription. He will follow up with me at the end of February." For our experiment we combine Assessment and Plan to be considered as a single section.

In this work we present clinical notes that contain the Chief Complaint (CC), History of Present

Findings of the Association for Computational Linguistics: NAACL 2024, pages 352–363
June 16-21, 2024

Illness (HPI), and Assessment & Plan (A&P) sections. We omit the Objective section because at the time of writing, the Objective section commonly contains information from a physical examination that has not been directly verbalized during the DoPaCos that are used in our dataset. We leave to future work the exploration of generating the Objective section of a SOAP note using a DoPaCo and incorporating additional information that was not verbalized during the encounter.

In order to ease the burden on a physician and accelerate workflows, recent research in Natural Language Processing (NLP) techniques are being explored to automatically generate SOAP notes using variants of the Transformer architecture (Vaswani et al., 2017). A common approach to the automatic generation of a SOAP note is to use an automatic speech recognition (ASR) system to create a transcript of the DoPaCo, based upon an audio recording of the encounter.

In this work, we present a comparison of two designs for generating a SOAP note. From the pretrained PEGASUS-X model (Phang et al., 2023) , we train a single fine-tuned model (GENMOD) to produce a clinical note, as well as 3 individual fine-tuned models (SPECMOD) to each produce a single section.

In order to compare these two note generation designs, ROUGE (Lin, 2004) is a common automatic metric for measuring the performance of summarization models. However, it is not always a reliable proxy for human preference, and a model with a lower ROUGE score may be preferred by humans (Ziegler et al., 2020). In particular, for comparing the two model approaches we expect that the SPECMOD design would be more likely than GENMOD to have conflicting content between sections, since in SPECMOD the output of a section such as A&P is not conditioned on the output text of any other section, e.g. HPI. For example, if the DoPaCo does not make clear reference to the gender of the patient, we expect that SPECMOD would be more likely than GENMOD to refer to the patient as female in HPI and mistakenly refer to the patient as a male in A&P. In this work we present an approach to use the Llama2 LLM (Touvron et al., 2023) as an additional measure of model quality for criteria not clearly captured by existing automatic metrics.

2 Related Work

Clinical note generation can be viewed as a summarization problem, since it can involve the use of a DoPaCo as input to summarize the content into a document that uses the appropriate clinical terminology and style. Recent discoveries in deep learning based NLP have enabled advancements in the creation of clinical notes from DoPaCos (Krishna et al., 2021; Su et al., 2022; Zhang et al., 2021; Michalopoulos et al., 2022) . (Zhang et al., 2021) investigate the use of a fine-tuned BART model (Lewis et al., 2020) for generation of the HPI section of a clinical note. Similarly, (Singh et al., 2023) generate a clinical note that contains an HPI, A&P, and Physical Examination section, and train a separate model for each section. (Ramprasad et al., 2023) seeks to improve the consistency of SOAP notes through the integration of section tokens and section-specific cross-attention parameters to encoder-decoder models. This approach uses a single BART model with a modified cross-attention mechanism to generate a SOAP note based on extracted segments of the DoPaCo, and produces a single section at a time based upon the special token pre-pended to the input conversation.

In order to evaluate the quality of these generated clinical notes, it can be difficult to find a reliable proxy for human evaluation. With the advent of ChatGPT/GPT-4 (OpenAI, 2023) and Llama2 (Touvron et al., 2023), the use of LLMs as a proxy for human evaluation is a popular subject of recent research (Zeng et al., 2024; Chiang and Lee, 2023; Gilardi et al., 2023; Zheng et al., 2023). (Chiang and Lee, 2023) found LLM based evaluation results to be consistent with human evaluation across several NLP tasks in terms of cohesiveness, among other criteria. (Zheng et al., 2023) finds that GPT-4 has the ability to match human preferences when comparing two different LLM generated answers to a question. (Liu et al., 2023) presents a framework called G-Eval which uses chain-of-thought prompting and form-filling to evaluate text outputs for coherence. The LLM Prometheus (Kim et al., 2024) is a fine-tuned Llama2-13B LLM designed to act as an evaluator LLM that is aligned with human preferences. (Xie et al., 2023) investigate the use of GPT-4 to evaluate medical notes in terms of factuality. To the best of our knowledge, this work is the first to evaluate the performance of an LLM in reviewing clinical notes for specific criteria of consistency.

ACI-Bench (Yim et al., 2023) provides results from comparison of full-note vs division-based note generation techniques, which corresponds to our GENMOD and SPECMOD designs, respectively. Their work finds that SPECMOD results in higher performance then GENMOD. However, ACI-Bench uses a smaller dataset of 207 encounters with an average conversation length of 1,300 tokens. Using our larger proprietary dataset with more average tokens per conversation, we seek to understand whether the comparison of GENMOD to SPECMOD is sensitive to the size of the dataset as well as the dimension upon which the two models are measured (i.e. in terms of full note consistency).

3 Data

The DoPaCos in the dataset for this experiment come from an asynchronous scribing configuration, similar to that which is described in detail in (Schaaf et al., 2021). The physician is aware that the audio is being provided to a human scribe after the encounter, and as a result, the audio may contain dictated portions where the doctor directly instructs the scribe regarding information that should be included in the note. The physicians in the dataset represent a mix of 20 different specialties, identified using the National Provider Identification (NPI) Registry (https://npiregistry.cms.hhs.gov)

We create three dataset splits for the experiment: Training, Validation, and Test. Information about these splits can be found in Table 1. The training, validation, and test data have similar length distributions for the input conversations and target clinical notes.

The MediQA (Ben Abacha et al., 2023) task uses the ACI-Bench (Yim et al., 2023) dataset for clinical note summarization, which contains 207 encounters of average length 1,300 tokens. This precludes it from being substituted as a training dataset for this experiment due to the small dataset size and shorter average token length of the conversations. Further, 112 of the 207 ACI-Bench encounters come from the ambient clinical intelligence setting, which does not match the asynchronous scribing domain that our experiment addresses.

4 Methodology

4.1 Training

For this experiment, we train models to generate clinical notes that contain 3 sections: CC, HPI, and A&P.

We train the transformer based PEGASUS-X large model (Phang et al., 2023), which is a 568M parameter model that builds on top of the PEGASUS model (Zhang et al., 2020) and uses a modified attention mechanism in order to support longer input sequences of up to 16,384 tokens, and has been additionally pre-trained using long sequence data. We expect our method to extend to other transformer based models as well. Training is performed on a compute cluster of 8 NVIDIA A100 GPUs.

Two methods for clinical note generation are trained:

1. General Model (GENMOD). Shown in Figure 1, this is a single PEGASUS-X model that produces the entire note in a single generation step. The model is trained to output 6 added special tokens, one token to indicate the start of a section (e.g. "<history_of_present_illness>"), and one to denote the end of a section (e.g. "</history_of_present_illness>"). This design allows for easy parsing of the note when scoring each section individually. It also allows for scoring of the note as a whole, since the special tokens can be skipped during the tokenizer decoding step. When generating automatic metrics (ROUGE, Factuality) as well as during human review, these special tags are omitted so as not to bias the model output to a higher score. Otherwise, the special tags would always be present in both the generated and reference note and would artificially inflate metrics that check for n-gram overlaps, such as ROUGE.

2. Specialized Model (SPECMOD). Shown in Figure 2, these are 3 individual PEGASUS-X models, one model trained for each section. Each model is trained to output a single section. For evaluations that use a fully generated clinical note, the transcript is provided to each model which generates its individual section. These outputs are then combined to form the full note.

Split	Rows	Spec	Phys.	Avg Dur (min)	Avg Tok. in Conv.	Avg Tok in Clinical Note
Train	9800	20	82	16.58	3,312	524
Val	516	15	54	16.14	3,430	525
Test	543	14	50	17.21	3,237	513

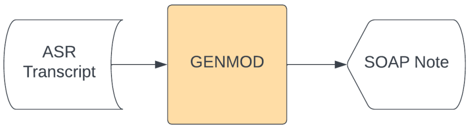

Figure 1: Creation of SOAP note with GENMOD

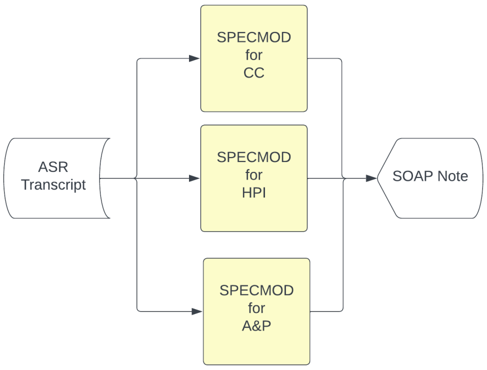

Figure 2: Creation of SOAP note with SPECMOD

4.2 Evaluation

After training each model configuration, we evaluate the model generated notes using common automatic metrics, human reviewers, and the Llama2 LLM. The notes are generated from the models using beam search generation with a beam size of 4, and a No Repeat N-Gram Size (NRNS) of 5. The automatic metrics indicate the performance of the models using the metrics commonly used to evaluate a model. The human and Llama2 evaluations help to expose differences between GENMOD and SPECMOD generated notes that are not captured by ROUGE or Factuality.

The automatic metrics used for evaluation are ROUGE (Lin, 2004) and Factuality (Glover et al., 2022). ROUGE is a common metric for use in measuring the performance of abstractive summarization tasks, and Factuality is a metric for measuring the factual content of the output compared to ground truth. The Factuality metric has been trained for medical concepts.

For the human and LLM evaluation, we collect data for four different criteria related to consistency, for a subset of 40 generated clinical notes found in the dataset test split. The cost and time required of human reviewers prevents the evaluation of the entire test split for this experiment. The humans and LLM are not provided with the reference (ground truth note) or the conversation transcript. They are displayed only a single generated note and asked to evaluate the following items:

1. Age consistency. The clinical notes may state the age of the patient in multiple sections of the note, and the reviewers are tasked with identifying whether that age is consistent throughout. For example, if the CC section mentions that the patient is 65 years old, but the HPI states that the patient is 70 years old, this is marked as inconsistent. If the age is only mentioned in a single location, the note is marked as consistent.

2. Gender consistency. Similar to age consistency, the clinical note should refer to the patient by the same gender throughout the clinical note. For example, if the HPI section refers to the patient as a female and uses she/her/hers pronouns, the A&P should also use she/her/hers pronouns.

3. Body Part consistency. In some cases (most commonly for orthopedic specialty), the patient is being seen for a specific injury, whether that is a left leg, a right hip, etc. If a specific body part and location is mentioned, this should remain consistent throughout the note. If the CC and HPI discuss the right foot, but the A&P addresses only the left foot or a right hip, this is inconsistent in terms of body part.

4. Coherence. The CC/HPI/A&P should be coherent with each other. The content of the A&P should be reasonable based on the HPI and CC sections. There can be some additional content in the A&P but it should not be

> contradictory to the HPI. For example, if the visit is for a followup, the A&P section may contain much information that is not stated in the HPI. As long as the content of the A&P looks reasonable given the HPI, that is considered coherent. However, if the HPI and CC are discussing depression, the A&P should have something related to depression. If the HPI and CC are about depression but the A&P is instead addressing diabetes, that is not consistent. Similarly, if the CC says the patient reports nausea but then the HPI says the patient is not experiencing nausea, that is not consistent.

In a realistic production environment, information about the patient such as age and gender is expected to be available. However, since this information is not available in the experimental setting, we find that these items serve as a helpful proxy for evaluating how well systems like an LLM are able to identify specific issues.

4.3 Human Evaluation

The human evaluation is performed using 5 human reviewers. 3 reviewers are medical experts, while the remaining 2 reviewers are not medical experts.

Each reviewer is shown the generated clinical note from GENMOD and SPECMOD for 40 different DoPaCo encounters from the test split, for a total of 80 notes. The clinical notes are presented to the reviewer one at a time in a randomized order. For each note they are asked to select whether each of the 4 evaluation criteria described in Section 4.2 are satisfied. Because they are not provided the ground truth clinical note, they are not evaluating whether the content is correct when measured against a reference note, but only that the note satisfies the specified criteria in terms of consistency with itself.

4.4 LLM Evaluation

The LLM used for evaluation is the Llama2 Chat model. The Llama2 family of models (Touvron et al., 2023) are open source, trained by Meta AI, and provide close to state-of-the-art performance on a variety of tasks. We experiment with a variety of sizes: 7B, 13B, and 70B. For the 13B and 7B model we also experiment with quantization of the weights to 8 bits. For clarity we present only the results of the 70B full precision model, but include a discussion of observed changes in quality in Appendix A. We evaluate the model using zero-shot, 1-shot, 2-shot, and 3-shot in-context prompting, to maximize possible performance improvements that can be gained through in-context learning (Brown et al., 2020). The purpose of using the LLM as an evaluator is to construct a prompt for the LLM in such a way that the LLM ranking of the clinical notes will closely align with the human ranking, so that the LLM can be useful as a proxy for human evaluation.

The Llama2 model is provided the individual generated clinical note from GENMOD and SPECMOD from the same 40 DoPaCo encounters that were provided to the human reviewers. For each of the 80 notes, Llama2 is provided 4 separate prompts, 1 for each evaluation criteria. The system prompts are specific to each evaluation criteria and are provided in Appendix B. In the zero-shot configuration, each evaluation request uses a new context window, such that its output is not being conditioned on any previous responses of the model. Each prompt requests that the model review the provided note and evaluate whether it meets a single criteria item (age/gender/body part consistency/coherent). In the 1-shot configuration, the model is provided a single example note and an accompanying answer and explanation. The example note is designed to be similar in style to a real note used for review, and is marked as consistent in the evaluation criteria being requested. In the 2-shot and 3-shot configuration, the model is provided at least one example of an inconsistent and one example of a consistent note in the evaluation criteria being requested, along with a detailed explanation about why that note met or did not meet the criteria. The example notes and answers were tailored to address corner cases that were observed when developing prompts on the evaluation dataset split. For example, an example note provided for the criteria of age specifically addresses how to handle the case of the patient age only being mentioned once throughout the whole note, even when other dates were mentioned: i.e. that the model should not try to infer age from random dates mentioned in the note (like dates of surgical procedures), but should only pay attention to specific references to the patient's age.

Similar to the human evaluation, the LLM is never provided the ground truth clinical note to compare against. It is provided a single hypothesis clinical note, example prompts when in the 1/2/3-shot configuration, and a single evaluation criteria request.

The prompts used with Llama2 were developed using notes generated from the evaluation set, and the final results reported are from the 80 notes generated by GENMOD and SPECMOD from the test set.

5 Results and Discussion

5.1 Automatic Metrics

The automatic metric results are reported in Table 2. We include ROUGE-1 (R-1), ROUGE-2 (R-2), ROUGE-3 (R-3), ROUGE-L (R-L), and Factuality (Fact).

During generation, a parameter No Repeat N-gram Size (NRNS) controls the maximum token sequence that can be repeated in a generation, and is a technique to reduce the repetition of an output. For the human evaluation and individual section automatic scoring, a NRNS of 5 is used. When using NRNS of 5, SPECMOD generally outperforms the GENMOD architecture across all sections by a score of less than 3%.

However, when relaxing the NRNS to 12, the gap between SPECMOD and GENMOD shrinks to a difference of less than 0.5% ROUGE, and reaches the same Factuality score. The improvement of GENMOD scores when adjusting NRNS can be explained by the nature of the GENMODs generation design. Since GENMOD is producing the entire note in a single generation step, a low NRNS prevents content that was in earlier sections from re-appearing in later sections, even when that repetition is reasonable. For example, the phrase "patient has fractured left fibula" may be reasonable to appear in both the HPI and the A&P for a clinical note, but would not have appeared when using an NRNS of 5 or lower.

Human evaluation and LLM evaluation was performed only on notes generated using NRNS of 5 due to resource limitations, and we leave to future work the continued exploration of how modified generation and decoding strategies effect the quality and consistency of clinical notes.

5.2 Human and LLM Review

Table 3 presents the reported percentage consistency of GENMOD and SPECMOD as measured by the 5 human reviewers and Llama2. Instead of reporting the results for each individual human reviewer we combine the results into four categories: Medical Experts (3 reviewers), Non-Medical Experts (2 reviewers), All (5 reviewers), and Consensus. The "consensus" human choice is created by selecting inconsistent/consistent for each criteria in the 80 clinical notes (40 notes from each model) based on the choice that the majority of the 5 human reviewers selected. All human reviewers have a preference to GENMOD for age, gender, and body part consistency. This supports the conclusion that GENMOD contains fewer contradictions inside itself for these categories and results in a more internally consistent note.

For the category of coherence, medical experts preferred SPECMOD while non-medical experts preferred GENMOD. A medical expert may be more likely to expect that a piece of content should appear in A&P that was mentioned in HPI (For example, a missing assessment/plan for a postnasal drip that was mentioned in HPI). However, when debriefing the reviewers, they indicated two differing interpretations of coherence. 2 reviewers (both medical experts) interpreted the requirement to be that a note should be marked as incoherent if content was missing from A&P that was in HPI. The remaining reviewers were only analyzing whether the A&P contained contradictions to content that appeared in the HPI. The 3 reviewers only analyzing for contradictions preferred GENMOD, while the 2 reviewers looking for all content to be present in both HPI and A&P preferred SPECMOD. As mentioned in Section 5.1, this preference for SPECMOD may also be related to the NRNS setting: the evaluation was performed on clinical notes generated with the lower NRNS of 5, which may have prevented GENMOD from producing the content in the A&P that was present in the HPI.

Table 3 also shows that for Llama2 evaluations, SPECMOD is only preferred by the 0-shot Llama2 parameter model for the category of coherence. In the 1-shot in-context prompting configuration, Llama was provided only a single positive example for each category, biasing the model to only mark a note as fulfilling the requirement if it was the exact situation mentioned in the example. For example, the in-context prompt for the age category was an example where the age was only mentioned once, for which the in-context prompt provided an answer of "The age is only mentioned once in the HPI section and this age was never contradicted in the note, therefore the answer is TRUE.". However, this biased the model to only mark a note as consistent for age if the age was only mentioned once in the entire note, which caused the model to diverge

Model	NRNS	Section	R-1	R-2	R-3	R-L	Fact
GENMOD	5	CC	**80.9**	**72.0**	64.1	**80.7**	**74.5**

Single Med Expert	0.79	0.49	0.82	0.58

Table 7: Cohen Kappa between consensus human choice and Llama-70B choice as well as a randomly selected medical expert human reviewer)

from human performance.

In order to understand the level of agreement between reviewers, we present the Fleiss Kappa (FK) Inter-Rater Reliability (IRR) via Table 4 and the Percentage Agreement via Table 5. Although agreement is high for age and gender consistency, the agreement is moderate for body part consistency and minimal for coherence. Because FK takes into account the probablity that reviewers could be agreeing with each other by chance, the FK may be low even when the percentage agreement is high. The low FK for coherence is reasonable based upon the discussion earlier: the coherence criteria was interpreted in two different ways which resulted in low agreement. However, if the Cohen Kappa (CK) is calculated between the 2 medical experts that indicated similar interpretations of the coherence category, Table 6 results in a higher IRR for coherence. The moderate agreement in body part consistency is due to the ambiguity in how to interpret a situation where the name is slightly different even though the meaning is near the same. For example, if the CC contained "Left foot pain" but the HPI referred to "Left big toe pain", some reviewers marked the example as inconsistent while others marked it as consistent.

Although every human reviewer had the same interpretation of how to score the categories of age and gender, the FK shows that their agreement is not perfect. This illustrates the difficulty in human review of specific categories: a manual review of the notes with conflicting human review for age and gender revealed that the choice selected by the majority of reviewers was correct, but at least one reviewer made a mistake and selected the wrong value.

We report the CK measurements of the consensus human choice vs Llama via Table 7, as well as the CK of a random human reviewer compared to the consensus human choice. For the categories of age and gender, a manual review confirmed that the consensus selection was always correct. However, the randomly chosen human reviewer did not always make the correct selection, resulting in a CK Age that is the same as the 2-shot Llama model, and a CK Gender worse than the 2-shot Llama.

The CK scores of 0 for 2 and 3-shot Llama is due to the model always selecting "consistent" for this category, which the CK statistic ranks as completely uncorrelated because the Llama performance is then no-better than a purely random selection, even if the percent agreement between Llama and the consensus human is moderately high. These results show that Llama2 results are correlated to human preferences.

6 Conclusion

The paper presents an empirical study on the quality of two distinct PEGASUS-X based designs for generating a clinical note. The GENMOD design reduces the ROUGE by less than 1% compared to SPECMOD, and has no difference in Factuality. Based on human review, our findings indicate that GENMOD improves the measured age, gender, and body part consistency by 4.5%, 2.5%, and 8.5%, respectively, when compared to SPECMOD. We highlight the difficulties of measuring the consistency of topics such as note coherence, as the criteria can be difficult to clearly specify in a way that is reliably understood by humans as well as LLMs. Lastly, we observe a Cohen Kappa inter-rater reliability of 0.79, 1.00, and 0.32 for consistency of age, gender, and body part injury, which shows that Llama2 can be a valuable proxy for human evaluation in specific evaluation criteria. This finding supports the usage of the Llama2 LLM as an evaluator on large datasets that would be impractical for comprehensive human review. This proves a promising area for future work to explore development of a robust evaluation suite that utilizes an LLM for clinical note analysis on an expanded variety of criteria.

7 Limitations

SPECMOD and GENMOD are trained using DoPaCo transcripts created by an ASR system. Although this does not impact their results compared to each other (since both SPECMOD and GENMOD utilized the same dataset), their absolute performance may be impacted by the quality of the ASR system, since ASR errors may decrease the generated note quality.

The human evaluation only includes 5 human reviewers of the 40 DoPaCos. Because of this, differences of rating on even a few encounters can have an out-sized impact on the results. The human and LLM review was performed on very specific categories and do not necessarily expand to other topics. The prompts used with the Llama2 LLM were developed using a dataset that contained similar specialties and physicians to that which existed in the 40 DoPaCos from the test set. The performance of Llama2 may change if it is used with clinical notes from physicians or specialties that do not exist in the dataset where the prompts were developed.

B System Prompts

The following system prompts are used for each evaluation criteria presented in 4.2

1. Age: "You are a medical assistant. You will be given a clinical note and should decide whether the age of the patient remains consistent throughout the note. If consistent, answer TRUE. If the age changes between CC and HPI, answer FALSE. If the age is only mentioned once, that means it is consistent and you should answer TRUE. @@NAME@@ is a de-indentification and does not have impact on the gender. Only pay attention to ages that are explicitly stated, do not infer age from any dates provided. Answer in a single word (TRUE or FALSE):"

2. Gender: "You are a medical assistant. You will be given a clinical note and should decide whether the gender is consistent throughout the note. If the pronoun or gender of the patient is different between the HPI and A&P, that means the answer is FALSE. Answer in a single word (TRUE or FALSE):"

3. Body Part consistency: "You are a medical assistant. You will be given a clinical note and should decide whether the injury body part mentioned is consistent throughout the note. For instance, if the CC mentions left foot pain, the HPI should also mention left foot pain. If the visit makes no mention of an injury for which a body part is relevant, then this item is not applicable and you should select TRUE. Answer in a single word (TRUE or FALSE):"

4. Coherence: "You are a medical assistant. You will be given a clinical note and should decide whether the A&P section appears to be reasonable based on the HPI section. If the A&P is reasonable based on the CC and HPI, answer TRUE. Otherwise, answer FALSE. If a condition is mentioned in the CC or HPI that was never addressed in the A&P Section, answer FALSE. There can be some additional content in the A&P but it should not be contradictory to the HPI. Answer in a single word (TRUE or FALSE):"

VOLTA: Improving Generative Diversity by Variational Mutual Information Maximizing Autoencoder

Abstract

The natural language generation domain has witnessed great success thanks to Transformer models. Although they have achieved state-of-the-art generative quality, they often neglect generative diversity. Prior attempts to tackle this issue suffer from either low model capacity or over-complicated architectures. Some recent methods employ the VAE framework to enhance diversity, but their latent variables fully depend on the input context, restricting exploration of the latent space. In this paper, we introduce VOLTA, a framework that elevates generative diversity by bridging Transformer with VAE via a more effective cross-attention-based connection, departing from conventional embedding concatenation or summation. Additionally, we propose integrating InfoGAN-style latent codes to enable input-independent variability, further diversifying the generation. Moreover, our framework accommodates discrete inputs alongside its existing support for continuous inputs. We perform comprehensive experiments with two types of Transformers on six datasets from three different NLG tasks to show that our approach can significantly improve generative diversity while maintaining generative quality.

1 Introduction

The rapid advancement of Natural Language Generation (NLG) has been propelled by the remarkable success of Transformer models, including the notable series of GPT models (Radford et al., 2018, 2019; Brown et al., 2020; Ouyang et al., 2022; OpenAI, 2023b,a), T5 (Raffel et al., 2020), OPT (Zhang et al., 2022), and LLaMA (Touvron et al., 2023), etc. While they have demonstrated unparalleled proficiency in autoregressive text generation (Li et al., 2020b; Hu et al., 2022b; Li et al., 2022; Qiu et al., 2024), they predominantly focus on learning to reassemble text from large corpora with high generative quality. However, the pursuit of generative diversity remains a critical yet underexplored frontier in NLG. Generative diversity is distinct from mere paraphrasing, as it encompasses not only altered syntax but also varied semantics. Early attempts, such as diverse beam search (Vijayakumar et al., 2018), have made strides in enhancing diversity by modifying the decoding process. Nonetheless, these methods often fall short in enhancing the model itself, limiting their ability to significantly improve diversity.

Context	Atop the Main Building's gold dome is a golden statue of the Virgin Mary. Immediately in front of the Main Building and facing it, is a copper statue of Christ with arms upraised with the legend "Venite Ad Me Omnes". Next to the Main Building is the Basilica of the Sacred Heart. Immediately behind the basilica is the Grotto ······
Q	What type of statue is on the main building?
A	golden statue of the Virgin Mary
Q	What is the name of the copper statue on the main building?
A	a copper statue of Christ with arms upraised with ···
Q	What is next to the main building?
A	Grotto

Table 1: Examples of generation diversity by VOLTA on the QAG task. Our framework enables generating three distinct question-answer pairs.

Variational Autoencoder (VAE) (Kingma and Welling, 2014) offers a framework addressing the low-diversity issue. By encoding inputs into lower-dimensional latent variables, VAE introduces the opportunity to diversify the decoding process: perturbing these latent variables allows generated sentences to deviate from annotated ones, thereby enhancing diversity. However, prior attempts like Info-HCVAE (Lee et al., 2020), utilizing LSTM-based VAEs, inherit limitations associated with LSTMs. While Transformers have emerged as the mainstream network, integrating them into the VAE framework poses challenges due to the parallelized self-attention mechanism. More pre-

Findings of the Association for Computational Linguistics: NAACL 2024, pages 364–378
June 16-21, 2024 ©2024 Association for Computational Linguistics

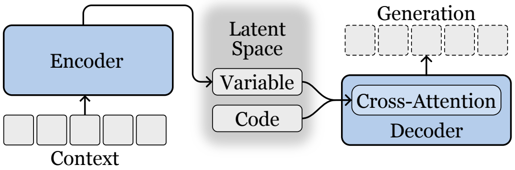

Figure 1: The overview of VOLTA. The encoder encodes the context into VAE latent variables. The variables, augmented with InfoGAN-style **latent codes**, can be continuous or discrete based on the input type. Subsequently, they are connected to the decoder through the **cross-attention** mechanism. Leveraging the variability inherent in the latent space, the decoder generates diverse content conditioned on the context.

cisely, this complexity arises from inserting a bottleneck layer of latent variables between Transformer layers, as the embeddings of the entire sequence pass through the model simultaneously. Optimus (Li et al., 2020a), pioneering the fusion of Transformers with VAEs, adopts BERT (Devlin et al., 2019) as the VAE encoder and GPT-2 (Radford et al., 2019) as the VAE decoder. Subsequent works attempt to improve upon Optimus (Hu et al., 2022a; Tu et al., 2022; Deng et al., 2023), yet they fall short in addressing its three major drawbacks. Firstly, it introduces embedding concatenation and summation to connect latent variables to the decoder, with Optimus performing optimally only upon their combined use. In contrast, our novel cross-attention-based connection proves more effective. Secondly, Optimus' model architecture is overly intricate. It relies on two distinct Transformer models, necessitating two unique tokenizers and extensive pretraining. We streamline this complexity by either employing a shared Transformer decoder as the backbone network or leveraging an encoder-decoder Transformer model. This renders our framework compatible even with Large Language Models (LLMs) such as LLaMA (Touvron et al., 2023) or GPT-4 (OpenAI, 2023a). Lastly, while Optimus solely handles continuous latent variables, VOLTA expands its scope to cover discrete inputs by encoding them into discrete latent variables, enriching the model's generalizability.

The VAE framework offers increased generative diversity, yet its input-dependent latent variables limit exploration within the latent space, restricting the model's ability to generate a wider array of diverse content. In pursuit of an input-independent approach to vary the generation process, we propose attaching latent codes to VAE latent variables, inspired by InfoGAN (Chen et al., 2016). Our method employs the Variational Mutual Information Maximization (VMIM) objective to encourage the decoder to autonomously identify distinct semantic features via latent codes. Consequently, this enables more variability in generated content without any reliance on the input. To the best of our knowledge, our work represents the first utilization of latent codes within NLG.

Our framework, dubbed **VOLTA** (**V**ariati**O**nal Mutua**L** Informa**T**ion Maximizing **A**utoencoder), derives its name from its adherence to the Variational Autoencoder framework and the incorporation of the Variational Mutual Information Maximization objective from InfoGAN. To validate the effectiveness of VOLTA, we benchmark it against state-of-the-art baseline models across six datasets from three representative NLG tasks: language modeling, question-answer generation, and dialog response generation. We also conduct comprehensive ablation studies to examine the impact of the different components of VOLTA.

The main contributions of this paper are:

- VOLTA proposes a novel cross-attention mechanism to integrate Transformer with VAE. It exhibits generalizability to both continuous or discrete latent variables and various Transformer architectures, including decoder-only or encoder-decoder Transformers.
- To attain input-independent variability, we propose attaching InfoGAN-style latent codes to VAE latent variables.
- Comprehensive experimental results on six datasets spanning three distinct NLG tasks validate the efficacy of our model in enhancing generative diversity while upholding quality.

2 Related Work

In recent years, a multitude of Transformer-based models has emerged, such as the GPT series (Radford et al., 2018, 2019; Brown et al., 2020; Ouyang et al., 2022; OpenAI, 2023b,a), T5 (Raffel et al., 2020), OPT (Zhang et al., 2022), and LLaMA (Touvron et al., 2023), etc. These models are primarily trained to optimize the alignment between generated content and annotations, often prioritizing quality over diversity in the generative process.

Variational Autoencoders (VAEs) (Kingma and Welling, 2014) represent a powerful approach to diverse generation in NLG. They diverge from Autoencoders (Hinton and Salakhutdinov, 2006) by introducing low-dimensional latent variables. Originally applied in computer vision, VAEs were later adapted for natural language processing. Early attempts, such as Info-HCVAE (Lee et al., 2020), employed LSTMs (Hochreiter and Schmidhuber, 1997) as both encoder and decoder, achieving diversity in question-answer generation (QAG). However, these LSTM-based models suffered from architectural complexities, utilizing separate LSTM modules for encoding and decoding context, questions, and answers. Optimus (Li et al., 2020a) addressed some of these challenges by using BERT (Devlin et al., 2019) as the encoder and GPT-2 (Radford et al., 2019) as the decoder, surpassing LSTM-based models in VAE language modeling. Subsequent models like VarMAE (Hu et al., 2022a) focused on applying VAEs in language understanding, while RegaVAE (Deng et al., 2023) attempted augmentation through retrieval methods, and AdaVAE (Tu et al., 2022) explored the usage of two adaptive GPT-2 models. Our VOLTA model further simplifies the architecture by leveraging a shared backbone network or utilizing an encoder-decoder Transformer model.

In pursuit of more variability and subsequently, higher diversity, several methods have employed unique strategies such as special prompt tokens or control phrases. These include SimpleTOD (Hosseini-Asl et al., 2020), CTRL (Keskar et al., 2019), Soloist (Peng et al., 2021), CGRG (Wu et al., 2021), and MEGATRON-CNTRL (Xu et al., 2020). Dathathri et al. (2020) proposed the Plug and Play Language Model, which guides language generation by plugging simple attribute classifiers into existing language models. InfoGAN (Chen et al., 2016) originally controlled image generation using latent codes trained with the Variational Mutual Information Maximization (VMIM) objective. In computer vision, attempts to merge InfoGAN with VAE for controllable generative models have resulted in models like VAE-Info-cGAN (Xiao et al., 2020) and InfoVAEGAN (Ye and Bors, 2021). However, InfoVAE (Zhao et al., 2019), InfoMax-VAE (Lotfi-Rezaabad and Vishwanath, 2020), Melis et al. (2022), and VAE-MINE (Qian and Cheung, 2019) applied VMIM to VAE to address the latent variable collapse problem rather than focusing on improving variability. To the best of our knowledge, our model is the first to integrate Transformer models with the VAE and InfoGAN frameworks in Natural Language Generation (NLG). Although we focus on diversity in this paper, other aspects of NLG are also worth exploring in the future (Song et al., 2023c,a,b; Ma et al., 2023), such as multi-modality, bias, and fairness.

3 Our Method

Our VOLTA framework is meticulously designed to facilitate diverse generation, leveraging latent variables from the VAE framework (Kingma and Welling, 2014) in conjunction with InfoGAN-style latent codes (Chen et al., 2016). Initially, VOLTA encodes the input into latent variables. Subsequently, by sampling new latent variables, slight alterations in the decoded content can be achieved, promoting greater diversity. Differing from VAE latent variables, InfoGAN-style latent codes operate independently of input, providing the freedom to explore a broader latent space. This distinct attribute offers an alternative avenue to introduce increased variability within the generated sequences. Figure 1 includes an overview of VOLTA.

3.1 Preliminaries

In the natural language generation domain, various tasks exist, including language modeling, dialog response generation, and question-answer generation. Generally, NLG aims to generate a new sequence $\boldsymbol{x}_g = [x_{g,1}, \ldots, x_{g,n}]$ based on a provided context sequence $\boldsymbol{x}_c = [x_{c,1}, \ldots, x_{c,m}]$, where each x represents an individual token. The objective is to identify a model $f(\cdot)$ capable of generating an appropriate sequence using the given context: $f(\boldsymbol{x}_c) \to \boldsymbol{x}_g$. In cases like extractive answer generation, the answer is denoted by a pair of integer indices $(s, e) \in \mathbb{N}^2$, indicating the start and end positions of the answer span. Then the answer tokens $\boldsymbol{x}_a = [x_{c,s}, \cdots, x_{c,e}]$ can be located within the context sequence $\boldsymbol{x}_c$. It constitutes a part of $\boldsymbol{x}_g$ unless explicitly specified otherwise.

3.2 Model Architecture

VOLTA adheres to the VAE framework, where the encoder $f_{enc}(\cdot)$ and the decoder $f_{dec}(\cdot)$ are both Transformer models. Unlike Optimus (Li et al., 2020a), which utilizes BERT as the encoder and GPT-2 as the decoder, our model offers the simplicity of a shared backbone network between the encoder and decoder. Additionally, VOLTA can adapt encoder-decoder Transformers (Vaswani et al., 2017) seamlessly into VAE, leveraging their inherent encoder and decoder architecture.

Latent variables from encoder. The encoder encodes the input sequence into multiple independent continuous or discrete latent variables, selecting the most suitable based on the input type. For instance, dialog responses and questions are aptly represented using continuous latent variables, aligning with their semantic nature. Conversely, discrete latent variables prove advantageous in modeling answer spans, aligning with their positions within the context. Specifically, latent variables can be calculated as follows:

$$\begin{aligned}&\boldsymbol{h}_{enc} = f_{enc}(\boldsymbol{x}_c, \boldsymbol{x}_g),\\ &\mu_i, \sigma_i = \text{FC}(\boldsymbol{h}_{enc}), \quad \boldsymbol{\pi}_j = \text{FC}(\boldsymbol{h}_{enc}),\\ &z_{g,i} \sim \mathcal{N}(\mu_i, \sigma_i^2), \qquad z_{a,j} \sim \text{Cat}(\boldsymbol{\pi}_j),\end{aligned} \tag{1}$$

where $\text{FC}(\cdot)$ is a single fully-connected layer and each instance has a distinct set of learnable parameters, indexing is omitted for simplicity; $\mathcal{N}(\cdot)$ is the Gaussian distribution with parameters μ_i and σ_i; $\text{Cat}(\cdot)$ is the categorical distribution whose parameters $\boldsymbol{\pi}_j$ represent the event probabilities of k categories. Back-propagation through the latent variables is achieved using the Gaussian distribution reparametrization trick (Wolpe and de Waal, 2019) for $\boldsymbol{z}_q = [z_{g,1}, z_{g,2}, z_{g,3}, \cdots]$ and Gumbel-Softmax (Maddison et al., 2017; Jang et al., 2017) reparametrization for $\boldsymbol{z}_a = [z_{a,1}, z_{a,2}, z_{a,3}, \cdots]$.

Latent codes. Supplementing the VAE latent variables, we incorporate InfoGAN-style latent codes (Chen et al., 2016) to infuse the model with input-independent variability. These latent codes come in two types: continuous latent codes, which can conform to either uniform distribution or Gaussian distribution, and discrete latent codes, which also adhere to categorical distribution:

$$\begin{aligned}&\boldsymbol{c}_g = [c_{g,1}, c_{g,2}, c_{g,3}, \cdots], \ \ c_{g,i} \sim \text{Uni}(-1, 1),\\ &\boldsymbol{c}_a = [c_{a,1}, c_{a,2}, c_{a,3}, \cdots], \ \ c_{a,j} \sim \text{Cat}(\boldsymbol{\rho}),\end{aligned} \tag{2}$$

where $\text{Uni}(\cdot)$ is the uniform distribution; the categorical distribution has parameters $\boldsymbol{\rho} = \frac{1}{k}\mathbf{1}$ that uses the same number of categories k as the discrete latent variables $\boldsymbol{z}_a$ because this compatibility is necessary as they will be concatenated together.

Cross-attention-based latent-space connection. Optimus (Li et al., 2020a) uses two channels to connect latent variables to the decoder: the 'embedding' channel involves a fully-connected layer to obtain a latent embedding, which is subsequently added to word embeddings. Meanwhile, the 'memory' channel generates latent embeddings for each Transformer block within the decoder. These latent embeddings are then concatenated with decoder hidden states as past information. The optimal performance is attained when both channels are utilized, albeit complicating the architecture.

In Transformers (Vaswani et al., 2017), the attention mechanism can take the form of self-attention or cross-attention. We introduce a unified and notably more effective cross-attention-based connection between the latent space and the decoder:

$$\begin{aligned}K_{\text{latent}} &= \text{FC}([\boldsymbol{z}_g, \boldsymbol{c}_g]),\\ V_{\text{latent}} &= \text{FC}([\boldsymbol{z}_g, \boldsymbol{c}_g]),\\ \text{Attention}(Q, K_{\text{latent}}, V_{\text{latent}})&\\ &= \text{softmax}(\frac{QK_{\text{latent}}^T}{\sqrt{d_k}})V_{\text{latent}}.\end{aligned} \tag{3}$$

We facilitate the transmission of latent space information into the decoder using K_{latent} and V_{latent}, queried by the decoder via Q. In cases where the Transformer model lacks pretrained weights for cross-attention layers, such as decoder-only Transformers, we retain Optimus' connection method. However, we streamline it by incorporating a shared backbone for both the encoder and decoder.

Generation. VOLTA is trained in the typical autoregressive manner to predict subsequent tokens by considering the preceding tokens:

$$\begin{aligned}\boldsymbol{h}_{g,t} &= f_{dec}(\boldsymbol{x}_c, \boldsymbol{x}_{g,<t}, [\boldsymbol{z}_g, \boldsymbol{c}_g]),\\ p(\boldsymbol{x}_g) &= \prod_{t=1}^{n} p(x_{g,t} \mid \boldsymbol{x}_c, \boldsymbol{x}_{g,<t}, [\boldsymbol{z}_g, \boldsymbol{c}_g])\\ &= \prod_{t=1}^{n} \text{softmax}(\text{FC}(\boldsymbol{h}_{g,t})),\end{aligned} \tag{4}$$

where $\boldsymbol{x}_{g,<t}$ means the first $t-1$ tokens in $\boldsymbol{x}_g$.

The process for generating discrete data follows a similar approach but involves a distinct prediction head. Specifically, in the scenario of answer generation:

$$\begin{aligned}&\boldsymbol{h}_a = f_{dec}(\boldsymbol{x}_c, [\boldsymbol{z}_a, \boldsymbol{c}_a]),\\ &p(s) = \text{softmax}(\text{FC}(\boldsymbol{h}_{a,1:m})),\\ &p(e) = \text{softmax}(\text{FC}(\boldsymbol{h}_{a,1:m})),\\ &s = \operatorname*{arg\,max}_{s \in \{1,\cdots,m\}} p(s),\\ &e = \operatorname*{arg\,max}_{e \in \{1,\cdots,m\}} p(e),\\ &\boldsymbol{x}_a = [x_{c,s}, \cdots, x_{c,e}],\end{aligned} \tag{5}$$

where $\boldsymbol{h}_a$ denotes the hidden states obtained from the decoder; the subscript $1:m$ means slicing

an array from index 1 to m, which corresponds to the context tokens. This results in a generated answer $\boldsymbol{x}_a$, where s denotes the starting index and e denotes the ending index.

3.3 Training Objectives

Since the marginal likelihood $p(\boldsymbol{x})$ is intractable to compute, we approximate the true posterior $p(z \mid \boldsymbol{x})$ with $q(z \mid \boldsymbol{x})$ based on our encoder $f_{enc}(\cdot)$. Following the standard VAE formulation, we define the evidence lower bound (ELBO) as ELBO $= -\mathcal{L}_{\text{AE}}(\boldsymbol{x}) - \mathcal{L}_{\text{REG}}(\boldsymbol{z})$. Here, $\mathcal{L}_{\text{AE}}$ stands for Autoencdoer (AE) reconstruction loss and $\mathcal{L}_{\text{REG}}$ represents $D_{\text{KL}}(q(z \mid \boldsymbol{x}) \parallel p(z))$ for regularization.

Latent variable regularization loss. The KL divergence for regularizing the continuous or discrete latent variable is:

$$\begin{aligned}
\mathcal{L}_{\text{REG}}(z_g) &= \log \frac{\sigma'}{\sigma} + \frac{\sigma^2 + (\mu - \mu')^2}{2\sigma'^2} - \frac{1}{2}, \\
\mathcal{L}_{\text{REG}}(z_a) &= \sum_{i=1}^{k} \pi_i \log \frac{\pi_i}{\pi'_i},
\end{aligned} \tag{6}$$

where $\mu, \sigma, \boldsymbol{\pi}$ follows Eq. (1); we assume that the priors $p(z_g)$ and $p(z_a)$ follow $\mathcal{N}(\mu', \sigma'^2)$ and $\text{Cat}(\boldsymbol{\pi'})$, respectively. In practice, μ', σ' and $\boldsymbol{\pi'}$ can be obtained by encoding only the context $\boldsymbol{x}_c$. The total $\mathcal{L}_{\text{REG}}$ is the mean over the latent variables. The derivations are in Appendix A.3, A.4.

Latent code VMIM loss. To prevent the model from ignoring the latent codes, we encourage it to recover the latent codes in the generation phase by optimizing the Variational Mutual Information Maximization (VMIM) objective (Chen et al., 2016):

$$\begin{aligned}
&I(c; f_{dec}(\boldsymbol{x}, [\boldsymbol{z}, c])) \\
&= H(c) + \mathbb{E}_{\boldsymbol{x'}}\Big[D_{\text{KL}}\big(p(c' \mid \boldsymbol{x'}) \parallel q(c' \mid \boldsymbol{x'})\big) \\
&\qquad + \mathbb{E}_{c'}\big[\log q(c' \mid \boldsymbol{x'})\big]\Big] \\
&\geq H(c) + \mathbb{E}_{\boldsymbol{x'}}\Big[\mathbb{E}_{c'}\big[\log q(c' \mid \boldsymbol{x'})\big]\Big] \\
&\triangleq H(c) - \mathcal{L}_{\text{VMIM}}(c),
\end{aligned} \tag{7}$$

where $\boldsymbol{x'} \sim f_{dec}(\boldsymbol{x}, [\boldsymbol{z}, c])$; $c' \sim p(c \mid \boldsymbol{x'})$ is the recovered latent code. Because the posterior $p(c \mid \boldsymbol{x'})$ is difficult to obtain, an auxiliary distribution $q(c \mid \boldsymbol{x'})$ based on $f_{dec}(\cdot)$ is added to approximate it. The entropy $H(c)$ is a constant and thus excluded from $\mathcal{L}_{\text{VMIM}}(c)$. The derivation of this objective is included in Appendix A.5.

In our model, a fully-connected layer is added to the decoder for recovering each latent code c:

$$\begin{aligned}
\theta &= \text{FC}(f_{dec}(\boldsymbol{x}, [\boldsymbol{z}, c])), \\
\mathcal{L}_{\text{VMIM}}(c) &= -\log p(c'; \theta),
\end{aligned} \tag{8}$$

where the parameter θ depends on the distribution type of the corresponding latent code c. The total VMIM loss is the mean over the latent codes.

Overall objective. By Eq. (6)(8), the overall loss:

$$\mathcal{L}(x) = \mathcal{L}_{\text{AE}}(\boldsymbol{x}) + \beta \mathcal{L}_{\text{REG}}(\boldsymbol{z}) + \gamma \mathcal{L}_{\text{VMIM}}(\boldsymbol{c}), \tag{9}$$

where β, γ denote the coefficients used to adjust the loss weights; the Autoencoder reconstruction loss $\mathcal{L}_{\text{AE}}(\boldsymbol{x})$ corresponds to the standard cross-entropy loss employed for language modeling.

4 Experiments

4.1 Tasks and Datasets

We evaluate VOLTA against various baselines across six datasets, spanning three distinct NLG tasks:

Dataset	PTB			YELP			YAHOO			SNLI		
Model	PPL ↓	MI	AU	PPL ↓	MI	AU	PPL ↓	MI	AU	PPL ↓	MI	AU
M. A.	101.40	0.00	0	40.39	0.13	1	61.21	0.00	0	21.50	1.45	2

iVAE$_{\text{MI}}$	0.239	0.355	0.285
T5	0.321	0.321	0.321
Optimus	0.313	0.362	0.336
VOLTA	**0.373**	**0.401**	**0.387**

Table 4: Performance comparison on dialog response generation. Baseline results are from Li et al. (2020a) except T5.

- **Dialog response generation**: we utilize the DailyDialog dataset (Li et al., 2017b), comprising approximately 13K multi-turn conversations, averaging eight turns per dialog;
- **Question-answer generation** (QAG): we employ the SQuAD dataset (Rajpurkar et al., 2016), with approximately 100K question-answer pairs where the answers are extractive;
- **Language modeling**: four LM datasets: Penn Treebank (PTB) (Marcus et al., 1993), SNLI (Bowman et al., 2015), YELP, and YAHOO (Yang et al., 2017; He et al., 2019).

4.2 Implementation Details

We conduct experiments using two Transformer model variants: the decoder-only Transformer, leveraging the GPT-2 base model (Radford et al., 2019), and the encoder-decoder Transformer, utilizing the T5 base model (Raffel et al., 2020). With the decoder-only Transformer, since it comprises solely Transformer decoder blocks, we employ it as the shared backbone for both the encoder and decoder within VOLTA. In contrast, the encoder-decoder Transformer features distinct Transformer encoder and decoder, aligning conveniently with the VOLTA encoder and decoder structures. Throughout our experiments, all Transformer-based models load pretrained checkpoints from Huggingface [1], undergoing fine-tuning exclusively on the respective datasets. Unlike the approach in Optimus (Li et al., 2020a), no secondary-stage pretraining is executed.

Our model utilizes a default configuration comprising 32 Gaussian latent variables, along with 4 uniform latent codes. For extractive answers, we utilize 20 categorical latent variables and 5 categorical latent codes, all comprising 10 categories, as shown in Table 5. Training is performed over 10 epochs with a learning rate set to 5×10^{-5}. To address the KL vanishing issue (Bowman et al., 2016), we employ a linear annealing schedule for β (Li et al., 2020a). This includes an initial increasing phase covering the first 25% of training, ascending from 0 to a maximum value of 0.1 (Lee et al., 2020). Additionally, we set $\lambda = 1.0$ in the KL thresholding scheme (Li et al., 2019) for language modeling. We conducted the experiments on four TITAN V GPUs.

4.3 Metrics

While our focus lies in achieving diverse NLG, maintaining generative quality is paramount, as completely random sentences might achieve perfect diversity scores but lack meaningful content.

Generative quality. In dialog response generation, we evaluate generative quality using BLEU-

Table 5: The ablation study of VOLTA's latent space on the QAG task. The orange text highlights the difference from the default configuration in row `DFLT`. *Abbreviations*: "Var.": variational(✓)/deterministic(✗) latent variables; "Rnd/Fix": random/fixed latent codes.

Context	The university is the major seat of the Congregation of Holy Cross (albeit not its official headquarters, which are in Rome). Its main seminary, Moreau Seminary, is located on the campus across St. Joseph lake from the Main Building ······
Q1	What catholic denomination is the university of new haven located in?
Q2	What is the main campus of moreau seminary?
Q3	What religious institution is located on the campus of moreau seminary?
Q4	What former retreat center is located near the grotto?
Q5	What religious denomination does the moreau seminary belong to?
Q6	What is the oldest building on campus?
Q7	What is the main seminary in the university of kansas?
Q8	What is the main seminary of the college?
Q9	What retreat center is located near the grotto?

Table 6: An example of latent variable interpolation.

precision (Papineni et al., 2002). For language modeling, we measure perplexity (PPL) and mutual information (MI) to assess quality. In question-answer generation, direct measurement against SQuAD reference sentences is not feasible because higher diversity in its nature means shifting the generated content away from these references. Instead, Zhang and Bansal (2019) proposed Question-Answering-based Evaluation (QAE), including three main steps: (a) use the QAG model to generate question-answer pairs for raw Wikipedia entries; (b) train a separate question-answering model on the generated QA pairs; (c) evaluate the QA model's performance on the SQuAD development set, using exact match (EM) and F1 metrics (Rajpurkar et al., 2016, 2018). Poor performance in step (c) reflects low quality of the generated QA pairs, indirectly assessing the QAG model's quality. BERT (Devlin et al., 2019) serves as the QA model in (b), and we utilize a QAMI loss to enhance QA pair relevance, akin to Info-HCVAE Lee et al. (2020).

Generative diversity. In dialog response generation, we assess diversity using BLEU-recall (Papineni et al., 2002) as the diversity measurement. In language modeling, we analyze the impact of VAE latent variables by tracking the number of active units (AU). Quantitatively measuring diversity in generated questions involves two metrics: Distinct-k (Li et al., 2016) and Self-BLEU (Zhu et al., 2018). Distinct-k calculates the ratio of distinct k-grams to the total number of generated words. Self-BLEU computes the average BLEU score (Papineni et al., 2002) for each sentence against all others, aiming for dissimilarity among generated sentences. We generate five QA pairs for each context.

4.4 Question-Answer Generation

We compare VOLTA with several state-of-the-art baselines on the question-answer generation task, as summarized in Table 2. We base it on GPT-2 to aim for the minimal model size, showcasing the efficiency of the VOLTA framework. The VAE components in VOLTA add a mere 0.46M parameters.

Context	Holy Cross Father **John Francis O'Hara** was elected vice-president in 1933 and president of Notre Dame in 1934. During his tenure at Notre Dame, he brought numerous refugee intellectuals to campus; ······
Q1	$c_q = -.8$ What was O'Hara's first name?
Q2	$c_q = -.6$ Who was elected vice president in 1933?
Q3	$c_q = -.0$ What was O'Hara's title prior to becoming vice president?
Q4	$c_q = +.4$ What was O'Hara's first title?
A	John Francis O'Hara

Context	During his 13 years the Irish won three national championships, had five undefeated seasons, won the Rose Bowl in 1925, and produced players such as George Gipp and the "Four Horsemen". ······	
A1 $c_a = 0$ five	**A2** $c_a = 3$ 1925	**A3** $c_a = 7$ three

Table 7: Continuous (c_q)/Discrete (c_a) latent code for varying question/answer generation.

The first four baseline models—GPT-2 (Radford et al., 2019), BART (Lewis et al., 2020), T5 (Raffel et al., 2020) and OPT (Zhang et al., 2022)—all rely on regular Transformer architectures, lacking the variational aspects found in VAE and thereby demonstrating lower generative diversity. Although Info-HCVAE (Lee et al., 2020) used VAE, it inherited LSTM's limitations. We therefore also adapt the Transformer-based VAE, Optimus (Li et al., 2020a), to question generation. Our VOLTA framework harnesses Transformer models' high capacity alongside the variability inherent in VAE and InfoGAN. It stands out by achieving superior diversity over all baselines while maintaining a relatively small model size.

4.5 Language Modeling

In language modeling, we employ T5-based VOLTA, comparing it with prior VAE approaches: M. A. (Bowman et al., 2016), C. A. (Fu et al., 2019), SA-VAE (Kim et al., 2018), Aggreesive Training (He et al., 2019), AE-BP (Li et al., 2019), and the Transformer-based VAE model, Optimus (Li et al., 2020a). Our findings revealed that when solely fine-tuned on LM datasets without prior extensive second-stage pretraining on large-scale datasets, the latent variables of the Optimus model (Li et al., 2020a) collapsed. The reason behind this could lie in Optimus employing two separate latent-space connection methods, which are challenging to optimize. On the contrary, VOLTA's unified cross-attention-based approach proves notably more stable.

4.6 Dialog Response Generation

We compare VOLTA with Optimus (Li et al., 2020a), the current state-of-the-art model, and several other baselines: Seq2Seq (Serban et al., 2016), SeqGAN (Li et al., 2017a), CVAE (Zhao et al., 2017), VHRED (Serban et al., 2017), VHCR (Subramanian et al., 2018), WAE (Gu et al., 2019), iVAE$_{\text{MI}}$ (Fang et al., 2019). VOLTA is based on T5 (Raffel et al., 2020) for dialog response generation, and we include T5 as a baseline to assess the impact of the VOLTA framework. We maintain VOLTA's generation process without incorporating a joint latent space and fusion regularization for history and response (Gao et al., 2019), enabling a more general approach compared to Optimus.

4.7 Ablation Study

To assess the impact of the cross-attention-based latent-space connection, we compare VOLTA with Optimus in language modeling and dialog response generation. Given that QAG uniquely involves both continuous and discrete latent variables/codes, we focus on ablating the latent space information specifically within this task. Hence, the impact of VOLTA's three primary components is as follows:

- **Cross-attention-based latent-space connection** (Table 3, 4): Optimus employs two distinct and intricate channels—embedding concatenation and summation—which pose challenges in optimization. In contrast, VOLTA's unified cross-attention-based approach is more stable. In language modeling, Optimus' latent variables even collapsed without their second-stage pretraining.

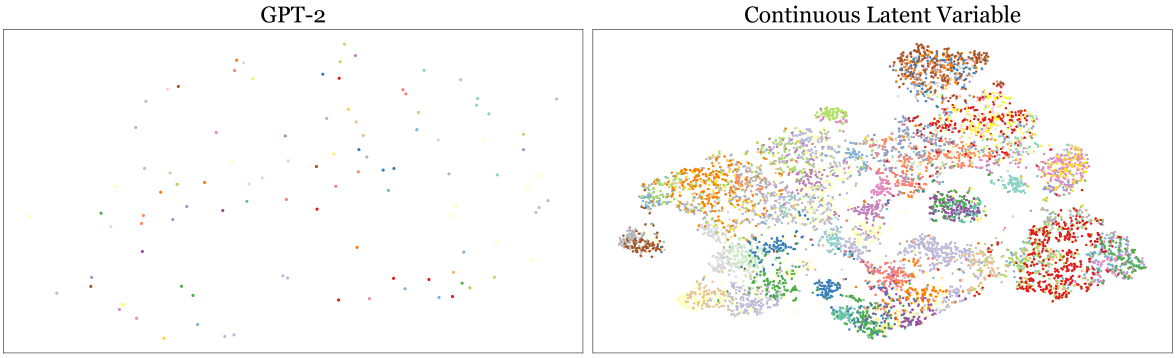

Figure 2: T-SNE visualization comparing question embeddings from GPT-2 with latent variable embeddings by VOLTA. Points of the same color depict embeddings from the identical context. VOLTA showcases diverse embeddings for each context, contrasting the deterministic nature of a vanilla LM.

- **Latent variables** (Table 5): Rows `A-D` show a general detriment when there is either an excess or a shortage of latent variables. Row `E` illustrates that when the latent variables become deterministic, the model essentially transforms into a conventional Autoencoder. Consequently, the performance experiences a significant decline, underscoring the critical role of the VAE framework.
- **Latent codes** (Table 5): Rows `F, G` depict a further decline in performance when we further fix the latent codes from Row `E`, underlining the latent codes' role in enhancing generative diversity.

4.8 Qualitative Analysis

Table 1 exemplifies a diverse instance of QAG achieved by the variational nature of VOLTA. Our model architecture facilitates two more methods to alter the generation process. One method involves interpolating latent variables, detailed in Table 6. The other method is centered on adjusting the InfoGAN-style latent codes, demonstrated in Table 7. In contrast to latent variables, latent codes are decoupled from the input context, affording the model more flexibility to explore the latent space.

To visualize the distribution of latent variables within the latent space, we utilize t-SNE (Van der Maaten and Hinton, 2008) to represent latent variable embeddings in a 2D space, comparing them with GPT-2 embeddings. Figure 2 illustrates that GPT-2 produces identical embeddings for a given context. Conversely, our model displays the ability to generate a cluster of diverse Gaussian latent variable points of the same color, subsequently decoded into a spectrum of distinct questions.

5 Conclusion

We present VOLTA, a framework merging the power of Transformers with the variability inherent in VAE and InfoGAN. Diverging from prior approaches, VOLTA introduces a novel cross-attention-based connection linking the latent space to the decoder, enhancing stability in optimization. This innovative architecture accommodates diverse Transformer types, including decoder-only or encoder-decoder architectures, and supports varying input types, be it continuous or discrete. Additionally, our framework incorporates InfoGAN-style latent codes, enabling input-independent variability, thereby further enriching generative diversity. Comprehensive experiments across six datasets spanning three distinct NLG tasks showcase VOLTA's significant enhancement in generative diversity while preserving quality.

6 Limitations

Given limited computational resources, we did not integrate LLM into the VOLTA framework, leaving this as a potential area for future exploration. As our model architecture is not confined to GPT-2 or T5, larger and more robust Transformer models could be employed to demonstrate its generalizability. Additionally, incorporating more NLG tasks and datasets could further reinforce our experimental results.

A Appendix

A.1 Notations

Because we use VAE in this paper, our model is the composition of its encoder and decoder: $f = f_{enc} \circ f_{dec}$.

	Symbol	Description
Constant	m/n	The length of the context/question
	k	The number of categories in a categorical distribution
Variable	$\boldsymbol{x}$	Text sequence
	$\boldsymbol{z}/\boldsymbol{c}$	Latent variable/code vector
	z/c	A single latent variable/code
	$\square_c/\square_q/\square_a$	Context/question/answer subscript
	$\square_{\square,i}$	Element index of a vector
	s/e	Answer span start/end token index
	$\square'$	Generated content
Model	$f_{enc}(\cdot)$, $f_{dec}(\cdot)$	Encoder, decoder
	FC$(\cdot)$	Single fully-connected layer
	$\mathcal{N}(\cdot)$	Gaussian distribution
	Uni$(\cdot)$	Uniform distribution
	Cat$(\cdot)$	Categorical distribution
	$[\cdots]$	Concatenation operation
	CE$(\cdot)$	Cross-entropy loss

Table 8: Notations used in this paper.

A.2 Basic Definitions

Information is defined as:

$$I(X) = -\log P(X) = \log \frac{1}{P(X)}.$$

Entropy is defined as:

$$\begin{aligned}
H(X) =& \mathbb{E}[I(X)] \\
=& \mathbb{E}[-\log(P(X))] \\
=& -\int p(x) \log p(x) \mathrm{d}x \\
H(X|Y) =& \mathbb{E}_{X,Y}[-\log \mathrm{P}(X|Y)] \\
=& -\int f(x,y) \log f(x|y) \mathrm{d}x\mathrm{d}y,
\end{aligned}$$

where $p(x,y)$ is the probability mass function of a discrete distribution, whereas $f(x,y)$ is the probability density function of a continuous distribution.

Then mutual information is:

$$\begin{aligned}
& I(X;Y) \\
=& D_{\mathrm{KL}}(P(X,Y) \parallel P(X)P(Y)) \\
=& \int p(x,y) \log \frac{p(x,y)}{p(x)p(y)} \mathrm{d}x\mathrm{d}y \\
=& -\int p(x,y) \log p(y) \mathrm{d}x\mathrm{d}y \\
& + \int p(x,y) \log \frac{p(x,y)}{p(x)} \mathrm{d}x\mathrm{d}y \\
=& -\int p(y) \log p(y) \mathrm{d}y \\
& + \int p(x,y) \log p(y|x) \mathrm{d}x\mathrm{d}y \\
=& H(Y) - H(Y|X) \\
=& H(X) - H(X|Y),
\end{aligned}$$

because Kullback–Leibler divergence is defined to be:

$$\begin{aligned}
& D_{\mathrm{KL}}(Q \parallel P) \\
& \quad = H(Q,P) - H(Q) \\
& \quad = \mathbb{E}_Q[-\log \mathrm{P}(X)] - \mathbb{E}_Q[-\log \mathrm{Q}(X)] \\
& \quad = \int q(x) \log \frac{q(x)}{p(x)} \mathrm{d}x \\
& \quad \geq 0,
\end{aligned}$$

where $H(Q,P)$ is the cross entropy of Q and P.

A.3 Optimus (Beta-VAE)

In Optimus (Li et al., 2020a; Kingma and Welling, 2014), we assume a normal distribution for a continuous latent variable:

$$\begin{aligned}
& f(x) = \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{x-\mu}{\sigma}\right)^2} \\
& \log f(x) \\
& \quad = -\log \sigma\sqrt{2\pi} - \frac{1}{2}\left(\frac{x-\mu}{\sigma}\right)^2 \\
& \quad = -\log \sigma - \frac{1}{2}\log 2\pi - \frac{1}{2}\left(\frac{x-\mu}{\sigma}\right)^2 \\
& \quad = -\frac{1}{2}\log \sigma^2 - \frac{1}{2}\log 2\pi - \frac{1}{2}\left(\frac{x-\mu}{\sigma}\right)^2.
\end{aligned}$$

We want $q(z|x) = N(\mu_q, \sigma_q^2)$ and the prior, $p(z) = N(\mu_p, \sigma_p^2) = N(0, 1)$, to be close

$$\begin{aligned}
&D_{\text{KL}}(Q \parallel P) \\
&= -\int q(z)\log p(z)dz + \int q(z)\log q(z)dz \\
&= \left(\frac{1}{2}(\log 2\pi\sigma_p^2) + \frac{\sigma_q^2 + (\mu_q - \mu_p)^2}{2\sigma_p^2}\right) \\
&\quad - \frac{1}{2}(1 + \log 2\pi\sigma_q^2) \\
&= \frac{1}{2}(\log \frac{\sigma_p^2}{\sigma_q^2}) + \frac{\sigma_q^2 + (\mu_q - \mu_p)^2}{2\sigma_p^2} - \frac{1}{2} \\
&= \frac{1}{2}\log\left(\frac{\sigma_p}{\sigma_q}\right)^2 + \frac{\sigma_q^2 + (\mu_q - \mu_p)^2}{2\sigma_p^2} - \frac{1}{2}
\end{aligned}$$

The mutual information between z and $z|x$ is

$$I(z, x) = H(z) - H(z|x),$$

where the negative entropy for normal distribution is (n_z is the dimension of latent variable z):

$$\begin{aligned}
-H(z|x) &= \mathbb{E}_{Q(z|x)}[\log(Q(z|x))] \\
&= -\int q(z)\log q(z)\mathrm{d}z \\
&= -\frac{1}{2}(1 + \log 2\pi\sigma_q^2) \\
&= -\frac{1}{2}(1 + \log 2\pi + \log \sigma_q^2) \\
&= -\frac{1}{2}\log 2\pi - \frac{1}{2}(1 + \log \sigma_q^2)
\end{aligned}$$

$$\begin{aligned}
&H(z) = \mathbb{E}_{q(z)}[-\log q(z)] \\
&= -\int q(z)\left(\log \sigma_q\sqrt{2\pi} + \frac{1}{2}\left(\frac{z - \mu_q}{\sigma_q}\right)^2\right)\mathrm{d}x \\
&= -\int q(z)\log \sigma_q\sqrt{2\pi}\mathrm{d}x \\
&\quad - \int q(z)\frac{1}{2}\left(\frac{z - \mu_q}{\sigma_q}\right)^2\mathrm{d}x \\
&= -\mathbb{E}_{q(z)}[\log \sigma_q\sqrt{2\pi}] - \mathbb{E}_{q(z)}\left[\frac{1}{2}\left(\frac{z - \mu_q}{\sigma_q}\right)^2\right] \\
&= -\log \sigma_q\sqrt{2\pi} - \mathbb{E}_{q(z)}\left[\frac{1}{2}\left(\frac{z - \mu_q}{\sigma_q}\right)^2\right] \\
&= -\log \sigma_q\sqrt{2\pi} - \frac{1}{2}\left(\frac{\mathbb{E}_{q(z)}\left[(z - \mu_q)^2\right]}{\sigma_q^2}\right) \\
&= -\frac{1}{2}\log \sigma_q^2 - \frac{1}{2}\log 2\pi - \frac{1}{2}\frac{(z - \mu_q)^2}{\sigma_q^2},
\end{aligned}$$

where $\mathbb{E}_{q(z)}\left[(z - \mu_q)^2\right]$ is simply the deviation of a single sample z from the mean μ_q.

A.4 Info-HCVAE

According to Info-HCVAE (Lee et al., 2020), some inputs are better suited to be encoded into discrete latent variables. In this case, we can make use of the categorical distribution:

$$f(x = i \mid \boldsymbol{p}) = p_i,$$

where the event probabilities $\boldsymbol{p} = (p_1, \ldots, p_k)$ and $\sum_{i=1}^{k} p_i = 1$; $k > 0$ is the number of categories.

The Gumbel-Softmax distribution enables back-propagation through discrete distributions. The Gumbel distribution is:

$$\text{Gumbel}(\mu, \beta) = f(x; \mu, \beta) = \frac{1}{\beta}e^{-(z + e^{-z})},$$

where $z = \frac{x - \mu}{\beta}$.

To sample a category from the categorical distribution using the Gumbel-Max re-parametrization trick, one can follow:

$$\arg\max_i (G_i + \log p_i),$$

where $G_i \sim \text{Gumbel}(0, 1)$. $\arg\max$ can be made differentiable by approximating it with the softmax function:

$$y_i = \frac{\exp((G_i + \log p_i)/\tau)}{\sum_j \exp((G_j + \log p_j)/\tau)},$$

Given two categorical distributions P and Q, parameterized by $\boldsymbol{p}$ and $\boldsymbol{q}$, respectively, the KL divergence between them is:

$$D_{\text{KL}}(Q \parallel P) = \sum_{i=1}^{k} q_i \log \frac{q_i}{p_i}.$$

A.5 InfoGAN

The input noise z is passed into the generator along with the latent code c: $G(z, c)$, where z is concatenated with c. Because the generator can simply ignore the latent code c, InfoGAN (Chen et al., 2016) adds Variational Mutual Information Maximization (VMIM) to maintain the mutual information between generated sample $x \sim G(z, c)$ and latent code c:

$$\begin{aligned}
&I(c;G(z,c))\\
=&H(c)-H(c|G(z,c))\\
=&H(c)+\mathbb{E}_{x\sim G(z,c)}[\mathbb{E}_{c'\sim P(c|x)}[\log P(c'|x)]]\\
=&H(c)+\mathbb{E}_{x\sim G(z,c)}\Big[\sum_{c'} p(c'|x)\log p(c'|x)\Big]\\
=&H(c)+\mathbb{E}_{x\sim G(z,c)}\Big[\sum_{c'} p(c'|x)(\log\frac{p(c'|x)}{q(c'|x)}\\
&\qquad\qquad+\log q(c'|x))\Big]\\
=&H(c)+\mathbb{E}_{x\sim G(z,c)}\Big[\sum_{c'} p(c'|x)\log\frac{p(c'|x)}{q(c'|x)}\\
&\qquad\qquad+\sum_{c'} p(c'|x)\log q(c'|x)\Big]\\
=&H(c)+\mathbb{E}_{x\sim G(z,c)}\big[D_{\text{KL}}(P(\cdot|x)\parallel Q(\cdot|x))\\
&\qquad\qquad+\mathbb{E}_{c'\sim P(c|x)}[\log Q(c'|x)]\big]\\
\geq&H(c)+\mathbb{E}_{x\sim G(z,c)}\left[\mathbb{E}_{c'\sim P(c|x)}[\log Q(c'|x)]\right],
\end{aligned}$$

Because the posterior $P(c|x)$ is hard to obtain, an auxiliary distribution $Q(c|x)$ is added to approximate $P(c|x)$, where Q is a neural network. In practice, the entropy of latent codes $H(c)$ is treated as a constant and omitted in the InfoGAN objective.

A.6 InfoVAE and InfoMax-VAE

The evidence lower bound (ELBO) of regular VAE is

$$\begin{aligned}
&\mathcal{L}_{\text{ELBO}}(x)\\
=&\mathcal{L}_{\text{AE}}(x)+\mathcal{L}_{\text{REG}}(x)\\
=&\mathbb{E}_{q_\phi(z|x)}[\log p_\theta(x|z)]-D_{\text{KL}}(q_\phi(z|x)\parallel p(z))\\
\leq&\log p_\theta(x).
\end{aligned}$$

InfoVAE (Zhao et al., 2019) and InfoMax-VAE (Lotfi-Rezaabad and Vishwanath, 2020) add mutual information to the loss:

$$\begin{aligned}
\mathcal{L}_{\text{ELBO}}(x)=&\mathcal{L}_{\text{AE}}(x)+\beta\mathcal{L}_{\text{REG}}(x)+\alpha I_q(x;z)\\
=&\mathbb{E}_{p_D(x)}[\mathbb{E}_{q_\phi(z|x)}[\log p_\theta(x|z)]]\\
&-\beta\mathbb{E}_{p_D(x)}D_{\text{KL}}(q_\phi(z|x)\parallel p(z))\\
&-\alpha D(q_\phi(x;z)\parallel q(x)q_\phi(z)),
\end{aligned}$$

Because $D(q_\phi(x;z)\parallel q(x)q_\phi(z))$ is usually intractable; thus, it can be approximated with any one of the following:

- KL divergence
- f-divergence (InfoMax)
- Donsker-Varadhan dual representation (InfoMax)
- Jensen Shannon divergence (AAE)
- Stein Variational Gradient
- Maximum-Mean Discrepancy

A.7 QA mutual information loss

We want to enforce the mutual information (QAMI) between the generated QA pair. Following Info-HCVAE (Lee et al., 2020), we base this QAMI objective on Jensen-Shannon Divergence, which uses a bilinear layer on top of the decoder to classify whether the question and answer is a true pair:

$$\begin{aligned}
&\boldsymbol{h}_q=\overline{\boldsymbol{h}}_{q,m+1:m+n}\quad \boldsymbol{h}_a=\overline{\boldsymbol{h}}_{a,1:m}\\
&g(q,a)=\sigma(\boldsymbol{h}_q{}^T\boldsymbol{W}\boldsymbol{h}_a)\\
&I(q,a)\geq\mathbb{E}[\log g(q,a)]+1/2\mathbb{E}[\log(1-g(\tilde{q},a))]\\
&\qquad\qquad+1/2\mathbb{E}[\log(1-g(q,\tilde{a}))]\\
&\qquad=-\mathcal{L}_{\text{QAMI}}(\boldsymbol{x}),
\end{aligned}\tag{10}$$

where the question and answer embeddings, $\boldsymbol{h}_q$ and $\boldsymbol{h}_a$, are the average of their contextualized token embeddings; $\boldsymbol{W}$ is the parameter matrix of the bilinear layer $g(\cdot)$; $\tilde{q}/\tilde{a}$ is a negative question/answer sample; $\sigma(\cdot)$ is the activation function.

A.8 Examples

We provide a few more examples of latent code control.

	Knute Rockne became head coach in 1918. Under Rockne, the Irish would post a record of 105 wins, 12 losses, and five ties ···	
Q1	$c_q=-1$	How many wins did Knute Rockne post?
Q2	$c_q=-.9$	How many wins did Knute Rockne have?

EcoSpeak: Cost-Efficient Bias Mitigation for Partially Cross-Lingual Speaker Verification

Divya V Sharma
IIIT-Delhi
divyas@iiitd.ac.in

Abstract

Linguistic bias is a critical problem concerning the diversity, equity, and inclusiveness of Natural Language Processing tools. The severity of this problem intensifies in security systems, such as speaker verification, where fairness is paramount. Speaker verification systems are biometric systems that determine whether two speech recordings are of the same speaker. Such user-centric systems should be inclusive to bilingual speakers. However, Deep neural network models are linguistically biased. Linguistic bias can be full or partial. Partially cross-lingual bias occurs when one test trial pair recording is in the training set's language, and the other is in an unseen target language. Such linguistic mismatch influences the speaker verification model's decision, dissuading bilingual speakers from using the system. Domain adaptation can mitigate this problem. However, adapting to each existing language is expensive. This paper explores cost-efficient bias mitigation techniques for partially cross-lingual speaker verification. We study the behavior of five baselines in five partially cross-lingual scenarios. Using our baseline behavioral insights, we propose EcoSpeak, a low-cost solution to partially cross-lingual speaker verification. EcoSpeak incorporates contrastive linguistic (CL) attention. CL attention utilizes linguistic differences in trial pairs to emphasize relevant speaker verification embedding parts. Experimental results demonstrate EcoSpeak's robustness to partially cross-lingual testing.

1 Introduction

Linguistic bias is a crucial problem that harms the diversity, equity, and inclusiveness of Natural Language Processing (NLP) tools. The severity of this problem further increases in security systems, such as speaker verification, where fairness is critical. Speaker verification systems are biometric systems that determine whether two speech recordings are of the same speaker. The two input speech recordings form a trial pair. Positive or negative trial pairs indicate whether the recordings are of the same speaker. Speaker verification systems have applications in forensics, e-commerce, law, and access-control mechanisms (Estevez and Ferrer, 2023). These systems can be text-independent or text-dependent (Wu and Liao, 2021). Text-independent systems verify speakers without any constraint on speech content. Such systems work by analyzing the acoustic differences in trial pairs, consequently saving users from memorizing passphrases. Therefore, text-independent systems offer a better user experience than text-dependent systems.

Deep Neural Network (DNN) models have shown outstanding results in text-independent speaker verification (Chung et al., 2018; Nagrani et al., 2020, 2017). However, the embeddings obtained from DNN models often entangle acoustic and linguistic information (Zhou et al., 2021). Consequently, DNN-based speaker verification models become linguistically biased (Lu et al., 2009; Yang et al., 2022). Linguistic bias makes the model consider irrelevant language information in embeddings while making decisions for speaker verification, leading to performance degradation on unseen target languages. Such a bias can be full or partial. In the fully cross-lingual scenario, both the test trial pair recordings are in the target language t that is different from the source (or the training set) language s. In contrast, partially cross-lingual is another crucial scenario where one of the test trial pair recordings is in s, and the other is in t

Most of the previous works focus on the fully cross-lingual scenario. However, about 40% of the global population is bilingual (Wu and Liao, 2021). Therefore, addressing the partially cross-lingual challenge is essential to enhance the usability of speaker verification models. A viable solution to this problem is domain adaptation (Lee et al., 2020; Zhu and Chen, 2022; Chen et al., 2020; Wang et al.,

Findings of the Association for Computational Linguistics: NAACL 2024, pages 379–394
June 16-21, 2024 ©2024 Association for Computational Linguistics

2019; Rohdin et al., 2019; Tu et al., 2019; Xia et al., 2019). However, adapting the model to each of the 7,000 existing languages is expensive. Alternatively, we can train models on large-scale cross-lingual datasets to enhance their generalizability to unseen languages (Chojnacka et al., 2021). However, this approach incurs enormous computational and storage costs. High computational cost leads to high carbon emissions, which impacts the environment (Schwartz et al., 2020; Xu et al., 2021).

In this work, we investigate cost-efficient techniques to mitigate partially cross-lingual bias in text-independent speaker verification. We propose EcoSpeak, a low-cost solution to mitigate partially cross-lingual bias. The EcoSpeak architecture incorporates a lightweight residual network, novel contrastive linguistic (CL) attention, and the bias corrector. Here, residual connections allow the model to emphasize the low-level acoustic features essential for speaker verification. Our proposed CL attention mechanism utilizes linguistic differences in trial pair recordings to generate attention weights for speaker verification. The bias corrector module penalizes the speaker verification probabilities based on linguistic differences in trial pair recordings. We first study the behavior of five baselines on five partially cross-lingual test sets created using speech recordings in four low-resource languages. Subsequently, we investigate the effectiveness of EcoSpeak on these test sets without domain adaptation. Furthermore, we explore low-cost fine-tuning techniques to enhance the generalizability of EcoSpeak for unseen low-resource languages.

We summarize our main contributions below:

1. We study the behavior of five baseline models on five partially cross-lingual test sets for four low-resource languages.
2. We propose EcoSpeak, a cost-efficient solution for bias mitigation in partially cross-lingual speaker verification.
3. We investigate the effectiveness of EcoSpeak on partially cross-lingual test sets. Furthermore, we explore cost-efficient fine-tuning strategies to enhance the model's generalizability to unseen languages.

2 Related Works

Partially Cross-Lingual Bias: Training on large-scale cross-lingual datasets mitigates partially cross-lingual bias (Wu and Liao, 2021; Qin et al., 2021). However, it is hard to find such cross-lingual labeled datasets (Wu and Liao, 2021). Moreover, this approach incurs enormous computational and storage costs. Another viable option is multi-task learning (Zhou et al., 2021). Multi-task learning can make the model jointly learn speaker identities and reduce the effect of linguistic bias. Furthermore, a fusion of multiple models can mitigate linguistic bias (Qin et al., 2021; Thienpondt et al., 2020). However, fusion would increase the system's inference cost. Notably, residual networks are relatively more robust to linguistic differences than many other models (Qin et al., 2021; Thienpondt et al., 2020). However, the reason still needs to be investigated. In this work, we study the behavior of residual networks in the partially cross-lingual scenario. To our knowledge, Thienpondt et al. (2020) is the most closely related work to our problem. In Thienpondt et al. (2020), the authors address the partially cross-lingual scenario where speakers speak Persian as their first language and English as their second language (Zeinali et al., 2019). They proposed subtracting a language compensation offset if the utterances in the trial pair are in different languages. Nevertheless, they focussed on closed-set speaker verification where the test utterance belongs to the set of known speakers within the training set. In contrast, we focus on the open-set scenario where test trial pair recordings can belong to unknown speakers outside the training set.

Green Speech Processing: The NLP community strives towards developing inclusive and environment-friendly models (Schwartz et al., 2020; Xu et al., 2021). However, speech processing is expensive, requiring enormous computational and storage resources. For instance, the training set of the SpeakerStew consisted of 20,618,000 utterances from 196,000 speakers (Chojnacka et al., 2021). Similarly, the XLS-R model contains about 2B parameters. The training set of XLS-R consisted of nearly half a million hours of speech recordings (Babu et al., 2022). In Qin et al. (2021), authors trained the model on speech recordings from 21,795 virtual speakers and the actual training set speakers for partially cross-lingual bias mitigation. High computational costs lead to high carbon footprints. Therefore, researchers have explored cost-effective bias mitigation techniques for fully cross-lingual speaker verification (Sharma and Buduru, 2022; Li et al., 2022). In this work, we investigate cost-efficient bias mitigation techniques for partially cross-lingual speaker verification.

3 Proposed Approach

The remarkable success of the Deep Convolutional Neural Network (CNN) based speaker recognition models motivates us to investigate linguistic bias in these models. These models consist of multiple CNN layers (Nagrani et al., 2020; weon Jung et al., 2020, 2022). Lower layers capture low-level speech features, whereas higher layers capture high-level speech features. Low-level speech features contain mostly acoustic information, essential for speaker verification (Lesenfants et al., 2019). On the other hand, high-level speech features contain more linguistic information (Nahum et al., 2008). Therefore, deeper models can learn more linguistic details during training and become biased. Thus, to mitigate linguistic bias in speaker verification, we propose EcoSpeak. This section describes the architectural details of EcoSpeak.

Hypothesis: We know that residual connections add lower layer output features to the higher layer output features in a deep CNN model (He et al., 2016). Consequently, low-level acoustic features get added to the higher-level advanced representations. This summation allows the model to emphasize the low-level acoustic features essential for speaker verification. Accordingly, we hypothesize that residual connections help mitigate linguistic bias by making the model focus more on low-level acoustic information.

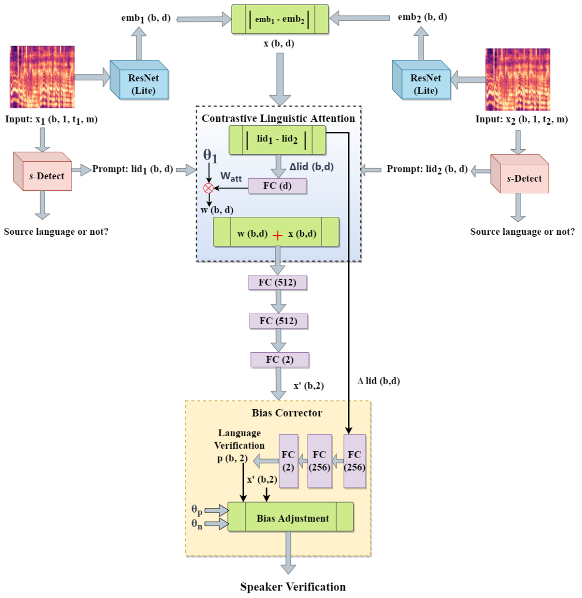

Figure 1: Architecture diagram for EcoSpeak.

Input: Firstly, we preprocess the trial pair recordings to crop silent parts. We then compute 64-dimensional normalized log mel spectrogram features of shape $(b, 1, t_i, m)$ as shown in Figure 1. Here, b denotes the batch size, 1 indicates mono-channel audio, t_i denotes the time steps, and m is the number of Mel bands (m=64). Since the duration of input speech recordings may vary during test time, the values of t_1 and t_2 may differ. Next, we pass these features through the ResNet (Lite) and the s-Detect model.

s-Detect: Partially cross-lingual trial pairs contain one speech recording in the source language s and the other speech recording in an unseen target language t. Thus, we use the s-Detect model to determine whether the input speech recording is in s. The model consists of three bidirectional gated recurrent unit (GRU) layers with a hidden size of 128 and a fully connected layer. As shown in Figure 1, it returns the output probability and a 256-dimensional lid_i embedding ($d = 256$).

ResNet (Lite): ResNet (Lite) is a lighter variant of the ResNet-34 (He et al., 2016).[1] The model is pre-trained for speaker identification. Speaker identification is a multi-class classification problem where the system accepts a speech recording as input and determines the speaker's identity from the known speakers in the training set. We use the pre-trained ResNet (Lite) in EcoSpeak to extract d-dimensional speaker embeddings as shown in Figure 1. First, we get emb_1 and emb_2 for the trial pair recordings from the avgPool layer of ResNet (Lite).[2] Next, we compute the absolute difference between these embeddings: $x = |emb_1 - emb_2|$. Computing the difference of the trial pair embeddings enables EcoSpeak to focus on the discriminatory information for speaker verification. Furthermore, computing absolute difference ensures that the model's output is unaffected by the input order, as absolute difference is a commutative operation.

Contrastive Linguistic (CL) Attention: Recent works have demonstrated the effectiveness of attention in speaker verification (Desplanques et al., 2020; weon Jung et al., 2020). We propose the contrastive linguistic (CL) attention mechanism for partially cross-lingual speaker verification. CL attention utilizes the linguistic differences between the trial pair recordings to generate attention weights. The attention block receives x as input and lid_1 and lid_2 as prompt inputs. CL attention works as

---

[1] We compared two ResNet-34 variants and chose a robust and lighter variant. Details are in the ablation study.

[2] Details of ResNet (Lite) layers is in Appendix (A).

follows:

1. **Generate attention weights:** First, we compute the absolute linguistic difference between the trial pair recordings. We then pass the resulting difference embedding through a fully connected layer and apply $ReLU$ to get the CL attention weights, W_{att} as shown below.

   $\Delta lid = |lid_1 - lid_2|$

   $W_{\text{att}} = ReLU(\Delta lid\, W^{\text{T}} + b_{\text{linear}})$

   Here W and b_{linear} are the weights and biases of the fully-connected layer.

2. **Apply attention:** We apply attention weights to the speaker embedding difference and get the output of the CL attention as follows:

   $x' = x + tanh(\theta_1) * W_{\text{att}}$

   Here θ_1 is a learned parameter.

Bias Corrector: To perform speaker verification, we feed x' through fully connected layers, as shown in Figure 1. We pass the resulting speaker verification probabilities to the bias corrector. The bias correction process involves two steps: language verification and bias adjustment.

Language verification: We jointly train EcoSpeak for speaker and language verification. Language verification is the binary classification task of determining whether the trial pair recordings are in the same language. For this task, we pass Δlid through fully connected layers to get the language verification probabilities p, as shown in Figure 1.

Bias adjustment: The decision of speaker verification models is influenced by the linguistic similarity in trial pair recordings. The speaker verification model may favor the positive class if the trial pair recordings are in the same language. On the other hand, if the trial pair recordings are in different languages, the speaker verification model may favor the negative class. Based on this intuition, EcoSpeak incorporates a bias adjustment module, thus ensuring fairness. If the language verification result is positive, the bias corrector prevents EcoSpeak from favoring the positive class while deciding on speaker verification. For this, the bias adjustment process adds a penalty to the negative class as follows: $x'[i, 0] = x'[i, 0] + |\theta_{\text{n}}|$. If the language verification result is negative, the bias corrector prevents EcoSpeak from favoring the negative class while deciding on speaker verification. For this, the bias adjustment process adds a penalty to the positive class as follows: $x'[i, 1] = x'[i, 1] + |\theta_{\text{p}}|$. Here θ_{p} and θ_{n} are learned parameters.

4 Experimental Setup

The datasets[3] and baseline models[4] used in this study are publicly available. All sets have an equal number of positive and negative trial pairs. In our experiments, English is the source language s, whereas Tamil, Telugu, Malayalam, and Kannada are the low-resource target languages t.

4.1 Datasets

Pre-train ResNet (Lite): We used the VoxCeleb-2 dev set to train ResNet (Lite) for speaker identification (Nagrani et al., 2020; Chung et al., 2018). The dataset contains 1,092,009 utterances from 5,994 speakers. Furthermore, we evaluated the model performance on the VoxCeleb-1 test set (Nagrani et al., 2017). It contains 37,720 trial pairs. The VoxCeleb datasets contain mostly English speech utterances (Qin et al., 2021). Thus, English is the source language s in our experiments.

Train s-Detect: We trained s-Detect using utterances in English and five Indian languages: Hindi, Tamil, Telugu, Malayalam, and Kannada.[5] We used the Indian-accented English data recorded for the NPTEL 2020 lectures (AI4Bharat, 2020). We obtained Hindi speech recordings from the Multilingual and code-switching ASR Challenge Dataset - sub-task1 (Diwan et al., 2021). In addition to the OpenSLR datasets, we utilized the Tamil and Telugu conversational speech recordings available in the Microsoft Speech Corpus (Microsoft, 2023). We used Malayalam and Kannada speech recordings available in OpenSLR (He et al., 2020).

Test Set	Positive Trial Pairs	Negative Trial Pairs
$\boldsymbol{tt-tt}$	both target (tt)	both target (tt)
$\boldsymbol{ts-tt}$	one target (t), one source (s)	both target (tt)
$\boldsymbol{ts-ts}$	one target (t), one source (s)	one target (t), one source (s)
$\boldsymbol{tt-ts}$	both target (tt)	one target (t), one source (s)
$\boldsymbol{ss-ss}$	both source (ss)	both source (ss)
$\boldsymbol{ss-st}$	both source (ss)	one source (s), one target (t)
$\boldsymbol{st-ss}$	one source (s), one target (t)	both source (ss)

Table 1: Brief description of the Low-Resource Language (LRL) Test Sets. Here, s represents the source language (English), and t represents the target language (the speaker's native language). The $tt-tt$ test set is fully cross-lingual, whereas $ss-ss$ is the same language test set. The remaining five test sets are partially cross-lingual.

Cross-lingual Speaker Verification: We used the NISP dataset for cross-lingual speaker verification experiments (Kalluri et al., 2021). The dataset consists of speech recordings from bilingual speakers having Hindi, Tamil, Telugu, Malayalam, or Kannada as their native language. These bilingual speakers use English as their second language. Thus, each speaker in the dataset has contributed recordings in English and their native language.

4.2 Low-Resource Language Test Sets

Our study focuses on Tamil, Telugu, Malayalam, and Kannada as the target low-resource languages (LRL). We used NISP-LRL native speaker data for cross-lingual testing. We consistently employ the following notations to present our experimental results:

1. s: The source language, i.e., English.
2. t: The target language, ie., the speaker's native language.
3. ts or st: Trial pair where one recording is in English s and the other is in the speaker's native language t.

We created seven LRL test sets described by the following notations:

1. $tt-tt$: All trial pair recordings are in the speaker's native language t.
2. $ts-tt$: Positive trial pair recordings are in different languages ts, whereas negative trial pair recordings are in the speaker's native language tt.
3. $ts-ts$: Each trial pair contains speech recordings in different languages ts.
4. $tt-ts$: Positive trial pairs contain both recordings in the speaker's native language tt, whereas negative trial pair recordings are in different languages ts.
5. $ss-ss$: All recordings are in English s.
6. $ss-st$: Positive trial pairs contain both recordings in English ss whereas negative trial pair recordings are in different languages st.
7. $st-ss$: Positive trial pair recordings are in different languages st, whereas negative trial pair recordings are in English ss.

Table 1 presents a compact description of the seven LRL test sets. Each LRL test set contains 100,000 trial pairs. These sets consist of 25,000 trial pairs from native speakers of each low-resource language. Speakers in negative trial pairs have the same gender. Accordingly, we generated a same language test set ($ss-ss$), fully cross-lingual test set ($tt-tt$) and five partially cross-lingual test sets ($ts-tt$, $ts-ts$, $tt-ts$, $ss-st$ and $st-ss$).

4.3 Baselines

We studied the behavior of the following five baselines on the LRL test sets: RawNet-3, ECAPA-TDNN, RawNet-2, X-Vectors, and VGG-M (weon Jung et al., 2022; Desplanques et al., 2020; Ravanelli et al., 2021; weon Jung et al., 2020; Snyder et al., 2018; Nagrani et al., 2020). The baselines were pre-trained for speaker identification. They accept speech recordings as input and return a speaker embedding. For speaker verification, we input each trial pair recording to the baseline. We compute the cosine similarity score from the obtained embeddings to determine if the recordings are of the same speaker. The X-Vector, ECAPA-TDNN, and RawNet-3 models were trained on combined VoxCeleb-1 and VoxCeleb-2 dev. VGG-M and RawNet-2 were trained on VoxCeleb-1 dev and VoxCeleb-2 dev, respectively.

4.4 Evaluation Metric

Equal Error Rate (EER) is the standard evaluation metric for speaker verification systems (Hansen and

Model	$tt-tt$	$ts-tt$	$ts-ts$	$tt-ts$	$ss-ss$	$ss-st$	$st-ss$
VGG-M (Baseline)	11.40	26.15	22.42	9.47	10.35	**7.90**	**28.06**
X-Vector (Baseline)	6.75	20.38	17.43	5.85	6.92	**5.25**	**22.19**
ECAPA-TDNN (Baseline)	12.46	20.93	19.57	11.96	11.40	**9.30**	**22.65**
RawNet-2 (Baseline)	38.24	**41.48**	39.21	**36.87**	37.90	37.00	39.80
RawNet-3 (Baseline)	41.34	**52.17**	46.54	**36.75**	41.71	44.10	43.60
ResNet+ (Hypothesis)	10.72	**13.55**	12.27	9.81	**9.51**	9.55	12.08
EcoSpeak (Scheme-A)	8.54	**13.88**	12.80	7.64	7.70	**7.37**	13.66
EcoSpeak (Scheme-B)	7.70	12.01	**12.65**	8.09	**7.23**	7.61	11.87
EcoSpeak (Scheme-C)	7.31	9.32	**11.16**	9.06	**6.81**	8.18	9.65

Table 2: Table showing the EER (%) of baselines, ResNet+, and EcoSpeak on the LRL test sets. We have represented each model's best and worst-case performance using bold font. Observations: 1.) Baselines performed the worst in ts - tt or st - ss. 2.) ResNet+ is stable compared to baselines. 3.) EcoSpeak (Scheme-C) performs better than other models on most test sets. It performed the worst in ts - ts, which deviates from the worst-case of baselines.

Hasan, 2015). EER is the value of the False Match Rate (FMR) and False Non-Match Rate (FNMR) when they are equal. FMR refers to the proportion of negative trial pairs incorrectly classified as positive by the system. In contrast, FNMR is the proportion of positive trial pairs incorrectly classified as negative by the system. EER is the value of the FMR when it becomes equal to the FNMR at a particular classification threshold. We used the EER to demonstrate the efficacy of this work. A lower EER indicates a better performance.

5 Experiments and Results

5.1 Baseline Behavioral Insights

The first step towards bias mitigation involves understanding the error patterns in baselines (Choe et al., 2022). Therefore, we examined the performance of baselines on the LRL test sets. As illustrated in Table 2, we observed elevated EER values on $ts-tt$ and $st-ss$. It indicates that a high-linguistic similarity in negative trial pair recordings (tt or ss) leads to performance degradation. This observation suggests that high-linguistic similarity makes the model favor the positive class. Likewise, a low-linguistic similarity in positive trial pairs (ts or st) also leads to performance degradation. This observation suggests that low-linguistic similarity makes the model favor the negative class. Furthermore, we observed lower EER values on the $tt-ts$ and $ss-st$ test sets. It indicates that the baselines perform the best when positive trial pair recordings have high linguistic similarity (ss or tt) and negative trial pair recordings have low linguistic similarity (ts or st). These observations indicate that the linguistic similarity in the trial pair influences the decision of baselines.

Key Observations:

1. We observed elevated EER values on $ts-tt$ and $st-ss$. Thus, baselines performed the worst on these test sets. It indicates that linguistic mismatch (ts or st) in positive trial pair recordings and linguistic match (tt or ss) in negative trial pair recordings causes performance degradation. Accordingly, we classify Positive-ts, Positive-st, Negative-tt, and Negative-ss as complex trial pair types.
2. We observed lower EER values on $tt-ts$ and $ss-st$. Thus, baselines performed the best on these test sets. It indicates that linguistic match (tt or ss) in positive trial pair recordings and linguistic mismatch (ts or st) in negative trial pair recordings leads to better baseline performance. Accordingly, we classify Positive-tt, Positive-ss, Negative-ts, and Negative-st as simple trial pair types.

5.2 Behavior of Residual Connections

Next, we investigated the impact of residual connections on cross-lingual testing. For this, we evaluated ResNet+ on LRL test sets. ResNet+ contains 64, 128, 256, and 512 channels for its first, second, third, and fourth layers, whereas ResNet (Lite) contains 32, 64, 128, and 256 channels. We compared the absolute difference between the models' highest and lowest EER scores on the LRL test sets. Table 2 illustrates that we achieved an EER difference of 4.04% (i.e., 13.55-9.51) using ResNet+. This difference is significantly less than that in most baselines. The EER differences for VGG-M, X-vector, ECAPA-TDNN, and RawNet-3 are 20.16%, 16.94%, 13.35% and 15.42%. It indicates that the ResNet+ is more stable than baselines on LRL test sets. Next, we compared the EER values achieved using the RawNet models on the VoxCeleb-1 and LRL test sets. We achieved EER values of 3.67% and 1.11% on the VoxCeleb-1 test set using RawNet-2 and RawNet-3. However, the performance of RawNet models significantly degraded on the NISP-LRL test sets with more than a 30% increase in EER values. In contrast, using ResNet+, we achieved an EER score of 9.97% on the VoxCeleb-1 test set. This value is closer to the ResNet+ results on LRL test sets. However, ECAPA-TDNN, RawNet-2, and RawNet-3 also incorporate residual connections in their architectures yet have demonstrated high linguistic bias on LRL test sets. It indicates that residual connections alone are not sufficient for bias mitigation.

Summary of Findings: ResNet+ is less linguistically biased than baselines. Thus, residual connections can help mitigate linguistic bias. However, residual connections alone are insufficient for bias mitigation.

5.3 Data Balancing Schemes

Focusing on the quality of training data rather than quantity can help mitigate linguistic bias cost-efficiently (Swayamdipta et al., 2020). Therefore, to explore the impact of data balancing in partially cross-lingual speaker verification, we investigated three data balancing schemes for fine-tuning EcoSpeak. These schemes involve training sets having different distributions of simple and complex trial pairs.

Methodology We created six trial pair types for fine-tuning EcoSpeak: Positive-ts, Positive-tt, Positive-ss, Negative-ts, Negative-tt, Negative-ss. Here, positive and negative indicate whether trial pair recordings are of the same speaker. The notations tt, ss, and ts indicate whether the trial pair recordings are in the same (tt or ss) or different languages (ts). Furthermore, our baseline behavioral insights reveal that Positive-ts, Negative-tt, and Negative-ss are complex trial pair types. In contrast, Positive-tt, Positive-ss, and Negative-ts are the simpler trial pair types. Accordingly, we investigated the following data balancing schemes:

1. *Scheme-A:* In Scheme-A, we generate 200,000 examples for each trial pair type.
2. *Scheme-B:* In Scheme-B, we generate 250,000 and 150,000 examples for each complex and easy trial pair type.
3. *Scheme-C:* In Scheme-C, we generate 300,000 and 100,000 examples for each complex and easy trial pair type.

Accordingly, we created 1,200,000 trial pairs for each scheme, thus obtaining separate training sets for each scheme. We fine-tuned EcoSpeak on the NISP-Hindi speaker data using these scheme-specific training sets. Consequently, we got three EcoSpeak models, one for each scheme. Furthermore, we evaluated the performance of these EcoSpeak models on the LRL test sets without domain adaptation. LRL test sets contain speech recordings of native speakers of Tamil, Telugu, Malayalam, and Kannada.

Observations: We compared the absolute differences between the best-worst case EER values of the three scheme-specific EcoSpeak models. As illustrated in Table 2, we noticed absolute differences of 6.51% (13.88-7.37), 5.42% (12.65-7.23), and 4.35% (11.16-6.81) using Scheme-A, Scheme-B, and Scheme-C. Thus, we achieved the most stable results using Scheme-C. The training set for Scheme-C contains more examples from the complex trial pair type. It suggests that appropriate data balancing schemes can cost-efficiently aid bias mitigation. Furthermore, contrary to what we observed in baselines, EcoSpeak (Scheme-C) performed the worst in $ts - ts$ (and not in $ts - tt$ or $st - ss$). This observation indicates that the performance trend of EcoSpeak deviates from baselines.

5.4 Dataset for fine-tuning EcoSpeak

Due to data scarcity in low-resource target languages, finding appropriate datasets for fine-tuning models is challenging. Therefore, we explored two fine-tuning options for EcoSpeak:

1.) Fine-tuning on weakly related but diverse data.
2.) Fine-tuning on strongly related but small data.

Methodology: For this experiment, we chose Tamil as the low-resource target language (t). We utilized the LRL test sets to create Tamil-LRL test sets. Tamil-LRL test sets include those LRL test set trial pairs that contain speech recordings of only Tamil native speakers. Thus, we got seven Tamil-LRL test sets containing 25,000 trial pairs each.

NISP-Hindi is a diverse dataset (103 speakers), but Hindi is weakly related to Tamil. NISP-Telugu, NISP-Malayalam, and NISP-Kannada are small (fewer speakers) datasets with speech recordings from 60 speakers each. However, these LRLs are strongly related to Tamil. Subsequently, we fine-

Test Set	EcoSpeak-Hindi	EcoSpeak-Telugu	EcoSpeak-Malayalam	EcoSpeak-Kannada
$tt-tt$	**8.31**	9.70	9.98	10.36
$ts-tt$	**10.25**	14.57	13.44	12.97
$ts-ts$	**11.42**	15.94	15.78	14.34
$tt-ts$	**8.86**	10.51	11.61	12.43
$ss-ss$	**6.26**	8.18	9.05	9.85
$ss-st$	**7.42**	10.26	11.04	12.46
$st-ss$	**8.94**	12.63	12.49	11.17

Table 3: Table showing the EER values (%) on Tamil-LRL test sets. The EcoSpeak model fine-tuned on NISP-Hindi native speaker data performed the best. NISP-Hindi is a diverse dataset, but Hindi is weakly related to Tamil.

Model	#Parameters	Size (MB)	Time (sec)	CO_2 (kgCO2eq)	Electricity (kWh)
RawNet-3	16,280,322	62.30	4000	0.46	0.73
ECAPA-TDNN	22,150,912	85.00	2195	0.23	0.36
RawNet-2	13,379,378	51.10	1360	0.13	0.20
VGG-M	17,909,219	68.40	1252	0.11	0.18
X-Vector	8,172,473	31.50	**1014**	**0.09**	**0.14**
EcoSpeak	**6,660,233**	**25.50**	1165	0.10	0.16

Table 4: Table comparing the cost of EcoSpeak with baselines. The model size and number of parameters reported for EcoSpeak include the size and parameters of s-Detect. The time, carbon emissions, and electricity consumption statistics reported in the table represent the inference cost on the $tt-tt$ LRL test set.

tuned EcoSpeak on these datasets to get EcoSpeak-Hindi, EcoSpeak-Telugu, EcoSpeak-Malayalam, and EcoSpeak-Kannada models.

Observations: Table 3 illustrates the EER values we achieved on the Tamil-LRL test sets using EcoSpeak-Hindi, EcoSpeak-Telugu, EcoSpeak-Malayalam, and EcoSpeak-Kannada. We observed lower EER using the EcoSpeak-Hindi model compared to other EcoSpeak models. Thus, the EcoSpeak-Hindi model performed the best on Tamil-LRL test sets. It indicates that fine-tuning on a weakly related diverse dataset can be better than fine-tuning on a strongly related limited dataset. Overfitting on small datasets can reduce the model's generalization ability.

5.5 Cost Analysis

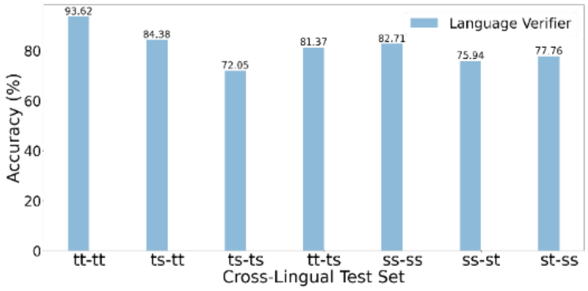
This work aims to investigate cost-efficient solutions to partially cross-lingual speaker verification. Therefore, we compared the costs associated with the baselines and our proposed EcoSpeak. We focussed on the model size, number of parameters, and the inference costs (time, carbon emission, and electricity consumption) of these models. Table 4 illustrates that EcoSpeak has a lesser model size and number of parameters than the baselines. Furthermore, we compared the inference costs of the EcoSpeak-Hindi model with the baselines on the $tt-tt$ LRL test set. Table 4 demonstrates that EcoSpeak-Hindi takes less inference time than most baselines. Additionally, we observed lower carbon emissions and electricity consumption from EcoSpeak-Hindi compared to most baselines when tested on the $tt-tt$ LRL test set. Table 4 shows that EcoSpeak's inference cost is comparable to the X-Vector model. However, Table 2 demonstrates that EcoSpeak is more stable than X-vector on the LRL test sets. It is because EcoSpeak (Scheme-C) shows an EER variation of 4.35% (i.e., 11.16-6.81) on the LRL test sets. In contrast, X-Vector shows an EER difference of 16.94% (i.e., 22.19-5.25) on the LRL test sets. Therefore, our findings indicate that EcoSpeak is a cost-efficient solution to partially cross-lingual speaker verification.

5.6 Ablation Study

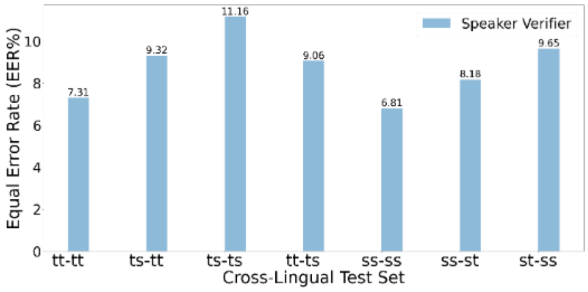
To analyze EcoSpeak results, we did an ablation study, as shown in Table 5. Firstly, we observed that *ResNet (Lite)* performs better than ResNet+ on the LRL test sets. Furthermore, it is lighter than ResNet+. In EcoSpeak, we chose ResNet (Lite) to extract speaker embeddings from the trial pair recordings. Next, instead of cosine similarity, we used fully connected layers for speaker verification in *ResNet (Lite)+fc*. We fed the absolute difference of the trial pair ResNet (Lite) embeddings

Model	$tt-tt$	$ts-tt$	$ts-ts$	$tt-ts$	$ss-ss$	$ss-st$	$st-ss$
ResNet+	10.72	**13.55**	12.27	9.81	**9.51**	9.55	12.08
ResNet (Lite)	9.52	**12.14**	10.96	**8.33**	8.54	9.13	10.58
ResNet (Lite)+fc	11.16	**14.72**	13.87	10.67	10.57	**10.29**	13.76
CL Attention	7.47	9.29	**11.70**	9.67	**6.94**	8.48	9.88
EcoSpeak	7.31	9.32	**11.16**	9.06	**6.81**	8.18	9.65

Table 5: Ablation study results for EcoSpeak. Observation: CL attention mitigates linguistic bias.



a) Language Verification



b) Speaker Verification

Figure 2: Figure shows a negative correlation between EcoSpeak's language and speaker verification performance. High language verification accuracy causes a low EER in speaker verification and vice-versa.

to the fully connected layer. The fully-connected layers were fine-tuned on the NISP-Hindi native speaker data using Scheme-C. The poor performance of ResNet (Lite)+fc indicates that data balancing alone is insufficient for bias mitigation. Still, we fine-tuned the CL attention model and EcoSpeak using Scheme-C, described in Section 5.3.

The *CL attention* model outperformed ResNet (Lite) on most LRL test sets. Interestingly, we observed significant improvements in the two most challenging partially cross-lingual scenarios, $ts-tt$ and $st-ss$. It suggests that the CL attention effectively emphasizes or de-emphasizes speaker verification embeddings based on linguistic differences in the trial pair recordings. *EcoSpeak* incorporates the CL attention and the bias corrector. It performed better than the CL attention model on most LRL test sets. EcoSpeak performed the worst on $ts-ts$. The reason is that EcoSpeak's performance in language verification affects its performance in speaker verification, as evidenced by Figure 2. EcoSpeak's higher language verification accuracy causes a lower EER score in speaker verification and vice-versa. The model performed the worst for language verification on $ts-ts$. It justifies EcoSpeak's worst-case speaker verification performance on $ts-ts$.

6 Conclusions and Future Work

This paper investigates the behavior of five baseline speaker verification models on five partially cross-lingual test sets. Empirical results demonstrate that a high linguistic similarity in negative trial pair recordings and a low linguistic similarity in positive trial pair recordings causes performance degradation. Furthermore, residual networks are relatively robust to cross-lingual testing. Using these insights, we proposed EcoSpeak, a low-cost solution to mitigate bias in partially cross-lingual speaker verification. EcoSpeak incorporates residual connections, contrastive linguistic attention, and the bias corrector. Empirical results demonstrate the robustness of our proposed model on partially cross-lingual test sets. EcoSpeak's performance trend deviates from the baselines. It turns out that utilizing linguistic differences to emphasize and de-emphasize relevant speaker verification embedding parts can mitigate partially cross-lingual bias.

Our insights can contribute to the development of more robust domain-invariant architectures. Furthermore, this work encourages the community to explore greener approaches to expensive speech processing. For instance, based on our empirical results, we recommend leveraging diverse datasets in a weakly related language for bias mitigation in an unseen low-resource target language. Additionally, our proposed data balancing schemes can save the cost of training on large-scale datasets. We also recommend a detailed cost analysis to develop environment-friendly and inclusive models.

7 Limitations

This work explores cost-efficient techniques for bias mitigation in partially cross-lingual speaker verification. Our proposed approach has the following limitations:

1. **Correlation between speaker and language verification performance:** EcoSpeak's performance on the language verification task affects its performance on the speaker verification task. One way to address this limitation is to use a more robust s-Detect model. It is because EcoSpeak accepts s-Detect embeddings as prompt inputs for CL attention and language verification. Therefore, having a more robust s-Detect can enhance the speaker verification performance of EcoSpeak.

2. **More experimental validation for contrastive linguistic (CL) Attention:** Our proposed CL attention mechanism relies on the intuition that the learned CL attention weights shall correlate with the speaker verification embeddings. Therefore, modulating the CL attention weights with the speaker verification embedding emphasizes those embedding parts that are more influenced by linguistic variations. However, CL attention is a relatively new approach. In this study, we experimented on five partially cross-lingual test sets created for four low-resource languages. Still, extensive experimental validation in more languages is required to validate the effectiveness of CL attention.

3. **Low-resource language datasets used to train s-Detect**: We did not explicitly fine-tune EcoSpeak on the target low-resource languages (Tamil, Telugu, Malayalam, and Kannada). However, we used speech recordings from different datasets in the target low-resource languages to train the s-Detect model. Nevertheless, this approach is practical as it is easier to find language identification datasets than cross-lingual datasets of bilingual speakers for speaker verification.

Linguistic bias is a complex problem to address using a single bias mitigation technique. This work offers a combination of low-cost bias mitigation techniques in the form of EcoSpeak. In the future, combining our proposed techniques with other novel ideas can further aid bias mitigation.

Table 6: Architecture details of the ResNet (Lite) speaker identification model.

B Training Setup

Firstly, we trained the ResNet (Lite) for speaker identification on VoxCeleb-2 dev. It took about 40 minutes for the completion of one epoch. One epoch caused 0.18 kgCO2eq carbon emissions and consumed 0.61 kWh of electricity. We trained the model for ten epochs. Secondly, we trained the s-Detect model to detect the source language (English). As described in Section 4.1, we combined speech recordings from different datasets to train s-Detect. We collected 23856, 24884, 20207, 1983, 3633, and 74563 speech recordings in Hindi, Tamil, Telugu, Malayalam, Kannada, and English. Next, we fine-tuned the s-Detect on the NISP-Hindi speaker data so that the EcoSpeak-Hindi model could adapt to the dataset-specific variations of NISP. We combined the NISP-Hindi speaker data with the s-Detect training set and used mixed training to fine-tune s-Detect. Finally, we used this adapted s-Detect to train the EcoSpeak-Hindi model on the NISP-Hindi speaker data. We fine-tuned EcoSpeak-Hindi for four Epochs to prevent overfitting due to data limitations. We froze the EcoSpeak's ResNet (Lite) weights during fine-tuning. We used the CrossEntropyLoss, Adam optimizer, and a learning rate 0.0005. We followed the same procedure to train the EcoSpeak-Tamil, EcoSpeak-Telugu, EcoSpeak-Malayalam, and EcoSpeak-Kannada models. We used one NVIDIA A100 GPU. We also used Librosa for pre-processing and feature extraction, Pytorch for model training, and CodeCarbon for tracking carbon emissions and electricity consumption (McFee et al., 2015; Paszke et al., 2019).[6]

Dataset	Test Set	RC	RAD

Table 7: EER (%) values on evaluating the RC and RAD on different LRL test sets. The RAD model outperformed RC on most test sets. It justifies our use of the absolute difference in EcoSpeak.

C Absolute Difference in EcoSpeak

EcoSpeak uses the absolute difference operation to compare trial pair embeddings (emb_1, emb_2) for speaker verification. This section describes the experiment that motivated us to use the absolute difference. We compared the following models:

ResNet (Lite)-Concat: In the ResNet (Lite)-Concat model (RC), we feed each trial pair recording through the ResNet (Lite) to get 256-dimensional embeddings (emb_1, emb_2). We concatenate these embeddings to get a 512-dimensional embedding. We feed this concatenated embedding through two fully connected layers having 512 units. Finally, we pass the resulting embedding through a fully connected layer consisting of two units for speaker verification. This model occupies 22.4 MB of disk space.

ResNet(Lite)-AbsoluteDifference: In the ResNet(Lite)-AbsoluteDifference (RAD) model, we feed each trial pair recording through the ResNet (Lite) to get 256-dimensional embeddings (emb_1, emb_2). We compute the absolute difference of these embeddings to get a 256-dimensional embedding. We feed this difference embedding through two fully connected layers having 256 units. Finally, we pass the resulting embedding through a fully connected layer consisting of two units for speaker verification. This model occupies 20.9 MB of disk space.

Language-Specific LRL test sets: We created separate test sets for each LRL under consideration. Thus, we got Tamil-LRL, Telugu-LRL, Malayalam-LRL, and Kannada-LRL test sets. These test sets are the subsets of the original LRL test sets described in Section 4.1. They include trial pairs of native speakers of these languages. Thus, each test set in Tamil-LRL, Telugu-LRL, Malayalam-LRL, and Kannada-LRL contains 25,000 trial pairs.

Observation: We compared the performance of RC and RAD on the LRL test sets (described in Section 4.2) and the language-specific LRLs. Table 7 illustrates that we achieved lower EER values using RAD than RC on most test sets. This observation motivated us to use the absolute difference operation in EcoSpeak.

D Extensive Experimental Validation

Table 8, Table 9, Table 10 and Table 11 illustrates the performance of the baselines, ResNet+ and EcoSpeak on the Tamil, Telugu, Malayalam, and Kannada LRL test sets described in Section C. These tables validate our observations in Sections 5.1, 5.2, and 5.3. Table 12, Table 13 and Table 14 demonstrate the result of the experiment described in Section 5.4 on the Telugu, Malayalam, and Kannada LRL test sets.

Table 12: Table showing the EER values (%) on Telugu-LRL test sets. The EcoSpeak model fine-tuned on NISP-Hindi native speaker data performed the best on most test sets. NISP-Hindi is a diverse dataset, but Hindi is weakly related to Telugu.

Test Set	EcoSpeak-Hindi	EcoSpeak-Tamil	EcoSpeak-Telugu	EcoSpeak-Kannada
$tt - tt$	**6.78**	8.06	7.22	8.56
$ts - tt$	**9.89**	10.62	10.43	10.56
$ts - ts$	**11.51**	12.42	12.98	12.93
$tt - ts$	**8.90**	9.91	9.90	11.34
$ss - ss$	**6.96**	8.47	8.02	8.43
$ss - st$	**8.27**	10.63	9.11	11.30
$st - ss$	**10.10**	11.50	12.41	10.63

Table 13: Table showing the EER values (%) on Malayalam-LRL test sets. The EcoSpeak model fine-tuned on NISP-Hindi native speaker data performed the best. NISP-Hindi is a diverse dataset, but Hindi is weakly related to Malayalam.

Test Set	EcoSpeak-Hindi	EcoSpeak-Tamil	EcoSpeak-Malayalam	EcoSpeak-Telugu
$tt - tt$	**7.73**	8.20	8.73	8.79
$ts - tt$	9.94	10.81	11.94	**8.60**
$ts - ts$	12.04	13.02	14.08	**11.11**
$tt - ts$	10.58	**9.46**	11.03	10.62
$ss - ss$	6.51	**6.30**	6.98	7.51
$ss - st$	9.65	**8.33**	8.94	9.49
$st - ss$	11.58	12.98	12.78	**10.84**

Table 14: Table showing the EER values (%) on Kannada-LRL test sets. EcoSpeak-Hindi's poor performance on Kannada-LRL test sets is due to a lack of Kannada data for training s-Detect. Tamil, Telugu, and Kannada belong to the Dravidian language family and hence have similarities. Therefore, EcoSpeak-Tamil and EcoSpeak-Telugu performed better than EcoSpeak-Hindi on the Kannada-LRL test sets.

Leveraging Contextual Information for Effective Entity Salience Detection

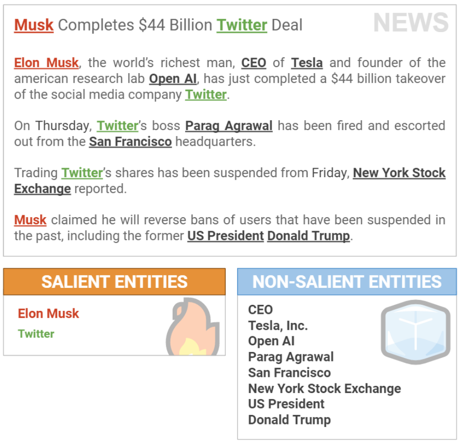
Abstract

In text documents such as news articles, the content and key events usually revolve around a subset of all the entities mentioned in a document. These entities, often deemed as salient entities, provide useful cues of the aboutness of a document to a reader. Identifying the salience of entities was found helpful in several downstream applications such as search, ranking, and entity-centric summarization, among others. Prior work on salient entity detection mainly focused on machine learning models that require heavy feature engineering. We show that fine-tuning medium-sized language models with a cross-encoder style architecture yields substantial performance gains over feature engineering approaches. To this end, we conduct a comprehensive benchmarking of four publicly available datasets using models representative of the medium-sized pre-trained language model family. Additionally, we show that zero-shot prompting of instruction-tuned language models yields inferior results, indicating the task's uniqueness and complexity.

1 Introduction

Many NLP studies have highlighted the importance of entities to understanding the semantics of a document (Wu et al., 2020b; Meij et al., 2012). Automatically identifying entities in unstructured text documents and linking them to an underlying knowledge base, such as Wikipedia, is one of the core NLP tasks, with multiple shared tasks (Tjong Kim Sang and De Meulder, 2003; Strauss et al., 2016), benchmarks (Hoffart et al., 2011; Hovy et al., 2006; Pradhan et al., 2013; Rijhwani and Preotiuc-Pietro, 2020; Derczynski et al., 2016), and studies (Kolitsas et al., 2018; Nguyen et al., 2014) dedicated to solving them.



Musk Completes $44 Billion Twitter Deal

Elon Musk, the world's richest man, CEO of Tesla and founder of the american research lab Open AI, has just completed a $44 billion takeover of the social media company Twitter.

On Thursday, Twitter's boss Parag Agrawal has been fired and escorted out from the San Francisco headquarters.

Trading Twitter's shares has been suspended from Friday, New York Stock Exchange reported.

Musk claimed he will reverse bans of users that have been suspended in the past, including the former US President Donald Trump.

Figure 1: An example of a document with salient and non-salient entities. Entity mentions are highlighted in text.

Although an entity may play a crucial semantic role in document understanding, not all entities in a text document play equal roles. Some entities are the central subjects or actors within a document, around which the content and the key events revolve. Others are mentioned only to provide additional context to the main event. For example, some entities may be actors in peripheral events, while others are deemed uninformative to the understanding of the document. Thus, *entity salience* in a text is defined as a binary or ordinal rating to quantify the extent to which a target entity is central to a given piece of text (Gamon et al., 2013; Dunietz and Gillick, 2014). Figure 1 provides an example text along with the mentioned entities and their salience. We note that the salience of an entity to a text is independent of the user's interest when reading or searching the document (Gamon et al., 2013), which is usually referred to as *entity relevance*. It is also distinct from *entity importance*, which quantifies the overall importance of the entity independent of the document. Automatically inferring entity salience was shown to aid search (Gamon et al., 2013), improve ranking results (Xiong et al., 2018), entity detection (Trani et al., 2018), and enable entity-centric applications such as entity-centric summarization (Maddela et al., 2022).

In this paper, we study the effectiveness of Transformer-based Pre-trained Language Models (PLMs) in the task of entity salience detection. Prior work on determining entity salience relied on heavy feature engineering to craft features explicitly covering relevant aspects, such as entity frequency (Dunietz and Gillick, 2014; Dojchinovski et al., 2016), position of entity mentions within a document (Dunietz and Gillick, 2014; Trani et al., 2018), relations to other entities (Trani et al., 2018), document features, such as its length (Gamon et al., 2013) and lexical features, such as the name of the entity or its context. Only a single recent work attempted to use PLMs in a pipeline which included key entity detection, albeit the scope of the evaluation was limited to a single high performing dataset (Zhao et al., 2021). In contrast, our proposed method uses a cross-encoder architecture where a target entity's name or alias and its contextual mentions in a text document are encoded by a PLM encoder. The classifier uses the contextual representation and, optionally, positional information about the entity encoded through the decile position embedding vector of mentions to determine the salience score of a target entity.

We conduct experiments on four publicly available datasets, two of which were human annotated and two that were curated semi-automatically. We fine-tune several cross-encoders using PLMs and demonstrate that these yield consistent and significant improvements over feature-based methods, as well as prompting instruction-tuned PLMs. The latter shows the novelty and complexity of the task of entity salience detection, which requires the model to learn significant task-specific semantic knowledge for this natural language understanding task.

Our contributions in this paper are the following:

- We propose a cross-encoder style architecture with explicit encoding of position information for entity salience detection that shows consistent improvements of 7 – 24.4 F1 scores over previous feature engineering approaches.
- We establish a uniform benchmark of two human annotated and two semi-automatically curated datasets for the task of entity salience detection that we expect to be beneficial to future study of this task;
- A faceted analysis of the models' predictive behaviour.

2 Related Work

Understanding the aboutness of a document is one of the long-standing goals of research in both Information Retrieval and Natural Language Processing (Gamon et al., 2013). Several types of approaches have been proposed, including extracting key-terms (Hulth, 2003; Mihalcea and Tarau, 2004), identifying latent topics (Blei et al., 2003), or generating text summaries (Erkan and Radev, 2004). There has been a recent focus in using entities to understand the content of a document. Towards this goal, the task of entity salience has been first described for web pages in (Gamon et al., 2013) and for news content in (Dunietz and Gillick, 2014). This task can be viewed as a restricted form of keyword or keyphrase extraction (Alami Merrouni et al., 2020) if salience is binary. For the rest of this study, we will use the concept of salience as described in (Gamon et al., 2013).

The salience labels for entities were obtained either by crowdsourcing labels from multiple raters to identify salient entities (Gamon et al., 2013; Dojchinovski et al., 2016; Trani et al., 2018; Maddela et al., 2022) or by using proxies. For example, (Dunietz and Gillick, 2014) hypothesize that salient entities are those that appear in the article's abstract. (Wu et al., 2020a) identifies an entity as salient if the Wikinews category that corresponds to the entity is also labeled as the category of the article.

Past studies mostly proposed machine learning methods to infer the salience of a given entity that relied on hand-crafted features. Features that can be computed from the target entity mentions and document alone can be categorized into the following: positional (e.g., position in the document, if entity is in the abstract) (Dunietz and Gillick, 2014), count-based (e.g., number of references to the entity) (Dunietz and Gillick, 2014; Wu et al., 2020a), local context (Trani et al., 2018), or global context (Ponza et al., 2019). Further, joint entity salience resolution can be performed by creating features using the entity graph (e.g., centrality in the entity graph) (Dunietz and Gillick, 2014; Trani et al., 2018). Finally, past work also showed that incorporating external knowledge about entities from knowledge bases can boost predictive performance (Dojchinovski et al., 2016).

Automatically inferring salience for entities can directly benefit multiple downstream applications, such as improving ranking results for queries containing entities (Xiong et al., 2018) or improving the performance of entity detection by joint modelling (Trani et al., 2018). Moreover, by inferring salience, new entity-centric applications can be built, such as highlighting salient entities in search (Gamon et al., 2013), improving the interpretability of news trends through salient entities (Ponza et al., 2021), or identifying entities for creating entity-centric summaries of news stories (Maddela et al., 2022; Hofmann-Coyle et al., 2022).

3 Problem Definition

We use the concept of salience as introduced in (Gamon et al., 2013): salient entities are entities explicitly mentioned in the document that are objectively important as a function of the structure of the text.

The goal of the salience model is to produce a single salience score $\psi(e)$ for the entity e using only the document D and the explicit entity mentions $\mathcal{M}_e$. We consider using external knowledge, such as information about entities from knowledge bases, to be outside the scope and leave integration of such knowledge for future work.

4 Methods

Pre-trained Language Models (PLMs) have shown a remarkable ability to encode syntactic and semantic knowledge in their parameters (Tenney et al., 2018, 2019) that can be leveraged when fine-tuned on downstream natural language understanding (NLU) tasks. We postulate that PLMs can be harnessed to help in entity salience detection, a target-based document-level NLU task. In this section, we present an architecture based on the cross-encoder setup adapted to the task of entity salience detection.

4.1 Cross-encoder

Encoding Given a document D and a target entity e, which is mentioned in the document, we concatenate the target entity's name and the document using a special `[SEP]` token. We then encode the text using a Transformer-based pre-trained encoder. Figure 2 shows the graphical representation of the cross-encoder model. This setup allows the model to have deep cross attention between the target entity and the entire document. Note that we use special marker tokens `[BEGIN_ENTITY]` and `[END_ENTITY]` around each mentions $m \in \mathcal{M}_e$ of entity e in document D.

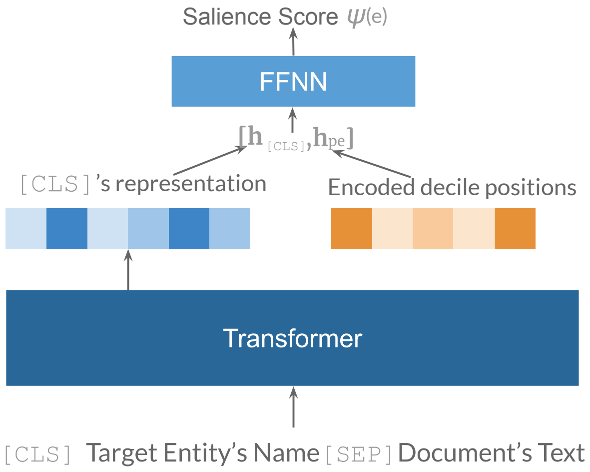

Figure 2: Graphical representation of the cross-encoder architecture with decile position encoding.

Position Encoding We compute the decile positions for each entity mention ($m \in \mathcal{M}_e$) in the document D by taking a positional index $p_m \in \{0, 1, \ldots, 9\}$, indicating which part of document the mention belongs to if the document is partitioned into 10 equal chunks. Depending on the number and positions of the mentions, the vector can contain multiple non-zero values in the p vector. For example, if an entity e has 1 mention in the first decile, 2 in the second decile, and 1 mention in the fifth decile, then the input to the positional encoder would be $p_m = [1, 1, 0, 0, 1, 0, 0, 0, 0, 0]$. Note that we do not capture the number of mentions in each decile in p_m. To obtain positional embeddings, we use an embedding layer that maps positional indices to a dense vector of dimension d_{model}, formally $\mathbf{h}_{pe}(m) = \texttt{Embedding}(p_m)$.

Scoring The output representation of the `[CLS]` token is concatenated with the mean position embedding vector $\mathbf{h}_{pe}$ and fed to a scorer module that produces a salience score $\psi(e) \in [0, 1]$ for entity e. The salience scorer is a feed-forward network with a sigmoid scoring function head. Formally,

$$\psi(e) = \sigma(\texttt{FFN}(\mathbf{h}_{\texttt{[CLS]}} || \mathbf{h}_{pe}))$$

4.2 Optimization

We fine-tune the model described above by minimizing the binary cross entropy loss that is calculated using the ground truth binary salience labels and the predicted salience score $\psi(e)$.

5 Datasets

In this section, we describe our entity salience benchmark, which consists of four datasets: two

Dataset	NYT-Salience	WN-Salience	SEL	EntSUM
# Docs	110,463	6,956	365	693
Doc Length (avg chars)	5,079	2,106	1,660	4,995
# Unique entities	179,341	23,205	6,779	7,854
# Mentions	4,405,066	145,081	19,729	20,784
% Salient entities	14%	27%	10%	39%
Ground-truth	Abstract Alignment	Category Alignment	Human	Human

Table 1: Summary statistics and label collection methods for the datasets used in our experiments.

datasets were curated using semi-automated methods and two used human annotations. We provide summary statistics of these datasets and label collection methods in Table 1.

NYT-Salience This dataset is introduced in (Dunietz and Gillick, 2014) and is the largest dataset to date for entity salience detection. The dataset is curated with an assumption that salient entities are mentioned in the abstract of a news article in the NYT Corpus (Sandhaus, 2008). Entities and their mentions are identified using a classical NLP pipeline involving POS tagging, dependency parsing, and noun phrase extraction. Despite being large-scale, the automatic dataset creation process could introduce noise as corroborated by moderate agreement numbers with human annotators on a subset of the data. The dataset contains a binary salience label for each entity.

WN-Salience Introduced in (Wu et al., 2020a), this is another automatically curated dataset consisting of Wikinews articles. These are annotated with Wikinews categories by their authors. WN-Salience identifies salient entities by using the hypothesis that an entity is salient if the Wikinews category that corresponds to the entity is also labeled as a category of the article. Similar to NYT-Salience, this dataset has binary salience labels.

SEL This is another dataset based on Wikinews released by (Trani et al., 2018). However, unlike WN-Salience, this dataset is human annotated, where multiple human annotators ranked the salience of entities into one of four categories. To conform with the binary labels of the other datasets, we map the 4 categories into binary labels of $\{0, 1\}$ by mapping the bottom two classes to not salient and the top two classes to salient.

EntSUM This dataset was introduced in (Maddela et al., 2022). To construct this dataset, a randomly selected set of entities spanning a subset of 693 articles from the NYT corpus were assigned salience labels by human annotators on a four-point scale, ranging between $[0, 3]$. For each document entity pair, two independent annotations were collected, which were increased up to 5 in case of disagreements. If the average annotation score is greater than 1.5 for an entity, it is assigned a positive salience label.

5.1 Data Enrichment with Inferred Mentions

Except for EntSUM, the datasets do not have explicit entity mention offsets as annotations, which are necessary for many feature-based approaches and to compute positional embeddings. While SEL contains only the mention surface texts per entity, NYT-Salience and WN-Salience only provide the start and end character indices (aka mention offsets) of the very first mention of an entity. To this end, we infer additional mentions of an entity within the text using a combination of Flair NER (Akbik et al., 2019) and pattern matching.

For SEL, since the mentions are available, we use a pattern matching approach to match the surface text of the mentions to infer mention offsets. For NYT-Salience and WN-Salience, we first use Flair NER to identify mentions of named entities in the text. We attempt to match these mentions to the first mention of each entity in the document provided in the respective datasets. Since the surface text of other mentions may differ from the first mention, we additionally use the overlap between a mention's surface text and the entity name as a candidate mention for that entity. Applying this approach, we infer additional mentions of an entity in the text and their offsets. While this process could introduce some noise, the overall quality of the datasets are enhanced through this process.

6 Experiments

We experiment on our entity salience benchmark with our proposed PLM-based method, other ML and heuristic-based approaches used in past research, as well as an instruction-tuned PLM.

6.1 Data Splits

Prior works (Dunietz and Gillick, 2014; Trani et al., 2018; Wu et al., 2020a) use inconsistent (or not reported) train/validation/test splits. NYT-Salience and WN-Salience datasets are provided with train/test splits (but no validation), whereas SEL dataset is provided without any splits. This makes it hard to benchmark previous works with a fair comparison across models. To overcome this issue, we do a temporal split of NYT-Salience's and WN-Salience's original training sets into a new train/validation sets based on the publication time of the news stories, which provides a more realistic testing setup (Huang and Paul, 2018; Rijhwani and Preotiuc-Pietro, 2020). We also perform a temporal split of SEL and EntSUM datasets into train/validation/test sets. Further details about the dataset splits are provided in Appendix A.

6.2 Baselines

First, we list all methods used in past research, for which we report the results from the original papers.

- *First Sentence*. Classifies an entity as salient if it appears in the first sentence of the document's body; used in both (Dunietz and Gillick, 2014) and (Wu et al., 2020a).
- *Position & Frequency (Dunietz and Gillick, 2014)*. Feeds the first sentence index and the frequency features of an entity into a logistic regression model.
- *All Features (Dunietz and Gillick, 2014)*. Uses a series of features based on position, frequency, and PageRank signals fed into a logistic regression model.
- *SEL (Trani et al., 2018)*. Uses a combination of features based on position, frequency, and Wikipedia graph statistics fed into a Gradient Boosted Decision Tree algorithm implemented in sklearn (Pedregosa et al., 2011).
- *SWAT (Ponza et al., 2019)*. Uses a set of features similar to the SEL Method described above, with the addition of features based on entity embeddings. All features are fed into a Gradient Boosted Decision Tree algorithm implemented in XGBoost (Chen et al., 2015).
- *Positional Feature (Wu et al., 2020a)*. Uses the index of the first sentence in which the entity is mentioned as a feature in a logistic regression model. This method provides best results on the WN Salience dataset in (Wu et al., 2020a).

Next, we re-implement a set of common methods based on the above baselines in order to be able to test them on all four datasets. This ensures the evaluation is performed on the same experimental setup.

- *Positional Headline*. Classifies an entity as salient whether it appears in the headline of the input document.
- *Positional Headline & Lead*. Classifies an entity as salient if it appears in the headline of the document or in the first sentence (lead sentence) of the document.
- *Entity Frequency*. Classifies an entity as salient if they are more frequent than a given value. For each dataset, we calculated different thresholds and reported the best results. Thresholds can be found in the Appendix.
- *Features & GBDT*. This method uses the most common features from past works (Dunietz and Gillick, 2014; Wu et al., 2020a; Trani et al., 2018; Ponza et al., 2019) — i.e., entity's first sentence index, and entity frequency — and feeds them into a GBDT model implemented using LightGBM (Ke et al., 2017).
- *SEL GBDT*. Follows the method from (Trani et al., 2018) and uses sklearn's GBDT (Pedregosa et al., 2011) to train a model on the features provided with the SEL dataset.
- *Target entity masking*. This method feeds the input to a Transformer-based encoder (RoBERTa-base) with the target entity mentions represented through a special mask token. The salience prediction is obtained by mean pooling the mask token representations and passing this through a feed-forward network.
- *Zero-shot prompting*. We test instruction-tuned LLMs using zero-shot prompting. The prompt introduces the task description, followed by the input text and a target entity, and it asks a yes/no question. It expects the model to generate either 'Yes' or 'No' as an answer. The LLMs, already instruction-tuned on a large collection of NLU tasks, attempt to provide an answer based on the prompt, input text, and target entity. This family of models has been demonstrated to be robust and versatile on multiple benchmarks (Chung et al., 2022). We use `Flan-UL2 (20B)` (Tay et al., 2023) and `LLaMa 2-Chat (7B)` (Touvron et al., 2023) for evaluation.

6.3 Experimental Setup

We use RoBERTa-base (Liu et al., 2019) and DeBERTa-v3-base (He et al., 2023) as the base PLM for experiments. For each of these base models, we train both a cross-encoder model and a cross-encoder model augmented with decile positional embeddings.

For training our proposed models, we use AdamW (Loshchilov and Hutter, 2019) as the optimizer. We perform a hyperparameter search for learning rate using the following set of values: $\{0.001, 0.0005, 0.0002, 0.0001, 0.00005\}$. We train our models for a maximum of 10 epochs with early stopping based on the validation set performance. We pick the best performing model checkpoints for each dataset based on the performance on the validation set. In Tables 2 and 3, we report the performance of our models and the baselines using the standard classification metrics (i.e., Precision, Recall, and F1) on the positive (salient) class, following previous research on entity salience.

For training and inference of each Transformer-based model, we use a single NVIDIA V100 GPU with 32GB GPU memory, 4 CPUs, and 128 GB of main memory.

6.4 Results

In Tables 2 and 3, we present the experimental results of the baselines and our proposed models on the four datasets described in Section 5.

Comparison with feature-based methods. We observe that the cross-encoder model significantly outperforms all baseline models in F1 score. It also yields better precision compared to the baselines for three of the four datasets. Only for the SEL dataset does the SEL GBDT model trained on publicly available pre-computed features produce a model with better precision than the cross-encoder. We observe that adding the decile positional embedding with cross-encoder improves the precision across all datasets, but also degrades the recall in every dataset except NYT-Salience.

The Target Entity Masking approach, which also leverages contextual information with a transformer-based model yields mixed results. Overall, the model is able to obtain better precision than the feature-based models for all datasets except SEL, but the model suffers from poor recall across all datasets, resulting in significantly worse F1 scores especially when compared to cross-encoder models.

Our re-implementation of positional methods and GBDT methods are consistent with the performance reported in prior works. The variance in numbers can be attributed to the enrichment of datasets with inferred mentions (Section 5.1) and the explicit train/dev/test data split used in our experiments (Section 6.1).

6.5 Zero-shot prompting of large language models

We formulate the problem of salience detection with zero-shot prompting as follows: given a definition of entity salience task and document text, we ask the model to generate a "yes" or a "no" if a particular entity is salient or not. We experimented with two open source models (`Flan-UL2 (20B)` and `LLaMa 2-Chat (7B)`) available on Hugging Face [1], and present the results in Table 4. To the best of our knowledge, this is the first evaluation of zero-shot prompting of instruction-tuned models for the entity salience detection task. We observe that the `LLaMa 2-Chat` model with 7 billion parameters fails to yield any meaningful results as it produces only positive labels for all data points (hence we observe 100% recall). The `Flan-UL2` model is able to generate both positive and negative labels. However, the precision remains too low across datasets. We further discuss causes for this performance in the Appendix (Section C), along with the implementation details. Overall, these experiments suggest that entity salience detection is a unique task that is not similar to any other tasks these two models are instruction tuned on.

7 Analysis

In this section, we perform an analysis of model predictions in order to gain more insights into model behavior and understand potential avenues for further improvement. We thus break down performance by different factors including: the importance of inferring all entity mentions, the position of the first entity mention, and entity mention frequency.

7.1 Impact of Inferred Mentions

In Section 5.1, we inferred additional mentions of an entity for the NYT-Salience and WN-Salience datasets. We compare the performance of our best model that leverages multiple mentions of an entity to its version trained with only the first mentions of entities in a document. The specific input formats for this experiment are presented in Appendix B The results in Table 5 show that doing so consistently improves the performance of our models across all datasets. In particular, for the largest dataset, NYT-Salience, our model achieves a substantial gain of 27.3 F1 points. This experiment showcases the importance of augmenting our datasets with additional mentions and the importance of explicitly modelling contextual information present around all entity mentions.

7.2 Stratified Analysis on First Mention Position

We compare our cross-encoder models against the Features & GBDT model, our re-implemented baseline that relies on the most popular features used in prior works (Dunietz and Gillick, 2014; Wu et al., 2020a; Trani et al., 2018). As shown in the results from Tables 2 and 3, among other features, positional features are most informative for salience. Intuitively, if an entity is mentioned in the headline or in the first sentence of a news article, there is high probability of that entity being salient.

Figure 3 shows that all models perform well when the first mention falls in the headline or the first sentence of the document. We notice that the cross-encoder models constantly outperform the Features & GBDT model and the largest gains are observed in the SEL and WN-Salience datasets. This observation indicates that the cross-encoder models are

Model	NYT-Salience			WN-Salience			SEL			EntSUM		
	P	**R**	**F1**	**P**	**R**	**F1**	**P**	**R**	**F1**	**P**	**R**	**F1**
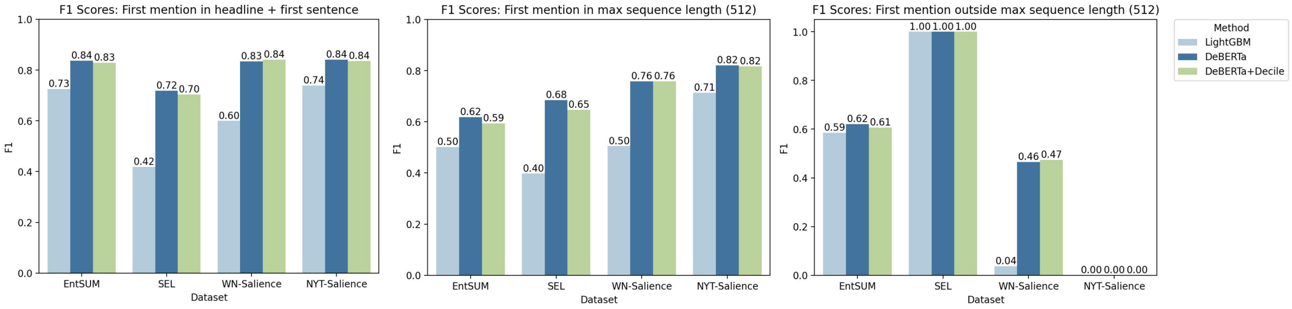
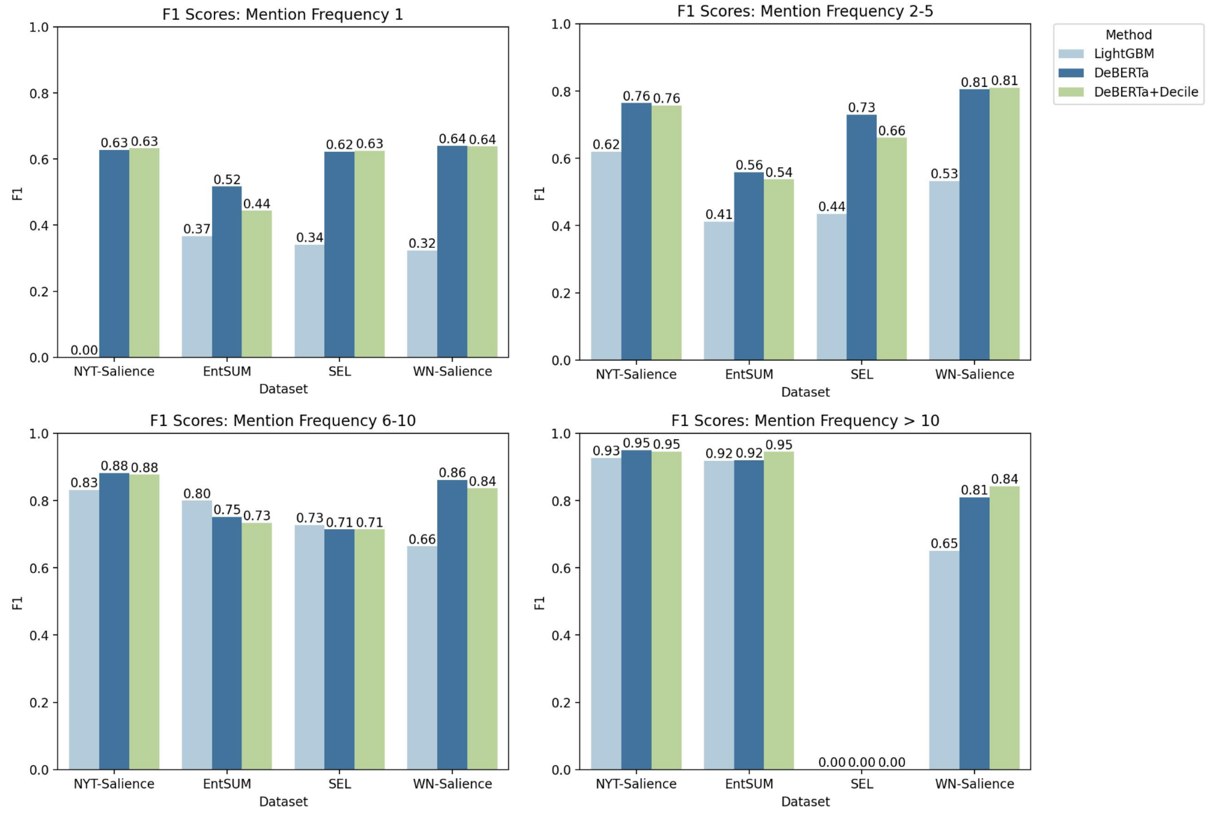
Cross-encoder w/ first mention	54.2	57.5	55.8	69.6	80.4	74.6	59.8	76.1	67.0	69.1	53.2	60.2
Cross-encoder w/ all mentions	77.5	87.4	82.1	71.5	78.3	74.8	64.1	73.6	68.5	64.9	59.2	61.9

Table 5: Performance comparison of cross-encoder models with only the first mention vs. all inferred mentions.



(a) Performance with respect to the position of the mentions. There are no mentions outside of the context window for NYT.



(b) Performance with respect to the frequency of the entities. The test split of SEL dataset does not contain any entity with more than 10 mentions in a document.

Figure 3: Stratified analysis across models and datasets.

able to use the context to identify that mentions that occur in the headline or the first parts of the document are often salient without explicitly using this information as a feature.

We also investigate the performance of the models when the first mention falls inside or outside the context window of the PLM (here, 512 tokens). When mentions fall inside the context window, we observe that the cross-encoder models consistently outperform the Features & GBDT model. When the mention falls outside the context window, the model predictions become close to random, which is expected, as the model does not have immediate contextual information around the mention. Using models that can deal with longer inputs would be a promising direction for improvement for these samples (Beltagy et al., 2020). Interestingly, for WN-Salience, the Features & GBDT model also performs considerably worse outside the first 512 tokens.

7.3 Stratified Analysis on Mention Frequency

Similar to mention position analysis, we compare our cross-encoder models against the Features & GBDT model, which uses mention frequency as one of its input features. Figure 3 shows how the cross-encoder models and Features & GBDT compare with varying frequency of entity mentions.

For salient entities with single mentions, the cross-encoder model performs significantly better than the Features & GBDT model. In particular, for the NYT-Salience dataset, the Features & GBDT model fails to predict any of the single mention entities as salient. This observation indicates that the cross-encoder models do not simply model the mention frequency, but potentially leverage other contextual information to determine the salience of entities with a single mention.

The performance of the Features & GBDT model improves with more mentions per entity. In fact, for the frequency range of 6-10 mentions per entity, the Features & GBDT model performs better than the cross-encoder models for EntSUM and SEL datasets. This observation indicates the overreliance of the Features & GBDT model on mention frequency to determine salience, but also that the cross-encoder cannot fully use this heuristic.

8 Conclusion

This paper aims to leverage the semantic knowledge encoded in pre-trained language models for entity salience detection. We propose the cross-encoder method based on Transformer-based PLMs with positional representations and compare its performance to several ML-based methods, heuristic methods, and instruction-tuned LLMs across four different datasets, two human-annotated and two automatically curated. Across all our experiments, the cross-encoder model based on pre-trained language models outperforms all other methods, often with double digit gains in F-1 score. Analyses of model behavior illustrate the important effects of mention frequency, mention position, and document length on performance, highlighting areas of future work.

9 Limitations

We only studied salience in English-language documents, but our methods are applicable to other languages directly as long as a pre-trained language model covering the target language is available.

We use entity mentions as annotated in our data or inferred through entity recognition and entity resolution for inference in some of the methods. This information may not be available at inference time in all applications.

The experiments with LLMs are limited to zero-shot prompts. We did not experiment with instruction tuning which could potentially help the model learn the salience detection task.

Finally, we do not use external knowledge about entities and their relationships in modelling, which was shown to marginally improve results in past studies (Dunietz and Gillick, 2014; Trani et al., 2018; Ponza et al., 2019). We consider this out of the scope of our analysis and a viable direction of future work.

10 Ethics Statement

We use publicly available datasets intended for the task of entity salience detection. The datasets and pre-trained models we used have permissive licenses allowing for research use. We do not envision any potential risks associated with the task discussed in this paper.

Appendix

A Details of Dataset Splits

Table 6 contains the train, dev, and test splits of each of the datasets after applying a temporal splitting strategy described in Section 6.1. These splits are used for model training and evaluation.

B Input Format for Experiments

As described in Section 4.1, we add special marker tokens around each mention of the target entity (i.e., the entity for which the model needs to predict the salience label.). In the following, we provide an example:

Text

Musk completes $44 billion Twitter deal. Elon Musk, the world's . . .

Model Input

[CLS] Elon Musk [SEP] [BEGIN_ENTITY] Musk [END_ENTITY] completes $44 billion Twitter deal. [BEGIN_ENTITY] Elon Musk [END_ENTITY], the world's . . .

For the experiment with first mention reported in Section 7.1, only the first mention is bounded by special marker tokens as shown in the following example:

Model Input

[CLS] Elon Musk [SEP] [BEGIN_ENTITY] Musk [END_ENTITY] completes $44 billion Twitter deal. Elon Musk, the world's . . .

Note that the second mention of `Elon Musk` is not bounded by marker tokens.

C Implementation details of zero-shot prompting of LLMs

Figure 4 and Figure 5 show the prompts we used for the `LLaMa 2-Chat (7B)` and `Flan-UL2 (20B)` models respectively. Table 7 lists the generation parameters. We speculate the following causes for the relatively lower precision obtained using this method:

- The instruction defines the salience task definition, but doesn't provide any reference examples (few-shot prompting) to align with the definition of salience. This leads to the model identifying an entity as salient based on its frequency in the document. However, creating a few-shot prompt is challenging as we need to limit the maximum input length of the prompt to prevent out-of-memory issues.
- We truncate the document text so that the entire prompt is 2048 tokens or less, thus throwing away any potential information present towards the end of a long document.

<s> [INST]
«SYS» The salience of an entity provides information about the importance or centrality of that entity to the entire document text. In the following, given an Entity and a Text, you need to answer 'Yes' if the Text document is about that Entity and 'No' if the Text is not about that Entity. «/SYS»
Is Entity: `entity` salient in Text: `text` [/INST]

Figure 4: Instruction for zero-shot prompting of LLaMa 2-Chat model.

Instruction
The salience of an entity provides infor- mation about the importance or centrality of that entity to the entire document text. In the following, given an Entity and a Text, you need to answer 'Yes' if the Text document is about that Entity and 'No' if the Text is not about that Entity.
Text: `text`
Entity: `entity`
Question: Is the above Entity salient in the above Text? Please answer Yes or No.
Answer:

Figure 5: Instruction for zero-shot prompting of Flan-UL2 model.

D Thresholds for Entity Frequency baseline

Figure 6 shows the performance of the Entity Frequency baseline by varying the minimum number of times an entity has to occur in the input document to be classified as salient.

Dataset	**# Doc-Entity pairs**	**Train**	**Validation**	**Test**
NYT-Salience	1,910,214	1,342,092	405,335	162,787
WN-Salience	62,537	41,625	11,902	9,009

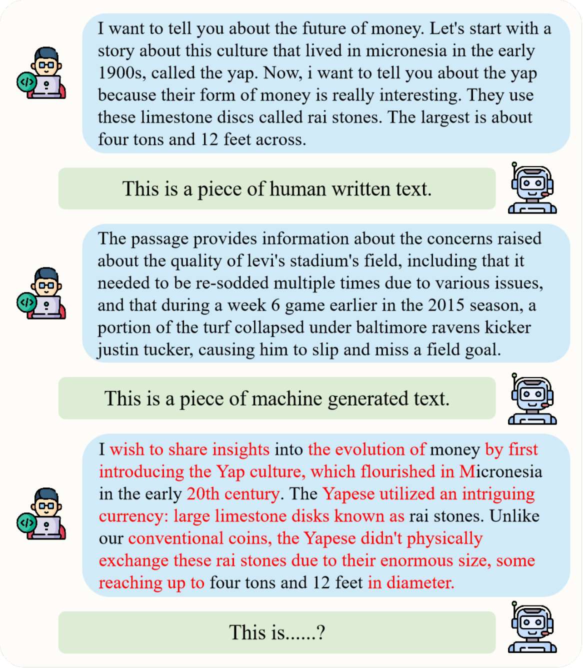
Abstract

With the rapid development and widespread application of Large Language Models (LLMs), the use of Machine-Generated Text (MGT) has become increasingly common, bringing with it potential risks, especially in terms of quality and integrity in fields like news, education, and science. Current research mainly focuses on purely MGT detection without adequately addressing mixed scenarios, including AI-revised Human-Written Text (HWT) or human-revised MGT. To tackle this challenge, we define *mixtext*, a form of mixed text involving both AI and human-generated content. Then, we introduce MIXSET, the first dataset dedicated to studying these mixtext scenarios. Leveraging MIXSET, we executed comprehensive experiments to assess the efficacy of prevalent MGT detectors in handling *mixtext* situations, evaluating their performance in terms of effectiveness, robustness, and generalization. Our findings reveal that existing detectors struggle to identify *mixtext*, particularly in dealing with subtle modifications and style adaptability. This research underscores the urgent need for more fine-grain detectors tailored for *mixtext*, offering valuable insights for future research. Code and Models are available at `https://github.com/Dongping-Chen/MixSet`.

1 Introduction

The remarkable advancement of Large Language Models (LLM) has sparked global discussions on the effective utilization of AI assistants (OpenAI, 2022, 2023b). Given that LLMs can correctly follow human instructions and produce useful texts efficiently, more and more people prefer to integrate these powerful tools into their workflow by revising Machine Generated Text (MGT) or using LLMs to polish their Human Written Text (HWT), such as fact-checking revising in journalism (Guerra, 2023) and enhancing storytelling in the game industry [1].



I want to tell you about the future of money. Let's start with a story about this culture that lived in micronesia in the early 1900s, called the yap. Now, i want to tell you about the yap because their form of money is really interesting. They use these limestone discs called rai stones. The largest is about four tons and 12 feet across.

This is a piece of human written text.

The passage provides information about the concerns raised about the quality of levi's stadium's field, including that it needed to be re-sodded multiple times due to various issues, and that during a week 6 game earlier in the 2015 season, a portion of the turf collapsed under baltimore ravens kicker justin tucker, causing him to slip and miss a field goal.

This is a piece of machine generated text.

I wish to share insights into the evolution of money by first introducing the Yap culture, which flourished in Micronesia in the early 20th century. The Yapese utilized an intriguing currency: large limestone disks known as rai stones. Unlike our conventional coins, the Yapese didn't physically exchange these rai stones due to their enormous size, some reaching up to four tons and 12 feet in diameter.

This is......?

Figure 1: Three kinds of text: Machine Generative Text (MGT), Human Written Text (HWT), and mixtext. The text come from users 🧑‍💻 is classified by detectors 🤖. The text in red is the HWT polished by LLMs.

Despite its various usages, The application of LLMs also causes the potential risk of MGT usage, raising public concerns on various misuse, as seen in the undermining of journalistic integrity and quality (Christian, 2023), reproducing and amplifying biases (Sison et al., 2023), plagiarism among students (Heavenarchive, 2023), and leading disruptions in trust towards scientific knowledge (Else, 2023). The misuse of machine-generated text has been a serious concern that is also raised by experts in different fields of work [2].

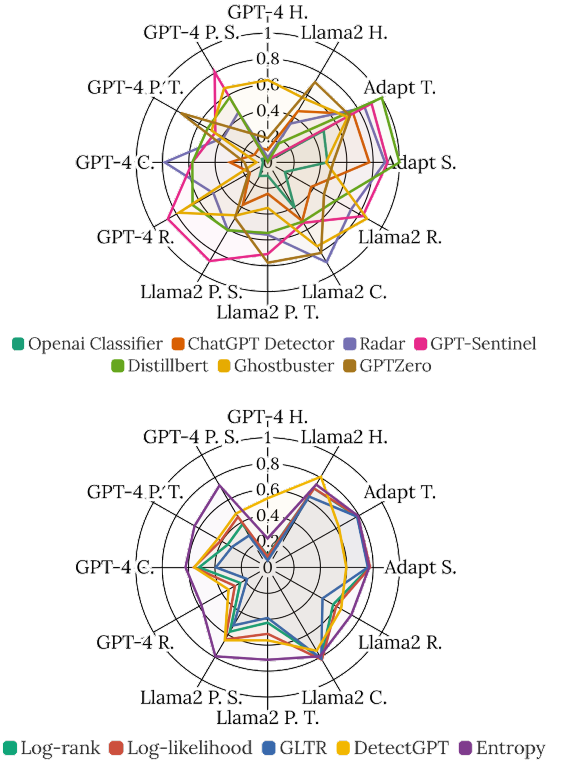

Figure 2: Accuracy of different dectors on MIXSET. (Above) Model-based methods; (Below) Metric-based methods. P.T. and P.S. signify token and sentence-level polish, respectively; C. for complete, R. for rewrite; Adapt T. and Adapt S. for token and sentence-level adapt. See 3 for details on revising operations.

Previous studies proposed many methods to detect MGT, including metric-based and model-based methods, where they have only tried to enhance the detection ability on binary classification, i.e., pure MGT or HWT. However, they did not pay much attention to revised texts (i.e., *mixtext*), but considered these cases as an attack on the detection system (Krishna et al., 2023) or complex cases for detection (Mitchell et al., 2023; Guo and Yu, 2023). However, the mixture of MGT and HWT is an essential scenario in our daily lives when using LLM assistants. For instance, thousands of non-native English speakers utilize LLMs to polish their drafts to avoid grammar problems. Moreover, LLMs can follow human instructions to produce new stories and interactive dialogue in game design [3]. Authors can also use LLMs to complete stories, providing them with new ideas and inspiration with LLM assistants like *Metaphoria* (Gero and Chilton, 2019) and *Sparks*, thereby generating metaphorical and science writing suggestions and supporting creative writing tasks (Gero et al., 2022).

Hence, there is a pressing demand to comprehensively analyze mixture cases and give a formal definition of them. Given that *mixtext* is a very common case in daily life and its amount continuously increases in NLP areas, it holds significant importance, especially in education. To end this, we propose a new dataset MIXSET, which is the first dataset that aims at the mixture of HWT and MGT, including both AI-revised HWT and human-revised MGT scenarios as illustrated in Figure 1, which addresses gaps in previous research. Further details of the dataset and definitions can be seen in Section 3. We also examine our dataset on mainstream detectors in binary and three-class settings to further analyze and raise concerns about these common but hard-to-detect cases.

To summarize, our work provides three main contributions:

- We defined *mixtext*, a form of mixed text involving both AI and human-generated content, providing a new perspective for further exploration in related fields.
- We proposed a new dataset MIXSET, which specifically addresses the mixture of MGT and HWT, encompassing a diverse range of operations within real-world scenarios, addressing gaps in previous research.
- Based on MIXSET, we conducted extensive experiments involving mainstream detectors and obtained numerous insightful findings, which provide a strong impetus for future research.

2 Related works

2.1 Machine Generated Text Detection

Current MGT detection methods can be broadly categorized into metric-based and model-based methods according to the previous study (He et al., 2023). Please refer to Appendix A for comprehensive related works.

Metric-based Methods. Building upon the observation that MGTs occupy regions with sharp negative log probability curvature, Mitchell et al. (2023) introduced a zero-shot whitebox detection method called DetectGPT, setting a trend in metric-based detection (Su et al., 2023; Mireshghallah et al., 2023; Bao et al., 2023). Recently, Yang et al. (2023a) also introduced a powerful detection method known as DNA-GPT, which leverages N-gram (Shannon, 1948) in a black-box setting.

---

[3] https://aicontentfy.com/en/blog/chatgpt-in-gaming-industry-enhancing-storytelling-and-interaction

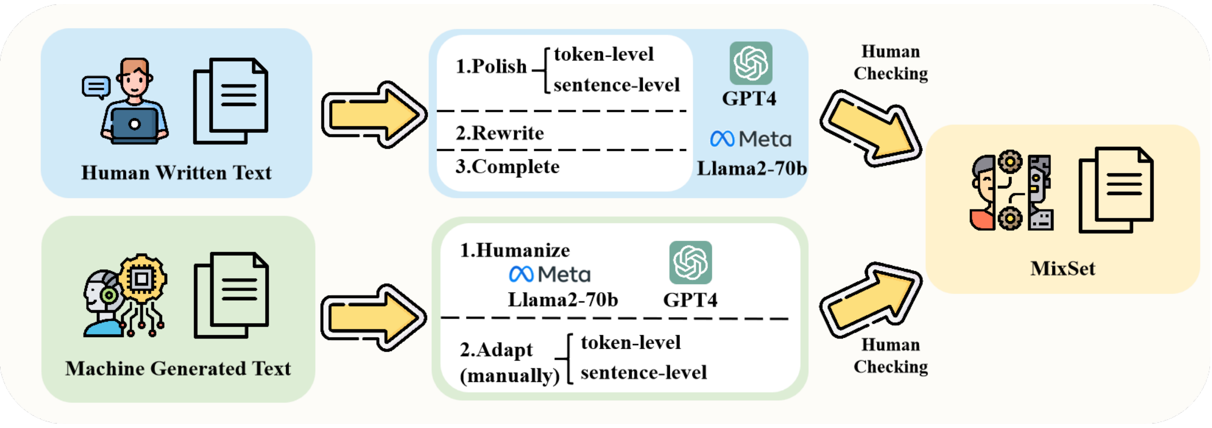

Figure 3: The process of MixSet generation. We perform distinct operations in HWT and MGT. In HWT, three operations—polish, rewrite, and complete—are employed. In MGT, we utilize LLama2 and GPT-4 to aid in humanization and conduct the adaptation operation manually.

Model-based Methods. In the era of Large Language Models (LLMs), Guo et al. (2023) developed the ChatGPT Detector based on a fine-tuned Roberta model. As for decoder-based detectors, GPT-sentinel (Chen et al., 2023) leverage the t5-small model (Muennighoff et al., 2022) and show convincing results when detecting MGT even in revised cases.

2.2 Previous study to mix of HWT and MGT

Prior studies have viewed the mixture of HWT and MGT in different settings. DNA-GPT (Yang et al., 2023a) and DetectGPT (Mitchell et al., 2023) notably utilized the T5 model (Raffel et al., 2020) to simulate scenarios where humans make limited, random modifications to MGT, creating complex test cases. Conversely, DIPPER (Krishna et al., 2023) and OUTFOX (Koike et al., 2023b) opted for a paraphrasing technique, using this method to craft adversarial attacks aimed at eluding the detection mechanisms of classifiers, thereby presenting a nuanced way to alter MGT while maintaining undetectability.

2.3 Datasets for MGT Detection

Previous studies have proposed many datasets of MGT, accompanied by their newly proposed detectors (Verma et al., 2023; Chen et al., 2023). Guo et al. (2023) leverages multiple previous Question-Answer (QA) datasets (Jin et al., 2019; Lin et al., 2021), allowing ChatGPT to generate corresponding answers without explicit prompts. This results in creating a comprehensive dataset comprising a large set of pairs of MGT and HWT. Following the QA pattern, many researchers (Mitchell et al., 2023; Su et al., 2023; Hu et al., 2023; He et al., 2023) propose datasets with the MGT from variant mainstream LLMs (OpenAI, 2022, 2023b).

However, these datasets typically consist of two distinct classes of texts, namely pure MGT or HWT, without accounting for the potential mixture cases. Furthermore, issues arise due to variations in prompts (Koike et al., 2023a), sampling methods, and the inherent differences in length, style, and quality among texts (He et al., 2023), posing variations challenges on the generalization ability of proposed detectors (Xu et al., 2023). In some instances, MGT included in datasets may not be thoroughly checked, with many noisy sentences not filtered well. For example, some sentences like *Let me know if you have any other questions* exist in the dataset, which will impact the effectiveness of the detectors (Guo et al., 2023).

3 MixSet Dataset

In this section, we present MixSet (**Mix**case Data**set**), the first dataset featuring a blend of HWT and MGT. Distinguished from earlier datasets exclusively composed of pure HWT and MGT, MixSet comprises a total of 3.6k mixtext instances, and the pipeline of its construction is shown in Figure 3. These operations are grounded in real-world application scenarios, each altered by a single LLM or through manual intervention, contributing 300 instances in our MixSet.

For our base data, we meticulously select pure HWT and MGT datasets. In the case of HWT, we gather datasets proposed before the widespread use of LLMs to mitigate potential contamination by MGT, as detailed in Table 1. For MGT, we choose samples from previous datasets (Rajpurkar et al., 2016a; Lin et al., 2022; Nishida et al., 2019), generated in a QA pattern by different LLMs, including the GPT family (OpenAI, 2022, 2023b), ChatGLM (Du et al., 2022), BloomZ (Muennighoff et al., 2022), Dolly [4], and StableLM (StabilityAI, 2023), all distinct from our MIXSET instances.

Table 1: The original resources of Human Written Texts in constructing our MIXSET.

Text Type	Original Resources
Email Content	Enron Email Dataset (CMU, 2015)
News Content	BBC News (Greene, 2006)
Game Review	Steam Reviews (Najzeko, 2021)
Paper Abstract	ArXiv-10 (Farhangi et al., 2022)
Speech Content	TED Talk (TheDataBeast, 2021)
Blog content	Blog (Schler et al., 2006)

3.1 Definition of Mixtext

Generally, *mixtext* is the mixed text involving both AI and human-generated content. To formulate it, we define a text sequence as $x \in X$, where X represents the set of all text sequences. The sequences in X can originate from either human-written text $\mathbb{X}_{\text{human}}$ or machine-generated text $\mathbb{X}_{\text{machine}}$. We denote the set of operations used to revise texts as $\mathbb{OP} = \{OP_1, OP_2, \ldots, OP_n\}$, categorized into two groups: $OP_{\text{human}}, OP_{\text{machine}}$. Here, OP_{human} refers to operations involving human revision on machine-generated text (MGT), while OP_{machine} refers to AI-driven operations on human-written text (HWT). In addition to $\mathbb{X}_{\text{human}}$ and $\mathbb{X}_{\text{machine}}$, we define $\mathbb{X}_{\text{mixtext}}$ as the union of all texts derived from $\mathbb{X}_{\text{human}}$ through OP_{machine} and all texts derived from $\mathbb{X}_{\text{machine}}$ through OP_{human}:

$$\begin{aligned}\mathbb{X}_{\text{mixtext}} = &\{OP_{\text{machine}}(x) \mid x \in \mathbb{X}_{\text{human}}\} \\ &\cup \{OP_{\text{human}}(x) \mid x \in \mathbb{X}_{\text{machine}}\}\end{aligned}$$

3.2 Dataset Construction

Combined with previous studies (Goyal et al., 2023; Wang et al., 2021) and real scenarios, we use five operations to generate mixtexts. They are divided into two operations shown in Table 2: 1) AI-revised: it contains three operations including 'polish', 'complete', and 'rewrite'. 2) Human-revised: it includes 'adapt' and 'humanize'.

Table 2: Different operations with their operation levels. ✔ demonstrate that MIXSET contains a subset operates at that level.

Operation	Token	Sentence	Paragraph
AI-Polish	✔	✔	✘
AI-Complete	✘	✘	✔
AI-Rewrite	✘	✘	✔
Human-Adapt	✔	✔	✘
Humanize	✔	✔	✔

- **Polish** (Chen, 2023): Polish operation contains token-level and sentence-level polishing. Token-level makes alterations at the individual word level, including changes such as adjusting words for precision or correcting spelling errors. On the other hand, sentence-level aims to enhance the overall coherence and clarity of the text by revising and restructuring the complete sentence.
- **Complete** (Zhuohan Xie, 2023): Complete operation involves taking 1/3 of every text and employing LLMs to generate the rest of the text.
- **Rewrite** (Shu et al., 2023): Rewrite operation requires LLMs to initially comprehend and extract key information from the given HWT and then rewrite them.
- **Humanize** (Bhudghar, 2023): Humanize operation typically refers to the modification of MGT to more closely mimic the natural noise for LLM (Wang et al., 2021) that human writing always brings. We employed LLMs to introduce various perturbations to the pure MGT, including *typo, grammatical mistakes, links*, and *tags*.
- **Adapt** (Gero et al., 2022): Adapt operation refers to modifying MGT to ensure its alignment to fluency and naturalness to human linguistic habits without introducing any error expression. The adapt operation is also divided into token-level and sentence-level adaptation. We accordingly performed manual annotations on the pure MGT dataset at both the token and sentence levels.

The detailed distribution of each category in MIXSET is shown in Table 3. All data generated from GPT-4 (300 items) and Llama2 (300 items) have undergone rigorous manual review and modification in the 'humanize' operation. For AI-revised *mixtext* generation, Llama2-70b and GPT-4 were used, both set to default parameters, including a temperature of 1. These models are chosen for their ability to produce high-quality, grammatically correct texts (Hugging Face, 2023). In human-revised

---

[4] https://www.databricks.com/blog/2023/04/12/dolly-first-open-commercially-viable-instruction-tuned-llm

operation, we leverage two LLMs to assist with 'humanize' operation. For the adapt operation, we invite eight human experts with excellent English skills to revise MGT carefully to align it with human expression better. The details of human annotation guidelines and prompt template are shown in Appendix B.1 and D. After collecting all revised texts, we conducted a manual evaluation involving data filtering and cleaning to ensure MIXSET is high quality, such as removing conversational phrases like 'Sure! Here's a possible completion'.

Table 3: Detailed distribution of different operations in MIXSET.

	Operation	GPT-4	Llama2	Human
AI Revised	Polish Tok.	300	300	—
	Polish Sen.	300	300	—
	Complete	300	300	—
	Rewrite	300	300	—
Human Revised	Humanize	—	—	(300+300)
	Adapt Tok.	—	—	300
	Adapt Sen.	—	—	300

3.3 Dataset Analysis

Our comprehensive analysis of the MIXSET dataset covers length distribution, self-BLEU (Zhu et al., 2018), Levenshtein distance (Levenshtein, 1966), and cosine similarity. We only show analysis of length distribution and cosine similarity analysis here; for self-BLEU and POS distribution, refer to Appendix B.2.

- **Length distribution:** Given that detectors generally perform better with medium to long texts than with short texts (He et al., 2023), and to ensure that the text lengths in the MIXSET reflect real-world usage patterns, we have systematically selected data with a word count that falls within the range of 50 to 250 words. This range was chosen to ensure that the data were sufficiently detailed to provide meaningful insights while being concise enough to allow for effective analysis and comparison. As shown in Figure 4, the text lengths of both the MIXSET, as well as the HWT and MGT, follow a normal distribution.
- **Cosine Similarity:** Figure 5 illustrates that the texts processed with token-level polish operations exhibit the highest similarity to the original texts, followed by sentence-level polish, rewrite, and complete. Texts modified through the 'humanize' operation demonstrate lower similarity than those altered by adaptation.
- **Levenshtein Distance:** The Levenshtein distance (Levenshtein, 1966) is a metric for measuring the difference between two strings. We can observe in Figure 6 that in terms of the extent of modification, the rewrite operation results in the most significant alterations to the original texts, followed by complete and sentence-level polish. We also observe that manual annotations at both the token-level and sentence-level adaptation exhibit a high degree of differentiation.

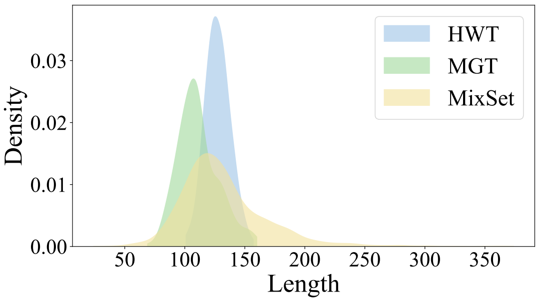

Figure 4: Length distribution of the HWT, MGT, and MixSet.

4 Experiments

4.1 Goals

We conduct experiments to understand better multiple facets of current detectors encountering our dataset MIXSET, including zero-shot and fine-tuning settings. We will figure out four questions:

- **Question 1.** How do current detectors perform in MIXSET dataset? Is there any classification preference in these detectors?
- **Question 2.** What is the performance of detectors retrained on our MIXSET? What about three-classed classification as we consider *mixtext* as a new class distinct from HWT and MGT?
- **Question 3.** What is the generalization ability of current detectors on our MIXSET?
- **Question 4.** Will the size of the training set impact the detection ability on *mixtext*?

4.2 Experiment Setup

Among our four experiments, We evaluate five metric-based and seven model-based detectors on three metrics in total, as shown in Tabel 4 and Table 5. We also outline the detailed training set construction in Table 6. Please refer to Appendix B.2 for a comprehensive introduction to detectors and metrics.

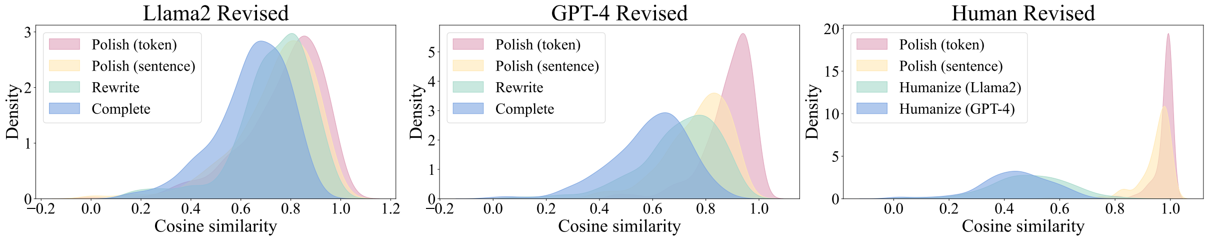

Figure 5: Cosine similarity of the MixSet

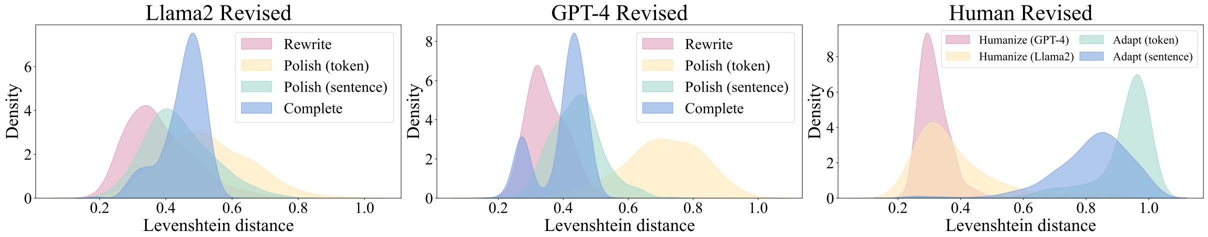

Figure 6: Levenshtein distance of the MixSet

Class Number. In real-world scenarios, people often aim to detect the presence of MGT in the text (e.g., spreading fake news or propaganda (Christian, 2023), reinforcing and intensifying prejudices (Sison et al., 2023)), and sometimes mixtext is also treated as MGT (e.g., student modified some words in MGT (i.e., mixtext) to generate homework, to avoid detection). Therefore, our experiments established two categorization systems: binary and three-class. In the binary classification, mixtext is categorized as MGT, while in the three-class classification, mixtext is treated as a separate class. The label setting is shown in Table 5.

Question 1. Based on MixSet, we evaluate current detectors to determine the classification preferences on mixtext, i.e., Does the detector tend to classify mixtext as MGT or HWT? We calculate the percentage of mixtext samples categorized to MGT in the experiment. For the DistilBERT detector and other metric-based detectors utilizing logistic regression models, we employ a training set comprising 10,000 pre-processed samples of both pure HWT and MGT. For other detectors, we use existing checkpoints [5] [6] or API [7] and evaluate them in a zero-shot setting.

Question 2(a). Following **Question 1**, our inquiry is whether the detector can accurately classify *mixtext* as MGT after training on MixSet. We fine-tune detectors on pure HWT and MGT data and a train split set of our MixSet labeled as MGT.

Table 4: Detectors used in different experiments.

	Detector	Q 1	Q 2	Q 3	Q 4
Metric-Based	Log-likelihood (Solaiman et al., 2019)	✔	✔	✘	✔
	Entropy (Gehrmann et al., 2019)	✔	✔	✘	✘
	GLTR (Gehrmann et al., 2019)	✔	✔	✘	✔
	Log-rank (Mitchell et al., 2023)	✔	✔	✘	✘
	DetectGPT (Mitchell et al., 2023)	✔	✔	✔	✔
Model-Based	Radar (Hu et al., 2023)	✔	✔	✘	✔
	ChatGPT Detector (Guo et al., 2023)	✔	✔	✔	✔
	DistillBert (Ippolito et al., 2019)	✔	✔	✔	✘
	GPT-sentinel (Chen et al., 2023)	✔	✔	✘	✔
	OpenAI Classifier (OpenAI, 2023a)	✔	✘	✘	✘
	Ghostbuster (Verma et al., 2023)	✔	✘	✘	✘
	GPTzero (Tian, 2023)	✔	✘	✘	✘

Question 2(b). On the other hand, assuming that *mixtext* lies outside the distribution of HWT and MGT, we conduct a three-class classification task, treating mixtext as a new label. In this scenario, we adopt multi-label training for these detectors while keeping all other settings consistent.

Question 3. As highlighted in prior research (Xu et al., 2023; He et al., 2023) that transfer ability

Q 3(Ope.)	$1k$	$0.5k$
Q 3(LLM)	$5k$	$1.5k$
Q 4	$1k/4k/7k/10k$	$0/1.5k/3k$

is crucial for detectors, our objective is to investigate the effectiveness of transferring across different subsets of MixSet and LLMs. We establish two transfer experiments to assess whether the transferability of current detection methods is closely linked to the training dataset, referred to as operation-generalization and LLM-generalization:

- **Operation-generalization:** We initially train our detectors on one MixSet subset operated by one of these operations, along with pure HWT and MGT datasets, and then proceed to transfer it to the subsets processed by other operations.
- **LLM-generalization:** In this experiment, we train detectors on GPT-generated texts and HWT, following which we evaluate the detectors on mixtext generated by GPT family (OpenAI, 2023b) and Llama2 (Touvron et al., 2023), respectively, to see whether there is a generalization gap between different LLMs.

Question 4. Empirically, incorporating more training data has been shown to enhance detection capabilities and robustness for generalization (Ying, 2019). To determine the relation between detectors' performance and the size of the training set, we follow **Question 2** and use varying sizes of training sets to retrain detectors, as illustrated in Table 6.

5 Empirical Findings

There is no obvious classification preference in current detectors on mixtext. In other words, the detectors do not exhibit a strong tendency to classify mixtext as either HWT or MGT. As we can observe from Figure 2 and Table 10, it is evident that the MGT percentage[8] of *mixtexts* is between MGT and HWT, indicating that the current detectors do not have a strong preference towards mixtext classification. This proves the success and effectiveness of our constructed MixSet in presenting mixed features of HWT and MGT, demonstrating the limitations of existing detectors in recognizing mixtext.

When dealing with mixtext, the detectors treat it as an intermediate state between HWT and MGT. Most detectors exhibit inconsistent classification within a single subset, fluctuating between accuracies of 0.3 and 0.7, akin to random choice. In AI-revised scenarios, subsets, such as polished tokens or sentences, pose extreme detection challenges. Mainstream detectors generally perform poorly in these cases due to the subtle differences between *mixtext* and original text, highlighted in previous studies (Krishna et al., 2023). Furthermore, texts generated by Llama2-70b are easier to detect than those by GPT-4, possibly due to GPT-4's closer generative distribution to human writing.

Supervised binary classification yields profound results; however, three-classes classification encounters significant challenges when applied to mixtext scenarios except Radar. As indicated in Table 7, retrained model-based detectors outperform metric-based methods in both binary and three-class classification tasks. Notably, Radar ranks first in our results, achieving a significant lead over other detectors. We suppose that this superior performance can be attributed to its encoder-decoder architecture, which boasts 7 billion trainable parameters, substantially more than its counterparts. We also examined the impact of retraining on MixSet on MGT detection performance. As indicated in Table 8, there was a slight decrease in the F1 score, while the AUC metric remained largely unaffected. Notably, post-retraining, the detector acquired the capability to identify mixtext—an advancement deemed highly valuable. This ability to detect mixtext, despite a minor trade-off in F1 score for MGT detection, represents a significant step forward, suggesting a promising direction for

---

[8] MGT percentage means the percentage of identifying samples as MGT of different sets in Experiment 1.

Table 7: F1 score of experiment 2 (a) and (b). Tok. stands for token level and Sen. stands for sentence level. We underscore the best-performing detector and **bold** the score greater than 0.8, which we consider as a baseline threshold for detection.

enhancing detector versatility and applicability in varied contexts.

In the three-class classification task, detectors based on LLMs, particularly the Radar detector, significantly outperformed those utilizing the BERT model. The BERT-based detectors' performance was markedly poor, akin to random guessing, with some models even underperforming a random baseline. This stark contrast underscores the efficacy of LLMs in capturing nuanced distinctions, as demonstrated in tasks like Mixtext. The superior performance of LLM-based Radar detectors lays a solid foundation for future explorations and applications in fine-grained classification tasks.

Current detectors struggle to generalize across different revised operation subsets of MIXSET and generative models. As shown in Figure 8 and Figure 13, significant variability is observed in the transfer capabilities of three different detectors. Additionally, training on texts generated by different revised operations results in different transfer abilities for these detectors. Overall, Radar exhibits the most robust transfer capability among the four model-based detectors, achieving an overall classification accuracy exceeding 0.9, followed by

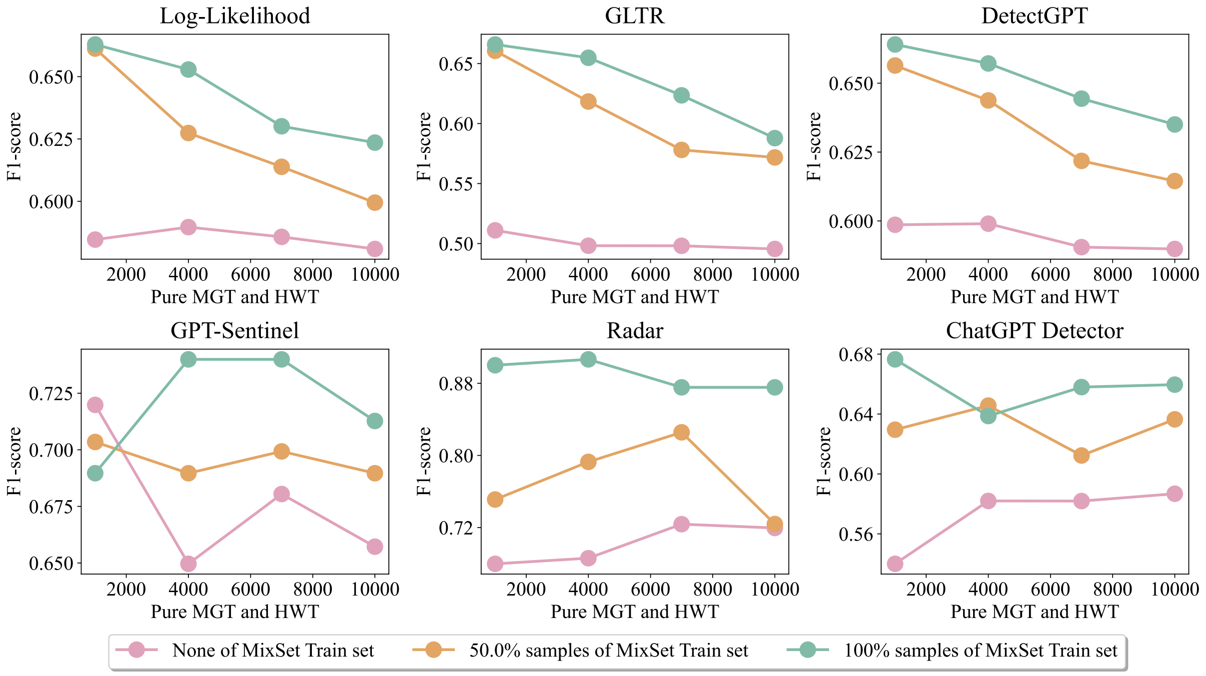

Figure 7: Analysis of the F1-score performance of various detectors across differing quantities of mixtext instances from MIXSET, as well as pure MGT and HWT.

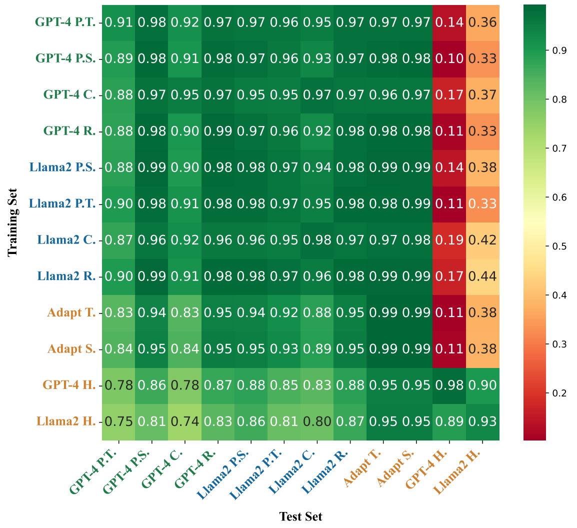

Figure 8: The AUC Heatmap of GPT-sentinel.

GPT-sentinel, DistillBert, and finally, the ChatGPT Detector. Among various operations, 'Humanize' exhibits the poorest transfer performance in almost all scenarios. Additionally, other operations also experience significant declines when dealing with 'Humanize' mixtexts. This suggests that 'Humanize' falls outside the current detectors' distribution of MGT, a gap that could be addressed by retraining on these specific cases. As shown in 9 It is also noteworthy that texts generated by Llama2-70b demonstrate stronger transfer abilities than those generated by GPT4.

Increasing the number of *mixtext* samples in the training set effectively enhances the success rate of *mixtext* detection. However, adding pure text samples does not yield significant improvements and may even have a negative impact on detector performance, especially for metric-based methods. This may be attributed to subtle distribution shifts between mixtext and pure text. The current detector still faces significant challenges in capturing these subtle shifts. For mixtext scenarios, a more powerful and fine-grained detection method is needed.

6 Conclusion

In this paper, we defined *mixtext*, the mixed text of human and LLM-generated content. Then, we proposed a dataset MIXSET to address the research gap in studying the mixed scenarios of machine-generated text (MGT) and human-written text (HWT). A thorough evaluation of the dataset is conducted, performing binary, three-class, and transfer experiments on mainstream detectors. The results underscore the complexities inherent in identifying mixtext, indicating the challenge of distinguishing the subtle differences in mixtext. As a result, there is a need for more robust and fine-grained detection methods.

7 Limitation

Bias Introduced by Human Participation. Although our study involved multiple human participants to modify the text, increasing the diversity and authenticity of the data, the text processing methods of different participants could vary due to their language habits and styles. This might affect the representativeness of the dataset and the generalization ability of the detection models.

Limitation in the Scale of the MixSet Dataset. As the MixSet dataset is the first to be proposed for studying mixed texts (mixtext), its overall scale is relatively small despite its comprehensive coverage in types. This could limit the comprehensiveness of model training and evaluation.

8 Ethics Statement

Opposition to Misuse of Mixed Text Scenarios. Our study highlights that the mixtext of HWT and MGT could significantly diminish the discerning abilities of detectors. However, we strongly oppose the misuse of mixtext to evade detection in specific scenarios, such as during examinations and homework assignments. We believe such misuse could severely harm the fairness of education and the integrity of academic practices.

Purpose for Scientific Research. This study aims purely for scientific exploration and understanding of the behavior and impact of mixtext in natural language processing. Our goal is to enhance understanding of mixed text processing and to advance the technological development in this area, not to encourage or support applications that may violate ethical standards.

Compliance with Licensing and Distribution Regulations. We affirm that all open-source resources utilized in our study, including detectors, language models, and datasets, have been employed in strict accordance with their respective licenses and distribution terms. This adherence extends to ensuring that any modifications, redistributions, or applications of these resources in our research comply with their original licensing agreements. Our commitment to these principles upholds the integrity of our research and contributes to a responsible and ethical academic environment.

Use of Publicly Available Data and Consideration for Privacy. The datasets used in our research are exclusively sourced from publicly available, open-source collections. While these datasets are publicly accessible and generally considered devoid of sensitive personal information, we acknowledge the potential for inadvertent inclusion of personal identifiers in datasets. We emphasize that our use of these datasets is aligned with their intended purpose and distribution terms. We also recognize the importance of respecting privacy and are committed to ongoing vigilance in this regard.

We reiterate that this research adheres to strict scientific and ethical standards, aiming to contribute to the field of natural language processing while ensuring that the results are not used for improper purposes. We also encourage our peers to consider these ethical factors when utilizing our research findings, ensuring their applications do not adversely affect society and individuals.

A.1 Detecting Machine Generated Text

Current MGT detection methods can be broadly categorized into metric-based and model-based methods according to previous study (He et al., 2023). Moreover, other detection methods such as watermark, retrieval-based methods, and in-context learning leveraging LLMs also lead to promising detection methods.

Metric-based Methods. Metric-based methods leverage the LLM backbone directly to extract its distinguishing features between HWT and MGT, operating within a white-box setting that requires access to the model. Former methods like Log-Likelihood (Solaiman et al., 2019), Entropy, Rank (Gehrmann et al., 2019), and Log-Rank (Mitchell et al., 2023) employ statistical analysis to measure information beyond the token level. GLTR (Gehrmann et al., 2019) utilizes a suite of metric-based methods to aid in human identification. However, with the advent of LLMs, the progressively increasing similarity between the distributions of HWT and MGT has weakened its detection accuracy (Ghosal et al., 2023).

Building upon the observation that MGTs occupy regions with sharp negative log probability curvature, Mitchell et al. (2023) introduced a zero-shot whitebox detection method called DetectGPT, setting a trend in metric-based detection (Su et al., 2023; Mireshghallah et al., 2023; Bao et al., 2023). Yang et al. (2023a) also introduced a powerful detection method known as DNA-GPT, which leverages N-gram in a black-box setting by analyzing the differences between truncated original text and regenerated text. Recently, they even extended the detection method to MGT code in a zero-shot setting, which is proven to achieve promising results (Yang et al., 2023b).

Model-based Methods. In the Large Language Models (LLMs) era, Guo et al. (2023) developed the ChatGPT Detector based on a fine-tuned Roberta model. As for decoder-based or encoder-decoder detectors, GPT-sentinel (Chen et al., 2023) and RADAR (Hu et al., 2023), utilizing T5-small (Raffel et al., 2020) and Vicuna-7B (Chiang et al., 2023) respectively, show convincing results when detecting MGT even in revised cases. Moreover, Verma et al. (2023) proposes a novel detection framework called Ghostbuster, which employs passing documents through a series of weaker language models. Using a small amount of training data, Guo and Yu (2023) leverages a black-box LLM to denoise input text with artificially added noise and then semantically compares the denoised text with the original to determine if the content is machine-generated, leading a new method for MGT detection.

However, it's important to note that some researchers have raised concerns about fine-tuning models for MGT detection. Bakhtin et al. (2019) and Uchendu et al. (2020) have argued that fine-tuning models can lead to overfitting and a loss of generalization, particularly when dealing with text generated by the latest LLMs. They highlight the challenge posed by out-of-distribution editing texts, which can undermine the effectiveness of pre-trained detectors, as demonstrated by research on paraphrasing.

Other detection methods. Watermarking imprints specific patterns of the LLM output text that can be detected by an algorithm while being imperceptible to humans. Kirchenbauer et al. (2023) developed watermarks for language modeling by adding a green list of tokens during sampling. Currently, Gu et al. (2023) introduces a learnable watermark by distilling LLM and watermark technology into one student model, finding that models can learn to generate watermarked text with high detectability.

In retrieval-based methods, Krishna et al. (2023) introduce a method to retrieve semantically similar generations and search a database of sequences previously generated by specific Large Language Models (LLMs), looking for sequences that match the candidate text within a certain threshold. Delving deeper, Wu et al. (2023) proposes a model-specific detection tool called LLMDet, which can detect source text from specific LLMs by constructing a text collection dictionary for each LLM.

In the in-context learning setting, Yu et al. (2023) introduced a straightforward method that analyzes the similarity between re-answering a question by generating a corresponding question in the context of the given answer. Moreover, Koike et al. (2023b) employed a pure in-context learning approach for detection and found that LLMs can distinguish between human and machine styles.

A.2 Previous study to mix of HWT and MGT

Prior studies have viewed the mixture of HWT and MGT in different settings. DNA-GPT (Yang et al., 2023a) and DetectGPT (Mitchell et al., 2023) notably utilized the T5 model (Raffel et al., 2020) to simulate scenarios where humans make limited,

POS: Possessive ending
JJ: Adjective
JJS: Adjective, superlative
VBZ: Verb, 3rd person singular present
RBS: Adverb, superlative
NNS: Nouns, plural
TO: to
VBD: Verb, past tense
MD: Modal
VBP: Verb, non-3rd person singular present
FW: Foreign word
DT: Determiner
VBN: Verb, past participle
UH: Interjection
RB: Adverb
NNP: Proper noun, singular
PDT: Predeterminer
EX: Existential there
WP: Wh-pronoun
RBR: Adverb, comparative
PRP: Personal pronoun
VB: Verb, base form
JJR: Adjective, comparative
WRB: Wh-adverb
SYM: Symbol
NN: Noun, singular or mass
RP: Particle
VBG: Verb, gerund or present participle
CC: Coordinating conjunction
CD: Cardinal number

random modifications to MGT, creating complex test cases. Conversely, DIPPER (Krishna et al., 2023) and OUTFOX (Koike et al., 2023b) opted for a paraphrasing technique, using this method to craft adversarial attacks aimed at eluding the detection mechanisms of classifiers, thereby presenting a nuanced way to alter MGT while maintaining undetectability. Recent research efforts have started to explore real-world applications of human-AI mixtext. Liang et al. (2024) explores the impact of AI, such as ChatGPT, on modifying content in academic peer reviews, aligning with our focus on the detection of mixtext.

A.3 Datasets for MGT Detection

Previous studies have proposed many datasets of MGT, often accompanied by their newly proposed detectors (Verma et al., 2023; Chen et al., 2023). Guo et al. (2023) leverages multiple previous Question-Answer (QA) datasets (Rajpurkar et al., 2016b; Kočiský et al., 2018; Jin et al., 2019; Lin et al., 2021), allowing ChatGPT to generate corresponding answers without explicit prompts. This approach results in creating a comprehensive dataset comprising a large set of pairs of MGT and HWT. Following the QA pattern, many researchers (Mitchell et al., 2023; Su et al., 2023; Hu et al., 2023; He et al., 2023) propose datasets with the MGT from variant mainstream LLMs (Du et al., 2022; Black et al., 2022; Anand et al., 2023; OpenAI, 2022, 2023b) [9]. Yu et al. (2023) only utilizes the answer section within the QA dataset (Hamborg et al., 2017; Möller et al., 2020) and employs ChatGPT to generate corresponding questions and re-answers.

However, these datasets typically consist of two distinct classes of texts, namely pure MGT or HWT, without accounting for the potential mixtext. Furthermore, issues arise due to variations in prompts (Koike et al., 2023a), sampling methods, and the inherent differences in length, style, and quality among texts in some datasets (He et al., 2023). These variations challenge the generalization of proposed detectors (Xu et al., 2023) and lie a vast diversity in distribution between the original and revised text (Ghosal et al., 2023). In some instances, the MGT included in datasets may not undergo thorough and careful evaluation. Many noisy sentences are not filtered well in the datasets. For example, some sentences like *Let me know if you have any other questions* exist in the dataset, which will impact the effectiveness of the detectors (Guo et al., 2023).

B Dataset Details

B.1 Construction Details

Eight Human revised the MGT to mixtext. The MGT is revised by eight human experts with professional English proficiency and costs them a total of 280 hours to complete this part. The guidelines for human revision are shown in Figure 22. And the labeling screenshot is shown in Figure 37.

B.2 Other Metrics in Evaluating MIXSET

- **Self-BLEU Score:** Self-BLEU is a metric used to assess the diversity of generated text. Generally, a lower Self-BLEU score indicates higher textual diversity. These results are shown in Figure 10. Overall, the HWT shows greater diversity than MGT, and the Rewrite category has the highest textual diversity in the MixSet. The self-BLEU score of HWT, WGT, and mixtext is shown in Figure 11 and 10.
- **POS distribution:** POS distribution refers to the frequency and pattern of Part-of-Speech tags in a text, categorizing words into grammatical classes like nouns, verbs, and adjectives. This analysis is key for understanding the text's syntactic structure and linguistic characteristics, which is important in NLP research fields.

Seven Model-Based detectors. We implement seven Machine Generative Text (MGT) detectors, encompassing both supervised and zero-shot settings. Firstly, we consider a robust closed-source online detector baseline: GPTZero (Tian, 2023). Secondly, we implement three open-source encoder-based detectors: OpenAI's classifier (OpenAI, 2023a), Roberta-based classifier (Guo et al., 2023). We also implement GPT-sentinel (Chen et al., 2023), RADAR (Hu et al., 2023), and Ghostwriter (Verma et al., 2023) as strong baselines. We also finetune a pre-trained language model built by Sanh et al. (2019) with an extra classification layer on top.

Three Evaluation Metrics Previous studies (Sadasivan et al., 2023; Mitchell et al., 2023) have proven the feasibility of using the Area Under The ROC Curve (AUROC) score for evaluating detection algorithm effectiveness. Given that most detectors can only give a predictive probability, we build a logistic regression model to provide concrete predictions, i.e., MGT or HWT, converting probability to accuracy and f1-score as the two other metrics for our detection evaluation.

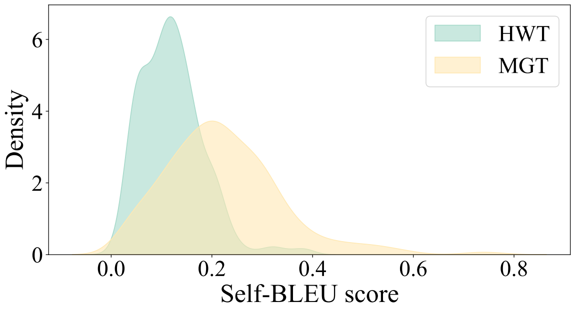

Figure 11: Self-BLEU score of HWT and MGT.

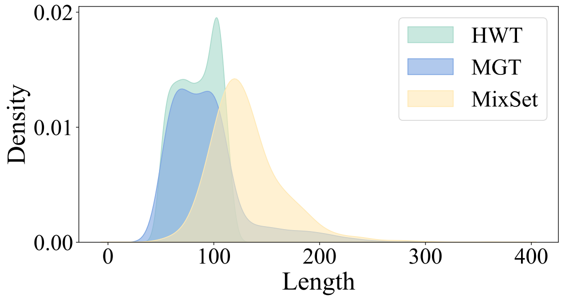

Figure 12: Length distribution of the training datasets and the MixSet.

Training set construction. We respectively select pure HWT and MGT for the train set from different datasets as illustrated in 1 and MGTBench (He et al., 2023), which is also the original dataset of our MIXSET. Since all datasets are specific, this selection strategy ensures only a small difference in data distribution. Firstly, we do data deduplication and pre-process it to erase the Unicode or other special tokens like `\n\n`. Then, we select pieces of sentences with a similar length distribution in our MIXSET, as illustrated in Figure 12. As we use accuracy as our evaluation metric, we restrict the amount of HWT and MGT to be the same in our dataset, as illustrated in Tabel 6.

Training details. We employ the standard binary-classification loss function and the AdamW optimizer (Loshchilov and Hutter, 2019), with an empirically determined learning rate. Specifically, for the Hello-Ai/Roberta-based model and the DistilBERT model, the learning rate is set to 5×10^{-7}. In contrast, for Radar and GPT-sentinel, the learning rates are 5×10^{-6} and 5×10^{-5}, respectively. Each supervised model undergoes training for three epochs on a dual-4090 server.

C Detailed Experiment Results

As for experiment 1, we put the detailed accuracy for different detectors in Table 10. In experiment 2, we also evaluate detectors with AUC metric, as shown in Table 11. We also post other detectors undergo our experiment 3 illustrated in Figure 13. As for experiment 4, we evaluate detectors with accuracy, precision, and recall metrics, as illustrated in Figure 14, 15, and 16.

D Prompt Template

We show the prompt template of LLM's operation, including complete, polish (token-level and sentence-level), rewrite, and humanize in Figure 17, Figure 18, Figure 19, Figure 20 and Figure 21.

E Case study in MIXSET

We selected two cases to show the comparison between the revised mixtext and the original text, where the highlighted content represents the modified content. The HWT original text can be found in figure 23, the AI revised text are shown in Figure 24, 25, 26, 27, 28, 29, 30, and 31. The MGT original text can be found in Figure 32, and the Human revised text can be found in Figure 33, 34, 35, and 36.

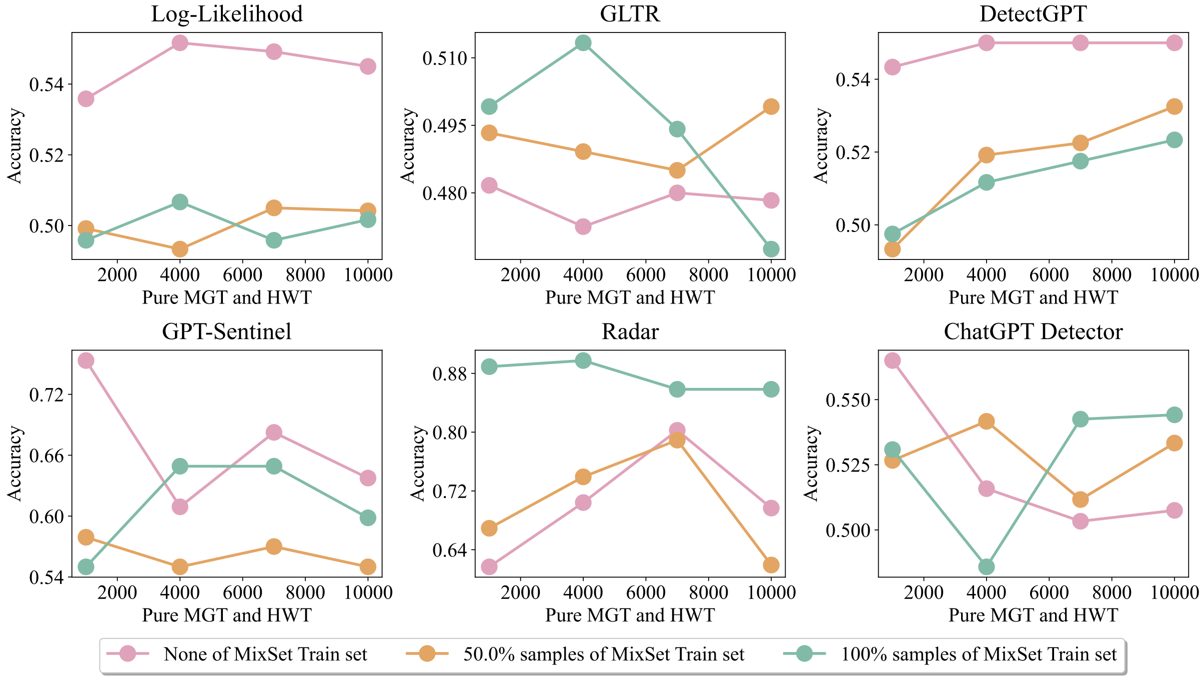

Figure 14: Analysis of the accuracy of various detectors across differing quantities of *mixtext* instances from MIXSET, as well as pure MGT and HWT.

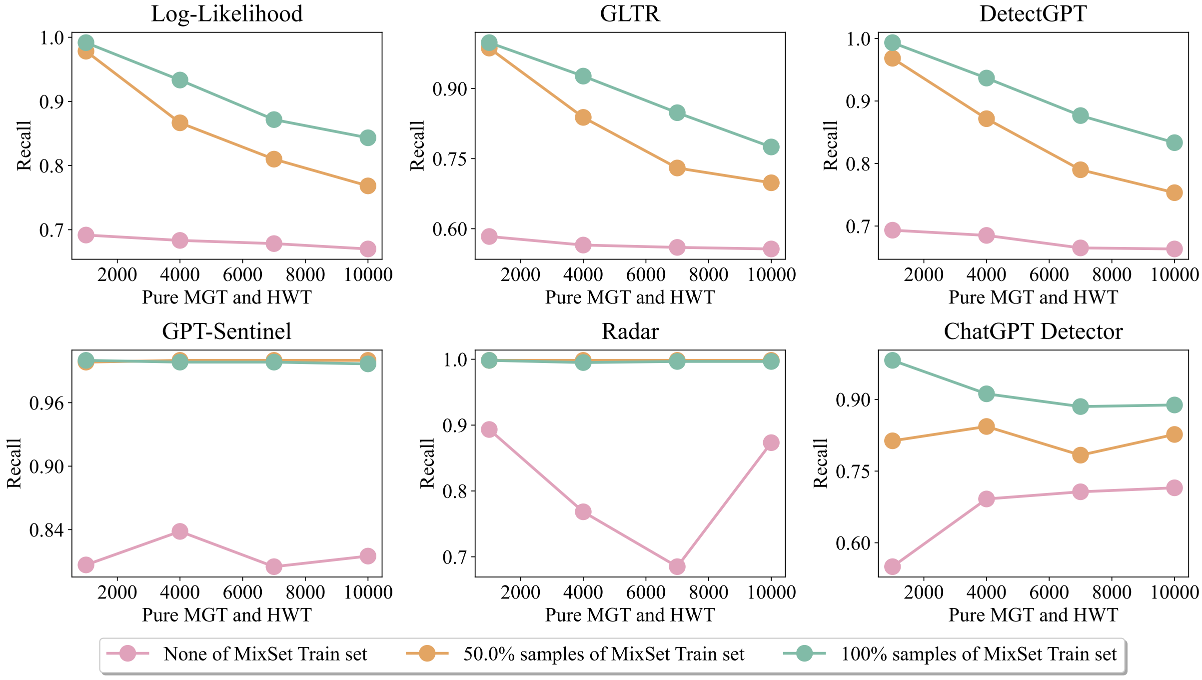

Figure 15: Analysis of the recall rate of various detectors across differing quantities of *mixtext* instances from MIXSET, as well as pure MGT and HWT.

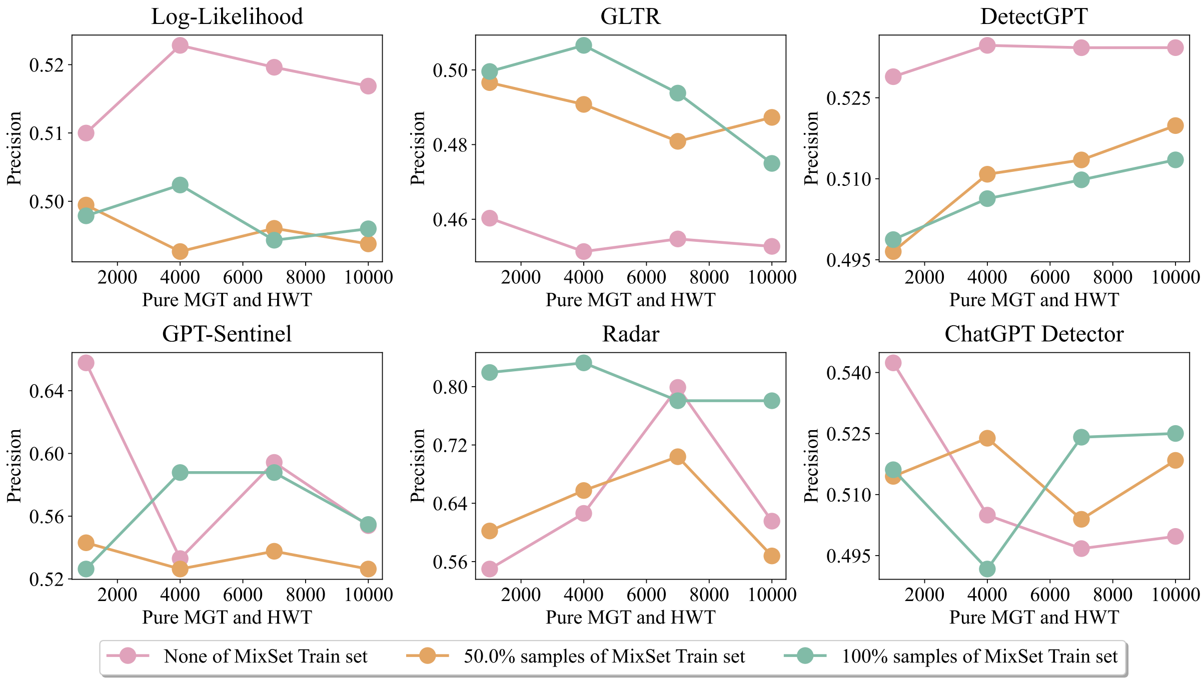

Figure 16: Analysis of the precision rate of various detectors across differing quantities of *mixtext* instances from MIXSET, as well as pure MGT and HWT.

Figure 17: Prompt(①)-LLM complete the HWT

I have an incomplete text and need it to be completed. Please expand this into a complete text where the total word count, including the original text I have provided, does not exceed 180 words. The original text must remain exactly as is, with its format (such as capitalization and punctuation) intact. Please do not modify any part of the original text. Here’s the text: {HWT}

Figure 18: Prompt(②)-LLM polish HWT in token level

Please carefully examine the following paragraph solely for spelling and grammatical errors, and replace any words that are repetitive, inaccurate, or poorly chosen. It is crucial to avoid any changes to the sentence order or structure. The focus should be strictly on the choice and usage of individual words to improve the clarity and appropriateness of the text without altering the original sentence construction: {HWT}

Figure 19: Prompt(③)-LLM polish HWT in sentence level

Please optimize the sentences in the following paragraph to enhance fluency and clarity. Do not alter the overall content or structure of the paragraph. Focus on the construction and expression of the sentences, ensuring that the text is coherent and the information is accurate: {HWT}

Figure 20: Prompt(④)-LLM rewrite HWT

Please extract the core ideas and keywords from the following English text and then rewrite a passage based on this information. The new text should maintain the essence of the original, with the word count varying by no more than 10% from the original. There’s no need to list the core ideas and keywords. Here is the text that needs to be processed: {HWT}

Figure 21: Prompt(④)-LLM humanize MGT

I need to modify a machine-generated text to make it appear more like it was written by a human. The objective is to introduce elements commonly found in human-written texts. Here are some optional modifications you can choose to apply:

1. Introduce spelling errors or typos(optional)
2. Create grammatical errors, such as randomly adding or deleting words (optional).
3. Include relevant but internet links, like blog posts or image links pertaining to the topic, you don’t have to use the real links, so you can freely write one (optional).
4. Add relevant hashtags, for instance, #TopicKeyword #Location #Activity (optional).
5. Use internet slang and abbreviations, e.g., ‘OMG’, ‘How r u’, ‘LOL’, (optional).

Please select any combination of these modifications to enhance the text’s human-like quality. The aim is to simulate the imperfections and stylistic choices typical in casual human writing.
The word count of the new text should not exceed 1.1 times that of the original text.
You should just give me the revised version without any other words.
Emojis are strictly prohibitive, so please ensure that it contains no emojis.
Here is the machine-generated text:{HWT}

Figure 22: Guidelines for Human Revision

The content under this document is generated by a large language model, such as ChatGPT. You are required to revise it to make it closer to the style of human-written text. You are responsible for the text under the IDs xx-xx, and you need to make the following three types of modifications to the content, generating two different sentences for each ID (each ID corresponds to 3 sentences):
The document is in JSON format. You can choose to use code editors like Visual Studio Code or text editors like Notepad for reading and writing.
1. Adapt Token: You need to modify any words or phrases in this passage that you think are too rigid, mechanical, obscure, or unusual into vocabulary typical of human texts. Be careful not to alter the sentence order or structure; only modify 'words' or 'phrases.'
2. Adapt Sentence: You need to revise any sentence structures that you find too mechanical or rigid to make them more in line with how humans typically write texts. This involves changes at the sentence level, which may include altering sentence order and structure.
Note:
1. After writing, please ensure to check that there are no 'grammatical errors' or 'spelling mistakes' in the text paragraphs.
2. Do not use ChatGPT or other large language models for data annotation, as it will severely degrade the data quality.
3. You may use translation platforms like Youdao (you) or Google [a]; or use Grammarly [b] to check for grammatical errors.
Below are some examples you can refer to:
[Example 1]
[Example 2]
[Example 3]

Figure 23: Case Study of revision on HWT: Original HWT

[Original HWT] We present a new mixed variable symplectic (mvs) integrator for planetary systems, that fully resolve close encounters. The method is based on a time regularisation that allows keeping the stability properties of the symplectic integrators, while also reducing the effective step size whenever two planets encounter. We use a high order mvs scheme such that it is possible to integrate with large time steps far away from close encounters. We show that this algorithm is able to resolve almost exact collisions (i.e. with a mutual separation of a fraction of the physical radius) while using the same time-step as in weakly perturbed problems such as the solar system. We demonstrate the long-term behavior on systems of six super-earths experiencing strong scattering for 50 kyr. We compare our algorithm to hybrid methods such as mercury and show that for an equivalent cost, we obtain much better energy conservation.

Figure 24: Case Study of revision on HWT: GPT-4 Polish (Token)

[GPT-4 Polish (Token)] We present a new mixed-variable symplectic (MVS) integrator for planetary systems that fully resolves close encounters. The method is grounded in a temporal regularization that maintains the stability properties of symplectic integrators while also diminishing the effective step size whenever two planets draw near each other. We employ a high-order MVS scheme, enabling integration with extended time steps when distant from close encounters. We demonstrate that this algorithm capably resolves nearly exact collisions (i.e., with a mutual separation of a small fraction of the physical radius) using a consistent time-step as in weakly perturbed problems such as the solar system. We exhibit the long-term dynamics on systems of six super-Earths undergoing intense scattering over 50 kyr. We contrast our algorithm with hybrid methods such as Mercury, revealing that, for a comparable cost, we achieve much improved energy conservation.

Figure 25: Case Study of revision on HWT: GPT-4 Polish (Sentence)

[GPT-4 Polish (Sentence)] We introduce a novel mixed variable symplectic (MVS) integrator specifically designed for planetary systems that efficiently manages close encounters. This method utilizes time regularization to maintain the stability characteristics inherent to symplectic integrators, while dynamically adjusting the effective step size during planetary encounters. Our high-order MVS approach enables integration at large time steps when planets are distantly separated, thereby optimizing computational efficiency. The algorithm proves capable of resolving near-exact collisions—with mutual separations as minute as a fraction of the planets' physical radii—without altering the time step used for more stable configurations, such as within the solar system. We examine the algorithm's long-term stability in simulations of six super-Earths undergoing significant scattering over 50,000 years. Furthermore, we benchmark our algorithm against hybrid methods like Mercury, demonstrating superior energy conservation at a comparable computational cost.

Figure 26: Case Study of revision on HWT: GPT-4 Complete

[GPT-4 Complete] We present a new mixed variable symplectic (mvs) integrator for planetary systems, that fully resolve close encounters. The method is based on a time regularisation that allows keeping the stability properties of the symplectic integrators, while also reducing the effective step size whenever two planets encounter. We use a modified leapfrog scheme to address the issues of traditional integrators when handling near-collision scenarios. The key improvement lies in an adaptive algorithm that dynamically adjusts the step size according to the proximity of the planetary bodies. As a result, our integrator ensures high accuracy and energy conservation even during complex dynamical interactions. Tests demonstrate that the mvs integrator significantly outperforms standard fixed-step symplectic methods in long-term stability and computational efficiency. This advancement opens up new possibilities for accurately simulating the evolution of planetary systems over extended timescales, providing valuable insights into the dynamical behavior of multi-body systems and enhancing our understanding of celestial mechanics.

Figure 27: Case Study of revision on HWT: GPT-4 Rewrite

[GPT-4 Rewrite] We introduce an advanced mixed variable symplectic (mvs) tailored for planetary systems, adept at handling close encounters precisely. This technique employs time regularization to maintain the stability characteristic of symplectic integrators and intelligently reduces the effective step size during planetary encounters. Employing a sophisticated mvs algorithm, it facilitates integration over large time steps when planets are not closely interacting . Our findings illustrate that the algorithm effectively manages near-collision events , simulating scenarios with planet separations just fractions of their physical sizes, using consistent time steps applicable to less disturbed systems like the solar system. The integrator's performance excels in extended simulations, such as tracking six super-earths in a dense scattering scenario for 50,000 years, showcasing superior energy conservation when contrasted with hybrid algorithms like the mercury method, and doing so computational cost.

Figure 28: Case Study of revision on HWT: Llama2 Polish (Token)

[Llama2 Polish (Token)] We introduce a novel mixed variable symplectic (MVS) integrator for planetary systems that accurately resolves close encounters. Our method is built upon a time regularization that preserves the stability attributes of symplectic integrators while adaptively decreasing the effective step size during planetary interactions . By employing a high-order MVS scheme, we can integrate with large time steps in regions where close encounters are not occurring . This algorithm enables the precise resolution of nearly exact collisions (with a mutual separation of a small fraction of the physical radius) using the same time step as in weakly perturbed problems, such as the solar system. We demonstrate the long-term behavior of our algorithm on systems consisting of six super-Earths undergoing intense scattering. Our approach shows superior energy conservation compared to hybrid methods like Mercury, while maintaining comparable computational efficiency .

Figure 29: Case Study of revision on HWT: Llama2 Polish (Sentence)

[Llama2 Polish (Sentence)] We introduce a novel mixed variable symplectic (MVS) integrator for planetary systems that accurately resolves close encounters. Our method is founded on a time regularization technique that preserves the stability attributes of symplectic integrators while adaptively decreasing the effective step size during planetary encounters. By employing a high-order MVS scheme, we can integrate with substantial time steps in regions unaffected by close encounters . Our algorithm efficiently handles near-collisions (with a mutual separation of a few percent of the physical radius) utilizing the same time-step as in weakly perturbed scenarios , such as the solar system. In a comprehensive analysis, we demonstrate the long-term behavior of our method on systems consisting of six super-Earths undergoing intense scattering over 50 kyr. Our findings indicate that, compared to hybrid approaches like Mercury, our algorithm achieves superior energy. conservation at an equal computational cost

Figure 30: Case Study of revision on HWT: Llama2 Complete

[Llama2 Complete] We present a new mixed variable symplectic (MVS) integrator for planetary systems, that fully resolves close encounters. The method is based on a time regularization that allows keeping the stability properties of the symplectic integrators, while also reducing the effective step size whenever two planets encounter. We use a simple and efficient algorithm to detect close encounters, and switch to a smaller step size during these events to ensure accurate trajectory propagation. This approach enables us to maintain the long-term accuracy of the simulation while significantly improving computational efficiency. Our MVS integrator can handle both collisional and non-collisional close encounters, and we demonstrate its performance through several test cases involving Earth-Moon and Jupiter-Io system simulations.

Figure 31: Case Study of revision on HWT: Llama2 Rewrite

[Llama2 Rewrite] We introduce a novel mixed variable symplectic (MVS) integrator for solving planetary systems that undergo close encounters. Our approach combines the benefits of symplectic integrators - stability and accuracy - with the ability to adaptively adjust the time step size during close encounters. This enables us to capture near-collisions with high precision while still utilizing large time steps in stable regions. We validate our algorithm's performance by simulating systems of six super-Earths over 50,000 years, demonstrating its superiority compared to hybrid methods like Mercury in terms of energy conservation, while maintaining comparable computational efficiency.

Figure 32: Case Study of revision on MGT: Original MGT

[Original MGT] The first coffee was brewed by the ancient egyptians over 4,000 years ago. As of 2023, coffee consumption increased 70-fold in the past 100 years. Today, 98% of americans drink coffee. Studies have shown that drinking two cups of coffee per day is beneficial for adults. However, more and more studies also show that drinking one or less coffee is also equally beneficial. Drinking coffee has also been linked to higher memory, alertness, and focus. Overall, coffee is good for your health.

Figure 33: Case Study of revision on MGT: GPT-4 Humanize

[GPT-4 Humanize] OMG did you kno that, like, the first cuppa joe was whipped up by ancient Egyptions like more than 4,000 yrs ago? Fast fwd to 2023, and whoa, coffee drinking's shot up a whoppin' 70 times in the last century! Nowadays, it's like 98% of Americans are sippin' on coffee. Some smarty-pants studies point out that knockin' back two cups a day's pretty good for grown-ups. But hold up, more research is spillin' the beans that maybe just one cup or even less can do the trick too. Crazy, right? Srsly tho, chuggin' coffee's got a rep for boostin' your memory and makin' ya more alert and focused. All in all, java's a thumbs up for your health.

#CoffeeLovers #HealthBenefits #StayAlert

BTW, if ya wanna dive deeper into the whole coffee vibe, there's this killer blog post over at "www.totallyrealcoffeeblog.com/history" that's got the low-down on coffee's past. And, like, for the visual folks out there, check out these pics on "www.picturesofcoffeeandstuff.com" – they've got some epic shots of coffee that'll make you wanna brew a pot, like, right now. LOL

Figure 34: Case Study of revision on MGT: Llama2 Humanize

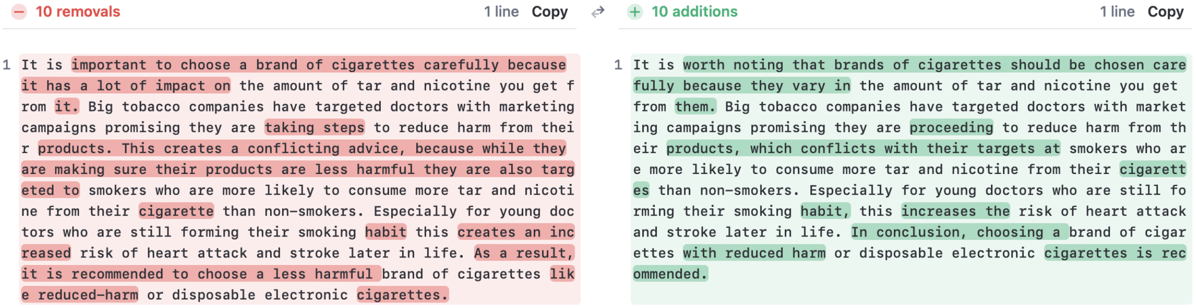
[Llama2 Humanize] Did you know that the ancient Egyptians were the first to brew coffee over 4,000 years ago? Crazy, right? And get this - coffee consumption has increased a whopping 70-fold in just the past 100 years! 98% of Americans can't start their day without their daily cup (or two) of joe. But here's the thing: while most people assume that downing multiple cups a day is the way to go, studies actually suggest that even just one cup can do the trick. Yep, you heard that right - one measly cup can boost your memory, alertness, and focus. Talk about a productivity hack! Of course, there's always the risk of overdoing it, but hey, everything in moderation, right? Bottom line: coffee = good stuff.

Figure 35: Case Study of revision on MGT: Adapt Token

[Adapt Token] The first coffee was brewed by the ancient Egyptians over 4,000 years ago. By 2023, coffee consumption has increased 70-fold in the past 100 years. Nowadays, 98% of Americans drink coffee. Studies have shown that drinking two cups of coffee every day is beneficial for adults. Additionally, more and more studies also show that drinking one or less coffee is also equally beneficial. Drinking coffee is also linked to better memory, alertness, and concentration. Overall, coffee is good for your health.

Figure 36: Case Study of revision on MGT: Adapt Sentence

[Adapt Sentence] The first coffee was brewed by the ancient Egyptians over 4,000 years ago. Coffee consumption has increased 70-fold in the past 100 years, along with 98% of Americans drinking coffee, according to the data up to 2023. Studies have shown that drinking two cups of coffee every day is beneficial for adults, while other studies indicate that drinking one or fewer cups of coffee is also equally beneficial. Drinking coffee is also linked to better memory, alertness, and concentration. Overall, coffee is good for your health.



It is important to choose a brand of cigarettes carefully because it has a lot of impact on the amount of tar and nicotine you get from it. Big tobacco companies have targeted doctors with marketing campaigns promising they are taking steps to reduce harm from their products. This creates a conflicting advice, because while they are making sure their products are less harmful they are also targeted to smokers who are more likely to consume more tar and nicotine from their cigarette than non-smokers. Especially for young doctors who are still forming their smoking habit this creates an increased risk of heart attack and stroke later in life. As a result, it is recommended to choose a less harmful brand of cigarettes like reduced-harm or disposable electronic cigarettes.

It is worth noting that brands of cigarettes should be chosen carefully because they vary in the amount of tar and nicotine you get from them. Big tobacco companies have targeted doctors with marketing campaigns promising they are proceeding to reduce harm from their products, which conflicts with their targets at smokers who are more likely to consume more tar and nicotine from their cigarettes than non-smokers. Especially for young doctors who are still forming their smoking habit, this increases the risk of heart attack and stroke later in life. In conclusion, choosing a brand of cigarettes with reduced harm or disposable electronic cigarettes is recommended.

`{name.lastname}@uva.nl`, `pushkarmishra@meta.com`, `helen.yannakoudakis@kcl.ac.uk`

Abstract

Community models for malicious content detection, which take into account the context from a social graph alongside the content itself, have shown remarkable performance on benchmark datasets. Yet, misinformation and hate speech continue to propagate on social media networks. This mismatch can be partially attributed to the limitations of current evaluation setups that neglect the rapid evolution of online content and the underlying social graph. In this paper, we propose a novel evaluation setup for model generalisation based on our few-shot subgraph sampling approach. This setup tests for generalisation through few labelled examples in local explorations of a larger graph, emulating more realistic application settings. We show this to be a challenging *inductive* setup, wherein strong performance on the training graph is not indicative of performance on unseen tasks, domains, or graph structures. Lastly, we show that graph meta-learners trained with our proposed few-shot subgraph sampling outperform standard community models in the inductive setup. We make our code publicly available.[1]

1 Introduction

The combination of connectivity and anonymity offered by social media inadvertently also provides the perfect channel for wide-spread dissemination of malicious content (Allcott and Gentzkow, 2017; Müller and Schwarz, 2017; European Commission, 2018; Derron, 2021). By *malicious content*, we consider any form of content detrimental to society, and focus on two specific forms: misinformation and hate speech. Mitigating the effect of malicious content requires content moderation, but this is a labour-intensive process that exacts an immense psychological toll on moderators (Vosoughi et al., 2018; Wiessner, 2021). Consequently, automated detection of malicious content has seen increased academic interest (Ruffo et al., 2023) and industry adoption.

Community models for malicious content detection are models that operate on *social graphs*, i.e., graphs of content and users. They 1) classify content nodes as malicious or not, 2) incorporate information from interacting users in the graph when doing so, and 3) leverage emergent network properties like homophily to boost detection performance (Ma et al., 2021; Hussain et al., 2021). For community modelling on large-scale heterogeneous online communities, Graph Neural Networks (GNNs) are the architecture of choice (Phan et al., 2023).

While community models for malicious content detection perform very well on benchmark datasets (Mishra et al., 2019; Gong et al., 2023), social media platforms continue to grapple with such content. Alharbi et al. (2021) find that high accuracy in malicious content detection is not indicative of trustworthiness in general, as predictions often rely on dataset-specific features. Models also become outdated quickly as online content and communities evolve (Monti et al., 2019). Bozarth and Budak (2020) find detection models to be brittle to changes in domain or publication date, a finding that Nielsen and McConville (2022) corroborate specifically for community models. Finally, Phan et al. (2023) conclude that "we [have] no graph benchmark data for fake news detection in the graph learning community" (p. 22), making any claims of state-of-the-art performance difficult to verify.

Evidently, there exists a mismatch in the performance of community models on research datasets and in more realistic application settings. Research datasets are static; they capture a view of the social graph weeks or months after relevant content has been introduced and spread. Current evaluation practices designed on static graphs are effectively *transductive* (Song et al., 2021b), i.e., they implicitly assume that no new content or users will be

---

[1] Our anonymised code-base is available at: `https://github.com/rahelbeloch/meta-learning-gnns`

Findings of the Association for Computational Linguistics: NAACL 2024, pages 437–463
June 16-21, 2024

introduced into the social graph, which leads to performance scores that obscure the discussed deficiencies.

In *realistic* settings, new users and content nodes are constantly added to the social graph, and the topic or style of malicious content often radically changes. This is a property inherent to online content and communities (Adamic et al., 2016; Guo et al., 2021). Thus, a successful community model should be able to rapidly adapt to domain shifts in content. Since labelling is prohibitively expensive, adaptation should occur in a few-shot manner. Furthermore, the community of interacting users also evolves. Initially, only a few users take note of some content, but as it gains traction, more and more users interact. To prevent harm from malicious content, detection must occur before wide-spread dissemination. This requires adaptation from a limited exploration of the social graph. Therefore, *inductive* evaluation is needed.

In this paper, we seek to more realistically assess the generalisation capabilities of community models for malicious content detection, specifically making the following contributions:

1. We design a novel evaluation setup based on a few-shot subgraph sampling procedure that test inductive generalisation. The subgraphs are local, contain limited context, and have only a few labels.
2. We test a state-of-the-art community model under this novel evaluation setup on unseen graphs, domains, and tasks. We find them lacking the capacity to generalise.
3. We show that graph meta-learners trained with our few-shot sampling outperform standard community models in inductive evaluation.

2 Related Work

2.1 Community Models

Community models have shown promise on static social graphs. Such models use social graphs to contextualise content by the users that interact with them, phrasing the detection task as node classification. Mishra et al. (2018, 2019) and Monti et al. (2019) find that GNNs over heterogeneous user–tweet graphs outperform models using only text or user-based features. Chandra et al. (2020) show that relational GNNs—which directly model edge relations between different types of nodes—yield significant improvements over a range of baselines. Shu et al. (2019b) argue for the inclusion of publishers as another node type, with Ren et al. (2021) also including topics.

Nguyen et al. (2022) utilise temporal replies to model the dynamic user–content interactions. Temporal representations aid in early detection of malicious content (Jian Cui et al., 2021; Song et al., 2021a). However, they still assume static content. Others have focused on directly detecting actors posting the content (Tan et al., 2023; Mehta et al., 2022); we explicitly exclude actor modelling from our methodology since it mandates different ethical considerations (Mishra et al., 2021).

Gong et al. (2023) provide a review of graph representation learning for malicious content detection. They also conclude that cross-domain generalisation remains an understudied problem for graph-based malicious content detection.

2.2 Generalisable Content-only Models

Developing malicious content detectors for cross-domain generalisation is receiving increased attention. For example, many task-aware domain adaptation approaches have been proposed (Zhang et al., 2020, 2021; Mosallanezhad et al., 2022; Lin et al., 2022; Yue et al., 2022). These methods are either "aware" of the distribution of representations in different datasets, or use external models to correct representations post-hoc. Generating representations that are invariant to domain shifts is a related direction (Ding et al., 2022; Huang et al., 2023).

Utilising (large) language models on unseen texts has also shown promising results (Lee et al., 2021b; Chiu et al., 2022; AlKhamissi et al., 2022). Lee et al. (2021c) use multitask fine-tuning on RoBERTa (Liu et al., 2019), and show that few-shot adaptation on related, but unseen datasets improves performance over fine-tuning on individual tasks. Yue et al. (2023) specifically train content-only misinformation detectors to rapidly adapt. We, however, focus solely on community models for malicious content on social graphs, and to the best of our knowledge, are the first to do so.

2.3 Subgraph Sampling & Meta-learning

Closely related to the idea of rapid adaptation to new tasks and domains is the field of meta-learning. Herein, models are trained to optimise themselves using a minimal amount of examples. In NLP, this has been investigated for document (Yu et al., 2018; van der Heijden et al., 2021), sentence (Dou et al., 2019; Bansal et al., 2020), and token-level tasks

Dataset	**GossipCop**	**CoAID**	**TwitterHateSpeech**

Table 1: Statistics of graph datasets post-processing. Further details are in Appendix B.

(Holla et al., 2020). For a thorough review, we refer the reader to Lee et al. (2021a, 2022).

To operationalise meta-learning from subgraphs, Huang and Zitnik (2021) propose G-Meta. They assume local subgraphs preserve information of a larger graph, such that training a GNN on relevant subgraphs can induce rapid adaptation from limited context. Other graph meta-learning procedures exist, however, they do not utilise episodes of local subgraphs. We refer the reader to Mandal et al. (2021) and Zhang et al. (2022) for a comprehensive review of the field.

3 Datasets & Tasks

We use three widely-adopted social graph datasets to train and evaluate community models. Social graph datasets are difficult to collect and degrade as users or content are moderated out. The first dataset, GossipCop, is used for pre-training. The other two datasets, CoAID and TwitterHateSpeech, are reserved for evaluating generalisation to unseen graphs. Table 1 provides some statistics, which are further complemented by Appendix B. All datasets were rehydrated, i.e., rebuilt through the API, using the Twitter Academic API prior to May 2023. See 'Redistribution of Twitter Content'.

GossipCop is one of two datasets introduced by Shu et al. (2019a). It comprises 20k fact-checked celebrity rumour articles, and around 500k interacting Twitter users. Labels correspond to the (now defunct) GossipCop fact-checking scores, covering a variety of (usually unreliable) publishers. Articles from a single trusted source, E!Online, were included to reduce class imbalance. Users are connected to articles and other users.

CoAID contains articles from the first months of the COVID-19 pandemic, collected by Cui and Lee (2020). We omit the "social media" category as most contain short, poorly formatted text. Fake news articles are labelled using a variety of fact-checking websites, whereas truthful news comes from (unverified) mainstream media outlets. After rehydration, this dataset is substantially smaller than when originally devised, with most lost documents corresponding to the fake class. Users are connected to articles and other users.

TwitterHateSpeech differs in task, domain, and relational schema from the other datasets. Document nodes are tweets generated by Twitter users during a few seed events. Waseem and Hovy (2016) identified prolific hate speech tweeters, and include their followers and followees in the graph. They manually labelled all tweets as racist, sexist or innocuous (none). Especially racist (0.3%) users are over-represented, leading to few diverse regions in the graph. User–document connections indicate authorship (as opposed to tweet/retweet interactions). Users are also connected to other users.

4 Methodology

A social graph, $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, consists of a set of nodes $\mathcal{V}$ and a set of edges $\mathcal{E}$ indicating which nodes are incident to each other. A node's r-radius neighbourhood $\mathcal{N}_r(v)$ contains all other nodes that can be reached by paths of length r (also called 'hops', a series of incident nodes), and always includes v.

All datasets considered require modelling two node-types: documents ($\mathcal{V}^{\text{docs.}}$) and users ($\mathcal{V}^{(\text{users})}$). Hence, the social graph $\mathcal{G}$ is heterogeneous. Document nodes v contain exogenous features x_v (i.e. the content representation), and have target labels $y_v \in \mathcal{Y}$. Documents are only connected to users ($\forall u \in \mathcal{N}_1(v), u \in \mathcal{V}^{(\text{users})}$), whereas users may

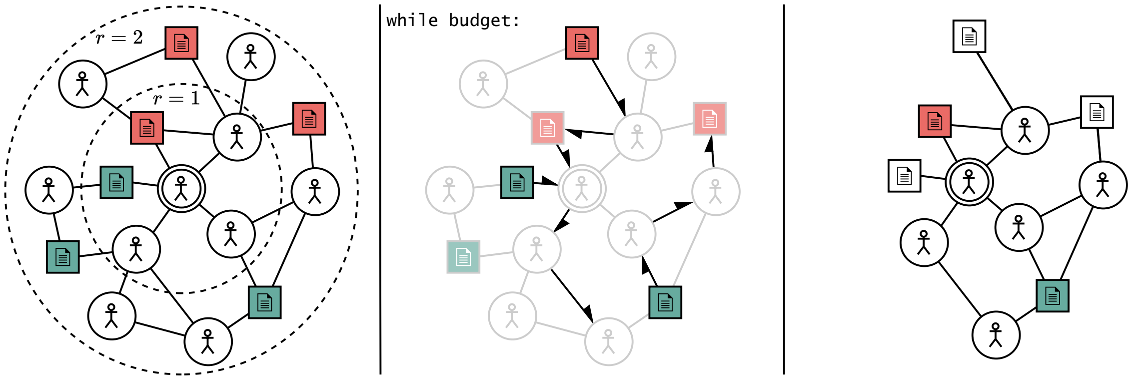

Figure 1: Support subgraph generation. Left: collect the r-radius neighbourhood of an anchor user. Middle: sub-sample using random walks from document nodes until reaching a maximum node count. Right: unmask document nodes inversely proportional to the number of subgraphs they appear in. Colours correspond to classes.

also be connected with other users based on their interactions or relations. Users are not labelled, and have no initial representation.

4.1 Community Modelling

Community models for malicious content detection classify content nodes in a social graph, taking into account the graph context around them to make the prediction $f_\theta(x_v; \mathcal{G})$. GNNs, a common representation learning framework, perform this contextualisation using non-linear message-passing schemes.

Some node v, at layer l, has as hidden state an aggregation of the representations in neighbouring nodes at layer $l-1$. We use Graph Attention Networks (GATs) (Veličković et al., 2018), which employ an additive attention mechanism for the neighbourhood aggregation. Specifically:

$$\mathbf{h}_v^l = \sigma(\textstyle\sum_{u \in \mathcal{N}_1(v)} \alpha_{v,u} \mathbf{W} \mathbf{h}_u^{l-1}) \qquad (1)$$

where σ is a non-linear activation function. The attention weights $\alpha_{v,u}$ are computed as:

$$\texttt{softmax}(\sigma(\mathbf{a}^\intercal [\mathbf{W}\mathbf{h}_v^{l-1} \| \mathbf{W}\mathbf{h}_u^{l-1}])) \qquad (2)$$

where $[\cdot\|\cdot]$ is concatenation, while $\mathbf{a}$ and $\mathbf{W}$ are the projection matrices.

More expressive architectures than GATs exist and have been applied to malicious content detection (Chandra et al., 2020; Gong et al., 2023). Such models, however, often introduce inductive biases specific to the task it seeks to solve. For example, relational attention aids performance but requires the relational schema to be consistent across datasets. Our evaluation and meta-learning setup is model agnostic.

Community modelling can be *transductive* or *inductive*. Transductive modelling assumes that the social graph remains static across training and prediction. Inductive modelling, instead, assumes the underlying social graph changes, in terms of content and users.

Herein we differ from the definition common to graph learning applications. Usually, inductive graph learning ’only’ assumes the nodes in the evaluation graph are unseen, with those nodes coming from the same underlying graph. As argued in the introduction, this does not apply to malicious content detection; the graph has shifted between training and deployment time. True inductive generalisation, therefore, requires generalisation to entirely different graphs. Currently, no graph datasets of malicious content exist that allow testing this manner of generalisation.

Due to the social network changing, inductive community models should not rely on superficial properties, like the content of malicious posts or specific user neighbourhoods, but rather leverage universal network properties. One such property is homophily: the tendency of nodes of a similar class to cluster together. We investigate the presence of homophily (or heterophily) in Appendix F.

4.2 Few-shot Subgraph Sampling

A successful community model for malicious content detection should be able to rapidly adapt to the constantly evolving social graph, even when presented with labelled examples.

More formally, a community model, f_θ, should be able to inductively learn to generalise from a limited exploration of a social graph $\mathcal{G}^{\mathcal{S}} \subset \mathcal{G}'$ to make accurate predictions elsewhere $\mathcal{G}^{\mathcal{Q}} = \mathcal{G}' - \mathcal{G}^{\mathcal{S}}$. In commonly-used meta-learning terminology, $\mathcal{S}$ would denote the support and $\mathcal{Q}$ the query set.

Algorithm 1 Few-shot Graph Sampling

```
Require: Graph $\mathcal{G} = \left(\left(\mathcal{V}^{(\text{doc})}, \mathcal{V}^{(\text{user})}\right), \mathcal{E}\right)$
Require: Central user $v$
Require: Maximum support graph size, budget

for $r$ in range(2, 5) do
    Get $r$-radius neighbourhood of $v$, $\mathcal{N}_r(v)$
    Find nodes per class $\mathcal{V}_y^{(\text{doc})}$
    if all($|\mathcal{V}_y^{(\text{doc})}| \geq k$-shot) then
        break
    end if
end for

Initialize empty support graph $\mathcal{G}'$
while $|\mathcal{G}'| <$budget do
    Pick class $y$ round-robin style
    Sample a node $u$ from $\mathcal{V}_y^{(\text{doc})}$
    Generate random walk path, $\mathcal{G}^{(\text{path})}$, from $u$
    $\mathcal{G}' \leftarrow \mathcal{G}' \cup \mathcal{G}^{(\text{path})}$
end while

return $\mathcal{G}'$ if it is a valid $k$-shot graph
```

For malicious content detection specifically, the notion of 'limited exploration' implies the following conditions for $\mathcal{G}^{\mathcal{S}}$:

1. **Locality**: all sampled document nodes come from the same graph region, due to a similar seed event, topic, or intended audience
2. **Limited Context**: moderation should precede wide-spread dissemination
3. **Few-shot**: labelling is expensive, therefore a minimal set of labels is available

Existing subgraph sampling procedures, like G-Meta, violate these conditions, especially 'locality'. Labelled nodes are sampled independently, i.e., nodes can come from entirely different regions of the graph, which in our case, would imply entirely unrelated forms of content.

To better conform to the listed desiderata, we perform user-centred sampling for generating $\mathcal{G}^{\mathcal{S}}$. Algorithm 1 presents pseudocode for our sampling approach, which is also depicted graphically in Figure 1. Various graph statistics are provided in Appendix C.

To ensure locality, we first sample an anchor user and collect the smallest r-hop neighbourhood that yields k documents of each class. In Figure 1, the double-circled user represents the anchor. Then, to limit social context, we take random walks from the documents nodes into the subgraph. This process starts from a document node, and is repeated until a maximum number of nodes is reached. Bold arrows in the middle column of Figure 1 show some random walks of length 3.

For the training process, only k document nodes of each class have their labels unmasked in a subgraph. Other document nodes are still allowed in the subgraph, but without labels. This is depicted in the right-most column of Figure 1.

Power-law distributed degrees of nodes is a property of social media networks. This means a few, very active users and their incident document nodes will be present in the majority of subgraphs. This reduces the diversity of support episodes and thus biases generalisability estimates. To reduce the effect of these users during the training process, document nodes are labelled inversely proportional to their frequency across all created subgraphs.

4.3 Gradient-based Meta-learning

Community models learn a neighbourhood-aware mapping of a content node's input features to target labels. Community meta-learners, instead, use an initial set of weights to produce community models only after adaptation, i.e. learning a community model from several episodes of $\mathcal{G}^{\mathcal{S}}$ and $\mathcal{G}^{\mathcal{Q}}$. By using our few-shot subgraph sampling method to create episodes for meta-training, the community meta-learners are better suited to inductive generalisation.

We focus on a specific subclass of meta-learners, namely, gradient-based meta-learners. Model-Agnostic Meta-Learning (MAML), introduced by Finn et al. (2017), is the most popular such learning framework. Its optimisation objective is:

$$\min_{\theta^{(\text{meta})}} \mathbb{E}[\mathcal{L}(\mathbf{y}_{\text{Q}}, f_{\theta^{(\text{task})}_{T_{\text{inner}}}}(\mathbf{x}_{\text{Q}}; \mathcal{G}^{\mathcal{Q}}))] \tag{3}$$

The induced update to $\theta^{(\text{meta})}$ is called the *outer-loop* update. The *inner-loop* occurs during adaptation to the support set, using a pre-defined number of SGD updates, $t \in \{1, \ldots, T_{\text{inner}}\}$, with gradients

$$\nabla_{\theta^{(\text{task})}_t} \mathcal{L}(\mathbf{y}_{\text{S}}, f_{\theta^{(\text{task})}_t}(\mathbf{x}_{\text{S}}; \mathcal{G}^{\mathcal{S}})) \tag{4}$$

This bi-level objective encourages the meta-learner's initial weights, $\theta^{(\text{meta})}$, to learn to adapt to new tasks, $\theta^{(\text{task})}$, using only T_{inner} updates.

Prototypical Initialisation MAML implicitly assumes a new permutation of classes in each episode and re-initialises the task-specific classification head during each outer-loop iteration. Prototypical Networks (ProtoNets) (Snell et al., 2017) are a non-gradient-based meta-learning alternative that does not utilise classification heads. Instead, support samples are used to form class prototypes $\mathbf{c}_y$:

$$\mathbf{c}_y = \frac{1}{k}\textstyle\sum_{\{\mathbf{x}_v|y_v=y\}} f_{\theta^{(\text{meta})}}(\mathbf{x}_{\mathcal{S}}; \mathcal{G}^{\mathcal{S}}) \qquad (5)$$

which classify query samples based on their distance to the prototypes.

$$p(y_v|\mathbf{x}_v) = \text{softmax}(-d(f_{\theta^{(\text{meta})}}(\mathbf{x}_v), \mathbf{c}_y)) \qquad (6)$$

Per Triantafillou et al. (2020), if using the Euclidean distance as d, this is equivalent to applying a linear projection $\mathbf{Wh} + \mathbf{b}$ with initialisation:

$$\mathbf{W} = 2\mathbf{c}_y, \quad \mathbf{b} = \|\mathbf{c}_y\|^2 \qquad (7)$$

Using this reformulation, Triantafillou et al. (2020) propose ProtoMAML, an approach that extends MAML such that the classification head is now parameterised by Eq. 7 and fully updatable during inner loop adaptation.

4.4 Implementation Details

Support graphs for episodes are sampled using the few-shot sampling procedure detailed in Sec. 4.2. We use the lowest possible radius r that satisfies the k-shot requirement. The maximum number of nodes in the support graph is 2048. All classes provide an equal amount of root nodes of the random walk sub-sampling. For meta-training, $k = 4$, and the query graph is generated by sampling a set of independent document nodes along with their $r = 2$ neighbourhood. During (meta-)testing, all non-training nodes are used.

Document nodes use the time-pooled averaged token representations from the penultimate RoBERTa (Liu et al., 2019) layer as initial representations. These are not trained further. Users nodes are initialised to all zeros, making them effectively anonymous and allowing for both transductive and inductive approaches. All models train end-to-end and do not include an auxiliary text-only classifier. Appendix D provides all additional modelling hyper-parameters.

Our GNN architecture is adapted from SAFER (Chandra et al., 2020). It consists of 2 ReLU activated GAT layers, each with 3 attention heads. These are concatenated together and linearly projected before being fed into a 2-layer MLP. We use dropout node-wise on the initial representations and element-wise on the layer representation and attention weights. We reduce the computational complexity of the GAT layers by merging successive projections in the attention layers (Brody et al., 2022). The use of 2 GAT layers means document nodes v have as receptive field $\mathcal{N}_2(v)$. We optimise our models using AdamW (Kingma and Ba, 2017; Loshchilov and Hutter, 2019).

In total, we experiment with models trained under 6 different learning paradigms. The first two (FULL and SUBGRAPHS) are non-episodic baselines, trained transductively on the full graph or inductively on few-shot sampled subgraphs respectively. FULL mimics the current practice of training transductively without generalisation to unseen graphs in mind. SUBGRAPHS makes generalisation feasible and allows us to isolate the contribution of meta-learning.

The last four are graph meta-learners. We use two MAML variants, one with a classification head shared across episodes (MAML-LH) and another where the classification head is randomly initialised at each episode (MAML-RH). Appendix E shows the effect of classifier head resetting on adaptation speed. We also train PROTONET and PROTOMAML variants to evaluate the effect of prototypical initialisation on the classification head.

MAML-based outer-loop updates (Eq. 3) require computing second-order gradients, which is prohibitively expensive. Instead, we use a first-order approximation (foMAML (Finn et al., 2017)) which usually does not significantly affect performance (Nichol et al., 2018; Antoniou et al., 2019).

5 Experiments and Results

5.1 Experimental Setup

We first assess within-dataset generalisation to unseen nodes using 5-fold stratified cross-validation. The folds are strict, with no document appearing in more than one validation set. We only keep the largest connected component. User nodes can appear in multiple folds, but since they are all zero-initialised, they cannot influence nodes in other folds.

Models are trained on GossipCop and then evaluated on all three datasets. On GossipCop, we assess both the non-episodic and episodic models. On other datasets, we assess the episodic models only

Table 2: Results on GossipCop. Brackets give the 90% confidence interval. Bold values denote the best column score (where comparison is possible) and underlined the second-best. † denotes 4-shot episodic evaluation. SAFER results taken from Chandra et al. (2020); FULL is our re-implementation since they do not release their data splits.

to ensure a few-shot generalisation setup. Within each episode, support nodes appear in the query graph but do not count towards classification performance metrics. This process is repeated 256 times, with summary statistics computed for each of the 5-fold model checkpoints. When aggregating over checkpoints, the inverse-variance weighted mean is used to estimate a common effect size (i.e., a fixed-effect meta-analysis (Schwarzer et al., 2015)).

To assess classification performance for each class in isolation, we use the F1-score. Matthews Correlation Coefficient (MCC) is used to assess holistically. Recent papers argue for the MCC as an informative metric, relatively robust to class imbalance (Chicco and Jurman, 2020, 2022). MCC values near 0 indicate random performance, values near 1 almost perfect performance, and negative values are worse than random. The Area Under the Precision-Recall curve (AUPR) is a multi-threshold metric, and can compare models on their ability to separate classes. We exclude it for CoAID and TwitterHateSpeech as there is no consistent way to do aggregate it in multi-class settings. Metrics are reported with 90% confidence intervals.

All hyper-parameters used were tuned on GossipCop's validation sets. The tuning procedure, optimizer, meta-learning and evaluation hyper-parameters are described in Appendix D.

5.2 GossipCop Results

Here, we test generalisation on unseen nodes from the same graph. Beyond the non-episodic baselines already described, we have two additional baseline methods on GossipCop. The first, TEXT, is a 2 layer MLP on top of the initial document embeddings meant to test the added benefit of a graph inductive bias. The second, USER ID, classifies test documents based on neighbouring users' most linked document class in the train split. The already reasonable performance indicates high homophily.

The GAT-based models leverage both text and social features. SUBGRAPHS clearly performs worse than FULL. MAML-LH, however, outperforms FULL even though it is inductive, demonstrating the generalisation power of meta-learning.

The lower three rows all include meta-learners which constantly re-initialise the classification head. Their performance is more in line with the non-episodic SUBGRAPHS, lagging considerably on fixed threshold metrics. This gap narrows in terms of AUPR, implying the final bias parameter may be to blame.

5.3 Generalisation to Unseen Graphs

Figure 2 shows the performance of models ported to the other two datasets.

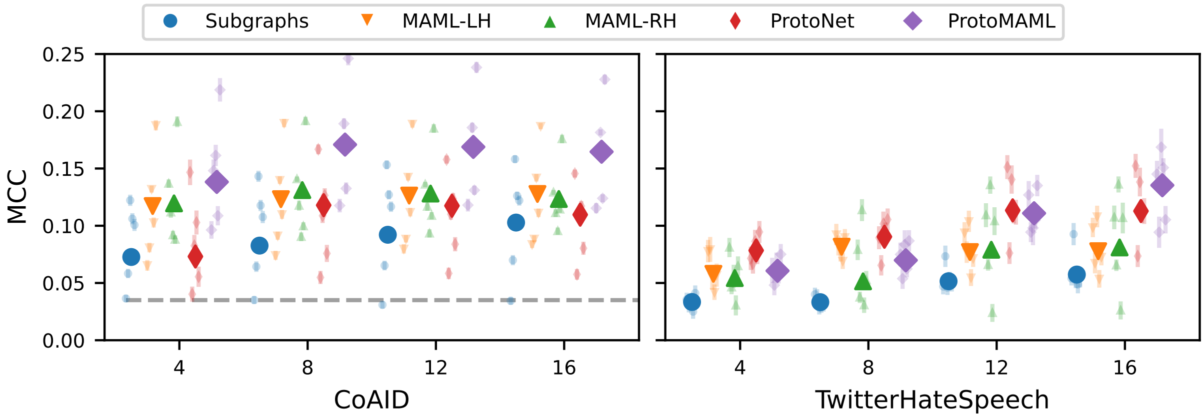

Figure 2: Generalisation of various models to CoAID and TwitterHateSpeech, in terms of MCC. See-through markers give the performance of each model instance, with error bars giving the 90% CI. Solid markers give the performance averaged across model instances. Markers are offset to avoid overlap. The horizontal axis gives the support graph k-shot. The dashed gray line for CoAID gives the zero-shot performance of the Subgraphs model, i.e., direct domain transfer. Colours and shape both denote a model instance.

Variance between the different model instances is large, although when aggregated their performance is relatively stable. PROTOMAML proves to be the best model on both datasets, particularly at larger k-shot values. PROTONET shows competitive performance on TwitterHateSpeech (especially in lower k-shot settings), but is considerably worse on CoAID. Prototypical initialisation seems to aid generalisation, mitigating classification head learning. Regardless, meta-learning methods outperform the non-episodic SUBGRAPHS model on either dataset, indicating that training for rapid adaptation helps generalisation to new malicious content forms.

Transfer to CoAID from Gossipcop, is essentially a form of domain transfer. As such, we provide the zero-shot performance of the SUBGRAPHS model as a baseline value. Despite the similar task definition, adaptation is clearly required for generalisation, as evidenced by the near-random performance of SUBGRAPHS in the zero-shot setting, and the aggressive hyperparameters required (see Appendix G.1.

Table 3 provides F1 scores for PROTOMAML on each class. All-in-all, the highest achieved MCC was 0.1709, for PROTOMAML at $k = 8$, corresponding to an F1-Fake of 0.1841. While low relative to other F1 scores reported, this should be compared to a class prevalence of 5%.

Relative to random performance, the greatest negative outlier is TwitterHateSpeech's majority class, 'None'. One possible explanation is the homophily pattern of TwitterHateSpeech (see Appendix F). Whereas racist and sexist tweets are primarily homophilic in the query set, a large proportion of innocuous tweets are highly *heterophilic*; i.e. these are contextualised by users predominantly authoring racist or sexist. The model is therefore more likely to err on those innocuous tweets, as their author shows a proclivity towards hate speech. Here, heterophily serves as noise. This is most likely an artefact of Waseem and Hovy's data collection process, with prolific racist and sexist authors serving as the anchor around which the rest of the graph is built.

In general, the results here do not correlate with those found in Table 2. Underperformers there show relatively better performance after adaptation to the other datasets. Hinting at overfitting to the GossipCop graph, this aligns with the line of argumentation presented in the introduction: performance on a single, static graph is not indicative of generalisation to emerging malicious content.

5.4 Ablating GossipCop Pre-Training

To test the effect of GossipCop pre-training on generalisation to other datasets, we ablate PROTOMAML's pre-trained weights, and repeat the evaluation under re-initialised weights. A comparison in terms of MCC is provided in Table 4. On CoAID, PROTOMAML outperforms PROTOMAML-RESET at all k-shot values. On TwitterHateSpeech, this only happens at the larger k-shot values, with PROTOMAML's MCC performance increase outpacing its RESET counterpart.

While low, comparing the performance on each class individually (Tables 3 and 15), PROTOMAML

k	CoAID		TwitterHateSpeech		
	Real	Fake	Racist	Sexist	None
4	0.7734	0.1762	0.1763	0.2181	0.3585
8	0.8245	0.1841	0.1934	0.2148	0.3530
12	0.8245	0.1732	0.2545	0.2554	0.3503
16	0.8321	0.1599	0.3021	0.3077	0.3163
B	0.6545	0.0955	0.1932	0.2799	0.5784

Table 3: F1 scores achieved by PROTOMAML during generalisation to the auxiliary datasets. Row B provides F1 scores for a random classifier (Flach and Kull, 2015). This table is complemented by Appendix G.

k	CoAID		TwitterHateSpeech	
	Trained	Reset	Trained	Reset
4	0.1383	0.1191	0.0607	0.0767
8	0.1709	0.1398	0.0699	0.0868
12	0.1689	0.1304	0.1109	0.1025
16	0.1646	0.1212	0.1354	0.1052
B	0.0000	0.0000	0.0000	0.0000

Table 4: MCC scores achieved by PROTOMAML (Trained) and PROTOMAML-RESET (Reset) during generalisation to the auxiliary datasets. This table is complemented by Appendix G.3.

is able to increase its performance on all classes simultaneously, whereas PROTOMAML-RESET only does so for the racist class, degrading performance on sexist and innocuous documents.

Regardless, the fact that a model trained specifically with generalisation in mind is barely able to outperform one with random weights is striking, and speaks to the inadequacy of GossipCop as an evaluation dataset. Furthermore, near perfect performance on unseen nodes of the pre-training graph does not imply inductive generalisation to new graphs.

6 Conclusion

This paper proposes a more realistic evaluation setup for community models on malicious content detection. We highlight several properties of evolving social graphs that are especially neglected: expensive labelling, limited context, and emerging content and users. Experiments verified our motivation, with performance on a single, static dataset in a transductive manner bearing little resemblance to performance during few-shot inductive generalisation.

Our proposed few-shot subgraph sampling approach presented in Section 4.2 is tailored to social media graphs and allows generalisation of community models to new networks, domains, and tasks. While standard community models performed poorly, incorporating our sampling procedure in graph meta-learners aided generalisation. Particularly promising are models with prototypical initialisation.

Ultimately, our results suggest that malicious content detection using community models is not 'solved', despite some models achieving near perfect evaluation scores. Current evaluation procedures neglect critical properties of malicious content, and models tested under these conditions will not prove useful in realistic deployment settings. This is a regrettable consequence, considering the high-stakes nature of malicious content detection. Much like the trend occurring in the content-only malicious content detection literature (see Section 2.2), we hope this work will lead to similar follow-up work for community models.

An open problem, warranting further investigation, is the application of meta-learning to class imbalanced datasets. Common to malicious content detection, class imbalance imposes a severe penalty on meta-learners that reset their classification heads.

7 Limitations

While we took care to increase the diversity of the training data (user-centred sampling, distributing the labels, adding dropout throughout models), ultimately, the diversity is limited by the underlying graph dataset. GossipCop is large, but it contains only a single task and a relatively uniform structure. Ideally, multiple, distinct graph datasets would be used in meta-training. However, few such datasets are available. For meta-learning, task diversity might be a critical factor in 'learning-to-learn', analogous to data diversity being critical in standard machine-learning setups. As such, our meta-learners are likely operating below capacity.

Phan et al. (2023) made the conclusion that no common benchmarks for community models of malicious content are currently in use. This work, despite making a step towards more realistic evaluation of such models, does not improve this situation. The presented performance metrics are in line with related work, but meaningful comparison will only be possible with the publication and adoption of open-access benchmark datasets. This seems an unrealistic short-term aspiration at the time of writing.

8 Ethical Considerations

Following the work of Mishra et al. (2021), we take some steps to ensure that our experimental setup addresses the ethical considerations that may arise when modelling users and communities. The authors highlight the following three considerations that apply to our work:

- *Personal vs. Population-level trends*, i.e., are generalisations being made from personal traits to population-level trends
- *Bias in datasets*, i.e., is there demographic, comment distribution, or label bias in the dataset(s) being used?
- *Purpose*, i.e., is the purpose of the modelling being done to classify content as malicious or users and communities too?

In order to tackle the *comment distribution* bias whereby the majority of documents may belong to a small number of users, we remove users with more than a certain number of documents from the dataset (where possible). Furthermore, to counter the *label distribution* bias where we only pick documents of a particular class from a specific user, we do user-centred sampling, incorporating the entire neighbourhood of a user in the user-document graph. We initialise all users to the same zero-embedding, ensuring that we do not generalise personal traits to population-level trends. Lastly, in our work, we solely leverage the user-document graph to be able to better classify the documents, not the users themselves as malicious, hence having a clear purpose to advance malicious content detection.

Table 5: A series of headlines taken from the NELA-GT corpora. All articles come from around Oct. 15th in their respective year.

Rumour Status	Anchor	Near	Far
True	It's been 10 years since Heath Ledger died of an accidental drug overdose. Since	Who cut the head off of the General Pickens statue and what is going on in the Cooper	When Pretty Little Liars and Teen Wolf collide we get Truth or Dare. Well, not really,
Fake	A man reportedly got his finger bitten off at a Beyoncé concert! The shocking twist: It wasn't	A white witch from North London has urged Hollywood star Angelina Jolie to cease	Is Cher concerned Chaz Bono will die from his weight issues? That's the claim from

Table 6: A similar set of snippets taken from the GossipCop dataset. The left column provides an anchor document, the middle another document near the anchor, and the right column a document far away from the anchor.

A Motivating Examples

DISCLAIMER: the chosen examples were taken verbatim from various malicious content corpora. They do not reflect the views of the authors.

As established in Section 1, malicious content and its social context evolves. This can happen quickly, and results in text that is very different from already seen forms of malicious content.

Table 5 shows such change, depicting titles from articles published by low (i.e. those that often publish severely biased or false news) and high credibility news sources, as found in the NELA-GT corpora (Horne, 2019; Horne and Gruppi, 2021, 2023).

Current models are adept at filtering out malicious content as in their training datasets, but quickly degrade when presented with novel content. For example, Table 5 shows substantial high-level semantic change across the years. Models relying on surface-level features will fail as new events spawn new content.

Currently, no existing social-network malicious content dataset captures this level of evolution. In fact, existing datasets are completely static, implicitly assuming the full network (users, content, and their connections) will be available at inference time. This paper argues that this assumption is a significant reason why malicious content continues to propagate unabated, despite the impressive classification scores reported in earlier work.

To showcase this lack of diversity, Table 6 depicts a similar array of texts, sampled from the GossipCop graph. While a variety of topics are discussed, the overarching subject remains the same. Comparatively, relying on surface level features can already lead to strong classification performance. Simply put, in this dataset, models need not account for evolving content.

In lieu of large, temporally diverse graph datasets, we propose an evaluation framework that approximates these effects through generalisation to new graphs. Requiring adaptation from a minimal set of examples, with limited social context will serve as a much better measure of the inference time performance of community models for malicious content detection. There is little point in good within dataset performance, when unseen content forms are free to cause harm.

Put otherwise, when it comes to malicious content detection, we want models that are able to filter out tomorrow's hate speech posts and fake news articles, not those seen yesterday.

B Additional Details on Datasets Used

Rehydrating many years after the datasets were released, not all documents and users could be recovered. This results in empty, missing or isolated documents. The collected graph datasets are thus subgraphs of the one presented in Shu et al. (2019a), Cui and Lee (2020) and Waseem and Hovy (2016). The additional preprocessing steps needed are described here:

1. **Tokenization**: all found documents were collected and tokenized. Any empty documents, or documents yielding only special tokens, were removed
2. **Document-User Interactions**: where possible, user and doc-user interactions were collected. One issue with GossipCop, as identified by Shu et al., is the inclusion of bots. These 'users' tend to disproportionately interact with documents of a single class, both in terms of volume and proportion. Therefore, following the recommendation made by Chandra et al. (2020), users sharing more than 30% of the documents of any class were removed. The type of doc-user interactions in Twitter-HateSpeech differs, resulting in a very small pool of racist users, so this restriction was relaxed. Documents without *any* user interactions, were also removed.
3. **User-user Interactions**: all remaining users and their interaction with other users were parsed at this point. To further reduce the number of bots, the top 1% most active users were removed on GossipCop. Then, again only on GossipCop, to further sparsify the graph, only the top 30k users were kept. Isolated documents were once again removed.

The effect of each filtering step and additional statistics of the dataset graph prior to generating episodic subgraphs, are presented in Table 7.

C Additional Information on Few-shot Subgraph Sampling

Algorithm 1 presents the few-shot subgraph sampling pseudocode. Although the models used can only aggregate information from at most an $r = 2$ radius subgraph, the initial graph can be expanded to larger r. This is to ensure at least k-shot examples of each label is present. For the used graph $r = 5$ usually contains the vast majority of the graph, and would only be needed for extremely sparse areas. In practise, however, the k-shot was achieved by $r = 3$ in all situations.

The random walk subsampling dramatically reduces the number of nodes and edges present in the subgraph. A similar strategy was employed by GraphSAINT (Zeng et al., 2020), resulting in efficiency improvements for a variety of inductive graph learners. We set our random walk length to 5 for all experiments, preferring fewer document nodes (with smaller walk length requiring more roots to get to the same node budget). An approximate budget of 2048 was used during training and evaluation.

Important statistic on the produced subgraphs, for both the support and query sets, are presented in Tables 8 and 9.

D Hyperparameters

D.1 GossipCop Training

The set of hyperparameters used for pre-training meta-learners on GossipCop are presented in Table 10. The model size was left constant. Input dimensions were determined by RoBERTa, and set to 768. The GAT attention heads, 3, used an internal dimensionality of 256, and all heads were concatenated afterwards. After GAT processing, representations were fed through a two layer ReLU activated MLP of dimensionality 64, before being classified.

All other hyperparameters were tuned on the validation graphs generated by inductive stratified 5-fold cross validation. Dropout was applied on the internal hidden dimensions. Dropout was applied node-wise on the initial node embeddings, stochastically setting entire nodes to 0. In our case specifically, this essentially means converting documents into users. Attention dropout was applied to the attention weights produced by the GAT layers (Equation 2). Alternatively, we also experimented with *node masking*, but we did not see a big difference in performance. (Mishra et al., 2020) AdamW (Kingma and Ba, 2017; Loshchilov and Hutter, 2019) was the outer-loop optimizer, with only the learning and weight decay terms tuned. The different algorithms required substantially different numbers of gradient update before convergence. Early stopping was used, with patience equal to 10% of the maximum allowed number of steps. Most checkpoints converged well before that

point. The learning rate was decayed in a stepwise manner, every 5% of the maximum number of steps, with a minimum learning rate at 0.01 of the initial value.

The inner-loop learning rate saw more variation between the different learning algorithms. MAML-LH performs best under minimal adaptation, yielding a single step inner loop with a low learning rate. Resetting the head in each episode, instead, forces adaptation, reflected in a larger, more aggressive inner loop. PROTOMAML, finally, reaches minimum validation loss only with large amounts of inner-loop adaptation.

During generalisation to unseen graphs, a more aggressive adaptation strategy was applied to most models. This was not tuned on the test set. Instead, the highest values possible were, such that no infinities appeared in the output logits.

D.2 Additional Training Details

All experiments were conducted on a Linux-based SLURM-based academic cluster. Nodes consisted of am Intel Xeon Platinum 8360Y CPU with 18 cores in user at 2.4 GHz, a single NVIDIA A100 GPU accelerator (yielding 40 GiB of HMB2 memory) and 128 GiB of DDR4 memory. The code is written exclusively using Python 3.10.6, PyTorch 1.13.0, built with CUDA 11.7. Graph modelling utilized PyTorch Geometric 2.3.0. All experiments were conducted under random seed 942. For local development we use Ubuntu 20.04.6 LTS (GNU/Linux 5.15.90.1-microsoft-standard-WSL2 x86_64).

E Comparing MAML-LH & MAML-RH

As originally described in Finn et al. (2017), MAML resets its classification head each episode in order to adapt to a new task with new labels. However, in our case, pre-training MAML uses only a single task, with a fixed label definition. Therefore, the classification head can be learned in the outer loop along with the other meta-initialized models. This setting we dubbed MAML-LH (learned head), and has the benefit of requiring

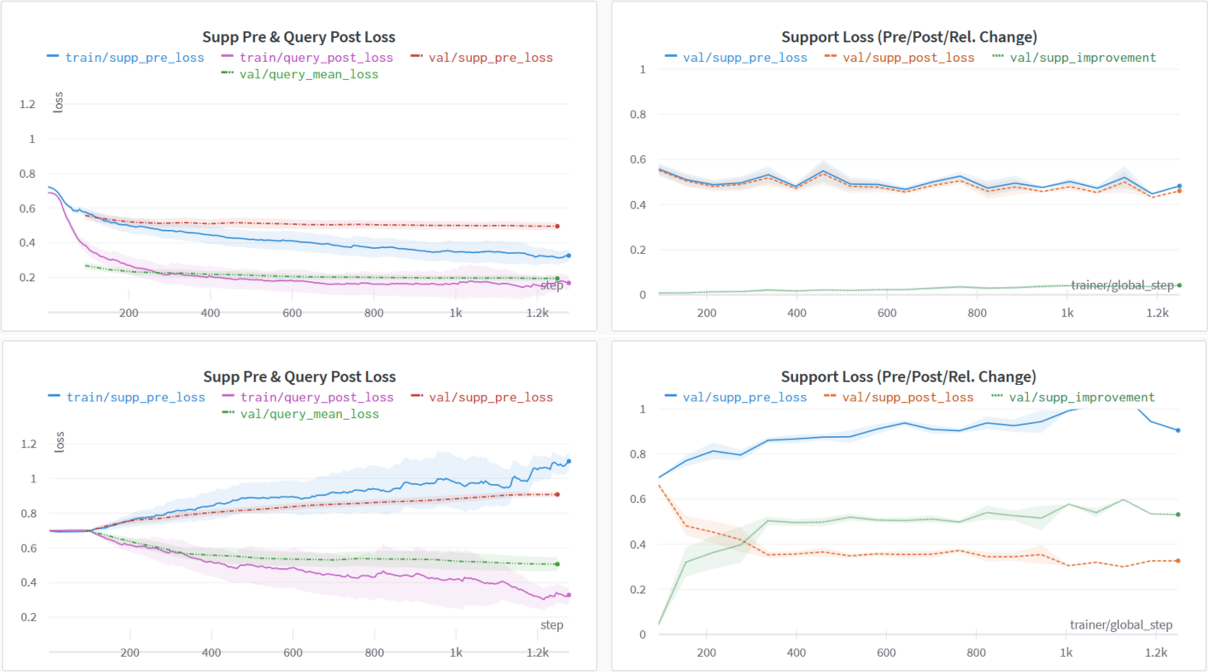

Figure 3: GossipCop training losses for (t) MAML-LH and (b) MAML-RH. The left column gives loss of the models on the support and query sets. Support loss is computed prior to the first adaptation step (blue and dashed orange lines), query loss after the last adaptation step (pink and dashed green lines). The left column provides the support loss prior to the first adaptation step (blue line) and after the last adaptation step (orange line). Finally, the green line gives the relative improvement of the support set loss.

less inner-loop adaptation; at least the classifier head is already task-specific. The standard MAML setup we dubbed MAML-RH (random head).

On GossipCop, at least, this had a dramatic effect on the degree of adaptation, and as a result, on the final performance scores. This can be seen in Figure 3, with the top row of figures giving various losses for MAML-LH, and the bottom row for MAML-RH. The left column of figures present the loss on the support set (prior to adaptation), along with the loss on the query set (post adaptation), on both the train and validation splits. MAML-LH acts like a standard machine learnig model. After random performance initially, train loss decreases steadily on both graphs, whereas validation loss stagnates earlier on. The query loss is lower, but as we're using foMAML with a disjoint support–query split this is to be expected (the model is never directly optimised on the support graphs). MAML-RH, on the other hand, shows rapid divergence in the support loss, while the support loss decreases as usual.

These loss patterns indicate a distinction between the two operating modes of MAML trained models. MAML-LH, seeing a stable learning objective, learns to initialise using representations optimal to all tasks. In the meta-learning literature this corresponds to 'feature reuse', and makes MAML-LH similar to the ANIL (Raghu et al., 2020) MAML variant. MAML-RH, on the other hand, has to leverage the support set to rapdily adapt in order to achieve non-random performance on the query set. Its initial weights are not usable for representation learning, but rather for optimizing itself into a representation learner. This phenomenon is called 'rapid learning'. This make MAML-RH more reminiscent of 'true' MAML, or the BOIL variant (Oh et al., 2021).

This is made more clear in the right column of Figure 3. Here the support loss before and after adaptation is shown, with a green line also indicating the relative decrease. For MAML-LH, there is barely any difference between the two, but the overall line is already relatively low; it simply does not need to adapt to achieve generalisble representations. MAML-RH, again, is a polar opposite, with diverging initial support loss, but a much lower final loss. The relative improvement is indicative of a model that 'learns-to-learn'.

In order to test which meta-learning property is more important for the task at hand, both were trained and applied. While MAML-LH clearly showed itself superior on GossipCop, we initially thought that added bias toward rapid adaptation might aid generalisation with MAML-RH.

F Homophily

Graph homophily is the property of nodes to prefer attaching to similar nodes. In social network users, where interaction usually denotes some form of kinship, this follows naturally from people's social relationships. In malicious content detection, this is likely a relevant feature as well. Our perception of real and fake news is influenced by our social network neighbourhood, and propagation usually occurs in homophilic settings (Sun et al., 2022).

The effect of homophily on GNN performance remains an open question. In a homophilic setting, node representations will be built from nodes of the same class, whereas in heterophilic settings, node representations contains representations of nodes of different classes. A third setting, less explored, is the case of randomness: nodes are just as likely to attach to nodes of a different class as its own. Zhu et al. (2020) define a homophily metric that measures the global propensity of links between similar nodes. They show that GNNs can fail in heterophilic settings, with an MLP being more effective, despite the graph setting. For a graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, they define homophily as,

$$h^{(\text{edge})} = \frac{|\{(u,v)|(u,v) \in \mathcal{E} \vee y_u = y_v\}|}{|\mathcal{E}|}, \quad (8)$$

i.e., the ratio of edges from nodes to similarly labelled nodes, to all edges.

Later papers dispute the claim that GNNs cannot perform under heterophily. Ma et al. (2021) find that GNNs require certain conditions to be met for class separation (used as a proxy for classification performance). Specifically, they indicate that as long as nodes of the same label share similar neighbourhood patterns, node representations will become more similar, despite dissimilar neighbouring nodes.

Lim et al. (2021) take issue with the definition of the homophily metric. Graphs with many node labels will naturally be less homophilic. They propose a metric that measures homophily while correcting for a randomly connected null model where nodes. Extending to neighbourhoods of radius r,

$$\begin{aligned} h_r^{(\text{class insen.})} &= \frac{1}{|C|-1} \sum_{c=1}^{|C|} \lfloor h_c^{(\text{neigh.})} - p_c \rfloor_+, \quad (9) \\ h_{r,c}^{(\text{neigh.})} &= \frac{\sum_{v \in \mathcal{V}_c} |\{u|\mathcal{N}_r(v) \wedge y_u = y_v\}|}{\sum_{v \in \mathcal{V}_c} |\{u|\mathcal{N}_r(v)\}|}, \\ p_c &= \frac{|\mathcal{V}_c|}{|\mathcal{V}|}. \end{aligned}$$

It may be interpreted as measuring the expected *excess* homophily present in neighbourhoods about nodes of class c.

The proposed metrics for measuring homophily summarize whole graphs, make no distinction between user or document nodes, and do differentiate between a randomly connected graph or a heterophilic graph. In the proposed method of this paper, a homophily metric must be comparable across many subgraphs. As such, inspired by the measure of assortativity, introduced by Newman (2003), we slightly modify the homophily definition as,

$$\begin{aligned} \hat{h}_{r,c}^{(\text{subgraph})} &= \frac{1}{|\mathcal{V}_c|} \sum_{v \in \mathcal{V}_c} \frac{h_{r,c}^{(\text{neigh.})}(v) - p_c}{1 - p_c}, \quad (10) \\ h_{r,c}^{(\text{neigh.})}(v) &= \frac{|\{u|\mathcal{N}_r^{(\text{docs})}(v) \wedge y_u = y_v\}|}{|\{u|\mathcal{N}_r^{(\text{docs})}(v)\}|}. \end{aligned}$$

For a subgraph, it defines the homophily of class c as the expected ratio of homophilic nodes in the r radius neighbourhood of nodes $v \in \mathcal{V}_c$, in excess of a random graph. The use of a neighbourhood to compute $h_{r,c}^{(\text{neigh.})}$ is deliberate. It can now measure the effect of other document nodes on the representation of the centre node. The division by $1 - p_c$ normalizes the excess: a score of 1 is achieved only if fully homophilic, 0 if random, and $-\frac{p_c}{1-p_c}$ if perfectly heterophilic. This allows for interpreting homophily on a scale.

More important, Equation 10 is applicable for support graphs (which have multiple nodes of each label), and query graphs (which have a single node from a single label). For the support graph, nodes' homophily scores are averaged, per class, to produce a single summary statistic. For the query graphs, the non-labelled nodes scores are simply omitted.

Rather than presenting a single summary metric, the distribution of homophilic nodes can be observed for sampled subgraphs. This is presented

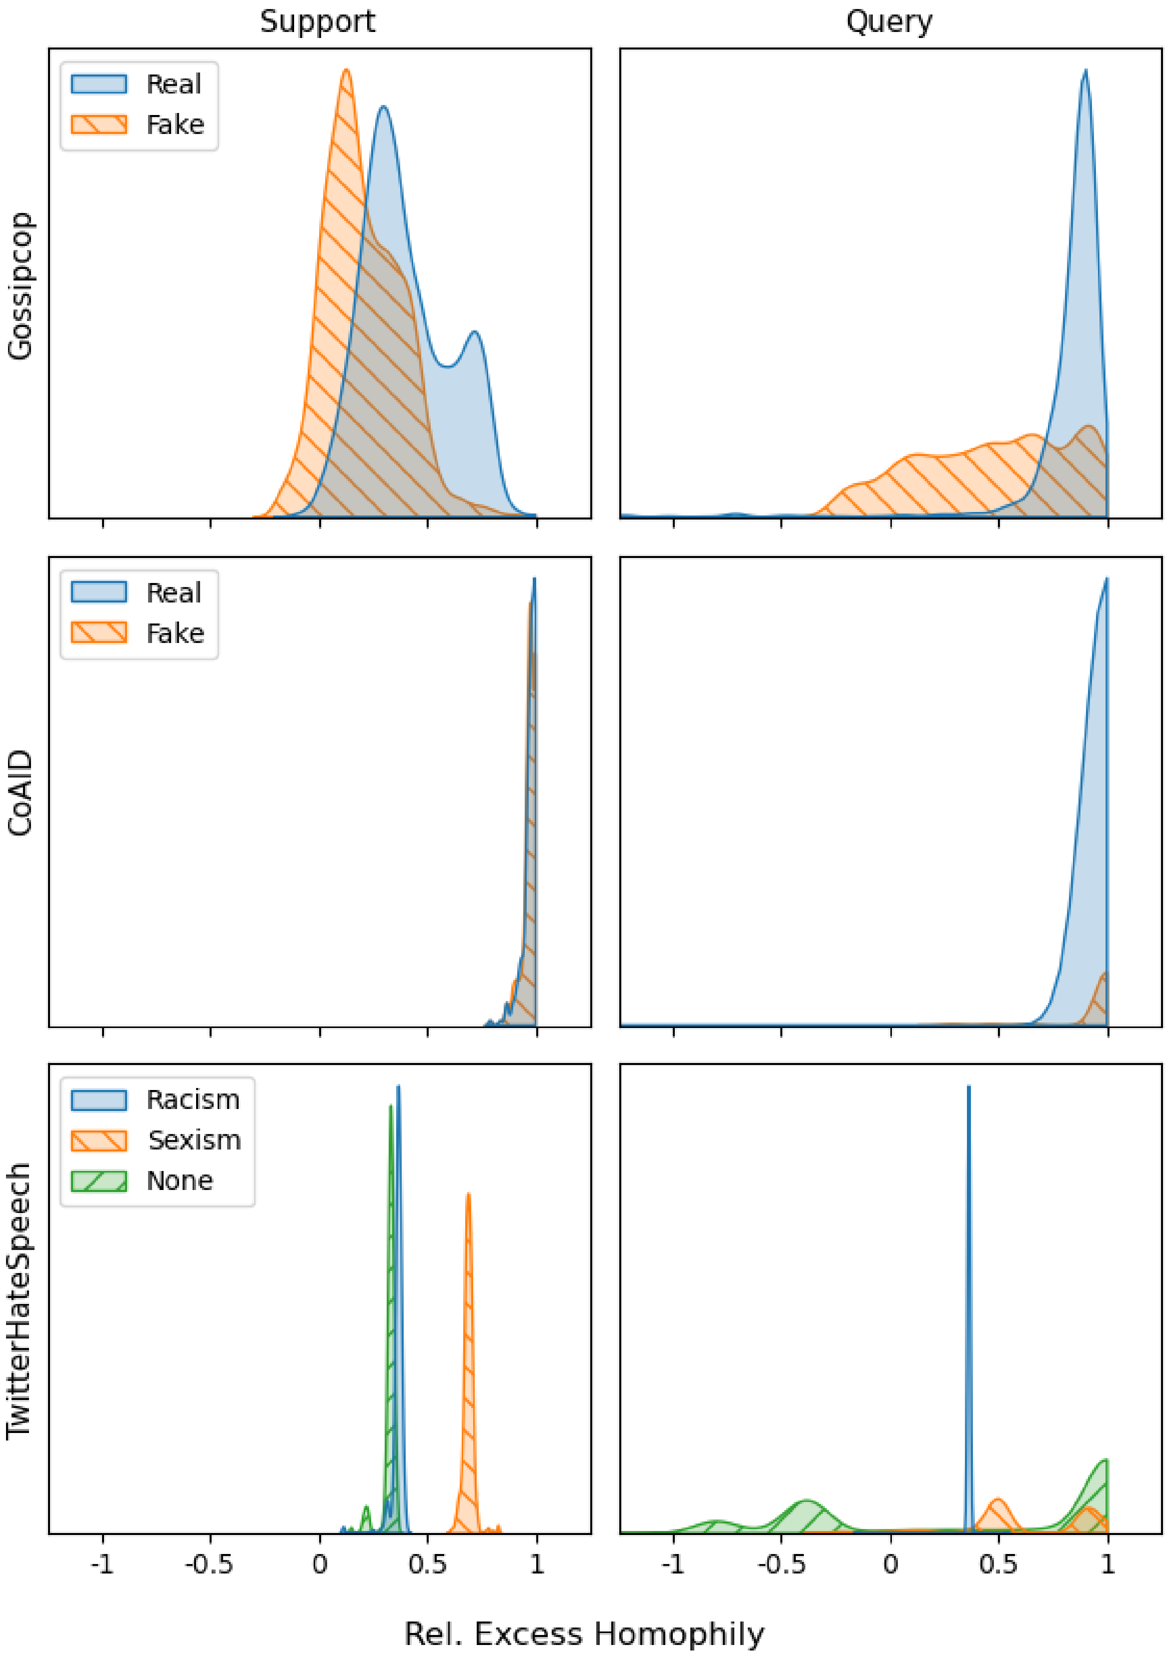

Figure 4: Kernel density estimates for the distribution of relative excess homophily (Equation 10) for sampled subgraphs. The left column present user-centred sampled graphs, the right column gives the r-radius neighbourhoods about document nodes from the query graph. The different rows give different datasets. On the x-axis, 0 corresponds to a random graph, 1 to a perfectly homophilic graph. Values below 0 indicate heterophily.

in Figure 4. The left column presents the distribution of homophily scores for support graphs, right the query graphs. The rows present the different datasets.

For GossipCop, the support graphs show a relatively broad distribution of homophily scores, with modes between the 0-0.5 range. The query graph, however, shows a significant difference between the two classes, with the real documents being highly homophilic, and fake less so. In other words, there are fake documents whose neighbourhood consists primarily of real documents. CoAID shows more consistent behaviour, with both node classes being extremely homophilic.

TwitterHateSpeech is somewhat of an outlier, with substantial differences between the classes. Again, the collection procedure used by Waseem and Hovy led to a small number of extremely active, racist users. Furthermore, user-document links represent authorship, not tweet/re-tweet interactions. As a result, document representations are built up entirely out of the *other* posts by the same user. As a result, the racist class has a narrow distribution, that indicates slight homophily. The innocuous class, 'None', gives a bimodal distribution in the query graphs. Many innocuous documents seem to be produced by regular Twitter users, whereas a large portion come from racist and sexist users (a large bump in the heterophilic range). Only the sexist class seems to be consistently homophilic. As a result, this dataset is relatively noisy, with representations being influenced by dissimilar documents.

G Extended Generalisation Results

G.1 CoAID

The results presented in Figure 2 are presented in tabular form in Tables 11 and 12. Since CoAID matches, approximately, the pre-training task used in GossipCop, models were initially adaptated using the same classification head (in case of SUBGRAPHS and MAML-LH) and inner-loop learning parameters. This corresponds to the low-adaptation setting, presented in Table 11. This setting estimates direct domain transfer, much like testing the Subgraphs model at $k = 0$. Performance proved disappointing for most models, with the most aggressive adapter (PROTOMAML), clearly exceeding all other tested models.

Therefore, we conducted a second round of experiments with similarly aggressive inner-loop learning, presented in Table 12. The only models exempted, were SUBGRAPHS at $k = 0$ and the PROTONET, as neither adapts. All models benefited from the more aggressive inner loop, indicating that the generalisation is not trivial. All-in-all, the highest achieved MCC was 0.1709, for PROTOMAML at $k = 8$, corresponding to an F1-Fake of 0.1841. While low relative to other F1 scores reported, this should be compared to a class prevalence of 5%.

G.2 TwitterHateSpeech

Similarly, the TwitterHateSpeech results presented in Figure 2 are presented in tabular form in Table 13. Having learnt from CoAID, only the high-adaptation hyperparameters were used. Lower k-shot values see the 'None' class dominate in terms of classification scores. Performance on the minority classes increased with larger k-shot values, at the cost of reduced innocuous tweet performance. Ultimately, ProtoMAML manages this trade-off best, with gradually increasing MCC scores.

G.3 Ablating GossipCop Pre-Training

Tables 14 and 15 show additional results pertaining to the ablation experiment described in Section 5.4. The largest addition, is the inclusion of the other type of GBML algorithm, MAML. The comparison model used is MAML-RH.

On CoAID, MAML-RESET yields 'always positive' models, giving constant MCC scores of 0. ProtoMAML, however, proves reasonably robust, with PROTOMAML-RESET performance that exceeds trained MAML-RH. The same effect also holds on TwitterHateSpeech, with PROTOMAML only overcoming its reset counterpart in the larger k-shot settings.

G.4 Extreme k-shot

To test the capacity of the meta-learners, a limited extension of the TwitterHateSpeech experiment was conducted. Instead of limiting ourselves to $k = 16$ examples, we increased to $k = 256$. Only PROTONET was used. Results are depicted graphically in Figure 5 and given numerically in Table 16.

We fully expect diminishing returns. Our graph setting implies that the k labelled nodes are already present in the support graph, just with its label masked. Unmasking additional labels should provide little additional information to the model; a good graph learner can already infer the masked labels. In fact, as discussed in Section 5.3, under

heterophily, one might expect the additional labels to provide additional noise for the innocuous class.

Precisely this can be observed in Table 16. While the MCC score does increase steadily, it comes at the cost of reduced F1 in the ‘None’ class, and stagnation in the ‘Racism’ class. The only class that sees improvements at very high k-shot values, is the homophilic ‘Sexist’ class.

Citation: A Key to Building Responsible and Accountable Large Language Models

Jie Huang **Kevin Chen-Chuan Chang**
Department of Computer Science, University of Illinois at Urbana-Champaign
`{jeffhj, kcchang}@illinois.edu`

Abstract

Large Language Models (LLMs) bring transformative benefits alongside unique challenges, including intellectual property (IP) and ethical concerns. This position paper explores a novel angle to mitigate these risks, drawing parallels between LLMs and established web systems. We identify "citation"—the acknowledgement or reference to a source or evidence—as a crucial yet missing component in LLMs. Incorporating citation could enhance content transparency and verifiability, thereby confronting the IP and ethical issues in the deployment of LLMs. We further propose that a comprehensive citation mechanism for LLMs should account for both non-parametric and parametric content. Despite the complexity of implementing such a citation mechanism, along with the potential pitfalls, we advocate for its development. Building on this foundation, we outline several research problems in this area, aiming to guide future explorations towards building more responsible and accountable LLMs.

1 Introduction

The landscape of artificial intelligence is undergoing rapid transformation, spurred by the emergence of large language models (LLMs) such as ChatGPT/GPT-4 (OpenAI, 2022, 2023). These models, recognized for their striking ability to generate human-like text, have shown enormous potential in various applications, from information provision to personalized assistance. Nonetheless, their capabilities bring along substantial risks, including intellectual property (IP) and ethical concerns (Carlini et al., 2021, 2023; Huang et al., 2022; Shao et al., 2024; Li et al., 2023; Lee et al., 2023; Frye, 2022; Chesterman, 2023; Bender et al., 2021; Brown et al., 2022; El-Mhamdi et al., 2022).

Research by Carlini et al. (2021); Huang et al. (2022), for instance, reveals that LLMs are prone to memorizing extensive segments of their training data, including sensitive information. This can result in violations of IP and ethical guidelines. Furthermore, studies by El-Mhamdi et al. (2022); Brown et al. (2022) suggest that current protective measures fail to provide a comprehensive and meaningful notion of safety for LLMs, making it seemingly impossible to develop safety-preserving, high-accuracy large language models even when trained on public corpora.

While the notion of building an entirely safe LLM might appear daunting, it is crucial to acknowledge that many well-established systems, such as the Web, grapple with similar challenges and have not yet reached absolute safety. Recent legislation like the Online News Act[1], which requires online search engines to compensate Canadian online news outlets for their content, underscores the ongoing issues around content use and compensation on the Web. Furthermore, the Web continues to be a breeding ground for both sensitive information and misinformation. Hence, expecting a completely risk-free LLM may be an overask. Instead, our focus should be on accurately quantifying these risks and developing effective mitigation strategies. It is not about achieving absolute security, but about responsibly managing and minimizing risks in an ethically sound manner.

Guided by these insights, we propose to examine the problem through a different lens: *Can we draw parallels between the risks inherent to LLMs and those experienced by established systems such as search engines and the Web? Can we devise strategies to decrease these risks by aligning with the practices of these mature systems?*

In examining systems like the Web and search engines, we observe a common and robust practice employed to manage IP and ethical concerns: the use of "citations". Broadly defined, a "citation" refers to the act of mentioning or referencing a

---

Findings of the Association for Computational Linguistics: NAACL 2024, pages 464–473
June 16-21, 2024

source or piece of evidence. For example, search engine results also serve as a form of citation, with each entry typically consisting of a title, URL, and brief description. These components collectively cite the webpage's content, offering the user an overview and inviting them to explore the source in greater depth. Citations thus act as anchors for accountability and credit in these systems, providing traceability, preventing plagiarism, and ensuring credit is correctly attributed. They also contribute to transparency, allowing users to verify the information's source.

Upon reflection, it becomes clear that LLMs lack this critical functionality. When LLMs generate content without citations, their output is perceived as independent and self-derived. This creates two significant issues: firstly, when the model produces valuable information, it fails to credit the source it relies on; secondly, when it generates harmful content, it becomes challenging to assign accountability. Incorporating the ability to cite could not only address these ethical and legal conundrums but also bolster the transparency, credibility, and overall integrity of the content generated by LLMs.

However, implementing a "citation" mechanism in LLMs is not as straightforward as it might seem. Unlike the Web, which explicitly links and references sources, LLMs internalize the information and transform it into hidden representations, making accurate citation a significant technical challenge. Although some strides have been made in this direction, as seen in systems like New Bing[2] and Perplexity AI[3], they fall short on several fronts. First, the citations provided in the response of existing systems are often inaccurate (Liu et al., 2023; Gao et al., 2023). Moreover, these systems typically only cite *non-parametric* content, i.e., content directly retrieved from external sources such as the Web. However, they neglect *parametric* content, the knowledge embedded in the model parameters, which also needs appropriate credit attribution and consideration for potential harm.

This position paper embarks on an exploratory journey into the potential of integrating a citation mechanism within large language models, examining its prospective benefits, the inherent technical obstacles, and foreseeable pitfalls. We delve into approaches to cite both non-parametric and parametric content, considering the unique characteristics of each type. We also identify and discuss potential setbacks, such as reduced creativity, dissemination of sensitive information, and citation bias. Building on this foundation, we lay bare the hurdles in our path, presenting them as enticing problems for future research. Through this endeavor, we aim to stimulate further discussion and research towards building responsible and accountable large language models.

2 Overview of Large Language Models

Large language models are typically built on the foundation of transformer architectures (Vaswani et al., 2017). The training process of LLMs usually involves self-supervised learning on vast quantities of text data, including books, articles, and internet content, primarily sourced from the Web. During this stage, models are exposed to diverse textual data, allowing them to learn grammar, facts (Petroni et al., 2019), and even reasoning abilities (Wei et al., 2022; Huang and Chang, 2023).

Following the initial training, models may undergo further training on smaller, labeled datasets. For instance, ChatGPT (OpenAI, 2022), a prominent LLM, is fine-tuned on a carefully curated dataset consisting of demonstrations and comparisons, which help the model learn how to generate appropriate responses in conversational contexts.

Risks in LLMs. While LLMs offer numerous benefits, they also pose significant risks (Carlini et al., 2021; Huang et al., 2022; Li et al., 2023; El-Mhamdi et al., 2022; Guo et al., 2022). El-Mhamdi et al. (2022) highlight these risks, concluding that it is fundamentally impossible to develop safety-preserving, high-accuracy LLMs due to the fundamental intrinsic impossibility of the foundation model learning problem. As they summarized, LLMs achieve optimal performance by employing high-dimensional interpolation, necessitating vast quantities of user-generated data. However, language data from genuine users is intrinsically diverse, with significant variations in individual preferences and styles. This results in empirical heterogeneity, which in turn contributes to the vulnerability of LLMs, particularly when handling sensitive data or encountering fabricated information from fake accounts.

3 "Citation" in LLMs

As discussed in the introduction, expecting a risk-free LLM may be an over-ask. The key lies in

---

[3] `https://www.perplexity.ai`

LLMs memorize a lot of training data.	LLMs memorize a lot of training data [1].
Women are better suited for caregiving roles than men.	According to [1], women are better suited for caregiving roles than men.

Figure 1: Examples without (left) and with (right) citations. In the first case, citations serve as a way to appropriately credit authors. In the second case, citing the original source of a biased statement ensures that the bias is not misconstrued as the model's opinion.

responsibly managing and minimizing risks in an ethically sound manner. By drawing a comparison between LLMs and the Web, we find that "citation" is a key missing component in LLMs.

Figure 1 illustrates model generations with and without citations. In the absence of a citation, there is a potential risk of misunderstanding, leading one to believe that the claim is an opinion or statement formulated by the LLM itself. This not only fails to appropriately credit the original authors, but could also result in ethical dilemmas if the claim is inaccurate or misrepresented.

On the other hand, the inclusion of citations can act as a multifaceted solution to these concerns. Primarily, it helps to mitigate intellectual property and ethical disputes by signaling that the information is not a product of the LLM's "opinion", but a reflection of the cited source. Additionally, citations would enhance the transparency and verifiability of the LLM's output. By indicating the source from which the information is derived, they provide a clear pathway for users to independently verify the validity and context of the information.[4]

4 RoadMap

In this section, we embark on exploring the potential of incorporating a "citation" mechanism within LLMs. We start our exploration by defining when it would be ideal for an LLM to provide a citation, drawing insights from established practices in academia and existing systems like search engines and the Web. We then delve into discussing the possible strategies for effectively implementing citations in LLMs, confronting the methodological and technical intricacies this endeavor involves.

4.1 When to Cite?

In academic or professional writing, a citation is typically required when using someone else's ideas, concepts, data, or specific language. For LLMs, determining when to provide a citation is a considerably more challenging task. Given the vast and varied range of queries posed to LLMs, it is crucial to establish when a citation would be appropriate or necessary.

A fundamental rule could be that any fact, idea, or concept that is not general knowledge should be cited. This mirrors the existing conventions on the Web, where sources for specific information are typically provided. For instance, widely known facts like "The Earth revolves around the Sun" would not necessitate a citation, while a less well-known fact like "The fastest spinning stars can rotate more than 600 times per second" would warrant one.

Moreover, the need for a citation could also depend on the nature of the task LLMs are performing. Certain tasks may not necessitate citations, particularly if the output is a reformulation or reinterpretation of the input. For example, in summarization tasks, LLMs condense the input data without introducing new information. The resultant summary is hence an interpretation of the input, and typically, a citation may not be needed for such tasks. Similarly, translation tasks involve converting content from one language to another, without the introduction of novel information.

In essence, while the need for citations in LLMs is task-dependent and context-specific, the guiding principles should be the commitment to knowledge integrity, respect for intellectual property, and adherence to ethical norms. These are similar principles that guide the management of intellectual property and ethical concerns on the Web and in search engines.

4.2 How to Cite?

Incorporating citations in LLMs ideally involves connecting outputs to the original source of information. However, this presents a notable technical challenge. During LLMs' training, information is transformed into hidden representations, unlike search engines which possess indices to track and retrieve information. In the case of LLMs, this index is absent, which makes referencing the original source a daunting task. In this section, we delve into the consideration of citations for both

---

[4] However, citation may also lead to certain potential pitfalls; please refer to Section 5 and Section 6 for more details.

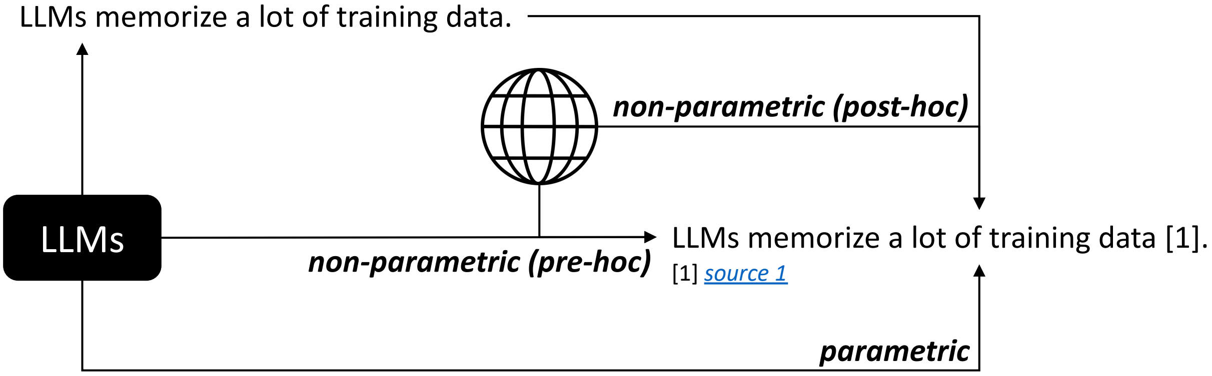

Figure 2: *Non-parametric* and *parametric* citations.

non-parametric and *parametric* content (Figure 2).

4.2.1 Citation for *non-parametric* content

As a potential solution to prevailing challenges, one could design a hybrid system that merges large language models with information retrieval (IR) systems. In this approach, the model is trained to discern when a citation might be required. Subsequently, the IR system is utilized to retrieve relevant sources, namely, *non-parametric* content. The LLM can then incorporate these sources into its responses as citations. We identify two strategies for citing non-parametric content:

- ***Pre-hoc citation***: This approach involves first identifying the need for a citation in the upcoming dialogue or content generation. Once this requirement is recognized, the LLM triggers the IR system to retrieve the necessary information. The LLM then generates its response, seamlessly incorporating the retrieved non-parametric content as citations. This technique can be associated with the broader body of research that augments language models with retrieval (Guu et al., 2020; Lewis et al., 2020; Izacard and Grave, 2021; Borgeaud et al., 2022; Izacard et al., 2022; Shi et al., 2023; Wang et al., 2023; Menick et al., 2022; Huang et al., 2023).
- ***Post-hoc citation***: Conversely, in this strategy, the LLM initially produces a response. An evaluation process then scrutinizes the generated content to ascertain whether a citation is necessary. If a citation is deemed necessary, the IR system is used to locate the appropriate non-parametric content, which is subsequently inserted into the existing text as a citation. Related research includes measuring or requiring attribution in LLMs (Rashkin et al., 2023; Gao et al., 2022; Honovich et al., 2022; Yue et al., 2023; Liu et al., 2023; Gao et al., 2023).

In practical applications, a combination of both *pre-hoc* and *post-hoc* citation methods could be adopted for an optimized method. This mixed approach would employ the initial identification and retrieval of potential citations in line with the *pre-hoc* method, followed by a *post-hoc* evaluation to refine the integration of citations based on the generated content. This blend of proactive retrieval and reactive refinement could facilitate the creation of robust, accurate, and well-supported content, while also mitigating intellectual property and ethical concerns surrounding LLMs.

4.2.2 Citation for *parametric* content

In addition to the *non-parametric* content, i.e., content directly retrieved from external sources such as the Web, *parametric* content, which refers to information internalized from the training data, also needs appropriate credit attribution and consideration for potential harm. However, crafting a citation strategy for *parametric* content presents its own set of unique challenges.

The fundamental challenge is the underlying nature of how LLMs process and internalize information. During training, LLMs assimilate vast amounts of data and transform them into an intricate, high-dimensional space that represents learned patterns and structures. The transformation process, rooted in complex mathematical operations, does not inherently retain any clear mapping back to individual data points in the training set. Consequently, generated content cannot easily be traced back to specific training data (Koh and Liang, 2017; Bae et al., 2022; Park et al., 2023; Grosse et al., 2023).

This situation is further complicated by the fact that an output generated by LLMs is typically influenced by a multitude of training data points, rather than a single source. This is due to the multifaceted and context-sensitive nature of language understanding and generation, where a single output can be influenced by a diverse range of linguistic patterns and structures. Thus, the task of accurately attributing a generated output to specific training data pieces is a complex and multifaceted problem that involves unpacking the high-dimensional representations in the model.

Despite these challenges, potential solutions exist. A conceivable approach involves ***training the model with source identifiers***, essentially tags that link specific pieces of information back to their original sources. During training, the model could then be encouraged to retain these identifiers. This would provide a more transparent lineage of information, thereby enhancing accountability. A relevant attempt in this direction was made by Taylor et al. (2022), which used special reference tokens to wrap citations and trained models to predict these citations. However, it exhibited certain limitations, such as citation inaccuracy and confinement to academic citations. The successful execution of this method would likely call for advancements in model architecture and training techniques, thereby highlighting intriguing directions for future research.

5 Pitfalls of Citation in LLMs

While citations in LLMs can potentially mitigate risks such as IP and ethical issues, as well as improve transparency and verifiability, it is crucial to consider potential pitfalls.

Over-Citation and Sensitive Information Dissemination. The implementation of a citation system in LLMs poses the risk of over-citation, where the excessive use of references might expose more information than necessary. This overexposure could lead to information overload, diluting the significance of critical citations. Moreover, over-citation might inadvertently elevate the risk of disseminating sensitive information (Huang et al., 2022; Shao et al., 2024; Li et al., 2023). An ill-intentioned user could exploit these extensive citations to gather additional sensitive information.

Inaccurate Citations. Another potential pitfall of implementing citations in LLMs is the risk of inaccurate citations (Liu et al., 2023; Gao et al., 2023). Given that LLMs may not possess a deep understanding of the content they are trained on or the sources they are citing, there is a chance that they could incorrectly attribute information to a source that does not actually contain that information. Inaccurate citations could mislead users, causing them to believe that a piece of information is verified and supported by a credible source, when in fact, it is not.

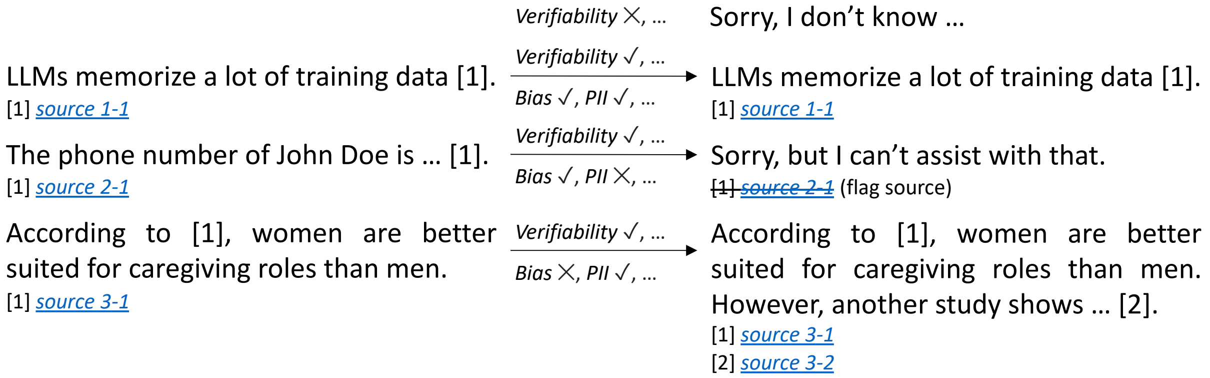
Outdated Citations. With the continuous expansion and evolution of knowledge, there is a risk that the sources an LLM cites may become outdated or irrelevant over time. This is particularly likely in fast-evolving fields where new discoveries or advancements quickly supersede existing knowledge. As LLMs are trained on a fixed dataset, their generated content and the sources they cite may not reflect the most current or accurate information. Therefore, there is a potential for LLMs to propagate outdated knowledge, misleading users who rely on the generated content and the cited sources for information.

Propagation of Misinformation. The risk of propagation of misinformation presents a significant concern in the application of LLMs (Pan et al., 2023). As LLMs generate output based on the data they have been trained on, there is a chance they could inadvertently cite or echo unreliable or misleading sources, thereby spreading misinformation. This problem could potentially be amplified by the addition of a citation mechanism. A misinterpreted or incorrect citation could be perceived as an authoritative endorsement, inadvertently lending credibility to inaccurate or misleading content.

Citation Bias. Implementing citations in LLMs can also lead to citation bias (Jannot et al., 2013; Greenberg, 2009; Bender et al., 2021; Metzler et al., 2021; Shah and Bender, 2022). Models may tend to cite certain types of sources over others, either due to the characteristics of the training data or inherent biases in the retrieval mechanism of the IR system. This could lead to an over-reliance on certain types of information and unintentional promotion of certain viewpoints.

Potential for Diminished Creativity. The integration of citations could inadvertently cause a decrease in the creative outputs of the model. When prompted to generate innovative text or propose creative solutions, LLMs might become over-reliant on existing, citable information, thus stifling their novel content generation.

Legal Implications. The utilization of citations could also bring forth legal implications. The in-



LLMs memorize a lot of training data [1].
[1] source 1-1

The phone number of John Doe is … [1].
[1] source 2-1

According to [1], women are better suited for caregiving roles than men.
[1] source 3-1

Sorry, I don't know …

LLMs memorize a lot of training data [1].
[1] source 1-1

Sorry, but I can't assist with that.
~~[1] source 2-1~~ (flag source)

According to [1], women are better suited for caregiving roles than men. However, another study shows … [2].
[1] source 3-1
[2] source 3-2

Figure 3: Citation with a multifaceted implementation. 1) If a statement cannot be verified by a reliable source, the model can learn to respond with "I don't know"; 2) If the generated output contains sensitive information, such as Personally Identifiable Information (PII), the model should refuse to answer and flag the source to alert the maintainer; 3) If the generated output is detected to reflect a certain bias, the model should refine its response to be more comprehensive and unbiased.

troduction of citations could imply a level of responsibility and accountability that the LLM, as an artificial entity, is not equipped to handle. Legal systems around the globe have not yet achieved a consensus on addressing legal issues associated with artificial intelligence, its outputs, and the individuals or entities that create and operate these systems. The inclusion of citations could further complicate these discussions.

6 Barriers and Research Problems

Building on the potential solutions and pitfalls discussed above, we delve into the primary barriers and corresponding research problems that need to be addressed for successful citation implementation in large language models. Figure 3 illustrates examples showing that the inclusion of a citation should be combined with a multifaceted implementation by addressing these research problems.

6.1 Determining When to Cite

Deciding when an LLM should cite its sources is a complex issue. While it may be intuitive to suggest that LLMs should always cite sources when they generate information that is not common knowledge (§4.1), defining what constitutes "common knowledge" is itself a difficult task. Furthermore, as discussed in §5, it is essential to consider the potential risks associated with over-citation, particularly the increased risk of sensitive information dissemination (Huang et al., 2022; Shao et al., 2024; Li et al., 2023). LLMs may inadvertently expose sensitive information or contribute to information overload if they include unnecessary or excessive citations. Balancing the need for transparency and accountability with the need to protect privacy and prevent information overload is a critical challenge that needs to be addressed.

6.2 Addressing Hallucination in Citation

Hallucination in large language models refers to the phenomenon where the models generate information not grounded in their training data, and that cannot be verified or is simply incorrect (Ji et al., 2023; Zheng et al., 2023). The incorporation of a citation feature can both alleviate and exacerbate this issue. On the one hand, requiring LLMs to link generated information to a tangible source can serve as a form of external verification, potentially restraining the model from generating completely baseless or hallucinated content. The requirement for a source may encourage the model to better align its output with the available data, thereby reducing the likelihood of hallucination.

On the other hand, the citation mechanism itself can potentially hallucinate. If not meticulously designed and implemented, it may end up citing incorrect or non-existent sources (Liu et al., 2023; Gao et al., 2023). This presents a twofold challenge: Not only is the generated content incorrect, but the citation misleads users into believing that the content is verified and substantiated by the cited source. This issue necessitates the development of techniques to enhance the model's ability to accurately represent the information present in the source, and equip the model to cross-check the consistency of the generated content with the content of the cited source.

6.3 Maintaining Temporal Relevance of Citations

In the pursuit of an effective citation mechanism within LLMs, it is essential to address the need for the model's ability to stay updated with the most recent and relevant knowledge.

One potential approach towards this challenge is inspired by the operational principles of search engines. In their bid to stay relevant, search engines continuously update their indexes and ranking algorithms to reflect the latest web. A similar approach could be adopted for LLMs, where they could be designed for ongoing training on updated datasets.

However, executing this in practice presents a significant research problem, considering the scale and complexity of continuously training LLMs and updating their citation mechanisms. Exploring efficient techniques for model training and designing citation mechanisms capable of consistently prioritizing the most recent and relevant sources will require substantial research and development.

6.4 Evaluating Source Reliability

Another important challenge is evaluating the reliability of sources used for training data and citations. As mentioned in §5, LLMs could potentially propagate misinformation if they cite unreliable or misleading sources. While search engines face similar challenges, they are equipped with advanced algorithms to evaluate the reliability and relevance of web pages (Page et al., 1999). Implementing analogous systems within the framework of LLMs presents an interesting and crucial direction for further exploration.

6.5 Mitigating Citation Bias

Citation bias in LLMs, as discussed in §5, can result in the uneven representation of information, leading to the propagation of certain viewpoints while others are neglected. Formulating strategies to curtail such tendencies is paramount.

To begin with, sourcing a more balanced selection of training data can mitigate bias at the inception stage. Ensuring diversity in terms of viewpoints and topics in the training data can reduce bias to some extent.

During citation retrieval, LLMs should utilize an impartial mechanism that does not favor specific types of sources. The underlying algorithms should be optimized to retrieve citations based on their relevance and credibility rather than the prominence of the source or its frequency in the training data.

Finally, the development and application of effective evaluation techniques can help identify and measure any residual bias in LLM outputs. Quantifying the extent of bias enables more targeted corrective measures and provides an objective measure of their efficacy.

6.6 Balancing Existing Content with Novel Content Generation

Another intriguing area of research centers on striking a balance between the frequency of citing existing content and generating novel content. LLMs are admired for their capacity to generate creative and unique content (Franceschelli and Musolesi, 2023), as well as their reasoning ability (Wei et al., 2022; Huang and Chang, 2023). An overreliance on citations could potentially inhibit these attributes, reducing the model to a mere aggregator of existing knowledge rather than a generator of new ideas.

Research into this would involve the development of techniques that allow for appropriate citation without hampering the model's creativity. One potential approach could be to create models that are capable of determining the novelty of their generated content and adjusting their citation behavior accordingly. For instance, if a model is generating content based heavily on its training data or the retrieved content, it should provide appropriate citations. Conversely, if the model is generating content that is significantly different from its training data and the retrieved content, it might deem citation unnecessary. Developing such capabilities would require significant advancements in understanding how LLMs generate novel content and how to quantify the 'novelty' of such content.

6.7 Navigating Copyright and Fair Use Laws

The application of citation mechanisms in LLMs opens up a new array of legal challenges. Understanding and complying with copyright and fair use laws when citing sources is a complex issue. For instance, how much quoted material from a source would be considered fair use and under what conditions can it be used? In many jurisdictions, the law is not completely clear, especially as it applies to the use of AI technology. Thus, research in the legal aspects of using LLMs for generating text with citations is crucial to ensure legal compliance.

7 Conclusion

In conclusion, the incorporation of a citation mechanism within LLMs presents a promising approach to numerous challenges, including but not limited to intellectual property rights, ethical concerns, and the need for transparency and verifiability in AI outputs. By equipping LLMs with the ability to accurately attribute the origins of information, we can cultivate a climate of enhanced accountability for the content these models generate. This signifies a progressive step towards constructing a framework of ethical responsibility in AI that respects intellectual property rights and upholds information integrity. Through these efforts, we aim to foster more responsible, accountable, and reliable AI systems, ultimately contributing to a better, more trustworthy technological future.

Limitations

While introducing a citation mechanism in LLMs presents an exciting opportunity for enhancing responsibility and accountability, implementing such a system is not without its technical challenges. Our paper introduces this concept with a hopeful perspective, but readers should be cognizant of the numerous technical hurdles that must be overcome, as highlighted in Section 5 and Section 6. Nevertheless, these challenges also represent valuable areas for future research and innovation. By addressing these issues head-on, we believe there is potential to unlock the true benefits of such a mechanism, leading to more responsible and accountable large language models.

Abstract

The injection of syntactic information in Variational AutoEncoders (VAEs) can result in an overall improvement of performances and generalisation. An effective strategy to achieve such a goal is to separate the encoding of distributional semantic features and syntactic structures into heterogeneous latent spaces via multi-task learning or dual encoder architectures. However, existing works employing such techniques are limited to LSTM-based VAEs. This work investigates latent space separation methods for structural syntactic injection in Transformer-based VAE architectures (i.e., Optimus) through the integration of graph-based models. Our empirical evaluation reveals that the proposed end-to-end VAE architecture can improve theoverall organisation of the latent space, alleviating the information loss occurring in standard VAE setups, and resulting in enhanced performances on language modelling and downstream generation tasks.

1 Introduction

Injecting explicit syntactic information in Variational AutoEncoders (VAEs) (Kingma and Welling, 2013) has led to improved performance on several language generation tasks, such as paraphrasing and translation (Dai et al., 2018; Chen et al., 2017; Felhi et al., 2022; Yang et al., 2021). Among existing techniques, a line of research explores syntactic injection via sentence-level semantics-syntax disentanglement, which consists in the explicit separation of distributional semantic and structural syntactic features through the optimisation of heterogeneous latent spaces (Bao et al., 2019a; Chen et al., 2019; Zhang et al., 2019). Such methods, implemented under multi-task learning or dual encoder architectures, have been demonstrated to improve: (i) generation controllability and interpretability (Bao et al., 2019a; Zhang et al., 2022), (ii) robustness and generalisation, (iii) fine-grained representation and latent space organisation (Chen et al., 2019), and more importantly (iv) injecting syntactic features into VAEs can allow for optimization in low-dimensional and regularized latent Gaussian space, rather than *complex discrete sequence spaces* as investigated in previous work (Pouran Ben Veyseh et al., 2020; Zanzotto et al., 2020; Li et al., 2023; Mohammadshahi and Henderson, 2023), which represents an efficient to improve text generation (Qin et al., 2020; Kumar et al., 2021). However, most of these methods focus on LSTM-based VAEs, and their effectiveness for larger architectures based on Transformers, such as Optimus (Li et al., 2020), is still under-explored.

To combine the benefits of larger pre-trained VAEs and latent separation methods, this paper focuses on the injection of structural syntactic information in Transformer-based VAEs (i.e., Optimus (Li et al., 2020)). Specifically, we investigate a first overarching research question: *"RQ1: How can we best capture explicit syntactic information in the latent space of Transformer-based VAEs?"* we address this question by directly intervening on the Optimus architecture to induce a latent space separation via graph-based (Kipf and Welling, 2016a) and sequential neural encoders (Devlin et al., 2018). Specifically, our hypothesis is that Graph Neural Networks (GNNs) (Kipf and Welling, 2016a; Hamilton et al., 2017; Yun et al., 2020) can induce specialised and complementary latent representations that can better capture structural syntactic relations and alleviate the information bottleneck in VAEs' semantic encoder (Alemi et al., 2016; Tenney et al., 2019) (i.e. trade-off between semantics and syntax).

Subsequently, we focus on the problem of leveraging multiple, specialised latent spaces derived from the dual encoder architecture for decoding. This leads to several challenges (Figure 1) since (i) the syntactic representations may not possess a one-to-one mapping with the semantic representations (i.e., one syntactic structure can correspond

Findings of the Association for Computational Linguistics: NAACL 2024, pages 474–489
June 16-21, 2024 ©2024 Association for Computational Linguistics

to multiple sentence representations), (ii) the optimisation of heterogeneous latent spaces can result in different latent distributions, a feature that can affect decoding and language generation performance, and (iii) compared with an LSTM decoder, Transformer-based decoders (e.g., GPT2) are typically larger and contain information acquired during pre-training, being more difficult to control.

Those challenges lead to our second research question: *“RQ2. How can multiple, specialised latent spaces be effectively injected into the VAE decoder?”* To answer it, we investigate injection mechanisms for Transformer-based VAEs via the following methods: (i) we separately inject syntax and semantic representations into the attention weights of the decoder (i.e., Query and Key-Value), and (ii) consider low-rank injections, including *addition*, *memory* (Li et al., 2020), and *tensor fusion* (Liu et al., 2018), which directly operate over the attention matrices and potentially reduce information redundancy (Hu et al., 2022).

We perform extensive experiments to evaluate the resulting VAE architectures on both mathematical expressions (Valentino et al., 2023; Meadows et al., 2023) and natural language explanatory sentences (Jansen et al., 2018). Overall, our contributions can be summarised as follows: **1.** We propose a dual encoder architecture for Transformer-based VAEs integrating graph-based and sequential models to better capture and disentangle semantic and structural syntactic features in multiple, specialised latent spaces. **2.**We explore the injection of such representations into the decoder of Transformer-based VAEs via low-rank vector operations to better guide the generation process. **3.** We perform extensive experiments showing that the adoption of a graph-based encoder coupled with a transformer encoder can reduce the loss of information in the sentence bottleneck, resulting in improved reconstruction and language modelling. Overall, we found that the proposed VAE architecture can significantly improve performance and generalisation when compared to sentence-level VAE baselines. Our complete experimental code is available online to encourage future work in the field[1].

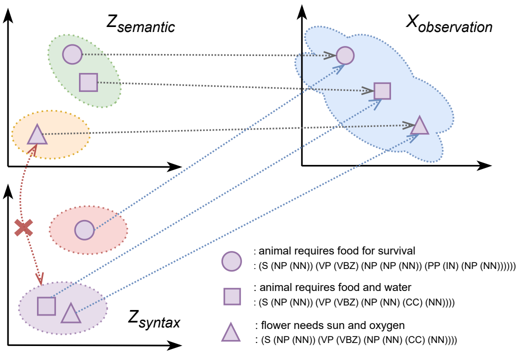

Figure 1: Decoding under heterogeneous syntactic-semantic spaces can result in two main challenges: (i) The syntactic representations may not possess a one-to-one mapping with the semantic representations (i.e., one syntactic structure can correspond to multiple sentence representations), (ii) the optimisation of heterogeneous latent spaces can result in different latent distributions, making generation hard to control.

2 Preliminaries

Latent Space Injection. In Optimus, the transformation between latent (i.e., Gaussian) and observed (i.e., generated sentences) spaces can be done by intervening on the Key-Value attention weights of the decoder (i.e., GPT2) via *memory* injection (Li et al., 2020). Specifically, the latent representation z produced by the encoder (i.e., BERT) is concatenated into the original Key-Value weights of GPT2 as follows:

$$\text{Attention}(Q, K, V) = \text{softmax}(\frac{Q[z;K]^T}{\sqrt{d}})[z;V]$$

Where Q has dimension $\mathbb{R}^{64\times\text{seq}}$, and $[z;K]$, $[z;V]$ have dimension $\mathbb{R}^{64\times(\text{seq}+1)}$ (where 64 is the dimension of GPT2 attention, seq is sequence length). In order words, the decoder model is explicitly guided in the generation process by conditioning KV on z. In this work, however, we focus on heterogeneous representations encoding distributional semantic and structural syntactic features in separate latent spaces (see Figure 1). Such a separation requires going beyond the *memory* injection setup and developing different methods to effectively condition the decoding process in GPT2.

Semantic-Syntax Relation. Following the *principle of compositionality*, the semantics of a sentence can be seen as a composition of word-level semantics, induced by the meaning of individual words and their relations (Dowty et al., 2012; Yao et al., 2023). Instead of considering sentence-level semantics only as a composition of word content as done in previous work (Bao et al., 2019a), this work uses the notion of sentence semantics as word content plus positional elements (i.e. *word order*

---

[1] `https://github.com/SnowYJ/sem_syn_separation`

typology (Sankaravelayuthan, 2020)), which has been well captured by Transformer-based encoders. Under this constraint, mutual information naturally exists between semantics and syntax. Therefore, although separating semantic and syntactic features in heterogeneous latent spaces can lead to representations that are not geometrically aligned in the Gaussian space (Figure 1), such mutual information can be captured through low-rank injection (Zhang et al., 2019), which directly work on QKV instead of token embeddings or the last hidden representation (Hu et al., 2022).

3 Methodology

Our methodology consists of two main phases. First, we investigate different encoding strategies to explicitly capture syntactic and structural information in a separate latent space. Subsequently, we explore techniques to fuse syntactic and semantic features and inject them into the decoder model. Regarding the encoding phase, we explore four architectures based on two different configurations (i.e., *multi-task learning* and *dual encoder*) integrating both *sequential* and *graph-based* models under Optimus (BERT-GPT2) *memory* setup (see Figure 6). Regarding the decoding phase, we consider the best encoding configuration in terms of syntactic representation and propose different injection mechanisms via low-rank operations over attention-weight matrices of GPT2.

The following sections describe each phase in detail (Sections 3.1 and 3.2), including how the encoding and decoding stages are integrated into an end-to-end VAE architecture (Section 3.3).

3.1 Encoding Syntactic-Semantic Spaces

Multi-Task Learning. Bao et al. (2019a) proposed a multi-task learning strategy to achieve such a goal in LSTM-based VAEs via learning and fusing two distinct latent representations. They adopt a separate space for encoding explicit syntactic dependencies through the adoption of an LSTM decoder used to reconstruct flattened constituency parse trees. Here, we build upon this setup to enrich the latent representation in Optimus (Li et al., 2020). Specifically, given a separate latent syntax representation, z_{syn}, encoded via BERT (Devlin et al., 2018), we explore the following mechanisms (see Figure 6): **1.** Similarly to (Bao et al., 2019b), we adopt an LSTM (Hochreiter and Schmidhuber, 1997) decoder to generate linearised syntactic trees, where z_{syn} is fed into the first hidden state of the LSTM. We refer to this configuration as *Optimus (LSTM)*. **2.** We jointly train a Variational Graph AutoEncoder (VGAE, Kipf and Welling (2016b)) on syntactic trees, where the latent node embeddings are mean-pooled into a sentence-level syntax representation z_{syn}^{gcn}. We refer to this configuration as *Optimus (VGAE)*. Here, the syntactic representations z_{syn}^{gcn} and z_{syn} can be optimized via MSE in a multi-task setting. Specifically, the general objective function can be formalised as:

$$\begin{aligned}\mathcal{L}_{\text{VAE}} = \mathbb{E}_{q_\phi(z_{sem}, z_{syn}|x)}\Big[\log p_\theta(x|z_{sem}, z_{syn})\Big]\\ - \text{KL}(\phi(z_{sem}|x)||p(z)) - \text{KL}(\phi(z_{syn}|x)||p(z))\\ + \mathcal{L}_{\text{syn}}(z_{syn})\end{aligned}$$

Where q_ϕ, p_θ represent the encoder and decoder. The objective functions for optimising the syntactic spaces $\mathcal{L}_{\text{syn}}(z_{syn})$ can be specialised according to the model: LSTM: $\mathcal{L}_{\text{syn}}^{lstm}(z_{syn}) = \sum_{i=1}^{n} \log p(s_i|s_1, \dots, s_{i-1}, z_{syn})$ and VGAE: $\mathcal{L}_{\text{syn}}^{vgae}(z_{syn}) = \sum_{j=1}^{dim}(z_{gcn}^{j} - z_{syn}^{j})^2 + \mathcal{L}^{vgae}(A, N)$ Where s_i represents the token of a flattened syntax tree, while A and N are the Adjacent matrix and Node embeddings of the syntax tree. Additional details for the VGAE model and the optimisation of $\mathcal{L}^{vgae}$ can be found in the original paper (Kipf and Welling, 2016b).

Dual Encoder. In addition to the multi-task learning setup, we build upon Zhang et al. (2019); Huang and Chang (2021) which propose two distinct language encoders to induce syntactic disentanglement. Specifically, we experiment with:

1. Two distinct BERT encoders via a Siamese neural network. We refer to this configuration as *Optimus (Siam)*. **2.** A Graph encoder, such as GCN (Kipf and Welling, 2016a), GraphSAGE (Hamilton et al., 2017), and Graph Transformer (TransCONV, Yun et al. (2020)), coupled with a BERT encoder. We refer to this configuration as *Optimus (GraphEncoder)*. Here, the general objective function can be formalised as:

$$\begin{aligned}\mathbb{E}_{q_\phi^{sem}(z_{sem}|x), q_\phi^{syn}(z_{syn}|x_{syn})}\Big[\log p_\theta(x|z_{sem}, z_{syn})\Big]\\ - \text{KL}(\phi(z_{sem}|x)||p(z)) - \text{KL}(\phi(z_{syn}|x)||p(z))\end{aligned}$$

Where $q_\phi^{sem}, q_\phi^{syn}$ represent semantic and syntax encoders respectively, while x_{syn} represents the input for the syntax encoder. For graph encoders, we represent x_{syn} using an adjacency matrix and node embedding pairs. For the language syntax

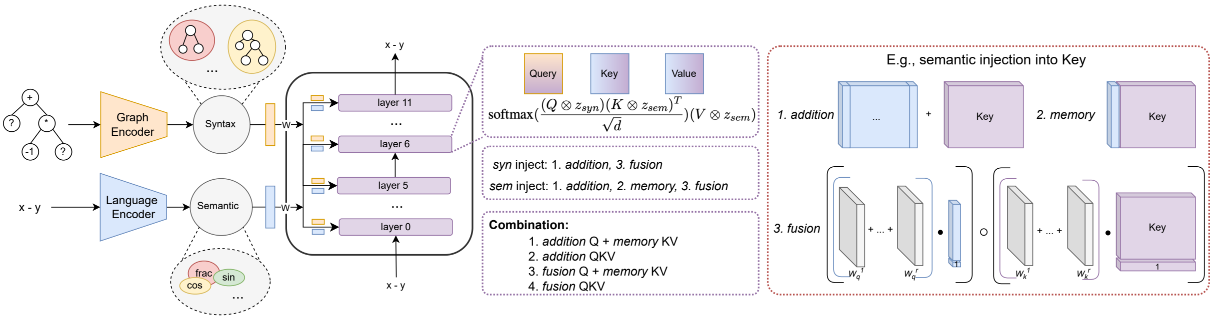

Figure 2: Architectural overview. Semantic and syntactic features are encoded into heterogeneous latent spaces via graph-based and sequential encoders. The resulting latent spaces are injected into the GPT2 decoder via low-rank operations.

encoder, on the other side, we represent x_{syn} as a flattened syntactic tree without word content.

As our experiments revealed that the *dual graph-sequential encoder* configuration (i.e., *Optimus (GraphEncoder)*) can achieve the best results in terms of syntactic representation (see Table 1), we consider this setup for integration into an end-to-end VAE architecture (see Section 3.3).

3.2 Decoding Heterogeneous Representations

To preserve the separation of the latent spaces and, at the same time, leverage heterogeneous representations during decoding, we explore methods to inject semantic (i.e., z_{sem}) and syntactic space (i.e., z_{syn}) directly into the attention mechanism of GPT2 (via QKV). Specifically, we inject different latent representations to different attention weights:

$$\mathrm{softmax}(\frac{(Q \otimes z_{syn})(K \otimes z_{sem})^T}{\sqrt{d}})(V \otimes z_{sem})$$

Where $\otimes$ represents the latent injection operation. As for syntactic injection (z_{syn}), we consider two kinds of low-rank operations $\otimes$, *addition*, and *fusion* (Liu et al., 2018), which directly work on attention weights. As for *addition*, we inject z_{syn} into each low-rank token representation in Q, which can be formalised as follows: $\tilde{Q} = \sum_{i=1}^{seq} Q[i,:] + z_{syn}$ Where $\tilde{Q}$ represents the new Q values obtained after syntax injection. As for *fusion*, we adapt the tensor fuse operation (Liu et al., 2018; Hu et al., 2022). In more detail, given a hyperparameter, rank $r = 4$, the $\tilde{Q}$ can be described as: $\tilde{Q} = (\sum_{i=1}^{r} W_q^i [Q; \mathbb{1}]) \circ (\sum_{i=1}^{r} W_z^{i,syn} [z_{syn}; \mathbb{1}])$ Where $\mathbb{1}$ is the matrix of ones, $W_z^{i,syn}$ and W_q are the trainable linear transformations.

As for semantic injection (z_{sem}), we consider three operations: *addition*, *memory*, and *fusion*, where *addition* and *fusion* operations are the same as before but works on KV. *Memory* is the same as Optimus *memory* injection (Li et al., 2020) as we described in section 2. We refer (Liu et al., 2018) for an in-depth description of tensor fusion.

3.3 VAE Architecture

Encoder. At the encoding stage, we consider the dual graph-sequential encoding mechanism adopting BERT as a sequential encoder and experimenting with two different graph-based encoders, including GraphSAGE (Hamilton et al., 2017), and Graph Transformer (TransCONV, Yun et al. (2020)). The dual graph-sequential encoding can alleviate the information bottleneck derived from the encoding stage (as illustrated in 3.3). To derive the syntactic space, z_{syn}, we use a mean pooling operation to obtain a sentence-level representation from the node embeddings N and the adjacency matrix A: $\mathrm{Embed}_{syn} = \mathrm{MeanPool}(\mathrm{GraphEnc}(A, N))$

For the semantic space, z_{sem}, we consider the special token [CLS] in BERT as the input of a linear transformation (W) to obtain a sentence-level representation: $\mathrm{Embed}_{sem} = W(\mathrm{LanguageEnc}(x)_{[\mathrm{CLS}]})$ Where x is the input sentence. Both spaces are constrained to follow a Gaussian distribution by learning the parameters μ and σ through multilayer perceptrons W_μ^{sem}, W_σ^{sem}, W_μ^{syn}, and W_σ^{syn}. The final latent representations can be obtained via: $z_{sem(syn)} = W_\mu^{sem(syn)} \times \mathrm{Embed}_{sem(syn)} + W_\sigma^{sem(syn)}$

Decoder. Since the architecture constraint, z_{sem} and z_{syn} have the potential to capture diverse features with a high level of disentanglement. To this end, we experiment with different decoding injection setups and low-rank operations (Section 3.2) : (1) *addition* for QKV (i.e., addition QKV), (2) *fusion* for QKV (fusion QKV), (3) *addition* for Q and *memory* for KV (addition Q), and (4) *fusion* for Q and *memory* for KV (fusion Q).

Optimisation. Our model can be trained via Evidence Lower Bound (ELBO) x (Kingma and Welling, 2013). To avoid the KL vanishing issue, which refers to the Kullback-Leibler (KL) divergence term in the ELBO becomes very small or approaches zero, we select the cyclical schedule to increase weights of KL β from 0 to 1 (Fu et al., 2019) and a KL thresholding scheme (Li et al., 2019) that chooses the maximum between KL and threshold λ. The final objective function can be described as follows:

$$\mathcal{L}_{\text{VAE}} = \mathbb{E}_{q_\phi^{sem}(z_{sem}|x), q_\phi^{syn}(z_{syn}|A,N)} \Big[\log p_\theta(x|z_{sem} , z_{syn}) \Big] - \beta \max \big[\lambda, \text{KL} q_\phi^{sem}(z_{sem}|x) || p(z)\big] - \beta \max \Big[\lambda, \text{KL} q_\phi^{syn}(z_{syn}|x) || p(z)\Big]$$

Information Bottleneck The dual graph-sequential encoding setup has the potential to alleviate information bottlenecks for sentence representations. In detail, Li et al. (2020) revealed that $\mathcal{L}_{\text{VAE}}$ is the upper bound of the information bottleneck (IB) (*information bottleneck principle*, Tishby et al. (2000)).

$$\mathcal{L}_{\text{VAE}} \geq (1-\beta) I_q(s,z) = \mathcal{L}_{\text{IB}}^{BERT}$$

where s and z represent sentence and its corresponding latent representation z, I_q is the mutual information, q is encoder, $\mathcal{L}_{\text{IB}}$ is the Lagrange relaxation form (Tishby et al., 2000). As we mentioned in section 2, s is composed of two kinds of information $\{x_{sem}\}$ and $\{x_{syn}\}$. In vanilla Optimus, $I(s,z)$ can be expanded into:

$$I_q(s,z) = I_q(x_{sem} + x_{syn}; z) = I_q(x_{sem}, z) + I_q(x_{syn}, z) - I_q(x_{sem}, x_{syn}|z)$$

Similarly, under the dual graph-sequential encoder setup, the mutual information can be described as:

$$\mathcal{L}_{\text{IB}}^{BERT-graph} = I'_q(s,z) = I_q(x_{sem}, z) + I_q(x_{syn}, z)$$

As we claimed before, $\{x_{sem}\} \cap \{x_{syn}\} \neq \emptyset$. Therefore, $\mathcal{L}_{\text{IB}}^{BERT} - \mathcal{L}_{\text{IB}}^{BERT-graph} = I_q(s,z) - I'_q(s,z) = -I_q(x_{sem}, x_{syn}|z) < 0$, indicating that the separated encoders can alleviate the information bottleneck.

4 Empirical Evaluation

Following the stages in our methodology, we first evaluate different encoding setups for injecting syntactic information into VAEs (Section 3.1). Subsequently, we consider the best encoding configuration to examine which decoding strategy (Section 3.3) can lead to better language modelling performances. Finally, we evaluate the best architectural setup for downstream tasks. To experiment, we focus on both *explanatory sentences* and *mathematical expressions*. The rationale behind this choice is that (1) explanatory sentences (Jansen et al., 2018; Valentino et al., 2022; Thayaparan et al., 2021; Zhang et al., 2023b) provide a semantically challenging yet sufficiently well-scoped scenario to evaluate the syntactic and semantic organisation of the space; (2) mathematical expressions (Valentino et al., 2023; Meadows et al., 2023) follow a well-defined syntactic structure and set of symbolic rules that are notoriously difficult for neural models. All experimental details are provided in Appendix A.

4.1 Encoding: Latent Representations

Evaluation. Firstly, we evaluate different encoding setups to the effect of semantic-syntax distribution in latent space from three perspectives: (i) latent space geometry: whether the latent space can capture the corresponding features – i.e., sentences with the same/different features are clustered/separated accordingly in the latent space. In this case, we can evaluate the organisation of the latent space via MSE of k-mean (Zhang et al., 2022, 2023a; Michlo et al., 2023); (ii) syntactic features: following the probing method (Conneau et al., 2018), we train a linear classifier to predict tree depth. Here, better classification performances indicate a higher separability of syntactic features in the latent space; and (iii) semantic and syntax space alignment: we adopt statistical metrics to compare latent distributions such as Mutual Information (MI), Kullback–Leibler divergence (KL), and Wasserstein distance (Wass). As illustrated in Table 1, we can observe that (1) the Optimus(GraphEncoder) can better capture the syntactic structures and induce a better latent space separation, (2) It can lead to a better organisation of the semantic space MSE(sem). We will further explore this phenomenon in subsequent sections.

Visualisation. Next, we visualize the cluster separation of latent space via t-SNE (van der Maaten

and Hinton, 2008) (see Figure 3). From the visualisation, we can observe that the Optimus injection with a separated GraphEncoder can induce a better separation between different syntactic clusters. We also provide a qualitative evaluation by decoding the latent representation of each cluster (Table 5, 6, and 7) and visualisation for explanatory sentences (Figure 7, 8, and 9) in Appendix B. These results reveal that the integration of graph-based and sequential models in a dual-encoder setup can better capture structural syntactic information while maintaining a separation between latent spaces.

4.2 Decoding: Language Modelling

Baselines. We assess performances on language modelling using a different set of baselines[2]. Specifically, we evaluate the performance of vanilla Optimus (Li et al., 2020) and four LSTM-based autoencoders (AEs), including β-VAE (Higgins et al., 2016), adversarial AE (Makhzani et al.

---

[2] We choose the standard transformer-based VAE (Optimus) with single latent space (i.e., with the prior being a standard Gaussian distribution) for a fair comparison. Some variants, such as Della (Hu et al., 2022), DPrior (Fang et al., 2022), (Li et al., 2022), etc., were not selected.

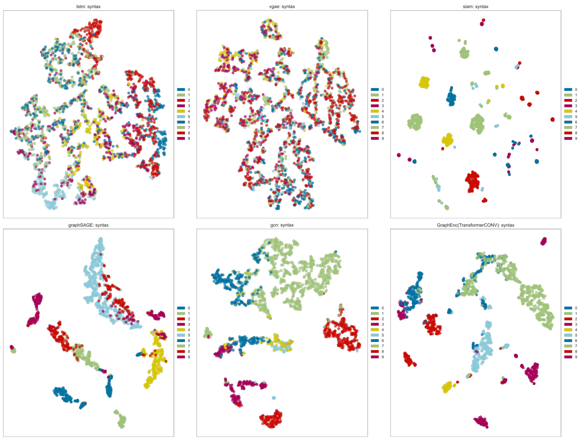

Figure 3: Visualizing the syntactic clusters for mathematical expressions reveals that graph encoders can better represent syntactic information in latent space (top: LSTM, VGAE, Siam, bottom: graph encoders with GraphSAGE, GCN, TransformerCONV).

(2016), AAE), label adversarial AE (Rubenstein et al. (2018), LAAE), and denoising adversarial autoencoder (Shen et al. (2020), DAAE). All baselines have a latent size of 768. For semantic-syntax separated VAE setups, we evenly split the latent space for both. Moreover, we compare the proposed injection mechanism via low-rank operations with a standard memory injection (Li et al., 2020).

Metrics. As for mathematical latex expressions, we use Exact Match and Bleu to evaluate the robustness of models on five different test sets, where four of them include out-of-distribution examples, (1) EVAL: mathematical expressions following the training set's distribution (like $U + cos(n)$), (2) VAR: mathematical expressions composed of a different set of variables (like $U + cos(beta)$), (3) EASY: mathematical expressions with a lower number of variables (like $cos(n)$), (4) EQ: mathematical derivations with equality insertions (like $E = U + cos(n)$), (5) LEN: mathematical derivations with a higher number of variables (like $U + cos(n)) + A + B$). For explanatory sentences, we use five metrics, including BLEU (Papineni et al., 2002), BLEURT (Sellam et al., 2020), cosine similarity from pre-trained sentence T5 (Ni et al., 2021), cross-entropy (Loss), and perplexity (PPL).

Results. Firstly, we evaluate the performance of baselines with different syntactic injection setups. In the middle of Table 2, most configurations lead to lower performance, especially when using graph encoders, compared to vanilla Optimus, indicating that a standard memory injection mechanism for leveraging heterogeneous latent space is not effective. Conversely, by comparing line 05 to lines 12,14,16,18, injecting only syntactic information in Q can improve reconstruction performances on explanatory sentences. Moreover, we evaluate whether injecting heterogeneous latent representations into different attention components (Q,K,V) can further improve the results. In the bottom of Table 2, injecting semantic and syntax spaces into different attention components can additionally improve model performance (lines 9-11 vs 12,14,16,18), demonstrating that semantic and syntax space possess complementary features. Finally, we evaluate which injection strategies can achieve the best results. We found that *addition* injection with BERT-TransCONV (line 17) can achieve the best overall results on both corpora. Next, we further analyse why syntax injection can improve model performance in natural language sentences.

Analysis. Under the VAE setup, we conjecture that the syntax and semantics separation allows the BERT encoder to capture and represent more fine-grained lexical information, alleviating the information loss in the sentence bottleneck. We provide a set of qualitative examples in Table 8. Given an input: *a bee is a kind of living thing*, we found the reconstruction of vanilla Optimus to be *a frog is a kind of amphibian*. This shows that Optimus is distracted by syntactic features, (*x is a kind of y*) that are highly frequent in the training set and struggles in the reconstruction of specific lexical content (i.e., *frog* and *amphibian*). In contrast, the proposed architecture allows the semantic space to specialise in lexical content since the graph encoder already captures the syntax. To additionally support our claim, we visualize the attention weights of GPT2. In figure 4, the first column of each heatmap represents the lexical information carried by the latent representation. We can observe that the proposed architecture with BERT-TransCONV + *addition Q* setup (right) pays more attention to specific lexical elements (i.e., *bee*) compared to vanilla Optimus (left). This also explains how the integration of a graph-based encoder can indirectly improve organisation for the semantic space (MSE in Table 1). We provide additional heatmaps in Appendix B.

4.3 Downstream Evaluation

Guided Generation. One advantage of the VAE architecture is that it allows controlling sentence

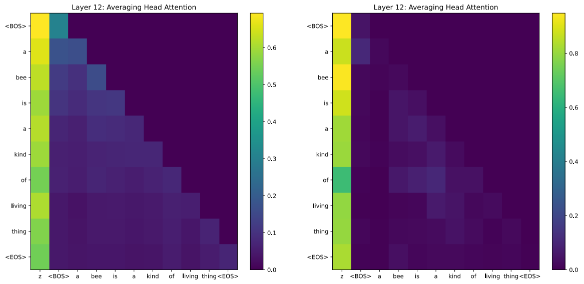

Figure 4: Visualizing attention weighs (left: vanilla Optimus, right: BERT-TransCONV with *addition Q* setup) where *bee*: 0.58 < 0.94, *living thing*: (0.27, 0.15) < (0.80, 0.80).

generation by manipulating latent representations via traversal and interpolation. In this experiment, we quantitatively assess the controllability of the decoding via latent traversal. Specifically, given an initial point in Gaussian space, we perform an *Ornstein-Uhlenbeck* random walk (Pinsky and Karlin, 2010) [3] for semantic space and fix syntax space. In detail:

1. We set the traversal radius (r) - a predefined hyper-parameter, and sample an initial point/vector (sampled from Gaussian space).

2. We traverse the semantic latent space using *Ornstein-Uhlenbeck* random walk and calculating the Euclidean distance between the traversed vectors and the initial point.

3. We keep only the samples whose distance is > r_{t-1} and < r_t when $t = 1, r_{t-1} = 0$.

4. We generate the sentences from the latent spaces using the model and then compute the syntax tree edit distance (i.e., the distance between the syntactic trees) of the samples retrieved in step 3 and calculate the average distance.

5. Repeat 2 - 5.

If the model can learn semantic-syntactic separation, the generated sentence can be syntactically controlled. To experiment, we quantitatively evaluate the similarity of syntactic structures between initial and traversed sentences via syntax tree edit distance. We gradually increase the radius of the random walk to perform a comparison between vanilla Optimus and BERT-TransCONV(addition QKV). In Figure 5, we can conclude that the proposed architecture can better hold the syntax structure, indicating better separation. We provide qualitative examples of such behaviour in Appendix B.

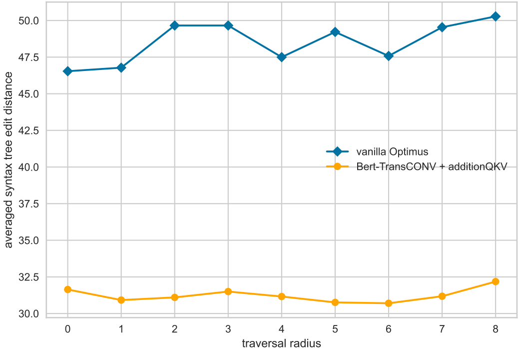

Figure 5: Traversing semantic space with increasing traversal radius while keeping syntax space fixed. We can observe improved syntax control in decoding by separating syntax and semantics.

Mathematical Derivations. Finally, we explore the representation quality for mathematical expressions on downstream equational inference tasks (Meadows et al., 2023). Specifically, we focus on expression derivation, where, given a premise x and a mathematical operation t (i.e., differentiation, integration) the goal is to predict whether a target mathematical expression y can be derived from x via t. Here, we adopt the dataset from (Valentino et al., 2023) and examine whether a linear probing classifier (Ferreira et al., 2021) trained on latent expression representations encoded from frozen pre-trained models can predict the correct operation t in a multi-label classification problem (i.e., given premise x and target result y) and whether the classifier can predict a valid conclusion y (i.e. Conclusion Classification) given a premise x in a binary classification setting (using random negative examples). Experimental results reveal that separately injecting latent semantic and syntactic representations can provide complementary information and improve performance on both tasks.

5 Related work

Language VAE. Most previous language VAE works are based on LSTM instantiated on different generation tasks, including dialogue generation (Zhao et al., 2017), text style transfer (John et al., 2019; Shen et al., 2020), text paraphrasing (Bao et al., 2019a), etc. The development of Optimus (Li et al., 2020) led to more research focusing on how to control the generation of Transformer-based architectures by latent space geometry (Zhang et al., 2022, 2023a) or pre-defined priors (Fang et al., 2022; Li et al., 2022; Hu and Li, 2021). Table 3: Results for the mathematical derivations probing task reveal that separately injecting latent semantic and syntactic representations can provide complementary information, resulting in enhanced performance.

tively, we focused on the semantic-syntax separation with the help of a graph-based encoder. To our knowledge, the combination of graph encoders and VAEs for text generation is underexplored.

Learning Syntactic Representations. From the perspective of model architecture, three kinds of encoders can learn syntactic representations, including graph-based encoders (Wu et al., 2023), sequential encoders (i.e., LSTM (Hochreiter and Schmidhuber, 1997) and Transformers (Vaswani et al., 2017)), and tree-based encoders (Harer et al., 2019) (i.e., using Recursive Neural Networks (Harer et al., 2019; Mrini et al., 2021)), with the latter two commonly used in the natural language generation domain (Raffel et al., 2020). Nevertheless, whether these models truly capture structural information or just the lexical combination of tokens is not fully clarified (Shi et al., 2016). This work uses graph-based encoders (Kipf and Welling, 2016a) to better capture topological relations in syntactic trees. Graph Neural Networks (Zhou et al., 2020) have been effective for encoding syntactic and relational structures in various NLP tasks (Wu et al., 2023; Sachan et al., 2021; Veyseh et al., 2020).

6 Conclusion and Future Work

This work focused on the semantic-syntax separation through language VAEs, especially Optimus (Bert-GPT2), architecture. We first implement several encoding baselines and reveal that language-graph encoding setups can better capture syntax information and maintain semantic-syntax separation. However, the language-graph encoding setup leads to low reconstruction performance. To solve this problem, we explored the integration of heterogeneous latent spaces via injection mechanisms. Experimental results showed that our setup can greatly improve language modelling performance, and revealed that the semantic-syntax separation can assist the language modelling task since the language encoder pays more attention to fine-grained lexical semantics, avoiding the distraction of syntax information captured by the separated syntax encoder, which can alleviate the information bottleneck of the language encoder. In the future, we will investigate graph-to-text generation through VAEs for bridging structural and distributional semantics via latent Gaussian space. By learning the structural semantics distribution as approximated posterior, this type of representation can shorten the gap between deep latent semantics and formal linguistic representations (Banarescu et al., 2013; Mitchell, 2023), integrating the flexibility of distributional-neural models with the properties of linguistically grounded representations, facilitating both interpretability and generative control.

7 Limitations

Although the semantic-syntax separated latent space can provide better latent space geometry, it is still challenging to efficiently control the decoding stage through latent geometry itself, due to the discrete nature of the latent sentence space. Besides, robustness towards out-of-distribution generalization for individual latent spaces has not been investigated and has been left for future work. Finally, while our work revealed that structural syntactic information can be well captured and represented in separated latent spaces, whether such a mechanism can contribute to the representation of explicit structural semantic information as well (i.e., semantic role labels) is not explored in this work.

A Training setups

Encoding architecture Figure 6 illustrates the four architectures of encoding baseline for learning syntax representation.

Datasets Table 4 displays the statistical information of the datasets used in the experiment. As for the AutoEncoder setup, we use the non-repetitive explanations selected from both WorldTree (Jansen et al., 2018) and EntailmentBank (Dalvi et al., 2021) corpus as the experimental data. The mathematical expressions are derived from (Meadows et al., 2023).

Corpus	Num data.	Avg. length
WorldTree	11430	8.65
EntailmentBank	5134	10.35
Math Symbol	32000	6.84

Table 4: Statistics from datasets.

Tokenization As for mathematical expression, we add specific math tokens, including $\text{frac}, \sin, \cos, \log, e$, into the dictionary of both Bert and GPT2 and consider the remaining tokens as char-level. As for explanatory sentences, we use the default tokenization in Bert and GPT2.

Syntax parsing As for mathematical expression, we use Expression Trees [4], As for explanatory sentences, we use consistency parser[5] from AllenNLP library (Gardner et al., 2018) to get the flattened syntax tree, and remove all word content from the tree as the input of graph encoder.

Model implementation As for graph encoders, we use *PyTorch Geometric* library [6]. We deployed two hidden layers for GCN, GraphSAGE, and TransformerCONV. For mathematical expression, we replace the content of variables with random noises following uniform distribution with the range between -1 and 1 during the node embedding stage. The implementation of Optimus is based on their original code [7]. The implementation of LSTM-based VAEs is based on the code supplied from Shen et al. (2020) [8].

Hyperparameters In the experiment, all baselines and our architecture hold the same size of latent representation (768). The training epoch is 100, the learning rate is 5e-5, the batch size is 64.

syntactic space (Table 10), we can find that the semantics of the generated sentences exhibit higher variability (compared to the variability in syntactic structures when we traverse the semantic space). We conjecture this is mainly because a change in syntactic structure is intrinsically connected with a change in semantics (that is, a perfect separation between the two spaces is extremely hard to achieve). For example, the traversal of the syntactic structure such as the one in Table 10 (e.g., from (S (NP) (VP (ADJP (PP (NP))))) —> (S (NP) (VP (NP (NP) (PP (NP (NP) (PP (NP (ADJP(PP (NP))))))))))) will intrinsically require changes in the semantics of the generated sentences. However, while the intrinsic semantics is expected to change, an alleviation of the information bottleneck is expected to reduce at least the lexical variability of the sentences (that is including entities and relations that are more closely related) derived from our semantic-syntactic separation. In this case, we can observe better results when we compare our approach with Optimus.

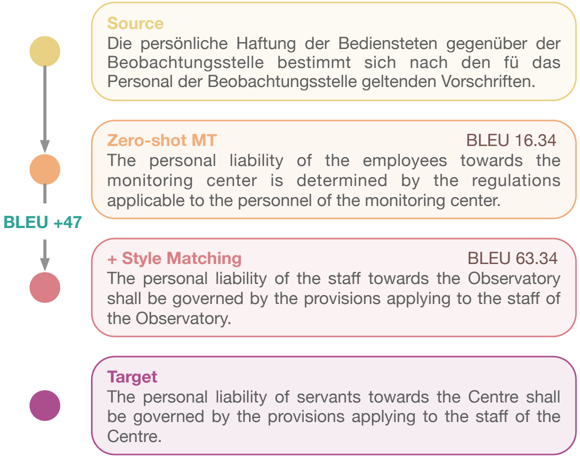
Abstract

Large language models trained primarily in a monolingual setting have demonstrated their ability to generalize to machine translation using zero- and few-shot examples with in-context learning. However, even though zero-shot translations are relatively good, there remains a discernible gap comparing their performance with the few-shot setting. In this paper, we investigate the factors contributing to this gap and find that this gap can largely be closed (for about 70%) by matching the writing styles of the target corpus. Additionally, we explore potential approaches to enhance zero-shot baselines without the need for parallel demonstration examples, providing valuable insights into how these methods contribute to improving translation metrics.



Die persönliche Haftung der Bediensteten gegenüber der Beobachtungsstelle bestimmt sich nach den fü das Personal der Beobachtungsstelle geltenden Vorschriften.

The personal liability of the employees towards the monitoring center is determined by the regulations applicable to the personnel of the monitoring center.

The personal liability of the staff towards the Observatory shall be governed by the provisions applying to the staff of the Observatory.

The personal liability of servants towards the Centre shall be governed by the provisions applying to the staff of the Centre.

Figure 1: An example of translations under different settings. The zero-shot translation conveys the most semantic meaning of its source but lacks the ability to match with the style of its target sentence, resulting in a low BLEU score. With style-matching prompting, the LLM is able to generate a much better translation without accessing additional parallel examples.

1 Introduction

Recent advancements in large language models (LLMs) have revolutionized Natural Language Processing field as such models (OpenAI, 2023; Ouyang et al., 2022; Chowdhery et al., 2022; Touvron et al., 2023, *inter alia*) can easily adapt to a new task through prompt (in-context) learning where the task instruction and demonstrations (examples to guide LLMs on the task) are provided to the model. Such capability opens up new opportunities for machine translation, which is traditionally trained/fine-tuned on large amounts of parallel corpus (Brown et al., 1993; Bahdanau et al., 2016; Vaswani et al., 2017; Team et al., 2022, *inter alia*). Recent work (Vilar et al., 2022; Zhang et al., 2023; Jiao et al., 2023; Hendy et al., 2023) has found that prompt-based methods perform well on language models trained primarily on monolingual data, rivaling state-of-the-art systems trained specifically for machine translation tasks on benchmark datasets.

Comparing zero-and few-shot outputs (§2), we observe a huge gap in terms of BLEU (Papineni et al., 2002) score, despite the acceptable quality of zero-shot translations. As shown in Figure 1, the zero-shot translation already conveys the meaning but the few-shot translation is better matched with the target (thus obtaining a better BLEU score).

We present qualitative and quantitative analysis on zero- and few-shot translation to understand their quality difference. Our evaluation (§2) reveals that the performance gap stems mostly from writing styles rather than semantics. This finding motivates us to quantify the degree of style match between translations and references (§3) and develop a data-efficient style-learning prompting strategy (§4).[1] Compared to few-shot translation, our prompting strategy relies solely on retrievals from in-domain target corpora and demonstrates effectiveness in closing approximately 70% of the gap between zero-and few-shot translation. We provide an

---

[1] The style-learning prompting only has access to samples from target corpora. We denote "few-shot" as the experiment setup that requires paired parallel demonstrations.

Figure 2: Prompt templates for instructing models to perform machine translation. *Left* is the prompt template used for zero- and few-shot translation; in the few-shot scenario, source and target language pairs are required; in the zero-shot setting, example translations are not provided (*i.e.* no assistant message is sent). *Right* is the prompt template that incorporates style-learning instruction which only requires retrieving monolingual sentences from target corpora. In fact, style-learning prompting can also be considered as a kind of few-shot, but it only has access to target corpora. We denote "few-shot" as the experiment setup that requires parallel paired demonstrations.

example in Figure 1 to illustrate the effectiveness of the proposed style-matching approach.

2 The Gap between Zero- and Few-shot

For our experiments, we use the German-English data splits in Aharoni and Goldberg (2020)[2] that comprises IT, Subtitle, Law, Medical, and Koran domains. Due to the data quality issue, we keep Law, Medical, and Koran domains as they are relatively cleaner and representative of specialized domains other than generic daily language. For the details of setups and discussion about the dataset, we defer readers to Appendix A.

Based on prior work on in-context learning (Brown et al., 2020; Zhang et al., 2023; Vilar et al., 2022; Jiao et al., 2023; Hendy et al., 2023; Sia and Duh, 2023, *inter alia*), we design prompts to instruct LLMs to perform zero- and few-shot translations. Specifically, for few-shot translation, we employ a retrieval-based prompting method (Hendy et al., 2023; Moslem et al., 2023; Vilar et al., 2022) that retrieves source and target pairs from the training corpus as in-context learning (ICL) demonstrations.

To facilitate this process, we create a prompt template illustrated in Figure 2 *Left*. In this template, the retrieved examples are embedded within the assistant message to aid in the few-shot translation. To retrieve relevant examples, we utilize the BM25 (Robertson et al., 1994) retriever, with source sentences serving as queries. By searching the source language corpus, we identify the top matches and extract aligned parallel sentence pairs as demonstration examples.

Method	**BLEU**	**COMET**
Vanilla Transformer	41.4	80.4
GPT3.5 0-shot	31.4	82.1
GPT3.5 5-shot	47.6	84.6

Table 1: We compare average BLEU scores for prompt-based methods (using gpt-3.5-turbo-0301 endpoint to translate from German to English) and vanilla transformer (a 6-layer encoder-decoder structure as introduced by Vaswani et al. (2017)) trained on the in-domain dataset. We found that with few-shot translation, LLM could generate translation that achieves much better performance than 0-shot as well as domain-specific models.

We evaluate translation outputs using BLEU (Papineni et al., 2002) and COMET (Rei et al., 2020), and the results are presented in Table 1. In comparison to the few-shot performance (5-shot), zero-shot translation exhibits a noticeable gap of 16.2 points on the BLEU score. However, the difference is less significant when considering COMET, as the

---

[2] The dataset is originally collected by Koehn and Knowles (2017).

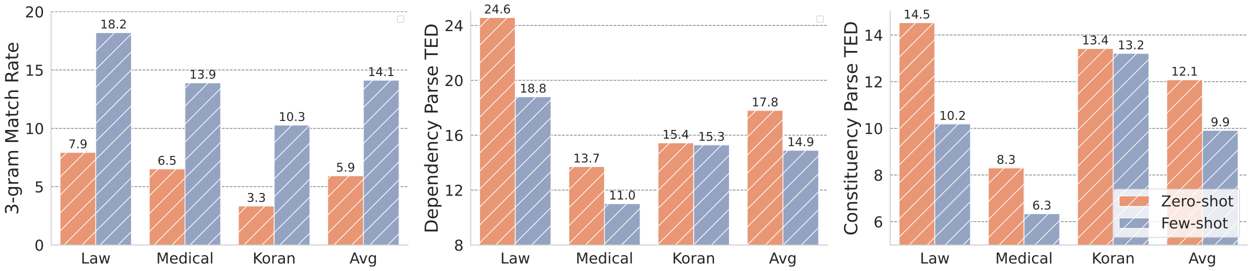

Figure 3: *Left*: trigram overlap analysis between *translations* and *retrieved examples*; the gaps between zero- and few-shot indicate that choices of lexicons in few-shot have been greatly impacted by retrieved demonstrations. *Mid*: averages of Tree Edit Distance (TED) between dependency parse trees from references and zero- or few-shot translations. Few-shot has a lower TED, showing that its grammar is more conformed with references. *Right*: averages of TED between constituency parses from references and zero- or few-shot translations. Again, the few-shot results with lower TED are more conformed in syntactical structure with references.

few-shot approach only outperforms the zero-shot counterpart by 2.5 points. To provide a better understanding of the COMET difference, we present a few examples in Figure 7 to illustrate how the score difference is reflected in translations.[3]

Examining the example with a COMET difference of 2.7 points, we observe that such a scale of difference, when mapped to lexicons, corresponds to only a few word changes, while the underlying semantics remain largely consistent with the reference. This minor difference in COMET scores indicates that zero-shot translations have already conveyed the semantic meaning of the source sentence, albeit with some variations in lexical choices and sentence structure.

3 How Much Does Style Contribute?

We have observed that the lexical difference between zero-shot and few-shot translations is more noticeable than their semantic difference. Following the traditional linguistic definition of language style (McDonald and Pustejovsky, 1985; Jin et al., 2022, *inter alia*), we can interpret this phenomenon as a distinction in writing style, where semantics remains consistent while aspects such as word choices, syntax, tones, etc., are altered.

To examine the potential impact of writing styles being learned through few-shot demonstrations, we investigate various aspects associated with writing styles to determine whether few-shot translation exhibits more consistent styles with target domains. We follow common techniques used in prior work (Calvo et al., 2014; Jankowska, 2017; Stamatatos et al., 2000) to analyze style matching through three aspects: lexical overlaps, syntactical structures, and word dependencies. These aspects provide valuable insights into the output style of different systems.

3.1 Choice of Lexicons

To understand how few-shot demonstrations affect lexicon usage in translations, we perform an analysis that identifies common n-gram presence between *retrieved samples* and *translations*. The match rate difference between zero- and few-shot indicates how much these examples change the choices of lexicons in translations. We compute average trigram match rates between top-5 retrieved samples and zero- and few-shot translations (shown in Figure 3 *Left*).[4] Across all domains, the n-gram match rates are much higher for few-shot translations, indicating that few-shot translations are being steered to be lexical-wise more similar to demonstrations. Given that few-shot translations obtain better scores on BLEU in general, we attribute a non-trivial portion of performance gain to lexicons learned from its demonstrations, *therefore better examples matched with target domains can potentially provide better guidance for few-shot translation*. A qualitative example is provided in Figure 6.

3.2 Organization of Sentence Structures

Word Semantic Relations The degree of style matching between translations and the references can be measured by comparing the roles of different words under dependency parse trees (shown in Figure 3 *Mid*).[5] We quantify the difference between parses using Tree Edit-Distance (TED),

---

[3] These examples serve as reference points to help readers qualitatively grasp the disparity in COMET scores.

[4] We explored a range of n-grams from unigram to 10-gram while observing a similar gap, thus presenting only the trigram results for simplicity.

[5] Dependency parsing and constituency parsing were performed using the spaCy toolkit (`https://spacy.io/`)

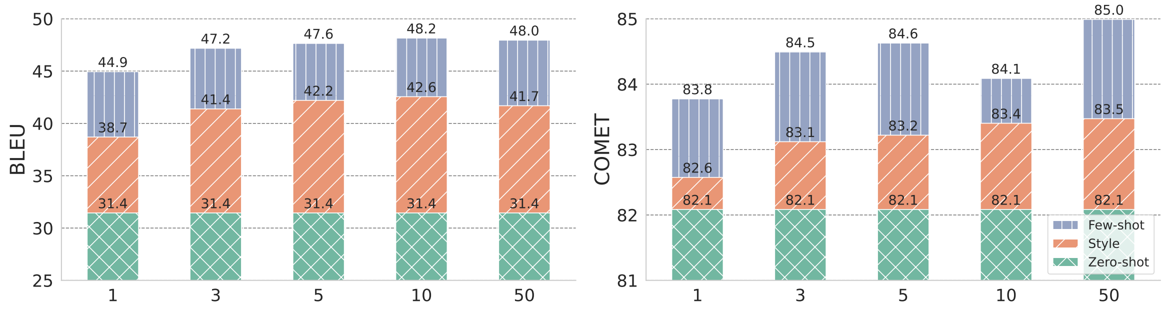

Figure 4: Results of few-shot, zero-shot, and zero-shot with style-learning prompting evaluated using BLEU and COMET. The x-axis is the number of demonstrations used in the prompt; in few-shot, they are parallel sentence pairs, whereas in zero-shot with style learning, they are just target samples. The y-axis is the metric score. Both few-shot and style-learning prompting improve from the zero-shot baseline substantially even with only one example.

where smaller mean closer (or more similar) between trees.[6] Few-shot translations exhibit a smaller overall TED, indicating closer alignments in word semantic relations with references.

Syntactical Structure Similarity We also apply TED on constituent trees to understand similarities of syntactical structures between translations and references.[7] Our results show that few-shot translations also demonstrates higher similarities in syntactical structures with target domains.

4 Narrowing the Gap via Matching Styles

From §3, we demonstrated that few-shot conforms to the target style better than zero-shot translation. Motivated by this observation, we investigate approaches to mitigate the style difference so that zero-shot translation can be improved without access to additional parallel examples.

We propose a novel style-learning prompting approach that leverages target corpora, as illustrated in Figure 2 *Right*. Our hypothesis is that style-relevant information primarily resides in the in-domain target corpus (in our case, English). Therefore, by retrieving samples from the corresponding monolingual corpus, the style-learning instruction would enhance style consistency in translation. This idea is in the same spirit as prior work in test time domain adaptation (Singh and Ortega, 2022; Zheng et al., 2022; Zhang et al., 2022; Hu et al., 2019, *inter alia*), where target domain information is used to guide model inference. In our case, we allow language models (LLMs) to access examples from the target corpora, enabling them to adjust their language styles.

Our approach has two steps: first, we employ zero-shot translation; then we take the translation output as a query to retrieve examples from the target language's corpus and *add them to the original translation prompt with a style-learning instruction*. By revising prompts with target examples, the approach allows us to align styles in translations without source-side demonstrations.

The performance comparison[8] among few-shot, zero-shot, and zero-shot with style matching is shown in Figure 4, where the number of demonstrations ranges from 1 to 50. From the results, few-shot prompting exhibits the best performance by leveraging both source and target information. Our style-learning prompts largely improve the zero-shot performance, reducing the gap by approximately 70%. To further validate these findings, we conducted experiments using the Llama2-7b model (Touvron et al., 2023), fixing the number of demonstrations at 5 for both German-English and English-German translation directions. As depicted in Table 2[9], the trend remains consistent, demonstrating that style-learning prompts effectively bridge the gap between zero-shot and few-shot translations. Interestingly, Llama2-7b shows less improvement with style-learning prompts and has a notably lower zero-shot baseline compared to GPT3.5, suggesting that the impact of style-learning varies among models, dependent on their initial translation capabilities.

Overall, few-shot prompting is still more effective and we attribute such advantages of few-

---

[6] TED is computed using the Zhang-shasa algorithm (Zhang and Shasha, 1989), a classical algorithm for computing similarity between two parses.

[7] We removed nodes at the bottom level so that TED would not reflect lexical differences.

[8] The breakdowns for domains are provided in Figure 8.

[9] Some numbers for GPT3.5 are slightly different from Figure 4 as they are rerun experiments over a 500 test subset

Direction	Method	Law		Med		Koran		Average	
		GPT3.5	Llama2	GPT3.5	Llama2	GPT3.5	Llama2	GPT3.5	Llama2
DE → EN	Zero-shot	37.2	32.5	44.5	39.2	17.9	14.4	33.2	28.7
	Style	48.9	46.1	57.8	44.6	19.8	15.5	42.2(+9.0)	35.4(+6.7)
	Few-shot	59.3	58.9	64.1	58.9	20.2	16.6	47.9(+14.7)	44.8(+16.1)
EN → DE	Zero-shot	32.1	22.6	38.8	28.7	12.8	8.3	27.9	19.9
	Style	41.1	28.0	47.8	32.9	23.5	14.9	37.4(+9.5)	25.2(+5.3)
	Few-shot	49.6	48.2	54.5	51.3	20.3	24.8	41.4(+13.5)	41.5(+21.6)

Table 2: GPT3.5 and Llama2-7b's performance (BLEU score) across different domains with zero-shot, few-shot, and style learning prompting. The style-learning prompting strategy improves both GPT3.5 and Llama2's performance with only monolingual information.

Prompt Style	Fewshot				Style			
	1-shot	5-shot	10-shot	Avg	1-shot	5-shot	10-shot	Avg
Tier 0	43.4	47.9	48.1	44.9	38.5	42.2	42.8	41.2
Tier 1	36.7	38.8	39.7	38.4 (-14%)	34.6	36.1	36.6	35.7 (-13%)
Tier 2	36.2	38.1	39.2	37.8 (-16%)	34.4	35.8	36.4	35.5 (-14%)
Tier 3	36.2	38.1	39.2	37.8 (-16%)	34.2	35.7	36.0	35.3 (-14%)

Table 3: Prompt performance (BLEU scores averaged across domains; more details in Table 5) with retrieved samples of varying quality. The evaluation results show that using a single demonstration from Tier 0 is more effective than using 10 demonstrations from Tier 1.

shot over style-learning prompting to:

- The few-shot setting has access to additional paired demonstrations, which can provide better guidance, such as language alignment, compared to monolingual examples employed in style-learning prompting.
- The retriever queries the target corpus with the potentially noisy translation generated from zero-shot translation for style-learning prompting.

Despite the remaining performance gap, our style-learning prompting method demonstrates increased data efficiency and adaptability of the language model to new domains where only monolingual resources are available.

Ablation on Retrieval Quality For both few-shot and our style-learning prompting, the quality of retrieved examples is important. We retrieved the 100 most similar samples with BM25 and separated them into four groups (tier 0 to 3, with 0 being the most similar group). As shown in Table 3, for both few-shot and style-learning, they benefit more from just a single example from tier 0 than from the 10 samplers from tier 1, indicating the importance of retrieval quality. For the full results, please refer to Table 5. In Figure 5, we also show that a dense retriever (based on sentence-transformer) obtains better demonstrations for the style-learning prompt. Though improving retrievers is orthogonal to our contribution of prompting strategy in this paper, we have shown that retriever is indeed essential in our pipeline for demonstration curation. We envision that a retriever that specifically attends to fine-grained style might be developed to further improve the style-learning prompting performance.

5 Conclusion

In this paper, we investigate the prompt-based zero- and few-shot translation performance on different domains. We attribute the performance gap to the style difference, and through our analysis, we verified that few-shot translation benefits from its retrieved samples by learning the target domain's style. We then design a style-learning prompting strategy that only requires monolingual information and effectively bridges the gap between zero- and few-shot translation.

Limitations

Model: This paper's experiment is currently based on the GPT3.5-0301 snapshot and LLaMa2-7b model, and we will include ICL performance from other LLMs in the future. However, we anticipate that the observed trends and findings would likely extend to other LLMs.

Translation Dataset: The translation datasets used in this study exclusively involve German-to-English translation, which represents a high-resource language pair. Consequently, the results may not be directly applicable to low-resource translation tasks or languages in which LLMs do not perform well. We leave the investigation of low-resource languages to future work.

A Experiment Setup

Model: For all our experiments, we use the publicly available ChatGPT *gpt-3.5-turbo-0301*[10] model. For hyper-parameters, we use *temperature* 0.3 throughout our experiments, and we set all other hyper-parameters using their default values.

Evaluation Metrics: We employ BLEU (Papineni et al., 2002) and COMET (Rei et al., 2020) to compare the reference and hypothesis.
