Preface

Welcome to the 8th International Joint Conference on Natural Language Processing (IJCNLP). IJCNLP was initiated in 2004 by the Asian Federation of Natural Language Processing (AFNLP) with the major goal to provide a platform for researchers and professionals around the world to share their experiences related to natural language processing and computational linguistics. In the past years, IJCNLPs were held in 7 different places: Hainan Island (2004), Jeju Island (2005), Hyderabad (2008), Singapore (2009), Chiang Mai (2011), Nagoya (2013) and Beijing (2015). This year the 8th IJCNLP is held in Taipei Nangang Exhibition Hall on November 27-December 1, 2017.

We are confident that you will find IJCNLP 2017 to be technically stimulating. The conference covers a broad spectrum of technical areas related to natural language processing and computation. Besides main conference, the program includes 3 keynote speeches, 6 tutorials, 17 demonstrations, 5 workshops, and 5 shared tasks (new event).

Before closing this brief welcome, we would like to thank the entire organizing committee for their long efforts to create an event that we hope will be memorable for you. Program chairs Greg Kondrak and Taro Watanabe coordinate the review process allowing for top quality papers to be presented at the conference. Workshop chairs Min Zhang and Yue Zhang organize 5 nice pre-conference and post-conference workshops. Tutorial chairs Sadao Kurohashi and Michael Strube select 6 very good tutorials. Demo chairs Seong-Bae Park and Thepchai Supnithi recommend 17 demonstrations. Shared Task chairs Chao-Hong Liu, Preslav Nakov and Nianwen Xue choose 5 interesting shared tasks. Sponsorship chairs Youngkil Kim, Tong Xiao, Kazuhide Yamamoto and Jui-Feng Yeh design sponsor packages and find financial supports. We thank all the sponsors. Publicity chairs Pushpak Bhattacharya, Xuanjing Huang, Gina-Anne Levow, Chi Mai Loung and Sebastian Stüker help circulate the conference information and promote the conference. We would like to express our special thanks to publication chairs Lung-Hao Lee and Derek F. Wong. After the hard work, they deliver an excellent proceeding to the participants.

Finally, we would like to thank all authors for submitting high quality research this year. We hope all of you enjoy the conference program, and your stay at this beautiful city of Taipei.

General Chair

Chengqing Zong, Institute of Automation, Chinese Academy of Sciences, China

Organization Co-Chairs

Hsin-Hsi Chen, National Taiwan University, Taiwan

Yuen-Hsien Tseng, National Taiwan Normal University, Taiwan

Chung-Hsien Wu, National Cheng Kung University, Taiwan

Liang-Chih Yu, Yuan Ze University, Taiwan

Message from the Program Co-Chairs

Welcome to the 8th International Joint Conference on Natural Language Processing (IJCNLP 2017) organized by National Taiwan Normal University and the Association for Computational Linguistics and Chinese Language Processing (ACLCLP) and hosted by The Asian Federation of Natural Language Processing (AFNLP).

Since the first meeting in 2004, IJCNLP has established itself as a major NLP conference. This year, we received 580 submissions (337 long and 243 short), which is by far the largest number ever for a stand-alone IJCNLP conference. From these, 179 papers (103 long and 76 short) were accepted to appear at the conference, which represents an acceptance rate of 31%. In particular, approximately 46% of the accepted papers are from Asia Pacific, 30% from North America, and 20% from Europe.

Our objective is to keep the conference to three parallel sessions at any one time. 86 long papers and 21 short papers are scheduled as oral presentations, while 17 long papers and 55 short papers will be presented as posters.

We are also very pleased to announce three exciting keynote talks by the renowned NLP researchers: Rada Mihalcea (University of Michigan), Trevor Cohn (University of Melbourne) and Jason Eisner (Johns Hopkins University).

The conference will conclude with the award presentation ceremony. The Best Paper Award goes to Nikolaos Pappas and Andrei Popescu-Belis for their paper “Multilingual Hierarchical Attention Networks for Document Classification.” The Best Student Paper award goes to “Roles and Success in Wikipedia Talk Pages: Identifying Latent Patterns of Behavior” by Keith Maki, Michael Yoder, Yohan Jo and Carolyn Rosé.

We would like to thank everyone who has helped make IJCNLP 2017 a success. In particular, the area chairs (who are listed in the Program Committee section) worked hard on recruiting reviewers, managing reviews, leading discussions, and making recommendations. The quality of the technical program reflects the expertise of our 536 reviewers. All submissions were reviewed by at least three reviewers. The review process for the conference was double-blind, and included an author response period, as well as subsequent discussions.

We would like to acknowledge the help and advice from the General Chair Chengqing Zong, and the Local Arrangements Committee headed by Liang-Chih Yu. We thank the Publication Chairs Lung-Hao Lee and Derek F. Wong for putting together the conference proceedings and handbook, and all the other committee chairs for their great work.

We hope you will enjoy IJCNLP 2017!

IJCNLP 2017 Program Co-Chairs

Greg Kondrak, University of Alberta
Taro Watanabe, Google

Organizing Committee

Conference Chair

Chengqing Zong, Institute of Automation, Chinese Academy of Sciences

Program Committee Co-Chairs

Greg Kondrak, University of Alberta
Taro Watanabe, Google

Workshop Co-Chairs

Min Zhang, Soochow University
Yue Zhang, Singapore University of Technology and Design

Tutorial Co-Chairs

Sadao Kurohashi, Kyoto University
Michael Strube, Heidelberg Institute for Theoretical Studies

Demo Co-Chairs

Seong-Bae Park, Kyungpook National University
Thepchai Supnithi, National Electronics and Computer Technology Center (NECTEC) of Thailand

Shared Task Workshop Co-Chairs

Chao-Hong Liu, ADAPT Centre, Dublin City University
Preslav Nakov, Qatar Computing Research Institute
Nianwen Xue, Brandies University

Publication Co-Chairs

Lung-Hao Lee, National Taiwan Normal University
Derek F. Wong, University of Macau

Sponsorship Co-Chairs

Youngkil Kim, ETRI
Tong Xiao, Northeast University
Kazuhide Yamamoto, Nagaoka University of Technology
Jui-Feng Yeh, National Chiayi University

Publicity Co-Chairs

Pushpak Bhattacharya, IITB
Xuanjing Huang, Fudan University
Gina-Anne Levow, University of Washington
Chi Mai Loung, Institute of Information Technology
Sebastian Stüker, Karlsruhe Institute of Technology

Financial Chair

Lun-Wei Ku, Institute of Information Sciences, Academia Sinica

Local Co-Chairs

Hsin-Hsi Chen, National Taiwan University

Yuen-Hsien Tseng, National Taiwan Normal University

Chung-Hsien Wu, National Cheng Kung University

Liang-Chih Yu, Yuan Ze University

Program Committee

Program Committee Co-Chairs

Greg Kondrak, University of Alberta
Taro Watanabe, Google

Area Chairs

Mausam (Information Extraction and Text Mining Area)
Asli Celikyilmaz (Semantics Area)
Wenliang Chen (Syntax and Parsing Area)
Colin Cherry (Machine Translation Area)
Jackie Chi Kit Cheung (Summarization and Generation Area)
Monojit Choudhury (Resources and Tools Area)
Kevin Duh (Semantics Area)
Micha Elsner (Discourse, Dialogue, Pragmatics Area)
Manaal Faruqi (Machine Learning Area)
Jianfeng Gao (Information Retrieval and Question Answering Area)
Yvette Graham (Machine Translation Area)
Gholamreza Haffari (Machine Learning Area)
Liang Huang (Syntax and Parsing Area)
Minlie Huang (Sentiment Analysis and Opinion Mining Area)
Mans Hulden (Morphology, Segmentation and Tagging Area)
Nancy Ide (Resources and Tools Area)
Jing Jiang (Sentiment Analysis and Opinion Mining Area)
Daisuke Kawahara (Semantics Area)
Mamoru Komachi (NLP Applications Area)
Fei Liu (Web and Social Media Area)
Zhiyuan Liu (Web and Social Media Area)
Wei Lu (Information Extraction and Text Mining Area)
Ryo Nagata (NLP Applications Area) Mikio Nakano (Discourse, Dialogue, Pragmatics Area)
Jong-Hoon Oh (Information Retrieval and Question Answering Area)
Thamar Solorio (Sentiment Analysis and Opinion Mining Area)
Xu Sun (Morphology, Segmentation and Tagging Area)
Jun Suzuki (Machine Learning Area)
Xiaojun Wan (Summarization and Generation Area)
Tiejun Zhao (Machine Translation Area)

Reviewers

Ahmed Abbasi, Željko Agić, Alan Akbik, Chris Alberti, Enrique Alfonseca, David Alvarez-Melis, Silvio Amir, Daniel Andrade, Marianna Apidianaki, Jun Araki, Yuki Arase, Yoav Artzi, Kristjan Arumae, Wilker Aziz

Invited Talk: Words and People

Rada Mihalcea

University of Michigan

Abstract

What do the words we use say about us and about how we view the world surrounding us? And what do we - as speakers of those words with our own defining attributes, imply about the words we utter? In this talk, I will explore the relation between words and people and show how we can develop cross-cultural word models to identify words with cultural bias – i.e., words that are used in significantly different ways by speakers from different cultures. Further, I will also show how we can effectively use information about the speakers of a word (i.e., their gender, culture) to build better word models.

Biography

Rada Mihalcea is a Professor in the Computer Science and Engineering department at the University of Michigan. Her research interests are in computational linguistics, with a focus on lexical semantics, multilingual natural language processing, and computational social sciences. She serves or has served on the editorial boards of the Journals of Computational Linguistics, Language Resources and Evaluations, Natural Language Engineering, Research in Language in Computation, IEEE Transactions on Affective Computing, and Transactions of the Association for Computational Linguistics. She was a program co-chair for the Conference of the Association for Computational Linguistics (2011) and the Conference on Empirical Methods in Natural Language Processing (2009), and a general chair for the Conference of the North American Chapter of the Association for Computational Linguistics (2015). She is the recipient of a National Science Foundation CAREER award (2008) and a Presidential Early Career Award for Scientists and Engineers awarded by President Obama (2009). In 2013, she was made an honorary citizen of her hometown of Cluj-Napoca, Romania.

Invited Talk: Learning Large and Small: How to Transfer NLP Successes to Low-resource Languages

Trevor Cohn

University of Melbourne

Abstract

Recent advances in NLP have predominantly been based upon supervised learning over large corpora, where rich expressive models, such as deep learning methods, can perform exceptionally well. However, these state of the art approaches tend to be very data hungry, and consequently do not elegantly scale down to smaller corpora, which are more typical in many NLP applications.

In this talk, I will describe the importance of small data in our field, drawing particular attention to so-called “low-” or “under-resourced” languages, for which corpora are scarce, and linguistic annotations scarcer yet. One of the key problems for our field is how to translate successes on the few high-resource languages to practical technologies for the remaining majority of the world’s languages. I will cover several research problems in this space, including transfer learning between high- and low-resource languages, active learning for selecting text for annotation, and speech processing in a low-resource setting, namely learning to translate audio inputs without transcriptions. I will finish by discussing open problems in natural language processing that will be critical in porting highly successful NLP work to the myriad of less-well-studied languages.

Biography

Trevor Cohn is an Associate Professor and ARC Future Fellow at the University of Melbourne, in the School of Computing and Information Systems. He received Bachelor degrees in Software Engineering and Commerce, and a PhD degree in Engineering from the University of Melbourne. He was previously based at the University of Sheffield, and before this worked as a Research Fellow at the University of Edinburgh. His research interests focus on probabilistic and statistical machine learning for natural language processing, with applications in several areas including machine translation, parsing and grammar induction. Current projects include translating diverse and noisy text sources, deep learning of semantics in translation, rumour diffusion over social media, and algorithmic approaches for scaling to massive corpora. Dr. Cohn’s research has been recognised by several best paper awards, including best short paper at EMNLP in 2016. He will be jointly organising ACL 2018 in Melbourne.

Invited Talk: Strategies for Discovering Underlying Linguistic Structure

Jason Eisner

Johns Hopkins University

Abstract

A goal of computational linguistics is to automate the kind of reasoning that linguists do. Given text in a new language, can we determine the underlying morphemes and the grammar rules that arrange and modify them?

The Bayesian strategy is to devise a joint probabilistic model that is capable of generating the descriptions of new languages. Given data from a particular new language, we can then seek explanatory descriptions that have high prior probability. This strategy leads to fascinating and successful algorithms in the case of morphology.

Yet the Bayesian approach has been less successful for syntax. It is limited in practice by our ability to (1) design accurate models and (2) solve the computational problem of posterior inference. I will demonstrate some remedies: build only a partial (conditional) model, and use synthetic data to train a neural network that simulates correct posterior inference.

Biography

Jason Eisner is Professor of Computer Science at Johns Hopkins University, where he is also affiliated with the Center for Language and Speech Processing, the Machine Learning Group, the Cognitive Science Department, and the national Center of Excellence in Human Language Technology. His goal is to develop the probabilistic modeling, inference, and learning techniques needed for a unified model of all kinds of linguistic structure. His 100+ papers have presented various algorithms for parsing, machine translation, and weighted finite-state machines; formalizations, algorithms, theorems, and empirical results in computational phonology; and unsupervised or semi-supervised learning methods for syntax, morphology, and word-sense disambiguation. He is also the lead designer of Dyna, a new declarative programming language that provides an infrastructure for AI research. He has received two school-wide awards for excellence in teaching.

Table of Contents

<i>Evaluating Layers of Representation in Neural Machine Translation on Part-of-Speech and Semantic Tagging Tasks</i>	
Yonatan Belinkov, Lluís Màrquez, Hassan Sajjad, Nadir Durrani, Fahim Dalvi and James Glass . . .	1
<i>Context-Aware Smoothing for Neural Machine Translation</i>	
Kehai Chen, Rui Wang, Masao Utiyama, Eiichiro Sumita and Tiejun Zhao	11
<i>Improving Sequence to Sequence Neural Machine Translation by Utilizing Syntactic Dependency Information</i>	
An Nguyen Le, Ander Martinez, Akifumi Yoshimoto and Yuji Matsumoto	21
<i>What does Attention in Neural Machine Translation Pay Attention to?</i>	
Hamidreza Ghader and Christof Monz	30
<i>Grammatical Error Detection Using Error- and Grammaticality-Specific Word Embeddings</i>	
Masahiro Kaneko, Yuya Sakaizawa and Mamoru Komachi	40
<i>Dependency Parsing with Partial Annotations: An Empirical Comparison</i>	
Yue Zhang, Zhenghua Li, Jun Lang, Qingrong Xia and Min Zhang	49
<i>Neural Probabilistic Model for Non-projective MST Parsing</i>	
Xuezhe Ma and Eduard Hovy	59
<i>Word Ordering as Unsupervised Learning Towards Syntactically Plausible Word Representations</i>	
Noriki Nishida and Hideki Nakayama	70
<i>MIPA: Mutual Information Based Paraphrase Acquisition via Bilingual Pivoting</i>	
Tomoyuki Kajiwara, Mamoru Komachi and Daichi Mochihashi	80
<i>Improving Implicit Semantic Role Labeling by Predicting Semantic Frame Arguments</i>	
Quynh Ngoc Thi Do, Steven Bethard and Marie-Francine Moens	90
<i>Natural Language Inference from Multiple Premises</i>	
Alice Lai, Yonatan Bisk and Julia Hockenmaier	100
<i>Enabling Transitivity for Lexical Inference on Chinese Verbs Using Probabilistic Soft Logic</i>	
Wei-Chung Wang and Lun-Wei Ku	110
<i>An Exploration of Neural Sequence-to-Sequence Architectures for Automatic Post-Editing</i>	
Marcin Junczys-Dowmunt and Roman Grundkiewicz	120
<i>Imagination Improves Multimodal Translation</i>	
Desmond Elliott and Ákos Kádár	130
<i>Understanding and Improving Morphological Learning in the Neural Machine Translation Decoder</i>	
Fahim Dalvi, Nadir Durrani, Hassan Sajjad, Yonatan Belinkov and Stephan Vogel	142
<i>Improving Neural Machine Translation through Phrase-based Forced Decoding</i>	
Jingyi Zhang, Masao Utiyama, Eiichiro Sumita, Graham Neubig and Satoshi Nakamura	152
<i>Convolutional Neural Network with Word Embeddings for Chinese Word Segmentation</i>	
Chunqi Wang and Bo Xu	163

<i>Character-based Joint Segmentation and POS Tagging for Chinese using Bidirectional RNN-CRF</i> Yan Shao, Christian Hardmeier, Jörg Tiedemann and Joakim Nivre	173
<i>Addressing Domain Adaptation for Chinese Word Segmentation with Global Recurrent Structure</i> Shen Huang, Xu Sun and Houfeng Wang	184
<i>Information Bottleneck Inspired Method For Chat Text Segmentation</i> S Vishal, Mohit Yadav, Lovekesh Vig and Gautam Shroff	194
<i>Distributional Modeling on a Diet: One-shot Word Learning from Text Only</i> Su Wang, Stephen Roller and Katrin Erk	204
<i>A Computational Study on Word Meanings and Their Distributed Representations via Polymodal Embedding</i> Joohee Park and Sung-Hyon Myaeng	214
<i>Geographical Evaluation of Word Embeddings</i> Michal Konkol, Tomáš Brychcín, Michal Nykl and Tomáš Hercig	224
<i>On Modeling Sense Relatedness in Multi-prototype Word Embedding</i> Yixin Cao, Jiaxin Shi, Juanzi Li, Zhiyuan Liu and Chengjiang Li	233
<i>Unsupervised Segmentation of Phoneme Sequences based on Pitman-Yor Semi-Markov Model using Phoneme Length Context</i> Ryu Takeda and Kazunori Komatani	243
<i>A Sensitivity Analysis of (and Practitioners' Guide to) Convolutional Neural Networks for Sentence Classification</i> Ye Zhang and Byron Wallace	253
<i>Coordination Boundary Identification with Similarity and Replaceability</i> Hiroki Teranishi, Hiroyuki Shindo and Yuji Matsumoto	264
<i>Turning Distributional Thesauri into Word Vectors for Synonym Extraction and Expansion</i> Olivier Ferret	273
<i>Training Word Sense Embeddings With Lexicon-based Regularization</i> Luis Nieto Piña and Richard Johansson	284
<i>Learning How to Simplify From Explicit Labeling of Complex-Simplified Text Pairs</i> Fernando Alva-Manchego, Joachim Bingel, Gustavo Paetzold, Carolina Scarton and Lucia Specia	295
<i>Domain-Adaptable Hybrid Generation of RDF Entity Descriptions</i> Or Biran and Kathleen McKeown	306

Roles and Success in Wikipedia Talk Pages: Identifying Latent Patterns of Behavior
Keith Maki, Michael Yoder, Yohan Jo and Carolyn Rosé.....1026

Conference Program

Tuesday, November 28, 2017

10:30–11:50 Machine Translation 1

10:30–10:50 *Evaluating Layers of Representation in Neural Machine Translation on Part-of-Speech and Semantic Tagging Tasks*

Yonatan Belinkov, Lluís Màrquez, Hassan Sajjad, Nadir Durrani, Fahim Dalvi and James Glass

10:50–11:10 *Context-Aware Smoothing for Neural Machine Translation*

Kehai Chen, Rui Wang, Masao Utiyama, Eiichiro Sumita and Tiejun Zhao

11:10–11:30 *Improving Sequence to Sequence Neural Machine Translation by Utilizing Syntactic Dependency Information*

An Nguyen Le, Ander Martinez, Akifumi Yoshimoto and Yuji Matsumoto

11:30–11:50 *What does Attention in Neural Machine Translation Pay Attention to?*

Hamidreza Ghader and Christof Monz

Tuesday, November 28, 2017

10:30–11:50 Syntax and Parsing

10:30–10:50 *Grammatical Error Detection Using Error- and Grammaticality-Specific Word Embeddings*

Masahiro Kaneko, Yuya Sakaizawa and Mamoru Komachi

10:50–11:10 *Dependency Parsing with Partial Annotations: An Empirical Comparison*

Yue Zhang, Zhenghua Li, Jun Lang, Qingrong Xia and Min Zhang

11:10–11:30 *Neural Probabilistic Model for Non-projective MST Parsing*

Xuezhe Ma and Eduard Hovy

11:30–11:50 *Word Ordering as Unsupervised Learning Towards Syntactically Plausible Word Representations*

Noriki Nishida and Hideki Nakayama

Tuesday, November 28, 2017

10:30–11:50 Semantics 1

- 10:30–10:50 *MIPA: Mutual Information Based Paraphrase Acquisition via Bilingual Pivoting*
Tomoyuki Kajiwara, Mamoru Komachi and Daichi Mochihashi
- 10:50–11:10 *Improving Implicit Semantic Role Labeling by Predicting Semantic Frame Arguments*
Quynh Ngoc Thi Do, Steven Bethard and Marie-Francine Moens
- 11:10–11:30 *Natural Language Inference from Multiple Premises*
Alice Lai, Yonatan Bisk and Julia Hockenmaier
- 11:30–11:50 *Enabling Transitivity for Lexical Inference on Chinese Verbs Using Probabilistic Soft Logic*
Wei-Chung Wang and Lun-Wei Ku

Tuesday, November 28, 2017

13:30–14:50 Machine Translation 2

- 13:30–13:50 *An Exploration of Neural Sequence-to-Sequence Architectures for Automatic Post-Editing*
Marcin Junczys-Dowmunt and Roman Grundkiewicz
- 13:50–14:10 *Imagination Improves Multimodal Translation*
Desmond Elliott and kos Kadar
- 14:10–14:30 *Understanding and Improving Morphological Learning in the Neural Machine Translation Decoder*
Fahim Dalvi, Nadir Durrani, Hassan Sajjad, Yonatan Belinkov and Stephan Vogel
- 14:30–14:50 *Improving Neural Machine Translation through Phrase-based Forced Decoding*
Jingyi Zhang, Masao Utiyama, Eiichiro Sumita, Graham Neubig and Satoshi Nakamura

Tuesday, November 28, 2017

13:30–14:50 Segmentation and Tagging

- 13:30–13:50 *Convolutional Neural Network with Word Embeddings for Chinese Word Segmentation*
Chunqi Wang and Bo Xu
- 13:50–14:10 *Character-based Joint Segmentation and POS Tagging for Chinese using Bidirectional RNN-CRF*
Yan Shao, Christian Hardmeier, Jörg Tiedemann and Joakim Nivre
- 14:10–14:30 *Addressing Domain Adaptation for Chinese Word Segmentation with Global Recurrent Structure*
Shen Huang, Xu Sun and Houfeng Wang
- 14:30–14:50 *Information Bottleneck Inspired Method For Chat Text Segmentation*
S Vishal, Mohit Yadav, Lovekesh Vig and Gautam Shroff

Tuesday, November 28, 2017

13:30–14:50 Semantics 2

- 13:30–13:50 *Distributional Modeling on a Diet: One-shot Word Learning from Text Only*
Su Wang, Stephen Roller and Katrin Erk
- 13:50–14:10 *A Computational Study on Word Meanings and Their Distributed Representations via Polymodal Embedding*
Joohee Park and Sung-Hyon Myaeng
- 14:10–14:30 *Geographical Evaluation of Word Embeddings*
Michal Konkol, Tomáš Brychcín, Michal Nykl and Tomáš Hercig
- 14:30–14:50 *On Modeling Sense Relatedness in Multi-prototype Word Embedding*
Yixin Cao, Jiaxin Shi, Juanzi Li, Zhiyuan Liu and Chengjiang Li

Tuesday, November 28, 2017

15:30–17:30 Poster and Demo

Unsupervised Segmentation of Phoneme Sequences based on Pitman-Yor Semi-Markov Model using Phoneme Length Context

Ryu Takeda and Kazunori Komatani

A Sensitivity Analysis of (and Practitioners' Guide to) Convolutional Neural Networks for Sentence Classification

Ye Zhang and Byron Wallace

Coordination Boundary Identification with Similarity and Replaceability

Hiroki Teranishi, Hiroyuki Shindo and Yuji Matsumoto

Turning Distributional Thesauri into Word Vectors for Synonym Extraction and Expansion

Olivier Ferret

Training Word Sense Embeddings With Lexicon-based Regularization

Luis Nieto Piña and Richard Johansson

Learning How to Simplify From Explicit Labeling of Complex-Simplified Text Pairs

Fernando Alva-Manchego, Joachim Bingel, Gustavo Paetzold, Carolina Scarton and Lucia Specia

Domain-Adaptable Hybrid Generation of RDF Entity Descriptions

Or Biran and Kathleen McKeown

ES-LDA: Entity Summarization using Knowledge-based Topic Modeling

Seyedamin Pouriyeh, Mehdi Allahyari, Krzysztof Kochut, Gong Cheng and Hamid Reza Arabnia

Procedural Text Generation from an Execution Video

Atsushi Ushiku, Hayato Hashimoto, Atsushi Hashimoto and Shinsuke Mori

Text Sentiment Analysis based on Fusion of Structural Information and Serialization Information

Ling Gan and Houyu Gong

Tuesday, November 28, 2017 (continued)

Length, Interchangeability, and External Knowledge: Observations from Predicting Argument Convincingness

Peter Potash, Robin Bhattacharya and Anna Rumshisky

Exploiting Document Level Information to Improve Event Detection via Recurrent Neural Networks

Shaoyang Duan, Ruifang He and Wenli Zhao

Embracing Non-Traditional Linguistic Resources for Low-resource Language Name Tagging

Boliang Zhang, Di Lu, Xiaoman Pan, Ying Lin, Halidanmu Abudukelimu, Heng Ji and Kevin Knight

NMT or SMT: Case Study of a Narrow-domain English-Latvian Post-editing Project

Inguna Skadina and Mārcis Pinnis

Towards Neural Machine Translation with Partially Aligned Corpora

Yining Wang, Yang Zhao, Jiajun Zhang, Chengqing Zong and Zhengshan Xue

Identifying Usage Expression Sentences in Consumer Product Reviews

Shibamouli Lahiri, V.G.Vinod Vydiswaran and Rada Mihalcea

Between Reading Time and Syntactic/Semantic Categories

Masayuki Asahara and Sachi Kato

WiNER: A Wikipedia Annotated Corpus for Named Entity Recognition

Abbas Ghaddar and Phillippe Langlais

Wednesday, November 29, 2017

10:30–11:50 Machine Learning 1

- 10:30–10:50 *Reusing Neural Speech Representations for Auditory Emotion Recognition*
Egor Lakomkin, Cornelius Weber, Sven Magg and Stefan Wermter
- 10:50–11:10 *Local Monotonic Attention Mechanism for End-to-End Speech And Language Processing*
Andros Tjandra, Sakriani Sakti and Satoshi Nakamura
- 11:10–11:30 *Attentive Language Models*
Giancarlo Salton, Robert Ross and John Kelleher
- 11:30–11:50 *Diachrony-aware Induction of Binary Latent Representations from Typological Features*
Yugo Murawaki

Wednesday, November 29, 2017

10:30–11:50 Discourse 1

- 10:30–10:50 *Image-Grounded Conversations: Multimodal Context for Natural Question and Response Generation*
Nasrin Mostafazadeh, Chris Brockett, Bill Dolan, Michel Galley, Jianfeng Gao, Georgios Spithourakis and Lucy Vanderwende
- 10:50–11:10 *A Neural Language Model for Dynamically Representing the Meanings of Unknown Words and Entities in a Discourse*
Sosuke Kobayashi, Naoaki Okazaki and Kentaro Inui
- 11:10–11:30 *Using Explicit Discourse Connectives in Translation for Implicit Discourse Relation Classification*
Wei Shi, Frances Yung, Raphael Rubino and Vera Demberg
- 11:30–11:50 *Tag-Enhanced Tree-Structured Neural Networks for Implicit Discourse Relation Classification*
Yizhong Wang, Sujian Li, Jingfeng Yang, Xu Sun and Houfeng Wang

Wednesday, November 29, 2017

10:30–11:50 Sentiment and Opinion 1

- 10:30–10:50 *Cross-Lingual Sentiment Analysis Without (Good) Translation*
Mohamed Abdalla and Graeme Hirst
- 10:50–11:10 *Implicit Syntactic Features for Target-dependent Sentiment Analysis*
Yuze Gao, Yue Zhang and Tong Xiao
- 11:10–11:30 *Graph Based Sentiment Aggregation using ConceptNet Ontology*
Srikanth Tamilselvam, Seema Nagar, Abhijit Mishra and Kuntal Dey
- 11:30–11:50 *Sentence Modeling with Deep Neural Architecture using Lexicon and Character Attention Mechanism for Sentiment Classification*
Huy-Thanh Nguyen and Minh-Le Nguyen

Wednesday, November 29, 2017

13:30–14:50 Machine Learning 2

- 13:30–13:50 *Combining Lightly-Supervised Text Classification Models for Accurate Contextual Advertising*
Yiping Jin, Dittaya Wanvarie and Phu Le
- 13:50–14:10 *Capturing Long-range Contextual Dependencies with Memory-enhanced Conditional Random Fields*
Fei Liu, Timothy Baldwin and Trevor Cohn
- 14:10–14:30 *Named Entity Recognition with Stack Residual LSTM and Trainable Bias Decoding*
Quan Tran, Andrew MacKinlay and Antonio Jimeno Yepes
- 14:30–14:50 *Neuramanteau: A Neural Network Ensemble Model for Lexical Blends*
Kollol Das and Shaona Ghosh

Wednesday, November 29, 2017

13:30–14:50 Discourse 2

- 13:30–13:50 *Leveraging Discourse Information Effectively for Authorship Attribution*
Elisa Ferracane, Su Wang and Raymond Mooney
- 13:50–14:10 *Lightly-Supervised Modeling of Argument Persuasiveness*
Isaac Persing and Vincent Ng
- 14:10–14:30 *Multi-Task Learning for Speaker-Role Adaptation in Neural Conversation Models*
Yi Luan, Chris Brockett, Bill Dolan, Jianfeng Gao and Michel Galley
- 14:30–14:50 *Chat Disentanglement: Identifying Semantic Reply Relationships with Random Forests and Recurrent Neural Networks*
Shikib Mehri and Giuseppe Carenini

Wednesday, November 29, 2017

13:30–14:50 Sentiment and Opinion 2

- 13:30–13:50 *Towards Bootstrapping a Polarity Shifter Lexicon using Linguistic Features*
Marc Schulder, Michael Wiegand, Josef Ruppenhofer and Benjamin Roth
- 13:50–14:10 *Cascading Multiway Attentions for Document-level Sentiment Classification*
Dehong Ma, Sujian Li, Xiaodong Zhang, Houfeng Wang and Xu Sun
- 14:10–14:30 *An Ensemble Method with Sentiment Features and Clustering Support*
Nguyen Huy Tien and Nguyen Minh Le
- 14:30–14:50 *Leveraging Auxiliary Tasks for Document-Level Cross-Domain Sentiment Classification*
Jianfei Yu and Jing Jiang

Wednesday, November 29, 2017

15:30–16:50 Word

15:30–15:50 *Measuring Semantic Relations between Human Activities*

Steven Wilson and Rada Mihalcea

15:50–16:10 *Learning Transferable Representation for Bilingual Relation Extraction via Convolutional Neural Networks*

Bonan Min, Zhuolin Jiang, Marjorie Freedman and Ralph Weischedel

16:10–16:30 *Bilingual Word Embeddings for Bilingual Terminology Extraction from Specialized Comparable Corpora*

Amir Hazem and Emmanuel Morin

16:30–16:50 *A Bambara Tonalization System for Word Sense Disambiguation Using Differential Coding, Segmentation and Edit Operation Filtering*

Luigi (Yu-Cheng) Liu and Damien Nouvel

Wednesday, November 29, 2017

15:30–16:50 Dialogue

15:30–15:50 *Joint Learning of Dialog Act Segmentation and Recognition in Spoken Dialog Using Neural Networks*

Tianyu Zhao and Tatsuya Kawahara

15:50–16:10 *Predicting Users' Negative Feedbacks in Multi-Turn Human-Computer Dialogues*

Xin Wang, Jianan Wang, Yuanhao Liu, Xiaolong Wang, Zhuoran Wang and Baoxun Wang

16:10–16:30 *Finding Dominant User Utterances And System Responses in Conversations*

Dhiraj Madan and Sachindra Joshi

16:30–16:50 *End-to-End Task-Completion Neural Dialogue Systems*

Xiujun Li, Yun-Nung Chen, Lihong Li, Jianfeng Gao and Asli Celikyilmaz

Wednesday, November 29, 2017

15:30–16:50 Web and Social Media

- 15:30–15:50 *End-to-end Network for Twitter Geolocation Prediction and Hashing*
Jey Han Lau, Lianhua Chi, Khoi-Nguyen Tran and Trevor Cohn
- 15:50–16:10 *Assessing the Verifiability of Attributions in News Text*
Edward Newell, Ariane Schang, Drew Margolin and Derek Ruths
- 16:10–16:30 *Domain Adaptation from User-level Facebook Models to County-level Twitter Predictions*
Daniel Rieman, Kokil Jaidka, H. Andrew Schwartz and Lyle Ungar
- 16:30–16:50 *Recognizing Explicit and Implicit Hate Speech Using a Weakly Supervised Two-path Bootstrapping Approach*
Lei Gao, Alexis Koppersmith and Ruihong Huang

Thursday, November 30, 2017

10:30–11:50 Summarization

- 10:30–10:50 *Estimating Reactions and Recommending Products with Generative Models of Reviews*
Jianmo Ni, Zachary C. Lipton, Sharad Vikram and Julian McAuley
- 10:50–11:10 *Summarizing Lengthy Questions*
Tatsuya Ishigaki, Hiroya Takamura and Manabu Okumura
- 11:10–11:30 *Concept-Map-Based Multi-Document Summarization using Concept Coreference Resolution and Global Importance Optimization*
Tobias Falke, Christian M. Meyer and Iryna Gurevych
- 11:30–11:50 *Abstractive Multi-document Summarization by Partial Tree Extraction, Recombination and Linearization*
Litton J Kurisinkel, Yue Zhang and Vasudeva Varma

Thursday, November 30, 2017

10:30–11:50 Information Extraction

- 10:30–10:50 *Event Argument Identification on Dependency Graphs with Bidirectional LSTMs*
Alex Judea and Michael Strube
- 10:50–11:10 *Selective Decoding for Cross-lingual Open Information Extraction*
Sheng Zhang, Kevin Duh and Benjamin Van Durme
- 11:10–11:30 *Event Ordering with a Generalized Model for Sieve Prediction Ranking*
Bill McDowell, Nathanael Chambers, Alexander Ororbia II and David Reitter
- 11:30–11:50 *Open Relation Extraction and Grounding*
Dian Yu, Lifu Huang and Heng Ji

Thursday, November 30, 2017

10:30–11:50 NLP Application

- 10:30–10:50 *Extraction of Gene-Environment Interaction from the Biomedical Literature*
Jinseon You, Jin-Woo Chung, Wonsuk Yang and Jong C. Park
- 10:50–11:10 *Course Concept Extraction in MOOCs via Embedding-Based Graph Propagation*
Liangming Pan, Xiaochen Wang, Chengjiang Li, Juanzi Li and Jie Tang
- 11:10–11:30 *Identity Deception Detection*
Verónica Pérez-Rosas, Quincy Davenport, Anna Mengdan Dai, Mohamed Abouelenien and Rada Mihalcea
- 11:30–11:50 *Learning to Diagnose: Assimilating Clinical Narratives using Deep Reinforcement Learning*
Yuan Ling, Sadid A. Hasan, Vivek Datla, Ashequl Qadir, Kathy Lee, Joey Liu and Oladimeji Farri

Thursday, November 30, 2017

13:30–14:50 Generation

- 13:30–13:50 *Dataset for a Neural Natural Language Interface for Databases (NNLIDB)*
Florin Brad, Radu Cristian Alexandru Iacob, Ionel Alexandru Hosu and Traian Rebedea
- 13:50–14:10 *Acquisition and Assessment of Semantic Content for the Generation of Elaborateness and Indirectness in Spoken Dialogue Systems*
Louisa Pragst, Koichiro Yoshino, Wolfgang Minker, Satoshi Nakamura and Stefan Ultes
- 14:10–14:30 *Demographic Word Embeddings for Racism Detection on Twitter*
Mohammed Hasanuzzaman, Gaël Dias and Andy Way
- 14:30–14:50 *Automatically Extracting Variant-Normalization Pairs for Japanese Text Normalization*
Itsumi Saito, Kyosuke Nishida, Kugatsu Sadamitsu, Kuniko Saito and Junji Tomita

Thursday, November 30, 2017

13:30–14:50 Documents and Questions

- 13:30–13:50 *Semantic Document Distance Measures and Unsupervised Document Revision Detection*
Xiaofeng Zhu, Diego Klabjan and Patrick Bless
- 13:50–14:10 *An Empirical Analysis of Multiple-Turn Reasoning Strategies in Reading Comprehension Tasks*
Yelong Shen, Xiaodong Liu, Kevin Duh and Jianfeng Gao
- 14:10–14:30 *Automated Historical Fact-Checking by Passage Retrieval, Word Statistics, and Virtual Question-Answering*
Mio Kobayashi, Ai Ishii, Chikara Hoshino, Hiroshi Miyashita and Takuya Matsuzaki
- 14:30–14:50 *Integrating Subject, Type, and Property Identification for Simple Question Answering over Knowledge Base*
Wei-Chuan Hsiao, Hen-Hsen Huang and Hsin-Hsi Chen

Thursday, November 30, 2017

13:30–14:30 Resources and Tools

13:30–13:50 *DailyDialog: A Manually Labelled Multi-turn Dialogue Dataset*
Yanran Li, Hui Su, Xiaoyu Shen, Wenjie Li, Ziqiang Cao and Shuzi Niu

13:50–14:10 *Inference is Everything: Recasting Semantic Resources into a Unified Evaluation Framework*
Aaron Steven White, Pushpendre Rastogi, Kevin Duh and Benjamin Van Durme

14:10–14:30 *Generating a Training Corpus for OCR Post-Correction Using Encoder-Decoder Model*
Eva D'hondt, Cyril Grouin and Brigitte Grau

Thursday, November 30, 2017

15:30–16:20 Best Paper Session

15:30–15:55 *Multilingual Hierarchical Attention Networks for Document Classification*
Nikolaos Pappas and Andrei Popescu-Belis

15:55–16:20 *Roles and Success in Wikipedia Talk Pages: Identifying Latent Patterns of Behavior*
Keith Maki, Michael Yoder, Yohan Jo and Carolyn Rosé

Evaluating Layers of Representation in Neural Machine Translation on Part-of-Speech and Semantic Tagging Tasks

Abstract

While neural machine translation (NMT) models provide improved translation quality in an elegant framework, it is less clear what they learn about language. Recent work has started evaluating the quality of vector representations learned by NMT models on morphological and syntactic tasks. In this paper, we investigate the representations learned at different layers of NMT encoders. We train NMT systems on parallel data and use the models to extract features for training a classifier on two tasks: part-of-speech and semantic tagging. We then measure the performance of the classifier as a proxy to the quality of the original NMT model for the given task. Our quantitative analysis yields interesting insights regarding representation learning in NMT models. For instance, we find that higher layers are better at learning semantics while lower layers tend to be better for part-of-speech tagging. We also observe little effect of the target language on source-side representations, especially in higher quality models.¹

1 Introduction

Neural machine translation (NMT) offers an elegant end-to-end architecture, while at the same time improving translation quality. However, little is known about the inner workings of these models and their interpretability is limited. Recent work has started exploring what kind of linguistic information such models learn on morphological (Vy-lomova et al., 2016; Belinkov et al., 2017; Dalvi et al., 2017) and syntactic levels (Shi et al., 2016; Sennrich, 2017).

¹Our code is available at <http://github.com/boknilev/nmt-repr-analysis>.

One observation that has been made is that lower layers in the neural MT network learn different kinds of information than higher layers. For example, Shi et al. (2016) and Belinkov et al. (2017) found that representations from lower layers of the NMT encoder are more predictive of word-level linguistic properties like part-of-speech (POS) and morphological tags, whereas higher layer representations are more predictive of more global syntactic information. In this work, we take a first step towards understanding what NMT models learn about semantics. We evaluate NMT representations from different layers on a semantic tagging task and compare to the results on a POS tagging task. We believe that understanding the semantics learned in NMT can facilitate using semantic information for improving NMT systems, as previously shown for non-neural MT (Chan et al., 2007; Liu and Gildea, 2010; Gao and Vogel, 2011; Wu et al., 2011; Jones et al., 2012; Bazrafshan and Gildea, 2013, 2014).

For the semantic (SEM) tagging task, we use the dataset recently introduced by Bjerva et al. (2016). This is a lexical semantics task: given a sentence, the goal is to assign to each word a tag representing a semantic class. The classes capture nuanced meanings that are ignored in most POS tag schemes. For instance, proximal and distal demonstratives (e.g., *this* and *that*) are typically assigned the same POS tag (DT) but receive different SEM tags (PRX and DST, respectively), and proper nouns are assigned different SEM tags depending on their type (e.g., geopolitical entity, organization, person, and location). As another example, consider pronouns like *myself*, *yourself*, and *herself*. They may have reflexive or emphasizing functions, as in (1) and (2), respectively:

- (1) Sarah bought herself a book
- (2) Sarah herself bought a book

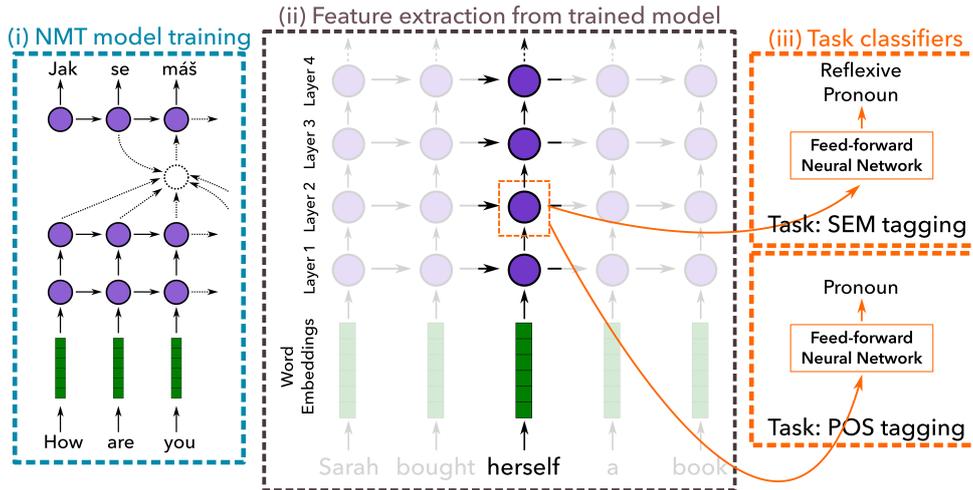

Figure 1: Illustration of our approach, after (Belinkov et al., 2017): (i) NMT system trained on parallel data; (ii) features extracted from pre-trained model; (iii) classifier trained using the extracted features. We train classifiers on either SEM or POS tagging using features from different layers (here: layer 2).

In these examples, *herself* has the same POS tag (PRP) but different SEM tags: REF for a reflexive function and EMP for an emphasizing function.

Capturing semantic distinctions of this sort can be important for producing accurate translations. For instance, example (1) would be translated to Spanish with the reflexive pronoun *se*, whereas (2) would be translated with the intensifier *misma*. Thus, a translation system needs to learn different representations of *herself* in the two sentences.

In order to assess the quality of the representations learned by NMT models, we adopt the following methodology from Shi et al. (2016) and Belinkov et al. (2017). We first train an NMT system on parallel data. Given a sentence, we extract representations from the pre-trained NMT model and train a word-level classifier to predict a tag for each word. Our assumption is that the performance of the classifier reflects the quality of the representation for the given task.

We compare POS and SEM tagging quality with representations from different layers or from models trained on different target languages, while keeping the English source fixed. Our results yield useful insights on representation learning in NMT:

- Consistent with previous work, we find that lower layer representations are usually better for POS tagging. However, we also find that representations from higher layers are better at capturing semantics, even though these are word-level labels. This is especially true with tags that are more semantic in nature such as discourse functions or noun concepts.

- In contrast to previous work, we observe little effect of the target language on source-side representation. We find that the effect of target language diminishes as the size of data used to train the NMT model increases.

2 Methodology

Given a parallel corpus of source and target sentence pairs, we train an NMT system with a standard sequence-to-sequence model with attention (Bahdanau et al., 2014; Sutskever et al., 2014). After training the NMT system, we fix its parameters and treat it as a feature generator for our classification task. Let \mathbf{h}_j^k denote the output of the k -th layer of the encoder at the j -th word. Given another corpus of sentences, where each word is annotated with a label, we train a classifier that takes \mathbf{h}_j^k as input features and maps words to labels. We then measure the performance of the classifier as a way to evaluate the quality of the representations generated by the NMT system. By extracting different NMT features we can obtain a quantitative comparison of representation learning quality in the NMT model for the given task. For instance, we may vary k in order to evaluate representations learned at different encoding layers.

In our case, we first train NMT systems on parallel corpora of an English source and several target languages. Then we train separate classifiers for predicting POS and SEM tags using the features \mathbf{h}_j^k that are obtained from the English encoder and evaluate their accuracies. Figure 1 illustrates the process.

3 Data and Experimental Setup

3.1 Data

MT We use the fully-aligned United Nations corpus (Ziems et al., 2016) for training NMT models, which includes 11 million multi-parallel sentences in six languages: Arabic (Ar), Chinese (Zh), English (En), French (Fr), Spanish (Es), and Russian (Ru). We train En-to-* models on the first 2 million sentences of the train set, using the official train/dev/test split. This dataset has the benefit of multiple alignment of the six languages, which allows for comparable cross-linguistic analysis.

Note that the parallel dataset is only used for training the NMT model. The classifier is then trained on the supervised data (described next) and all accuracies are reported on the English test sets.

Semantic tagging Bjerva et al. (2016) introduced a new sequence labeling task, for tagging words with semantic (SEM) tags in context. This is a good task to use as a starting point for investigating semantics because: *i*) tagging words with semantic labels is very simple, compared to building complex relational semantic structures; *ii*) it provides a large supervised dataset to train on, in contrast to most available datasets on word sense disambiguation, lexical substitution, and lexical similarity; and *iii*) the proposed SEM tagging task is an abstraction over POS tagging aimed at being language-neutral, and oriented to multi-lingual semantic parsing, all relevant aspects to MT. We provide here a brief overview of the task and its associated dataset, and refer to (Bjerva et al., 2016; Abzianidze et al., 2017) for more details.

The semantic classes abstract over redundant POS distinctions and disambiguate useful cases inside a given POS tag. Examples (1-2) above illustrate how fine-grained semantic distinctions may be important for generating accurate translations. Other examples of SEM tag distinctions include determiners like *every*, *no*, and *some* that are typically assigned a single POS tag (e.g., DT in the Penn Treebank), but have different SEM tags, reflecting universal quantification (AND), negation (NOT), and existential quantification (DIS), respectively. The comma, whose POS tag is a punctuation mark, is assigned different SEM tags representing conjunction, disjunction, or apposition, according to its discourse function. Proximal and distant demonstratives (*this* vs. *that*) have different SEM tags but the same POS tag. Named-entities,

		Train	Dev	Test
POS	Sentences	38K	1.7K	2.3K
	Tokens	908K	40K	54K
SEM	Sentences	42.5K	6.1K	12.2K
	Tokens	937K	132K	266K

Table 1: Statistics of the part-of-speech and semantic tagging datasets.

whose POS tag is usually a single tag for proper nouns, are disambiguated into several classes such as geo-political entity, location, organization, person, and artifact. Other nouns are divided into “role” entities (e.g., *boxer*) and “concepts” (e.g., *wheel*), a distinction reflecting existential consistency: an entity can have multiple roles but cannot be two different concepts.

The dataset annotation scheme includes 66 fine-grained tags grouped in 13 coarse categories. We use the silver part of the dataset; see Table 1 for some statistics.

Part-of-speech tagging For POS tagging, we simply use the Penn Treebank with the standard split (parts 2-21/22/23 for train/dev/test); see Table 1 for statistics. There are 34 POS tags.

3.2 Experimental Setup

Neural MT We use the `seq2seq-attn` toolkit (Kim, 2016) to train 4-layered long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) attentional encoder-decoder NMT systems with 500 dimensions for both word embeddings and LSTM states. We compare both unidirectional and bidirectional encoders and experiment with different numbers of layers. Each system is trained with SGD for 20 epochs and the model with the best loss on the development set is used for generating features for the classifier.

Classifier The classifier is modeled as a feed-forward neural network with one hidden layer, dropout (ratio of 0.5), a ReLU activation function, and a softmax layer onto the label set size.² The hidden layer is of the same size as the input coming from the NMT system (i.e., 500 dimensions). The classifier has no explicit access to context other than the hidden representation gen-

²We use a non-linear classifier because previous work found that it outperforms a linear classifier, while showing very similar trends (Qian et al., 2016b; Belinkov et al., 2017).

	MFT	UnsupEmb	Word2Tag
POS	91.95	87.06	95.55
SEM	82.00	81.11	91.41

Table 2: POS and SEM tagging accuracy with baselines and an upper bound. MFT: most frequent tag; UnsupEmb: classifier using unsupervised word embeddings; Word2Tag: upper bound encoder-decoder.

erated by the NMT system, which allows us to focus on the quality of the representation. We chose this simple formulation as our goal is not to improve the state-of-the-art on the supervised task, but rather to analyze the quality of the NMT representation for the task. We train the classifier for 30 epochs by minimizing the cross-entropy loss using Adam (Kingma and Ba, 2014) with default settings. Again, we use the model with the best loss on the development set for evaluation.

Baselines and an upper bound we consider two baselines: assigning to each word the most frequent tag (MFT) according to the training set (with the global majority tag for unseen words); and training with unsupervised word embeddings (UnsupEmb) as features for the classifier, which shows what a simple task-independent distributed representation can achieve. For the unsupervised word embeddings, we train a Skip-gram negative sampling model (Mikolov et al., 2013) with 500 dimensional vectors on the English side of the parallel data, to mirror the NMT word embedding size. We also report an upper bound of directly training an encoder-decoder on word-tag sequences (Word2Tag), simulating what an NMT-style model can achieve by directly optimizing for the tagging tasks.

4 Results

Table 2 shows baseline and upper bound results. The UnsupEmb baseline performs rather poorly on both POS and SEM tagging. In comparison, NMT word embeddings (Table 3, rows with $k = 0$) perform slightly better, suggesting that word embeddings learned as part of the NMT model are better syntactic and semantic representations. However, the results are still below the most frequent tag baseline (MFT), indicating that non-contextual word embeddings are poor representations for POS and SEM tags.

BLEU scores are given for reference. Statistically significant differences from layer 1 are shown at $p < 0.001^{(*)}$ and $p < 0.01^{(**)}$. See text for details.

4.1 Effect of network depth

Table 3 summarizes the results of training classifiers to predict POS and SEM tags using features extracted from different encoding layers of 4-layered NMT systems.³ In the POS tagging results (first block), as the representations move above layer 0, performance jumps to around 91–92%. This is above the UnsupEmb baseline but only on par with the MFT baseline (Table 2). We note that previous work reported performance above a majority baseline for POS tagging (Shi et al., 2016; Belinkov et al., 2017), but used a weak global majority baseline (all words are assigned a single tag) whereas here we compare with a stronger baseline that assigns to each word the most frequent tag according to the training data. The results are also far below the Word2Tag upper bound (Table 2).

Comparing layers 1 through 4, we see that in 3/5 target languages (Ar, Ru, Zh), POS tagging accuracy peaks at layer 1 and does not improve

³The results given are with a unidirectional encoder; in section 4.5 we compare with a bidirectional encoder and observe similar trends.

at higher layers, with some drops at layers 2 and 3. In 2/5 cases (Es, Fr) the performance is higher at layer 4. This result is partially consistent with previous findings regarding the quality of lower layer representations for the POS tagging task (Shi et al., 2016; Belinkov et al., 2017). One possible explanation for the discrepancy when using different target languages is that French and Spanish are typologically closer to English compared to the other languages. It is possible that when the source and target languages are more similar, they share similar POS characteristics, leading to more benefit in using upper layers for POS tagging.

Turning to SEM tagging (Table 3, second block), representations from layers 1 through 4 boost the performance to around 87-88%, far above the UnsupEmb and MFT baselines. While these results are below the Word2Tag upper bound (Table 2), they indicate that NMT representations contain useful information for SEM tagging.

Going beyond the 1st encoding layer, representations from the 2nd and 3rd layers do not consistently improve semantic tagging performance. However, representations from the 4th layer lead to significant improvement with all target languages except for Chinese. Note that there is a statistically significant difference ($p < 0.001$) between layers 0 and 1 for all target languages, and between layers 1 and 4 for all languages except for Chinese, according to the approximate randomization test (Padó, 2006).

Intuitively, higher layers have a more global perspective because they have access to higher representations of the word and its context, while lower layers have a more local perspective. Layer 1 has access to context but only through one hidden layer which may not be sufficient for capturing semantics. It appears that higher representations are necessary for learning even relatively simple lexical semantics.

Finally, we found that En-En encoder-decoders (that is, English autoencoders) produce poor representations for POS and SEM tagging (last column in Table 3). This is especially true with higher layer representations (e.g., around 5% below the MT models using representations from layer 4). In contrast, the autoencoder has excellent sentence recreation capabilities (96.6 BLEU). This indicates that learning to translate (to any foreign language) is important for obtaining useful representations for both tagging tasks.

	Ar	Es	Fr	Ru	Zh	En
POS	88.7	90.0	89.6	88.6	87.4	85.2
SEM	85.3	86.1	85.8	85.2	85.0	80.7

Table 4: SEM and POS tagging accuracy using features extracted from the 4th NMT encoding layer, trained with different target languages on a smaller parallel corpus (200K sentences).

4.2 Effect of target language

Does translating into different languages make the NMT system learn different source-side representations? In previous work (Belinkov et al., 2017), we found a fairly consistent effect of the target language on the quality of encoder representations for POS and morphological tagging, with differences of $\sim 2-3\%$ in accuracy. Here we examine if such an effect exists in both POS and SEM tagging.

Table 3 also shows results using features obtained by training NMT systems on different target languages (the English source remains fixed). In both POS and SEM tagging, there are very small differences with different target languages ($\sim 0.5\%$), except for Chinese which leads to slightly worse representations. While the differences are small, they are mostly statistically significant. For example, at layer 4, all the pairwise comparisons with different target languages are statistically significant ($p < 0.001$) in SEM tagging, and all except for two comparisons (Ar vs. Ru and Es vs. Fr) are significant in POS tagging.

The effect of target language is much smaller than that reported in (Belinkov et al., 2017) for POS and morphological tagging. This discrepancy can be attributed to the fact that our NMT systems in the present work are trained on much larger corpora (10x), so it is possible that some of the differences disappear when the NMT model is of better quality. To verify this, we trained systems using a smaller data size (200K sentences), comparable to the size used in (Belinkov et al., 2017). The results are shown in Table 4. In this case, we observe a variance in classifier accuracy of 1-2%, based on target language, which is consistent with our earlier findings. This is true for both POS and SEM tagging. The differences in POS tagging accuracy are statistically significant ($p < 0.001$) for all pairwise comparisons except for Ar vs. Ru; the differences in SEM tagging accuracy are significant for all comparisons except for Ru vs. Zh.

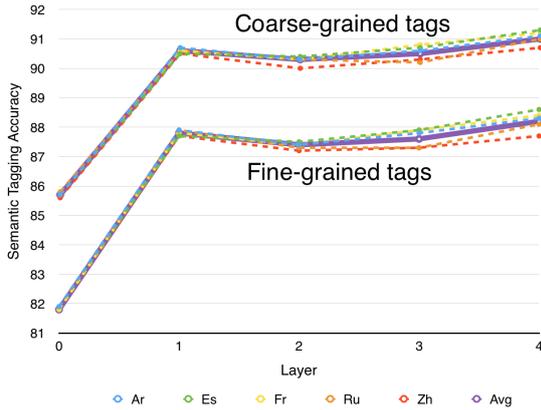

Figure 2: SEM tagging accuracy with fine/coarse-grained tags using features extracted from different encoding layers of 4-layered NMT models trained with different target languages.

Finally, we note that training an English autoencoder on the smaller dataset results in much worse representations compared to MT models, for both POS and SEM tagging (Table 4, last column), consistent with the behavior we observed on the larger data (Table 3, last column).

4.3 Analysis at the semantic tag level

The SEM tags are grouped in coarse-grained categories such as events, names, time, and logical expressions (Bjerva et al., 2016). In Figure 2 (top lines), we show the results of training and testing classifiers on coarse tags. Similar trends to the fine-grained case arise, with higher absolute scores: significant improvement using the 1st encoding layer and some additional improvement using the 4th layer, both statistically significant ($p < 0.001$). Again, there is a small effect of the target language.

Figure 3 shows the change in F_1 score (averaged over target languages) when moving from layer 1 to layer 4 representations. The blue bars describe the differences per coarse tag when directly predicting coarse tags. The red bars show the same differences when predicting fine-grained tags and micro-averaging inside each coarse tag. The former shows the differences between the two layers at distinguishing among coarse tags. The latter gives an idea of the differences when distinguishing between fine-grained tags within a coarse category. The first observation is that in the majority of cases there is an advantage for classifiers trained with layer 4 representations, i.e., higher layer representations are better suited for learning the SEM

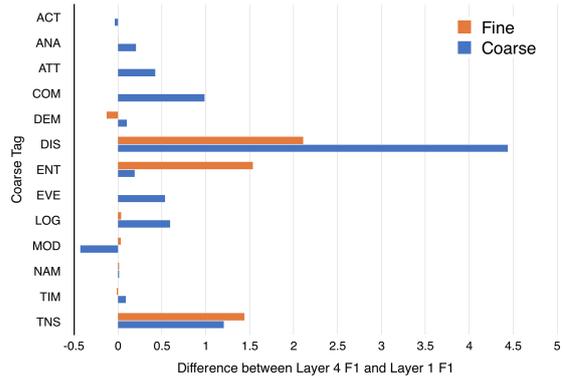

Figure 3: Difference in F_1 when using representations from layer 4 compared to layer 1, showing F_1 when directly predicting coarse tags (blue) and when predicting fine-grained tags and averaging inside each coarse tag (red).

tags, at both coarse and fine-grained levels.

Considering specific tags, higher layers of the NMT model are especially better at capturing semantic information such as *discourse relations* (DIS tag: subordinate vs. coordinate vs. apposition relations), semantic properties of nouns (*roles* vs. *concepts*, within the ENT tag), *events* and *predicate tense* (EVE and TNS tags), *logic relations* and *quantifiers* (LOG tag: disjunction, conjunction, implication, existential, universal, etc.), and *comparative constructions* (COM tag: equatives, comparatives, and superlatives). These examples represent semantic concepts and relations that require a level of abstraction going beyond the lexeme or word form, and thus might be better represented in higher layers in the deep network.

One negative example that stands out in Figure 3 is the prediction of the MOD tag, corresponding to *modality* (necessity, possibility, and negation). It seems that such semantic concepts should be better represented in higher layers following our previous hypothesis. Still, layer 1 is better than layer 4 in this case. One possible explanation is that words tagged as MOD form a closed class, with only a few and mostly unambiguous words (“no”, “not”, “should”, “must”, “may”, “can”, “might”, etc.). It is enough for the classifier to memorize these words in order to predict this class with high F_1 , and this is something that occurs better in lower layers. One final case worth mentioning is the NAM category, which stands for different types of named entities (person, location, organization, artifact, etc.). In principle, this seems a clear case of semantic abstractions suited for higher layers,

but the results from layer 4 are not significantly better than those from layer 1. This might be signaling a limitation of the NMT system at learning this type of semantic classes. Another factor might be the fact that many named entities are out of vocabulary words for the NMT system.

4.4 Analyzing discourse relations

In this section, we analyze specific cases of disagreement between predictions using representations from layer 1 and layer 4. We focus on discourse relations, as they show the largest improvement when going from layer 1 to layer 4 representations (DIS category in Figure 3). Intuitively, identifying discourse relations requires a relatively large context so it is expected that higher layers would perform better in this case.

There are three discourse relations in the SEM tags annotation scheme: subordinate (SUB), coordinate (COO), and apposition (APP) relations. For each of those, Figure 4 (examples 1-9) shows the first three cases in the test set where layer 4 representations correctly predicted the tag but layer 1 representations were wrong. Examples 1-3 have subordinate conjunctions (*as*, *after*, *because*) connecting a main and an embedded clause, which layer 4 is able to correctly predict. Layer 1 mistakes these as attribute tags (REL, IST) that are usually used for prepositions. In examples 4-5,

the coordinate conjunction *and* is used to connect sentences/clauses, which layer 4 correctly tags as COO. Layer 1 wrongly predicts the tag AND, which is used for conjunctions connecting shorter expressions like words (e.g., “murder *and* sabotage” in example 1). Example 6 is probably an annotation error, as *and* connects the phrases “lame gait” and “wrinkled skin” and should be tagged as AND. In this case, layer 1 is actually correct. In examples 7-9, layer 4 correctly identifies the comma as introducing an apposition, while layer 1 predicts NIL, a tag for punctuation marks without semantic content (e.g., end-of-sentence period). As expected, in most of these cases identifying the discourse function requires a fairly large context.

Finally, we show in examples 10-12 the first three occurrences of AND in the test set, where layer 1 was correct and layer 4 was wrong. Interestingly, two of these (10-11) are clear cases of *and* connecting clauses or sentences, which should have been annotated as COO, and the last (12) is a conjunction of two gerunds. The predictions from layer 4 in these cases thus appear justifiable.

4.5 Other architectural variants

Here we consider two architectural variants that have been shown to benefit NMT systems: bidirectional encoder and residual connections. We also experiment with NMT systems trained with

different depths. Our motivation in this section is to see if the patterns we observed thus far hold in different NMT architectures.

Bidirectional encoder Bidirectional LSTMs have become ubiquitous in NLP and also give some improvement as NMT encoders (Britz et al., 2017). We confirm these results and note improvements in both translation (+1-2 BLEU) and SEM tagging quality (+3-4% accuracy), across the board, when using a bidirectional encoder. Some of our bidirectional models obtain 92-93% accuracy, which is close to the state-of-the-art on this task (Bjerva et al., 2016). We observed similar improvements on POS tagging. Comparing POS and SEM tagging (Table 5), we note that higher layer representations improve SEM tagging, while POS tagging peaks at layer 1, in line with our previous observations.

Residual connections Deep networks can sometimes be trained better if residual connections are introduced between layers. Such connections were also found useful for SEM tagging (Bjerva et al., 2016). Indeed, we noticed small but consistent improvements in both translation (+0.9 BLEU) and POS and SEM tagging (up to +0.6% accuracy) when using features extracted from an NMT model trained with residual connections (Table 5). We also observe similar trends as before: POS tagging does not benefit from features from the upper layers, while SEM tagging improves with layer 4 representations.

Shallower MT models In comparing network depth in NMT, Britz et al. (2017) found that encoders with 2 to 4 layers performed the best. For completeness, we report here results using features extracted from models trained originally with 2 and 3 layers, in addition to our basic setting of 4 layers. Table 6 shows consistent trends with our previous observations: POS tagging does not benefit from upper layers, while SEM tagging does, although the improvement is rather small in the shallower models.

5 Related Work

Techniques for analyzing neural network models include visualization of hidden units (Elman, 1991; Karpathy et al., 2015; Kádár et al., 2016; Qian et al., 2016a), which provide illuminating, but often anecdotal information on how the network works. A number of studies aim to ob-

tain quantitative correlations between parts of the neural network and linguistic properties, in both speech (Wu and King, 2016; Alishahi et al., 2017; Belinkov and Glass, 2017; Wang et al., 2017) and language processing models (Köhn, 2015; Qian et al., 2016a; Adi et al., 2016; Linzen et al., 2016; Qian et al., 2016b). Methodologically, our work is most similar to Shi et al. (2016) and Belinkov et al. (2017), who also used hidden vectors from neural MT models to predict linguistic properties. However, they focused on relatively low-level tasks (syntax and morphology, respectively), while we apply the approach to a semantic task and compare the results with a POS tagging task.

Our methodology is reminiscent of the approach taken by Pérez-Ortiz and Forcada (2001), who trained a recurrent neural network POS tagger in two steps. However, their goal was to improve POS tagging while we use it as a task to evaluate neural MT models.

6 Conclusion

While neural network models have improved the state-of-the-art in machine translation, it is difficult to interpret what they learn about language. In this work, we explore what kind of linguistic information such models learn at different layers. Our experimental evaluation leads to interesting insights about the hidden representations in NMT models such as the effect of layer depth and target language on part-of-speech and semantic tagging.

In the future, we would like to extend this work to other syntactic and semantic tasks that require building relations such as dependency relations and predicate-argument structure or to evaluate semantic representations of multi-word expressions. We believe that understanding how semantic properties are learned in NMT is a key step for creating better machine translation systems.

Abstract

In Neural Machine Translation (NMT), each word is represented as a low-dimension, real-value vector for encoding its syntax and semantic information. This means that even if the word is in a different sentence context, it is represented as the fixed vector to learn source representation. Moreover, a large number of Out-Of-Vocabulary (OOV) words, which have different syntax and semantic information, are represented as the same vector representation of *unk*. To alleviate this problem, we propose a novel context-aware smoothing method to dynamically learn a sentence-specific vector for each word (including OOV words) depending on its local context words in a sentence. The learned context-aware representation is integrated into the NMT to improve the translation performance. Empirical results on NIST Chinese-to-English translation task show that the proposed approach achieves 1.78 BLEU improvements on average over a strong attentional NMT, and outperforms some existing systems.

1 Introduction

Neural Machine Translation (NMT) (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Bahdanau et al., 2015), has shown prominent performances in comparison with the conventional Phrase Based Statistical Machine Translation (PBSMT) (Koehn et al., 2003). In NMT, a source sentence is converted into a vector representation by an RNN called *encoder*, then another RNN

called *decoder* generates target sentence word by word based on the source representation with attention information and target history.

One advantage of NMT systems is that each word is represented as a low-dimension, real-valued vector, instead of storing statistical rules as in PBSMT. This means that even if the word is in a different sentence context, it is represented as the fixed vector to learn source representation. Figure 1 (a) shows two pair of Chinese-to-English parallel sentences in which two Chinese sentences contain the same word “*da*”. Intuitively, the “*da*” denotes “beating” in the first Chinese sentence while the “*da*” denotes “playing” in the second Chinese sentence. It is obvious that the “*da*” which denotes different meanings in a specific sentence is represented as the same word vector in the encoder of NMT, as show in Figure 1 (b). Although the RNN-based encoder can capture the sentence context for each word, we believe that offering better word vector with context-aware representation might help improve translation quality of NMT.

Moreover, a large number of Out-Of-Vocabulary (OOV) words which have different syntax and semantic information are represented as the same vector representation of *unk*. Actually, this kind of simple approach may cause ambiguity of the sentences since the single *unk* breaks the structure of sentences, thus hurts representation learning of source sentence and translation prediction of the target word. For example, the *unk* firstly affects source representation learning in *encoder*; then the negative effect would be further transformed to the *decoder*, which generates the poverty context vector and hidden layer state for translation prediction, as shown in the gray parts of Figure 1 (c). Besides, when the generated target word may also be *unk*, the negative effect of *unk* will become more severe.

*Kehai Chen was an internship research fellow at NICT when conducting this work.

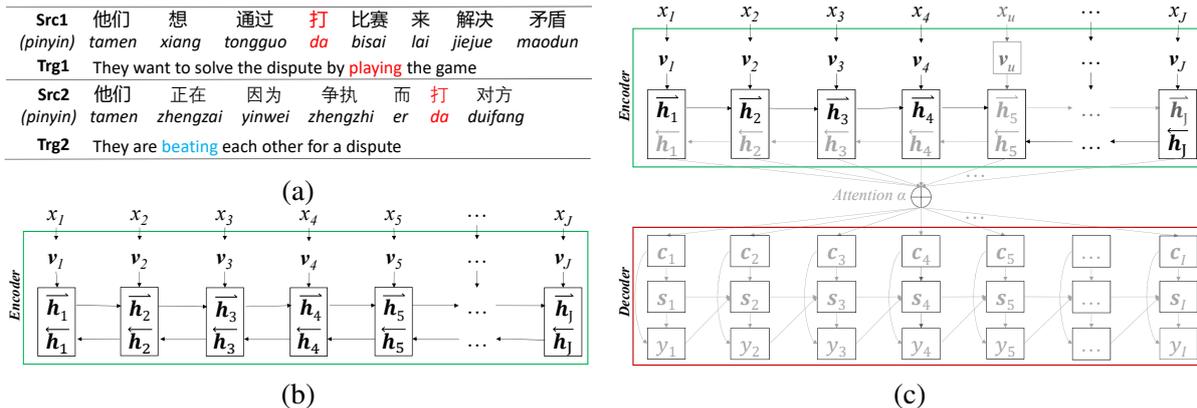

Figure 1: (a) Two parallel Chinese-to-English sentence pair; (b) The encoder of NMT; (c) The NMT with OOV, these gray parts indicate the parameters of NMT which are affected by the OOV x_u .

In this paper, we propose a novel context-aware smoothing method to dynamically learn a Context-Aware Representation (**CAR**) for each word (including OOV words) depending on its local context words in a sentence. We then use the learned CAR to extend word vector in a sentence, thus enhancing source representation for improving the translation performance of NMT. First, compared with the single *unk* vector, we encode the context words of each OOV as a Context-Aware Representation (**CAR**), which has the potential to capture the *OOV*'s semantic information. Second, we also extend the context-aware smoothing method to in-vocabulary words, which enhances *encoder* and *decoder* of NMT by more effectively utilizing context information by the learned CAR. To this end, we proposed two unique neural networks to learn the context-aware representation for each word depending on its context words in a fixed-size window. We then design four NMT models with CAR to improve translation performance by smoothing the encoder and decoder.

The remainder of the paper is organized as follows. Section 2 introduces the related work in the NMT. Section 3 presents two novel neural models to learn the CAR for each word. Section 4 integrates the CAR into the NMT by using smoothing strategies. Section 5 reports the experimental results obtained in the Chinese-to-English task. Finally, we conclude the contributions of the paper and discuss the further work in Section 6.

2 Related Work

In traditional SMT, there are many research works to improve the translations of OOVs. Fung and Cheung (2004) and Shao and Ng (2004) adopt comparable corpora and web resources to extract translations for each unknown word. Marton et al. (2009) and Mirkin et al. (2009) applied paraphrase model and entailment rules to replace unknown words with in-vocabulary synonyms before translation. A series of works (Knight and Graehl, 1997; Jiang et al., 2007; Al-Onaizan and Knight, 2002) utilized transliteration and web mining techniques with external monolingual/bilingual corpora, comparable data and the web resource to find the translation of the unknown words. Nearly most of the related PBSMT researches focused on finding the correct translation of the unknown words with external resources and ignored the negative effect for other words.

Compared with PBSMT, due to high computational cost, NMT has a more limited vocabulary size and severe OOV phenomenon. The existing PBSMT methods that used external resources to translate unknown words for SMT are hard to be directly introduced into NMT, because of NMT's *soft*-alignment mechanism (Bahdanau et al., 2015). To relieve the negative effect of unknown words for NMT, Luong et al. (2015) proposed a word alignment algorithm, allowing the NMT system to emit, for each OOV word in the target sentence, the position of its corresponding word in the source sentence, and to translate every OOV in a post-processing step using a external bilingual dictionary. Although

these methods improved the translation of OOV, they must learn external bilingual dictionary information in advance.

From the point of vocabulary size, many works tried to use a large vocabulary size, thus covering more words. [Jean et al. \(2015\)](#) proposed a method based on importance sampling that allowed NMT model to use a very large target vocabulary for relieving the OOV phenomenon in NMT, which are only designed to reduce the computational complexity in training, not for decoding. [Arthur et al. \(2016\)](#) introduced discrete translation lexicons into NMT to improve the translations of these low-frequency words. [Mi et al. \(2016\)](#) proposed a vocabulary manipulation approach by limiting the number of vocabulary being predicted by each batch or sentence, to reduce both the training and the decoding complexity. These methods focused on the translation of OOV itself and ignored the other negative effect caused by the OOV, such as the translations of the words around the OOV.

Recently, many works exploited the granularity translation unit from words to smaller subwords or characters. [Sennrich et al. \(2016\)](#) introduced a simpler and more effective approach to encode rare and unknown words as sequences of subword units by Byte Pair Encoding ([Gage, 1994](#)). This is based on the intuition that various word classes are translatable via smaller units than words. [Luong and Manning \(2016\)](#) segmented the known words into character sequence, and learned the unknown word representation by character-level recurrent neural networks, thus achieving open vocabulary NMT. [Li et al. \(2016\)](#) replaced OOVs with in-vocabulary words by semantic similarity to reduce the negative effect for words around the OOVs. [Costa-jussà and Fonollosa \(2016\)](#) presented a character-based NMT, in which character-level embeddings were in combination with convolutional and highway layers to replace the standard lookup-based word representations. These methods extended the vocabulary to a larger or unlimited vocabulary and improved the performance of NMT tasks, especially in the morphological rich language pairs.

Instead of utilizing larger vocabulary or sub-unit information, we exploit to relieve more translation performance for NMT from the negative effect of OOVs by learning context-aware representations for OOVs. As a result, the

proposed method can smooth the representation of word and reduce the *unk*'s negative effect in attention model, context annotations and decoding hidden states, thus improving the performance of NMT.

3 Context-Aware Representation

Intuitively, when one understands natural language sentence, especially including polysemy words or OOVs, one often infers the meaning of these words depending on its context words. Context plays an important role in learning distributed representation of word ([Mikolov et al., 2013a,b](#)). Motivated by this, we propose two neural network methods, including Feedforward Context-of-Word Model (**FCWM**) and Convolutional Context-of-Words Model (**CCWM**), to learn a Context-Aware Representation (**CAR**) for each word.

3.1 Feedforward Context-of-Words Model

Inspired by the representation learning of word ([Bengio et al., 2003](#)), the proposed FCWM includes an input layer, a projection layer, and a non-linear output layer, as shown in Figure 2 (a).

Specifically, suppose there is a source language sentence, $\{x_1, x_2, \dots, x_j, \dots, x_J\}$. If the context window is set as $2n$ ($n = 2$), the context of each word x_i is defined as its historical n words and future n words:

$$L_j = x_{j-n}, \dots, x_{j-1}, x_{j+1}, \dots, x_{j+n}. \quad (1)$$

In the input layer, each word in L_j is transformed into one-hot representation.¹ The projection layer concatenates one-hot representations in L_j to a $(2nm)$ -dimension vector L_j ,²

$$L_j = [v_{j-n} : \dots, v_{j-1} : v_{j+1} : \dots : v_{j+n}], \quad (2)$$

where “:” denotes the concatenation operation of word vectors.

We then approximate to learn its semantic representation $V_{L_j} \in R^m$ by a non-linear output layer instead of softmax layer:

$$V_{L_j} = \sigma(W_1 L_j + b_1)^T, \quad (3)$$

¹If the L_j includes OOV, we use original *unk* vector to represent it. Besides, we also try the average vector of the current sentence word to represent it, but gain the similar translation performance.

²In this paper, the bold variable denotes a continuous space vector.

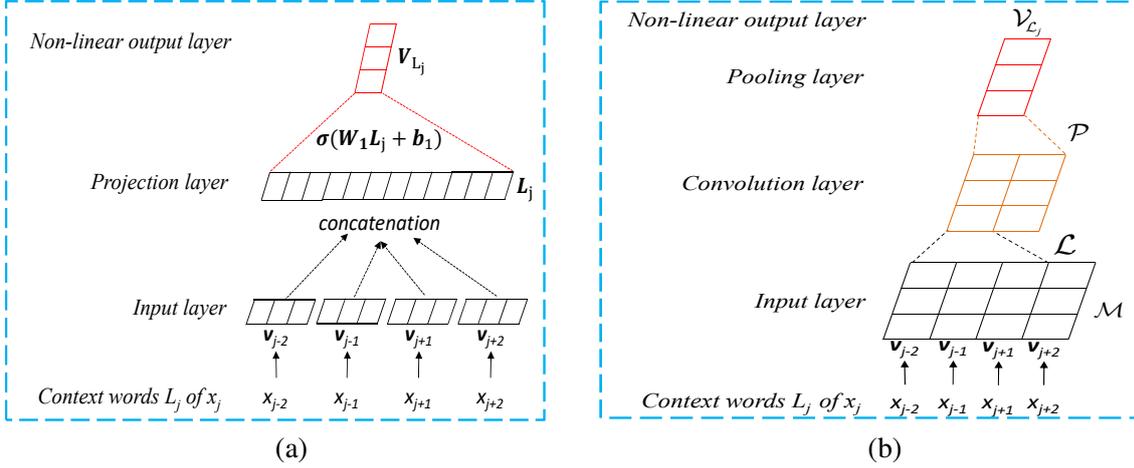

Figure 2: (a) Feedforward Context-of-Word Model; (b) Convolution Context-of-Word Model.

where σ is a non-linear activation function (e.g., *Tanh*), T represents matrix transpose, and \mathbf{W}_1 is a weight matrix and \mathbf{b}_1 is a bias term.

Finally, we extend each word with the learned CAR vector \mathbf{V}_{L_j} , thus feeding into the NMT to enhance source representation for improving target word prediction. Therefore, the proposed FCWM plays the role of the function φ parameterized by θ_1 , which maps the context L_j of each word into vector \mathbf{V}_{L_j} as follows:

$$\mathbf{V}_{L_j} = \varphi(L_j; \theta_1). \quad (4)$$

3.2 Convolutional Context-of-Words Model

Compared with the FCWM, the proposed CCWM indirectly encodes the context words of each word as a compositional semantic representation to represent the OOV. Specifically, the proposed CCWM is a novel variant of the standard convolutional neural network (Collobert et al., 2011), including an input layer, a convolution layer, a pooling layer and a non-linear output layer, as shown in Figure 2 (b).

Input Layer: When the dimension of word vector is m and the context window is set to $2n$, the input layer is denoted as one vector matrix $\mathcal{M} \in R^{m \times 2n}$. In \mathcal{M} , each column denotes context words of word x_j , that is, \mathcal{M} is $[\mathbf{v}_{j-n}, \dots, \mathbf{v}_{j-1}, \mathbf{v}_{j+1}, \dots, \mathbf{v}_{j+n}]$ for the context $\{x_{j-n}, \dots, x_{j-1}, x_{j+1}, \dots, x_{j+n}\}$ of x_j .

Convolutional Layer: In the convolutional layer, let the filter window size be $m \times k$ ($2 \leq k \leq 2n$), where the k is set to 3 in our experiments, thus generating feature map \mathcal{L}_j as follows:

$$\mathcal{L}_j = \psi(\mathbf{W}_2[\mathbf{v}_j : \mathbf{v}_{j+1} : \dots : \mathbf{v}_{j+k}] + \mathbf{b}_2), \quad (5)$$

where ψ is a non-linear activation function,³ $\mathbf{W}_2 \in R^{m \times k \cdot m}$ is the weight matrix and $\mathbf{b}_2 \in R^m$ is a bias term. After the filter traverses the input matrix, the output of the feature map \mathcal{L} is:

$$\mathcal{L} = [\mathcal{L}_1, \dots, \mathcal{L}_{2n-k+1}]. \quad (6)$$

Pooling Layer: The pooling operation (e.g., *max*, *average*) is commonly used to extract robust features from convolution. For the output feature map of the convolution layers, a column-wise *max* is performed over the consecutive columns of window size 2 as follows:

$$\mathcal{P}_l = \max[\mathcal{L}_{2l-1}, \mathcal{L}_{2l}], \quad (7)$$

where $1 \leq l \leq \frac{2n-k+1}{2}$. After the *max* pooling, the output of the feature map \mathcal{P} is:

$$\mathcal{P} = [\mathcal{P}_1, \dots, \mathcal{P}_{\frac{2n-k+1}{2}}]. \quad (8)$$

Non-linear Output Layer: The output layer is typically a fully connected layer multiplied by a matrix. In this paper, first row-wise averaging from the pooling layers is performed without any parameters, and gain CAR of each word by non-linear active function σ (e.g., *Tanh*); hence, the CAR $\mathbf{V}_{\mathcal{L}_j}$ of word x_j is obtained by

$$\mathbf{V}_{\mathcal{L}_j} = \sigma(\mathbf{W}_3(\text{average}(\sum_{l=1}^{\frac{2n-k+1}{2}} \mathcal{P}_l)) + \mathbf{b}_3). \quad (9)$$

Therefore, the above CCWM plays the role of the function φ parameterized by θ_2 , which maps

³We used a ReLU activation function.

the context \mathcal{L}_j of word x_j into vector $\mathbf{V}_{\mathcal{L}_j}$ as follows:

$$\mathbf{V}_{\mathcal{L}_j} = \varphi(\mathcal{L}_j; \theta_2) \quad (10)$$

In this case, the word x_j is represented as a CAR $\mathbf{V}_{\mathcal{L}_j}$.

4 NMT with Context-Aware Smoothing

4.1 NMT Background

An NMT model consists of an *encoder* process and a *decoder* process, and hence it is often called *encoder-decoder* model (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Bahdanau et al., 2015), as shown in Figure 1. Typically, each unit of source input (x_1, \dots, x_j) is firstly embedded as a vector \mathbf{v}_{x_j} , and then represented as annotation vector \mathbf{h}_j by

$$\mathbf{h}_j = f_{enc}(\mathbf{v}_{x_j}, \mathbf{h}_{j-1}), \quad (11)$$

where f_{enc} is a bidirectional Recurrent Neural Network (RNN) (Bahdanau et al., 2015). These annotation vectors $\{\mathbf{h}_1, \dots, \mathbf{h}_J\}$ are used to generate target word in *decoder*.

An RNN *decoder* is used to compute the target word y_i probability by a softmax layer g :

$$P(y_i | y_{<i}, x) = g(\mathbf{v}_{y_{i-1}}, \mathbf{s}_i, \mathbf{c}_i), \quad (12)$$

where $\mathbf{v}_{y_{i-1}}$ is vector representation of the previously emitted word y_{i-1} , \mathbf{s}_i is an RNN hidden state for the current time step and the \mathbf{c}_i is the current context vector.

4.2 Smoothing Strategy

In this subsection, we will introduce NMT with the learned CAR. This would relieve the translation performance of NMT from source representation. To this end, we use OOV as an example to integrate FCWM or CCWM into NMT; and then extend them to in-vocabulary words.

To learn the representation of source sentence, the proposed FCWM or CCWM are integrated into the *encoder* of NMT. If the source word x_j is in-vocabulary, its annotation vector \mathbf{h}_j is learned by the traditional *encoder*; if the source word x_j is not in-vocabulary (OOV x_u), the FCWM or CCWM proposed in section 3 are used to learn its CAR instead of single *unk* vector, and further learn its annotation vector \mathbf{h}_j . According to the eq.(11), the *encoder* with CAR learns the annotation vector

\mathbf{h}_j by the eq.(13):

$$\mathbf{h}_j = \begin{cases} f_{enc}(\mathbf{h}_{x_j}, \mathbf{h}_{j-1}), & x_j \in V_s \\ f_{enc}(\varphi_e(\mathbf{V}_{L_{x_j}}), \mathbf{h}_{j-1}), & x_j \notin V_s, \end{cases} \quad (13)$$

where V_s is source-side vocabulary table in NMT, φ_e is the proposed FCWM or CCWM integrated into the *encoder* according to eq.(4) or eq.(10), and \mathbf{V}_{L_j} is the learned CAR over the source-side L_j from eq.(1):

$$L_j = x_{j-n}, \dots, x_{j-1}, x_{j+1}, \dots, x_{j+n}.^4 \quad (14)$$

Similarly, the proposed FCWM or CCWM are also integrated into the *decoder* in NMT. Compared with the *encoder* with CAR, the target-side OOV's context words of training processing is different from that of the decoding in which target-side OOV's future context is unknowable. That is, only the historical n words of y_{i-1} are used to learn the CAR of $\mathbf{V}'_{L'_{i-1}}$. To be consistent with the decoding process, the previous $2n$ words of OOV are regarded as its context L'_{i-1} instead of the previous n words and future n words. Therefore, the *decoder* with CAR predicts the next target word by the eq.(15):

$$P(y_i | y_{<i}, x) = \begin{cases} g(\mathbf{v}_{y_{i-1}}, \mathbf{s}_i, \mathbf{c}_i), & y_{i-1} \in V_t \\ g(\varphi_d(L'_{i-1}), \mathbf{s}_i, \mathbf{c}_i), & y_{i-1} \notin V_t, \end{cases} \quad (15)$$

where V_t is target-side vocabulary table in NMT, φ_d denotes the proposed FCWM or CCWM integrated into the *decoder* according to eq.(4) or eq.(10), and $\mathbf{V}'_{L'_{i-1}}$ is the learned CAR over the target-side context L'_{i-1} from eq.(1):

$$L'_{i-1} = y_{i-2n}, \dots, y_{i-n}, \dots, y_{i-1}.^5 \quad (16)$$

4.3 Models

Based on the above smoothing strategy, we design four novel NMT models: **CARNMT-Encoder**, **CARNMT-Decoder**, **CARNMT-Both** and an **ALLSmooth**, all of which can make use of CAR to enhance *encoder* or *decoder* of NMT for improving the translation performance:

- **CARNMT-Encoder**: Only smoothing source-side unk to relieve the influence in the *encoder*, as shown in Figure 3 (a).

⁴If the number of previous context or future context words is less n , we pads a sentence start symbol *BEG* or sentence end symbol *EOS*.

⁵If the number of previous context words is less $2n$, we pads L'_{i-1} using a sentence start symbol *BEG*.

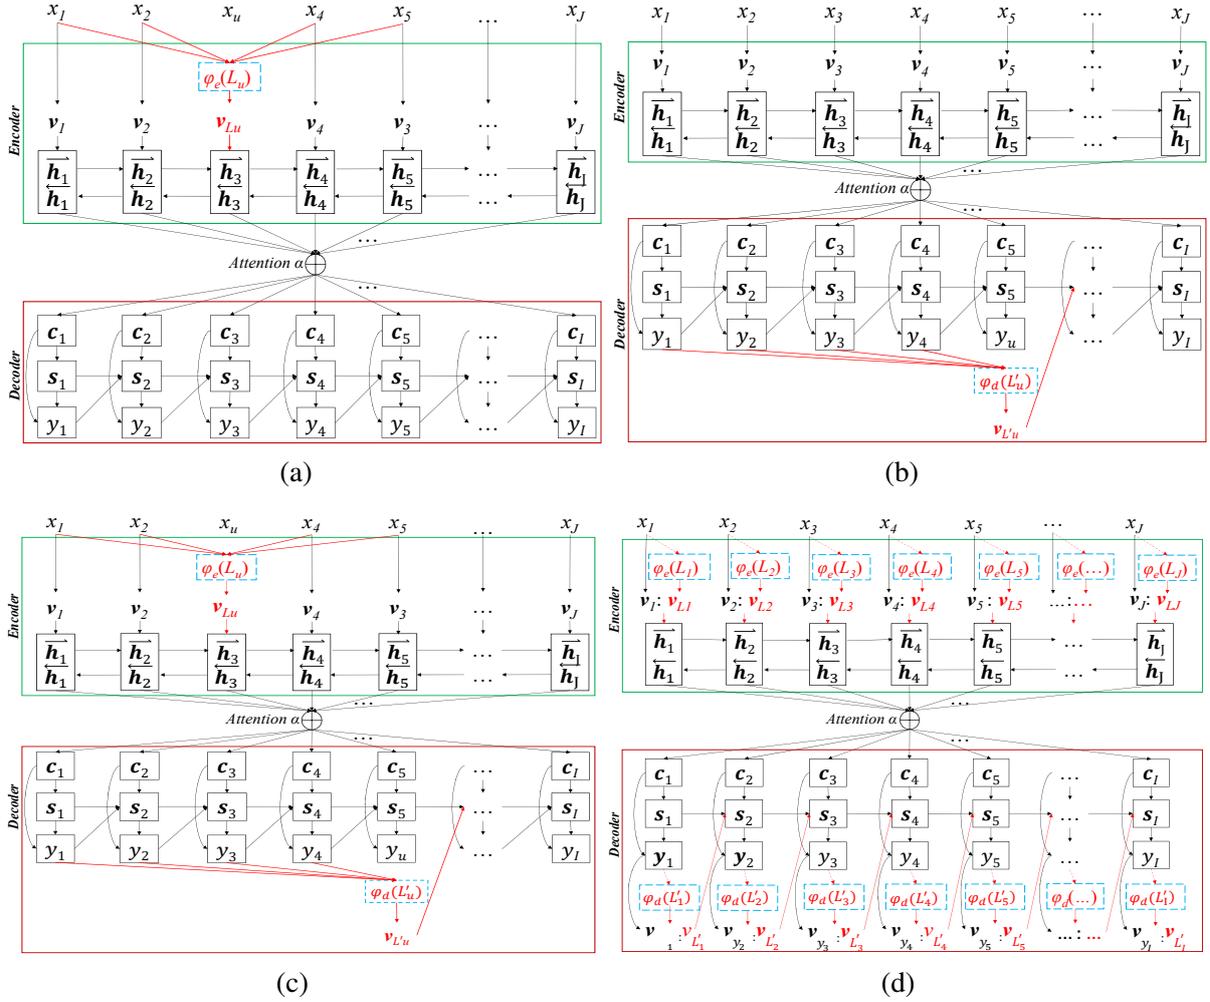

Figure 3: (a) **CARNMT-Encoder**; (b) **CARNMT-Decoder**; (c) **CARNMT-Both**; (d) **ALLSmooth**, in which the red dotted arrows obtain the context words of each word according to eq.(14) or eq.(16). The blue dotted boxes denote FCWM or CCWM proposed in section 2.

- **CARNMT-Decoder**: Only smoothing target-side unk in the *decoder*, as shown in Figure 3 (b).
- **CARNMT-Both**: Both smoothing the unks of source-side and target-side in the NMT, as shown in Figure 3 (c).
- **ALLSmooth**: this model smooths not only the *unk* words, but also all source-and target-side in-vocabulary words by the learned CARs, as shown in Figure 3 (d). Meanwhile, the vector of in-vocabulary word and its CARs are concatenated as a novel vector to represent the semantic information of the word instead of replacing the word vector with its CAR.

In our experiments, each model has two variants according to the integrated FCWM or CCWM.

For example, “CARNMT-encoder (CCWM)” indicates that the CAR for OOV is learned by the CCWM proposed in the section 3. In Figure 3, we take FCWM to learn the CAR for each word (including OOV). Therefore, there is easy to use the proposed CCWM instead of the FCWM.

Moreover, the proposed NMT models with CAR are an integrative architecture without any external information. Especially, the NMT and FCWM or CCWM, which are not isolated from each other, are trained by optimizing their parameters jointly. In other words, the θ_1 or θ_2 and the parameters of NMT are optimized jointly.

5 Experiments

5.1 Setting up

We carry out experiments on the Chinese-to-English translation task. The training dataset

Table 1: Results on NIST Chinese-to-English Translation Task. “*” indicates statistically significant better than Bahdanau et al. (2015) at p -value < 0.05 and “**” at p -value < 0.01 . “‡” indicate statistically significant difference (p -value < 0.05) from the Li et al. (2016) which performed the best among baselines and “†” at p -value < 0.01 . **AVG** is average BLEU scores for MT03-MT08 test sets. The bold denotes the proposed model is superior to the Li et al. (2016) over the same test set.

consists of 1.42M sentence pairs extracted from LDC corpora.⁶ We choose the NIST 2002 (MT02) and the NIST 2003-2008 (MT03-08) datasets as validation set and test sets, respectively. Case-insensitive 4-gram NIST BLEU score (Papineni et al., 2002) is as evaluation metric, and the signtest (Collins et al., 2005) was as statistical significance test.

The baseline systems included the standard PB-SMT implemented in Moses (Koehn et al., 2007) and the standard attentional NMT (Bahdanau et al., 2015). We also compared with state-of-the-art enhanced NMT methods for OOV: subword-based NMT (Sennrich et al., 2016), character-based NMT (Costa-jussà and Fonollosa, 2016), and replacing *unk* with similarity semantic in-vocabulary words (Li et al., 2016). All of these baselines and the proposed method are implemented in Nematus⁷ (Sennrich et al., 2017).

For all NMT systems, we limit the source and target vocabularies to 30K, and the maximum sentence length is 80. We shuffle training set before training and the mini-batch size is 80. The word embedding dimension is 620-dimensions⁸, the hidden layer dimension is 1000, and the default dropout technique (Hinton et al., 2012) in Nematus is used on the all the layers. Training is conducted on a single Tesla P100 GPU. All NMT models trained for 15 epochs⁹ using ADADELTA

optimizer (Zeiler, 2012), and our training time is only about 10% slower than the standard attentional NMT.

5.2 Results and Analyses

Table 1 shows the translation performances on test sets measured in BLEU score. The standard attentional NMT (Bahdanau et al., 2015) outperforms Moses by 2.78 BLEU points on average, indicating that it is a strong baseline NMT system. All the comparison methods, including Sennrich et al. (2016), Costa-jussà and Fonollosa (2016), and Li et al. (2016), outperform the standard attentional NMT.

1) Over the standard attentional NMT, CARNMT-Encoder (FCWM/CCWM) gain improvements of 0.86/0.94 BLEU points on average, and CARNMT-Decoder (FCWM/CCWM) gain improvements of 0.45/0.33 BLEU points on average. CARNMT-Both (FCWM/CCWM) gain improvements of 1.02/1.30 BLEU points on average, which indicates that improvement in encoder and decoder are essentially orthogonal.

2) ALLSmooth (FCWM/CCWM) surpass CARNMT-Both (FCWM/CCWM) by 0.28/0.62 BLEU points on average. This indicates that the proposed context-aware smoothing method not only helps relieve the OOV affect, but also enhances representations of in-vocabulary words.

3) ALLSmooth (FCWM/CCWM) also outperforms the best performed baseline Li et al. (2016), which replaces the *unk* words by using external lexicon similarity, by 0.24/0.78 BLEU points on

⁶LDC2002E18, LDC2003E07, LDC2003E14, Hansards portion of LDC2004T07, LDC2004T08, and LDC2005T06.

⁸For the ALLSmooth, the 360 dimensions are from V_{x_j} or V_{y_i} and the 260 dimensions were from the learned CAR

⁹All NMT models are convergent in the 15 epochs.

SRC: 用好 这个 战略 机遇期 (OOV), 力争 有所 作为, 必须 把 发展 科学技术 放在 更加 重要, 更加 突出的 位置 (pinyin) yonghao zhege zhanlue jiyuqi, lizheng yousuo zuowei, bixu ba fazhan kexue jishu fangzai gengjia zhongyao, gengjia tuchu de wieshi

Bahdanau et al. (2015): to make good use of this strategy, we should strive for the development of science and technology, and must put the development of science and technology into an even more important and prominent position

This work: in making good use of this strategic plan and striving to accomplish something, it is necessary to place the development of science and technology in a more important and more prominent position

Ref: to well use this strategic period of opportunity and strive to accomplish some achievements, the development of science and technology should be placed in a more prior and prominent position

Figure 4: Translation sample for source sentence with one OOV. The English phrases in color indicate they are translations from the corresponding Chinese phrase with the same color.

average.

4) The CCWM performs slightly better than FCWM. The reason may be that the convolution neural network can summarize the contextual information better than the feedforward neural network.

5.3 Translation Qualities for Sentences with Different Numbers of OOV

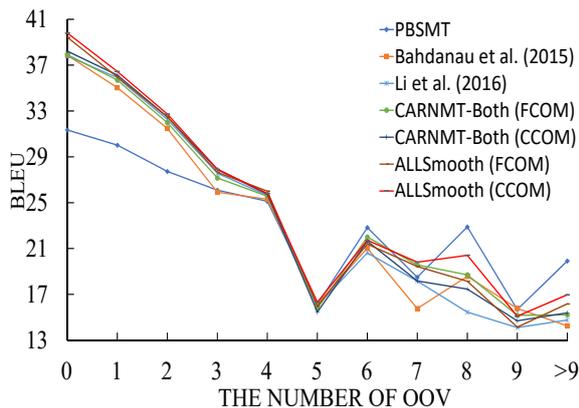

Figure 5: Translation qualities for sentences with different numbers of OOV.

To further verify our methods, we group sentences of same number OOVs all the test sets (MT03-08), for example, “5” indicates that all the source sentences include five OOV words in the group, and compute a BLEU score per group.

1) In Figure 5, we observe that when the number of OOVs is zero (no OOV), ALLSmooth (FCWM/CCWM) outperform other baseline systems, and the performances of CARNMT-Both (FCWM/CCWM) are similar to standard attentional NMT. This means that CARNMT-Both (FCWM/CCWM) degrade into standard attentional NMT because of these sentences not include

OOV, but our context-aware smoothing method enhances the representation of in-vocabulary words in the ALLSmooth (FCWM/CCWM).

2) With the increasing in the number of OOVs (especially when more than five), the gap between our methods and other methods (except PBSMT) become larger. This indicates that our methods are especially good at dealing with multi-OOV situation, in comparison with other NMT methods.

5.4 Samples Analysis

This subsection shows one translation sample for source sentence with one OOV, as shown in Figure 4. We compare our method ALLSmooth (CCWM) with Bahdanau et al. (2015) on the translation of a source sentence with the OOV “jiyuqi” (“period of opportunity” in English).

1) For both of Bahdanau et al. (2015)’s method and the proposed method, the OOV “jiyuqi” itself is not translated.

2) For Bahdanau et al. (2015)’s method, the phrase “lizheng yousuo zuowei” (“strive to accomplish some achievements” in English) after “jiyuqi” is not translated. The purple part of source sentence are translated twice in (Bahdanau et al., 2015)’s method. This is in consistent with our hypothesis in Section 1: the OOV which makes the structure of source sentence discontinuous affects source representation learning in encoder; then the negative effect would be further transformed to the decoder by the source annotation vectors, thus generating the poverty context vector and hidden layer state for translation prediction.

3) In comparison, the proposed method translates it into “striving to accomplish something”, which is quite close to the reference. This indicates that our proposed context-aware smoothing method can relieve more translation

performance for NMT from the OOV’s negative effect shown in Section 1.

6 Conclusion

In this paper, we explored the context information to smooth source representation with OOVs, and integrate the learned CAR into the Encoder and Decoder of NMT to improve the translation performance. Especially, we extended the method to smooth each word in-vocabulary, and further gained improvements over the proposed models for the NMT.

In the future, we will exploit richer context information, such as pos-tagger and named entity, to enhance the semantic representation of vocabulary in NMT.

Abstract

Sequence to Sequence Neural Machine Translation has achieved significant performance in recent years. Yet, there are some existing issues that Neural Machine Translation still does not solve completely. Two of them are translation of long sentences and “over-translation”. To address these two problems, we propose an approach that utilize more grammatical information such as syntactic dependencies, so that the output can be generated based on more abundant information. In addition, the output of the model is presented not as a simple sequence of tokens but as a linearized tree construction. Experiments on the Europarl-v7 dataset of French-to-English translation demonstrate that our proposed method improves BLEU scores by 1.57 and 2.40 on datasets consisting of sentences with up to 50 and 80 tokens, respectively. Furthermore, the proposed method also solved the two existing problems, ineffective translation of long sentences and over-translation in Neural Machine Translation.

1 Introduction

Our task is to construct a model which learns input in sequence form and decodes output as a linearized dependency tree. In this work, we propose an approach in which dependency labels are incorporated into the model to represent more grammatical information in the output sequence. As we know, the Sequence to Sequence (Seq2Seq) Learning model (Sutskever et al., 2014; Aharoni et al., 2016) is extremely effective on a va-

riety of tasks that require a mapping between a sequence to sequence. Therefore, it is used to solve many tasks in natural language processing. The Seq2Seq model consists of an encoder-decoder neural network which encodes a variable-length input sequence into a vector and decodes it into a variable-length output. Since the model uses the information of the source representation and the previously generated words to produce the next-word token, this distributed representation allows the Seq2Seq model to generate appropriate mapping between the input and the output (Li et al., 2016). For specific tasks, Neural Machine Translation (NMT) model, which is based on the Seq2Seq learning, has achieved excellent translation performance in recent years (Sutskever et al., 2014; Bahdanau et al., 2015; Luong et al., 2015; Firat et al., 2016). In particular, the NMT model which is built upon an encoder-decoder framework with attention mechanism (Bahdanau et al., 2015) can also pay attention and its decoder knows which part of the input is relevant for the word that is currently being translated. Therefore, it has shown competitive results and outperformed conventional statistical methods (Bentivogli et al., 2016). Despite of these advantages, NMT model still has a couple particular issues to be solved such as dealing with fixed vocabulary, not applicable to small-data, additional phrases, wrong lexical choice errors, long sentence translation, over and under translation, etc. In this paper, we touch upon the following two major problems:

- Translation of long sentences
- Over-translation

Since the decoder of the Seq2Seq model produces the target language word by word simply based on the previous target words and the source-side representation vector until it reaches the spe-

This author’s present affiliation is CyberAgent, Inc., Tokyo, Japan, yoshimoto.akifumi_xa@cyberagent.co.jp

cial end token, it is incapable in capturing long-distance dependencies in history, so ineffective for long sentences translation (Zhang et al., 2016; Toral and Sánchez-Cartagena, 2017). Even with an attention mechanism, the Seq2Seq model just pays attention to the current alignment information between the inputs and the output at the current position but ignores past alignments information. Therefore, it cannot keep track of the attention history when it updates information at each current time step, leading to the over-production (Tu et al., 2016a,c; Mi et al., 2016; Tu et al., 2016b).

In order to address the above two issues, it is worth considering that using syntactic dependency information and representing the output as a tree structure would be effective. This approach allows the next tokens to be output based on not only the previous tokens but also the syntactic dependencies so far, thereby conditioning them on more abundant information so it has the ability to make smarter predictions. Basically, in this paper, we train the model with an encoder-decoder neural network and using dependencies in which the input of the source language is in sequence form and the output of the target language will be generated in a linearized dependency-based tree structure. That is, instead of predicting only words at each time step, the model trains the network to predict both words and their grammatical dependencies as a dependency tree at each time step. Therefore, it is hoped that the accuracy of output will be improved.

The major contributions of this work are as follows:

1. To utilize the information of both “head” words and syntactic dependencies between them to produce better output.
2. To settle the problems in the NMT task. In this paper, we desire to solve two tasks. First is the ineffective translation for long sentences. Second is the over-translation in NMT task.

Empirically, to assess the performance of the proposed method, we used Conditional Gated Recurrent Unit with Attention mechanism model of Bahdanau (2015) on the French-English portions of the Europarl-v7 dataset. As a result, the BLEU score is improved by 1.57 and 2.40 points for sentences of length up to 50 and 80 tokens, respec-

tively. Also, we compare and analyze the results of attention-based Seq2Seq model and the proposed approach.

2 Related Work

In fact, the effectiveness of using dependency information of words has been reported in some previous NLP tasks, for example, in dependency-based word embeddings, relation classification and sentence classification tasks (Liu et al., 2015; Socher et al., 2014; Levy and Goldberg, 2014; Komnios, 2016; Ono and Hatano, 2014). It has been shown that the combination of words and their dependency information can boost performance. Besides, in the work of Vinyals et al. (Vinyals et al., 2014), they also represent output as a linearized tree structure, but their work showed that generic sequence-to-sequence approaches can achieve excellent results on syntactic constituency parsing. At a glance, our proposed method is a little similar to the works of Dyer et al., Aharoni et al., Eriguchi et al., Wu et al. (Dyer et al., 2016; Aharoni and Goldberg, 2017; Eriguchi et al., 2017; Wu et al., 2017) in use of parse tree and generation. However, Dyer et al. and Aharoni et al.’s works concern predicting constituent trees. Eriguchi et al.’s model employs syntactic dependency parsing but their model is hybridized the decoder of NMT and the Recurrent Neural Network Grammars, and the target sentences are parsed in transition-based parsing. Wu et al.’s model also employs dependency parsing but their model separately predicts the target translation sequence and parsing action sequence which maps to translation. On the other hand, our proposed model’s decoder directly predicts the linearized dependency tree itself in a single neural network in *Depth-first pre-order* order so that the next-word token is generated based on syntactic relations and tree construction itself. In other words, our model is able to learn and produce a tree of words and their dependency relations by itself.

3 Sequence-to-Dependency Model

In our proposed approach, the neural network model is trained to map the target-side output in a linearized dependency tree construction from the source-side input in a sequence. Thus, we call this model Sequence-to-Dependency (Seq2Dep) model. The problem is defined as follows: Given a source sequence $\mathbf{X} = (x_1, x_2, \dots, x_N)$ of length

N , we want the model to encode the input sequence X and decode it to a tree structure with both words and dependency information conditioned on the encoded vector. Therefore, the output will be represented in the form $(LY) = (\mathbf{ly}_1, \mathbf{ly}_2, \dots, \mathbf{ly}_M)$. The conditional probability $p(\mathbf{ly}|x)$ is decomposed as:

$$p(\mathbf{ly}|x) = \prod_{i=1}^{\infty} p(\mathbf{ly}_i | \mathbf{ly}_{<i}, x), \quad (1)$$

in which $(\mathbf{ly}_1, \mathbf{ly}_2, \dots, \mathbf{ly}_M)$ are words or dependency labels.

Therefore, the hidden state \mathbf{s}_j at time step j is computed as follows:

$$\mathbf{s}_j = \text{cGRU}_{\text{att}}(\mathbf{s}_{j-1}, \mathbf{ly}_{j-1}, \mathbf{C}_j), \quad (2)$$

and the next token \mathbf{ly}_j , which may be a word or dependency label, will be generated as follows:

$$\mathbf{ly}_j = f(\mathbf{s}_j, \mathbf{ly}_{j-1}, \mathbf{C}_j), \quad (3)$$

In this paper, dependencies are defined as the dependency labels which are achieved from the Stanford Dependency Parser (Chen and Manning, 2014). The decoder will decode the next output based on relations between governors and dependents in a linearized tree structure. In regards to the order of generating the dependency labels and the words, the decoder will produce these symbols in a manner called *Depth-first pre-order* traversal. In this section, we will describe the model step-by-step as follows:

3.1 Processing Data

Since there is no parallel corpus in which the source-side is represented in sequence and target-side is represented in linearized dependency tree, we have to prepare data for training by doing dependency parsing for the target-side language.

3.1.1 Dependency Parsing

In this paper, we do experiments on a French-English language pair so we use the Stanford Dependency Parser to obtain dependency parsing results for English. The Stanford Dependency Parser produces results in the form of a tree structure in which each word of the sentence is the dependent of exactly one token, either another word in the sentence or the distinguished “ROOT-0” token. The parsing result is represented in the format “*abbreviated relation name(governor, depen-*

dent)” in which a governor is a head word and dependency is a syntactic relation between a governor and a dependent. The governor and the dependent are words in the sentence. This dependency parsing result will be transformed in another step for traversing the tree, which will be described in the next section to create a dependency tree. The dependency tree represents the target language as an ordered tree structure which is necessary for training. The reason we chose the Stanford Dependency Parser for the parsing portion of this method is because it can represent the order of words in sentence. This information of the order is useful to traverse tree in the following step.

3.1.2 Transformation and Tree Traversal

In this section, we describe the Tree Transform and Tree Traversal process in which output in a linearized dependency tree form is created from the Stanford Dependency Parsing tree. For example, given a sentence “*She ate an apple today .*”, after obtaining dependency parsing tree from the above dependency parsing phase, we move the rooted “*ate*” and “*apple*” headwords to the same layers of their *dependents* which are directly connected to the headwords. We also concurrently make consideration to their positions in order while shifting headwords. The headwords are shifted in such a manner that the word order of sentence can be preserved, so we can evaluate the translated output afterwards. Next, the tree structure obtained in the first step will be transformed into another tree structure for the next tree traversal step. Then we traverse this tree in a *Depth-first pre-order* traversal, which is the search tree in which tree is traversed from its left subtree to right subtree recursively until current node is empty, to create output with a linearized tree structure to train the model. That is, for each rooted subtree, governors and dependency labels of the sentence are predicted first, and their information will be used to predict the next dependent words. In other words, the model can capture the dependency information between label-word and word-word pairs to predict the next tokens. This means that the model is capable of modeling grammatical dependencies in the output symbols. Also, in Seq2Dep model, we define the *Nonterminal* “{*DEPENDENCY LABEL*”, and *Node-closing* “}” tokens. *Nonterminal* indicates subtree (Dong and Lapata, 2016), which means open subtree to visit its children nodes. *Node-closing* indicates end-of-

Algorithm 1 Tree Transform

8:       label's parent & children
9:       if (label's children order is larger
10:        than label's parent order) then
11:         INSERT label's parent first
12:       else
13:         INSERT label's children
```

subtree, that means finishing subtree traversal and returning to the upper layer to continue the next subtree traversal. And these defined tokens do not appear in original source and target datasets. Algorithms 1 and 2 show the definition of transformation and tree traversal in more detail respectively. The purpose of using *Depth-first pre-order* traversal is as follows:

1. To keep the words of the target language sequence in order when they are generated. With this generating order, the word order of the sentence is preserved, thus, we do not have to do any post-processing subsequently.
2. To utilize both information of the words and the dependency labels generated in the previous rooted subtree to predict the tokens of the next rooted subtree.

Figures 1, 2 and 3 show the Stanford dependency parsing tree, tree structure after the positions of “head” words are shifted and *Depth-first pre-order* Tree Traversal.

3.2 Sequence-to-Dependency Model

The proposed (Seq2Dep) model consists of an encoder which is a bidirectional GRU layer as in Bahdanau’s model (2015)¹. The input embeddings of the source sentences are shared by the forward and backward GRU, and the hidden states of the corresponding forward and backward GRU are added to obtain the hidden representation for that time step. The decoder of the model will decode the output as words and dependency labels in a linearized dependency tree structure in

a *Depth-first pre-order* traversal. Figure 4 shows the decoder which generates both dependency labels and words in the Seq2Dep model. In Figure 4, the previous token and context vector feeding are omitted for simplicity.

4 Experiments

4.1 Dataset

In our experiment, the proposed model was trained on the French-English parallel corpus of the *Europarl-v7* dataset. We used *newstest2011* and *newstest2012* of WMT16 as development and test data respectively. To confirm translation for long sentences, the whole test set was used without removing any sentences with a maximum length of 50 or 80. We performed experiment on the following two datasets:

- *Europarl-v7* dataset consisting of sentences with a maximum length of 50.
- *Europarl-v7* dataset consisting of sentences with a maximum length of 80.

For preprocessing data, we filtered out sentences which were longer than the above maximum lengths and cleaned the special symbols or characters which were not strings. We also omitted sentences which had multiple sentences in one line. The reason is that the parsing results obtained from the Stanford Dependency Parser in parsing

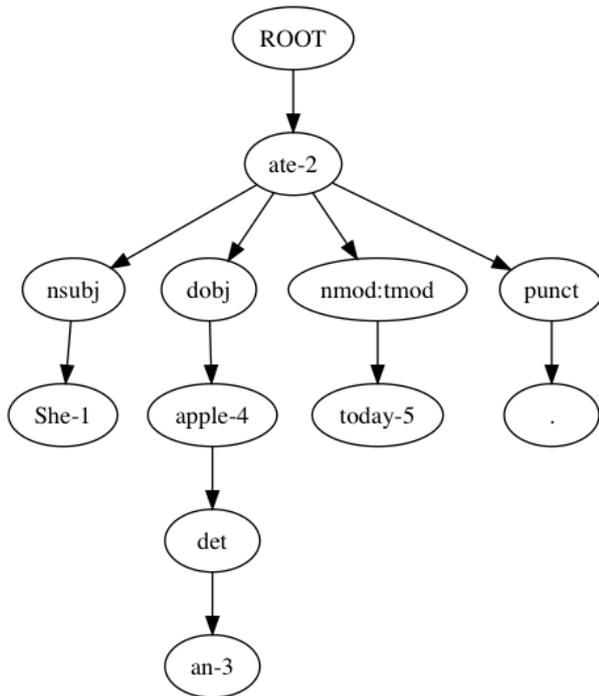

Figure 1: Stanford Dependency Parsing Tree

step would contain multi “{ROOT}” tokens for sentences which have multiple sentences in one line, while it is necessary to generate the next child nodes starting from just one top {ROOT} of a tree. Next, we tokenize and lowercase this dataset and perform dependency parsing. After that, we traverse the tree in a *Depth-first pre-order* to create the parallel corpus for the training model in which the source language, French is in sequence form, and the target language, English is in a linearized dependency tree structure form. The longer sentences are (particularly sentences with a maximum length of 80 tokens), the more CPU’s memory and time cost for this processing data step.

In addition, we built a dictionary of the target language (English) that consists of both words and dependency labels. In this dictionary, we define 74 dependency labels based on the current representation of grammatical relations of the Stanford Dependency Parser.

4.2 Settings

In order to evaluate the performance of the proposed method, we set the same hyperparameters as the attention-based cGRU model in DL4MT-Tutorial and compare the obtained results of both Seq2Seq and Seq2Dep models.

The recurrent transformation weights for gates

and hidden state proposal matrices were initialized as random orthogonal matrices. Weights were optimized using the Adadelta algorithm and were updated with a mini-batch size of 32 sentences. The vocabulary sizes of both source and target languages were set at 30k words, the beam size was set to 5, dropout was not applied and the gradients were clipped at 1.0. Moreover, because the generated tokens are not only words but also dependency labels in Seq2Dep model, the maxlen parameter was set up so that dependency labels are not counted, therefore long sentences will not be removed in training.

4.3 Model Training

In the experiments, we trained the following 2 models on 1.65M sentences with a maximum length of 50 and 1.89M sentences with a maximum length of 80 from the Europarl-v7 French-English bitext.

Baseline Model

This model is a Seq2Seq model with attention mechanism as in Firat (2016) that consists of an encoder that encodes the source language input in sequence form and a decoder that decodes target language output in sequence form.

Seq2Dep Model The proposed method. In this model, the model architecture is the same as the attention-based Seq2Seq model but the input is in sequence form and the output is in linearized dependency tree structure.

5 Results

In the Seq2Dep model, because the output consists of both words and dependency labels, we evaluated the result with post-processing, which is the process that removes the dependency labels from the translated result. From this section onwards, we will refer to the Seq2Seq and Seq2Dep models with sentences of maximum length 50 and 80 tokens as Seq2Seq-50, Seq2Dep-50, Seq2Seq-80 and Seq2Dep-80. As a result, the BLEU score of Seq2Dep-50 with post-processing was 20.88, which is higher than the BLEU score of 19.31 obtained by the attention-based Seq2Seq-50 model with a gain of up to 1.57 points. Similarly, the BLEU score improved by 2.40 points for datasets with maximum sentence lengths of 80.

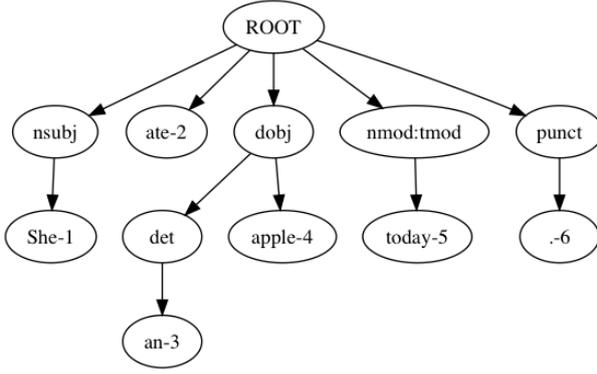

Figure 2: Dependency tree after shifting the positions of “head” words

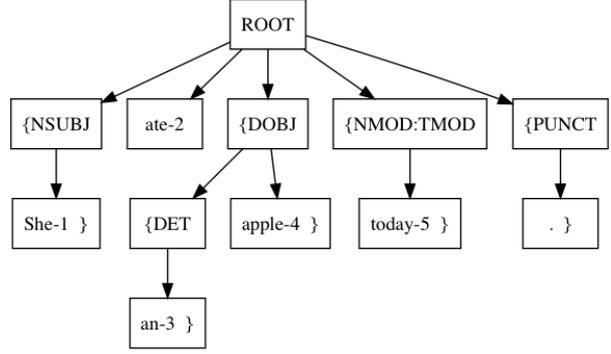

Figure 3: *Depth-first pre-order* Tree Traversal

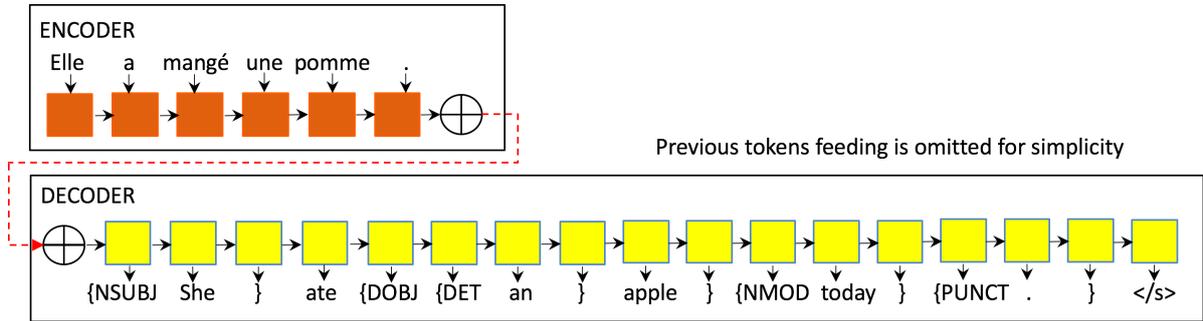

Figure 4: Encoder and decoder of Seq2Dep model

Table 1 shows BLEU and METEOR scores and TER error of the attention-based Seq2Seq and Seq2Dep models. Figure 5 shows the relation between BLEU score and the length of sentence.

Moreover, when we made a trial to evaluate the translation results without post-processing, the BLEU scores without post-processing were 42.76 and 43.41 for both datasets. From these scores, it is thought that the model can predict not only word-based tokens but also dependency labels well.

6 Additional Experiments

In order to verify the ability of the proposed approach to solve the repetition problem of NMT, over-translation, we measured the repetition of words in the translation results of attention-based Seq2Seq and Seq2Dep learnings in this section. The repetition rate is measured by the following formula:

$$rep_rat = \sum_{i=1}^{T(y)} \frac{1 + r(\tilde{y}_i)}{1 + r(Y)}, \quad (4)$$

in which \tilde{y}_i and Y_i are the i^{th} hypothesis sentence and i^{th} reference sentence respectively, and r is the number of the repeated words and is computed by:

$$r(X) = len(X) - len(set(X)) \quad (5)$$

in which $len(X)$ is the length of the sentence X and $len(set(X))$ is the number of words that are not repeated in sentence X . For example, given the sentence $X = \text{“The big fish ate the smaller fish”}$, in this case, $set(X) = \{\text{The, big, fish, ate, smaller}\}$, $len(X) = 7$, $len(set(X)) = 5$. Figure 6 shows the comparison of repetition rate in both models in which the horizontal axis is the length of sentences, vertical axis is the repetition rate respectively. In Figure 6, the repetition rate in both Seq2Seq and Seq2Dep learnings decreases as the length of the sentences increases. From Figure 6, we can see that the more tokens the model learns, the more the repetition rate decreases. Also, the repetition rate is reduced in the Seq2Dep model compared to the attention-based Seq2Seq model.

Table 1: Translation quality as measured by different metrics.

Model	Post-processing		
	BLEU	METEOR	TER
Seq2Seq-50	19.31	26.3	66.1
Seq2Dep-50	20.88	27.0	62.5
Seq2Seq-80	16.97	25.5	78.5
Seq2Dep-80	19.37	25.6	65.6

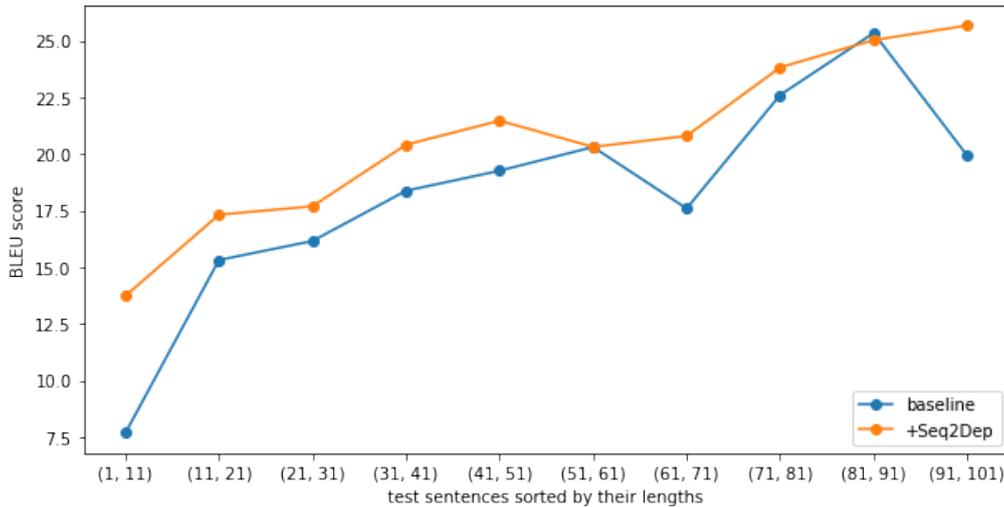

Figure 5: Comparison of BLEU score with respect to the length of sentences

7 Analysis and Discussion

In figure 5, except the span in which the sentence length is between 41 and 51 words, the BLEU score of the Seq2Dep model goes up gradually and almost overcomes that of the attention-based Seq2Seq model. The BLEU score falls from 19.31 to 16.97 with a 2.34 points difference for the attention-based Seq2Seq model while the point difference is 1.51 in the Seq2Dep model. From the experiments, we confirm that by using the syntactic dependency information, the Seq2Dep model can learn well and reduce the drop in BLEU score compared to the baseline model even if the sentence is very long. Besides, we can see the BLEU score is low for short sentences which have a length of 10 words or less. This is because of the brevity penalty on short sentences in BLEU (Papineni et al., 2002).

With regards to the BLEU score without post-processing, we see that the score of the Seq2Dep-80 model is higher than that of the Seq2Dep-50 model. The reason could be: The longer the sentences are, the more syntactic de-

pendencies the models require for generating better outputs.

Also, in terms of the over-translation problem, Figure 6 shows that the repetition rates of the two models decrease gradually with respect to the length of the sentences and the Seq2Dep model has a lower repetition rate. When we checked the translation results, we saw that *Node-closing* token “}” was almost generated after each subtree. Moreover, we saw that there were some very long sentences which the over-generation of “UNK”’s occurred in the translation result of Seq2Seq model while that did not occur in translation results of Seq2Dep model. Our assumption is that after generating subtree, the Seq2Dep model can learn that it should generate the *Node-closing* token “}” next, instead of a chain of words. In other words, as mentioned in Kuncoro et al.’s work (Kuncoro et al., 2016) in which modeling of composition can achieve better performance, the Seq2Dep model which learns about the syntactic dependencies and tree structure performance is probably able to learn the blocks of the form “*Non-terminal* word }” like a phrase-structure in sen-

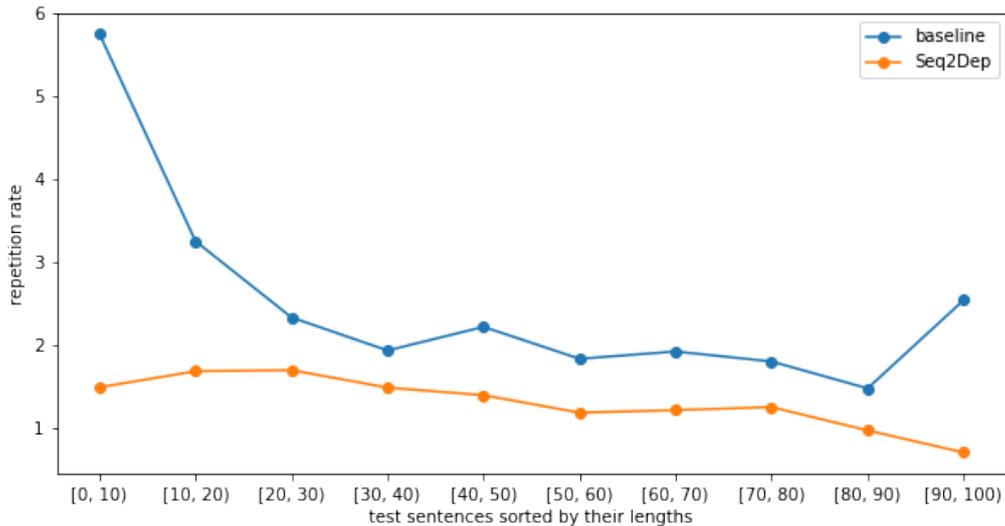

Figure 6: Comparison of the repetition rate of the baseline and Seq2Dep models

tences, so it is unlikely to generate the same word repeatedly. Therefore, it is possible to prevent the long repeated words in long sentences. Usually, because the block of the form “*Nonterminal word* }” is seen as a phrase in sentence or a subtree in tree structure, and it is rare for a phrase to occur repeatedly in sentence or for a subtree to repeat in a tree structure, so it is assumed that repetition of the blocks of form “*Nonterminal word* }” are also rare.

8 Conclusion

In this work, we proposed a method in which the Seq2Dep NMT model is trained by utilizing syntactic dependencies to provide the model more abundant information. In other words, Seq2Dep model learns the potential internal relative connections among tokens and their long term syntactic dependencies to predict the next-word tokens. Furthermore, the Seq2Dep model can also generate output as a linearized dependency tree structure in a *Depth-first pre-order* tree traversal over words and dependencies. The purpose of this work is to alleviate issues of translating long sentences and repetitive translation. We conduct experiments on the French-English parallel corpus of the Europarl-v7 dataset to compare the performance of the proposed method with the attention-based Seq2Seq model. The results demonstrated that the proposed model achieved a 1.57 and 2.40 points BLEU score improvement for sentences of length at most 50 and 80 tokens re-

spectively. Moreover, experiments verify that the proposed model also reduces the over-translation, particularly long sentences with over-generation of “*UNK*”s.

9 Future work

- Confirm how accurate the Seq2Dep model generates the dependency labels and the whole tree structure as well.
- In this paper, to compare performance of the proposed method with the baseline model, we set the same hyperparameters as the attention-based cGRU model in dl4mtutorial and trained the Seq2Dep model on only Europarl-v7 dataset. Since experiments were done on small vocabulary size and dataset, we plan to train the model on larger vocabulary and datasets with subword units segmentation.
- For future work, we plan to train models on datasets which consist of only long sentences with more than 50 or 80 tokens to compare the performance of long-sentences translation of the approach and baseline model.

What does Attention in Neural Machine Translation Pay Attention to?

Hamidreza Ghader and Christof Monz

Informatics Institute, University of Amsterdam, The Netherlands

`h.ghader, c.monz@uva.nl`

Abstract

Attention in neural machine translation provides the possibility to encode relevant parts of the source sentence at each translation step. As a result, attention is considered to be an alignment model as well. However, there is no work that specifically studies attention and provides analysis of what is being learned by attention models. Thus, the question still remains that how attention is similar or different from the traditional alignment. In this paper, we provide detailed analysis of attention and compare it to traditional alignment. We answer the question of whether attention is only capable of modelling translational equivalent or it captures more information. We show that attention is different from alignment in some cases and is capturing useful information other than alignments.

1 Introduction

Neural machine translation (NMT) has gained a lot of attention recently due to its substantial improvements in machine translation quality achieving state-of-the-art performance for several languages (Luong et al., 2015b; Jean et al., 2015; Wu et al., 2016). The core architecture of neural machine translation models is based on the general encoder-decoder approach (Sutskever et al., 2014). Neural machine translation is an end-to-end approach that learns to encode source sentences into distributed representations and decode these representations into sentences in the target language. Among the different neural MT models, attentional NMT (Bahdanau et al., 2015; Luong et al., 2015a) has become popular due to its capability to use the most relevant parts of the source sentence at each translation step. This capability

also makes the attentional model superior in translating longer sentences (Bahdanau et al., 2015; Luong et al., 2015a).

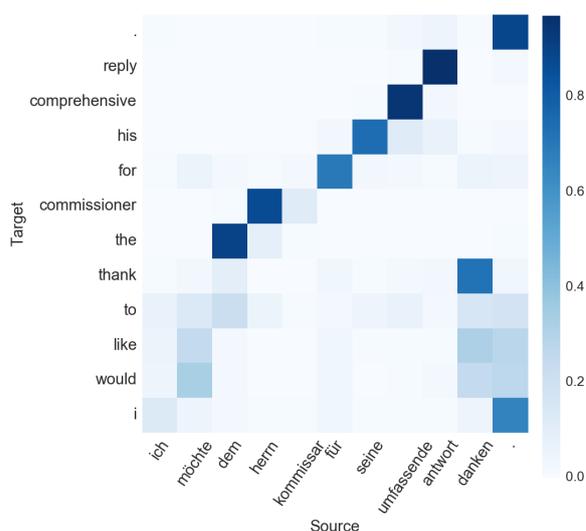

Figure 1: Visualization of the attention paid to the relevant parts of the source sentence for each generated word of a translation example. See how the attention is ‘smeared out’ over multiple source words in the case of “would” and “like”.

Figure 1 shows an example of how attention uses the most relevant source words to generate a target word at each step of the translation. In this paper we focus on studying the relevance of the attended parts, especially cases where attention is ‘smeared out’ over multiple source words where their relevance is not entirely obvious, see, e.g., “would” and “like” in Figure 1. Here, we ask whether these are due to errors of the attention mechanism or are a desired behavior of the model.

Since the introduction of attention models in neural machine translation (Bahdanau et al., 2015) various modifications have been proposed (Luong et al., 2015a; Cohn et al., 2016; Liu et al., 2016). However, to the best of our knowledge

there is no study that provides an analysis of what kind of phenomena is being captured by attention. There are some works that have looked to attention as being similar to traditional word alignment (Alkhouli et al., 2016; Cohn et al., 2016; Liu et al., 2016; Chen et al., 2016). Some of these approaches also experimented with training the attention model using traditional alignments (Alkhouli et al., 2016; Liu et al., 2016; Chen et al., 2016). Liu et al. (2016) have shown that attention could be seen as a reordering model as well as an alignment model.

In this paper, we focus on investigating the differences between attention and alignment and what is being captured by the attention mechanism in general. The questions that we are aiming to answer include: Is the attention model only capable of modelling alignment? And how similar is attention to alignment in different syntactic phenomena?

Our analysis shows that attention models traditional alignment in some cases more closely while it captures information beyond alignment in others. For instance, attention agrees with traditional alignments to a high degree in the case of nouns. However, it captures other information rather than only the translational equivalent in the case of verbs.

This paper makes the following contributions: 1) We provide a detailed comparison of attention in NMT and word alignment. 2) We show that while different attention mechanisms can lead to different degrees of compliance with respect to word alignments, global compliance is not always helpful for word prediction. 3) We show that attention follows different patterns depending on the type of the word being generated. 4) We demonstrate that attention does not always comply with alignment. We provide evidence showing that the difference between attention and alignment is due to attention model capability to attend the context words influencing the current word translation.

2 Related Work

Liu et al. (2016) investigate how training the attention model in a supervised manner can benefit machine translation quality. To this end they use traditional alignments obtained by running automatic alignment tools (GIZA++ (Och and Ney, 2003) and fast_align (Dyer et al., 2013)) on the training data and feed it as ground truth to the

attention network. They report some improvements in translation quality arguing that the attention model has learned to better align source and target words. The approach of training attention using traditional alignments has also been proposed by others (Chen et al., 2016; Alkhouli et al., 2016). Chen et al. (2016) show that guided attention with traditional alignment helps in the domain of e-commerce data which includes lots of out of vocabulary (OOV) product names and placeholders, but not much in the other domains. Alkhouli et al. (2016) have separated the alignment model and translation model, reasoning that this avoids propagation of errors from one model to the other as well as providing more flexibility in the model types and training of the models. They use a feed-forward neural network as their alignment model that learns to model jumps in the source side using HMM/IBM alignments obtained by using GIZA++.

Shi et al. (2016) show that various kinds of syntactic information are being learned and encoded in the output hidden states of the encoder. The neural system for their experimental analysis is not an attentional model and they argue that attention does not have any impact for learning syntactic information. However, performing the same analysis for morphological information, Belinkov et al. (2017) show that attention has also some effect on the information that the encoder of neural machine translation system encodes in its output hidden states. As part of their analysis they show that a neural machine translation system that has an attention model can learn the POS tags of the source side more efficiently than a system without attention.

Recently, Koehn and Knowles (2017) carried out a brief analysis of how much attention and alignment match in different languages by measuring the probability mass that attention gives to alignments obtained from an automatic alignment tool. They also report differences based on the most attended words.

The mixed results reported by Chen et al. (2016); Alkhouli et al. (2016); Liu et al. (2016) on optimizing attention with respect to alignments motivates a more thorough analysis of attention models in NMT.

3 Attention Models

This section provides a short background on attention and discusses two most popular attention models which are also used in this paper. The first model is a non-recurrent attention model which is equivalent to the “global attention” method proposed by Luong et al. (2015a). The second attention model that we use in our investigation is an input-feeding model similar to the attention model first proposed by Bahdanau et al. (2015) and turned to a more general one and called *input-feeding* by Luong et al. (2015a). Below we describe the details of both models.

Both non-recurrent and input-feeding models compute a context vector c_i at each time step. Subsequently, they concatenate the context vector to the hidden state of decoder and pass it through a non-linearity before it is fed into the softmax output layer of the translation network.

$$\tilde{h}_t = \tanh(W_c[c_t; h'_t]) \quad (1)$$

The difference of the two models lays in the way they compute the context vector. In the non-recurrent model, the hidden state of the decoder is compared to each hidden state of the encoder. Often, this comparison is realized as the dot product of vectors. Then the comparison result is fed to a softmax layer to compute the attention weight.

$$e_{t,i} = h_i^T h'_t \quad (2)$$

$$\alpha_{t,i} = \frac{\exp(e_{t,i})}{\sum_{j=1}^{|x|} \exp(e_{t,j})} \quad (3)$$

Here h'_t is the hidden state of the decoder at time t , h_i is i th hidden state of the encoder and $|x|$ is the length of the source sentence. Then the computed alignment weights are used to compute a weighted sum over the encoder hidden states which results in the context vector mentioned above:

$$c_i = \sum_{i=1}^{|x|} \alpha_{t,i} h_i \quad (4)$$

The input-feeding model changes the context vector computation in a way that at each step t the context vector is aware of the previously computed context c_{t-1} . To this end, the input-feeding model feeds back its own \tilde{h}_{t-1} to the network and uses the resulting hidden state instead of the context-independent h'_t , to compare to the hidden states of

	RWTH data
# of sentences	508
# of alignments	10534
% of sure alignments	91%
% of possible alignments	9%

Table 1: Statistics of manual alignments provided by RWTH German-English data.

the encoder. This is defined in the following equations:

$$h_t'' = f(W[\tilde{h}_{t-1}; y_{t-1}]) \quad (5)$$

$$e_{t,i} = h_i^T h_t'' \quad (6)$$

Here, f is the function that the stacked LSTM applies to the input, y_{t-1} is the last generated target word, and \tilde{h}_{t-1} is the output of previous time step of the input-feeding network itself, meaning the output of Equation 1 in the case that context vector has been computed using $e_{t,i}$ from Equation 6.

4 Comparing Attention with Alignment

As mentioned above, it is a commonly held assumption that attention corresponds to word alignments. To verify this, we investigate whether higher consistency between attention and alignment leads to better translations.

4.1 Measuring Attention-Alignment Accuracy

In order to compare attentions of multiple systems as well as to measure the difference between attention and word alignment, we convert the hard word alignments into soft ones and use cross entropy between attention and soft alignment as a loss function. For this purpose, we use manual alignments provided by RWTH German-English dataset as the hard alignments. The statistics of the data are given in Table 1. We convert the hard alignments to soft alignments using Equation 7. For unaligned words, we first assume that they have been aligned to all the words in the source side and then do the conversion.

$$Al(x_i, y_t) = \begin{cases} \frac{1}{|A_{y_t}|} & \text{if } x_i \in A_{y_t} \\ 0 & \text{otherwise} \end{cases} \quad (7)$$

Here A_{y_t} is the set of source words aligned to target word y_t and $|A_{y_t}|$ is the number of source words in the set.

After conversion of the hard alignments to soft ones, we compute the *attention loss* as follows:

$$L_{At}(y_t) = - \sum_{i=1}^{|x|} Al(x_i, y_t) \log(At(x_i, y_t)) \quad (8)$$

Here x is the source sentence and $Al(x_i, y_t)$ is the weight of the alignment link between source word x_i and the target word (see Equation 7). $At(x_i, y_t)$ is the attention weight $\alpha_{t,i}$ (see Equation 3) of the source word x_i , when generating the target word y_t .

In our analysis, we also look into the relation between translation quality and the quality of the attention with respect to the alignments. For measuring the quality of attention, we use the attention loss defined in Equation 8. As a measure of translation quality, we choose the loss between the output of our NMT system and the reference translation at each translation step, which we call *word prediction loss*. The word prediction loss for word y_t is logarithm of the probability given in Equation 9.

$$p_{nmt}(y_t | y_{<t}, x) = \text{softmax}(W_o \tilde{h}_t) \quad (9)$$

Here x is the source sentence, y_t is target word at time step t , $y_{<t}$ is the target history given by the reference translation and \tilde{h}_t is given by Equation 1 for either non-recurrent or input-feeding attention models.

Spearman’s rank correlation is used to compute the correlation between attention loss and word prediction loss:

$$\rho = \frac{\text{Cov}(R_{L_{At}}, R_{L_{WP}})}{\sigma_{R_{L_{At}}} \sigma_{R_{L_{WP}}}} \quad (10)$$

where $R_{L_{At}}$ and $R_{L_{WP}}$ are the ranks of the attention losses and word prediction losses, respectively, Cov is the covariance between two input variables, and $\sigma_{R_{L_{At}}}$ and $\sigma_{R_{L_{WP}}}$ are the standard deviations of $R_{L_{At}}$ and $R_{L_{WP}}$.

If there is a close relationship between word prediction quality and consistency of attention versus alignment, then there should be high correlation between word prediction loss and attention loss. Figure 2 shows an example with different levels of consistency between attention and word alignments. For the target words “will” and “come” the attention is not focused on the

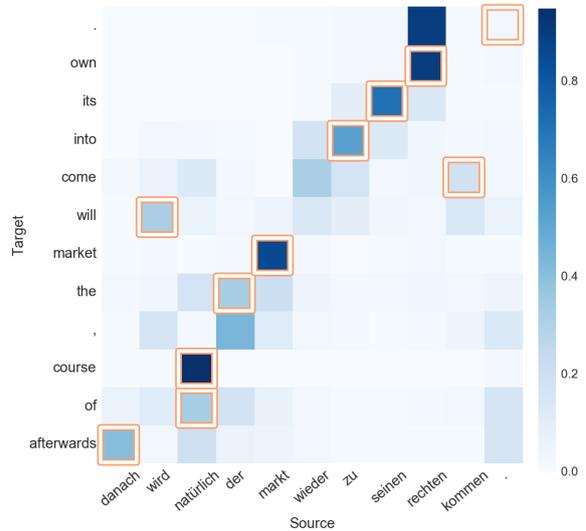

Figure 2: An example of inconsistent attention and alignment. The outlined cells show the manual alignments from the RWTH dataset (see Table 1). See how attention is deviated from alignment points in the case of “will” and “come”.

manually aligned word but distributed between the aligned word and other words. The focus of this paper is examining cases where attention does not follow alignment, answering the questions whether those cases represent errors or desirable behavior of the attention model.

4.2 Measuring Attention Concentration

As another informative variable in our analysis, we look into the attention concentration. While most word alignments only involve one or a few words, attention can be distributed more freely. We measure the concentration of attention by computing the entropy of the attention distribution:

$$E_{At}(y_t) = - \sum_{i=1}^{|x|} At(x_i, y_t) \log(At(x_i, y_t)) \quad (11)$$

5 Empirical Analysis of Attention Behaviour

We conduct our analysis using the two different attention models described in Section 3. Our first attention model is the global model without input-feeding as introduced by Luong et al. (2015a). The second model is the input-feeding model (Luong et al., 2015a), which uses recurrent attention. Our

System	test2014	test2015	test2016	RWTH
Non-recurrent	17.80	18.89	22.25	23.85
Input-feeding	19.93	21.41	25.83	27.18

Table 2: Performance of our experimental system in BLEU on different standard WMT test sets.

NMT system is a unidirectional encoder-decoder system as described in (Luong et al., 2015a), using 4 recurrent layers.

We trained the systems with dimension size of 1,000 and batch size of 80 for 20 epochs. The vocabulary for both source and target side is set to be the 30K most common words. The learning rate is set to be 1 and a maximum gradient norm of 5 has been used. We also use a dropout rate of 0.3 to avoid overfitting.

Data	# of Sent	Min Len	Max Len	Average Len
WMT15	4,240,727	1	100	24.7

Table 3: Statistics for the parallel corpus used to train our models. The length statistics are based on the source side.

5.1 Impact of Attention Mechanism

We train both of the systems on the WMT15 German-to-English training data, see Table 3 for some statistics. Table 2 shows the BLEU scores (Papineni et al., 2002) for both systems on different test sets.

Since we use POS tags and dependency roles in our analysis, both of which are based on words, we chose not to use BPE (Sennrich et al., 2016) which operates at the sub-word level.

	non-recurrent	input-feeding	GIZA++
AER	0.60	0.37	0.31

Table 4: Alignment error rate (AER) of the hard alignments produced from the output attentions of the systems with input-feeding and non-recurrent attention models. We use the most attended source word for each target word as the aligned word. The last column shows the AER for the alignment generated by GIZA++.

We report alignment error rate (AER) (Och and Ney, 2000), which is commonly used to measure alignment quality, in Table 4 to show the difference between attentions and human alignments provided by RWTH German-English dataset. To compute AER over attentions, we follow Luong

	non-recurrent	input-feeding
Attention loss	0.46	0.25

Table 5: Average loss between attention generated by input-feeding and non-recurrent systems and the manual alignment over RWTH German-English data.

et al. (2015a) to produce hard alignments from attentions by choosing the most attended source word for each target word. We also use GIZA++ (Och and Ney, 2003) to produce automatic alignments over the data set to allow for a comparison between automatically generated alignments and the attentions generated by our systems. GIZA++ is run in both directions and alignments are symmetrized using the grow-diag-final-and refined alignment heuristic.

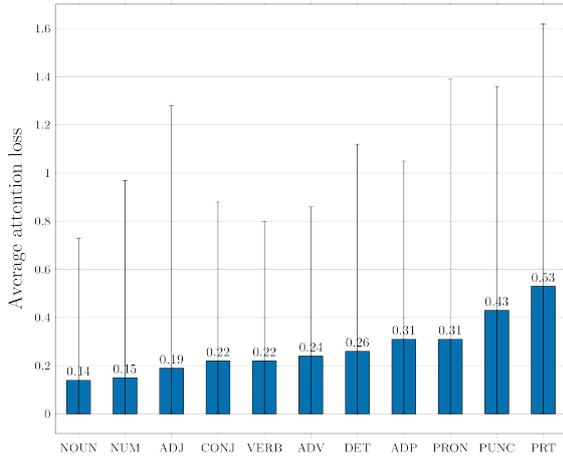

As shown in Table 4, the input-feeding system not only achieves a higher BLEU score, but also uses attentions that are closer to the human alignments.

Table 5 compares input-feeding and non-recurrent attention in terms of attention loss computed using Equation 8. Here the losses between the attention produced by each system and the human alignments is reported. As expected, the difference in attention losses are in line with AER.

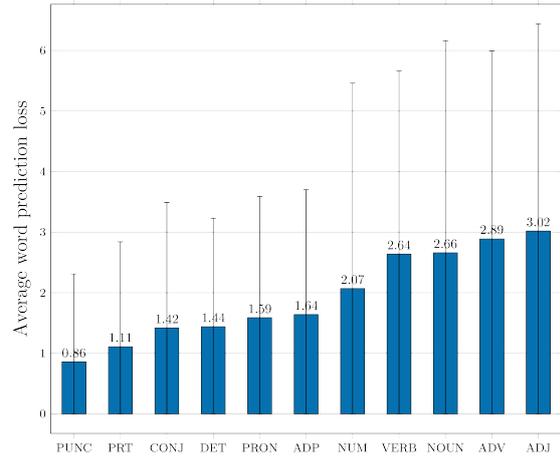

The difference between these comparisons is that AER only takes the most attended word into account while attention loss considers the entire attention distribution.

5.2 Alignment Quality Impact on Translation

Based on the results in Section 5.1, one might be inclined to conclude that the closer the attention is to the word alignments the better the translation. However, Chen et al. (2016); Liu et al. (2016); Alkhouli et al. (2016) report mixed results by optimizing their NMT system with respect to word prediction and alignment quality. These findings warrant a more fine-grained analysis of attention. To this end, we include POS tags in our analysis and study the patterns of attention based on POS tags of the target words. We choose POS tags be-

(a) Average attention loss based on the POS tags of the target side.

(b) Average word prediction loss based on the POS tags of the target side.

Figure 3: Average attention losses and word prediction losses from the input-feeding system.

Tag	Meaning	Example
ADJ	Adjective	large, latest
ADP	Adposition	in, on, of
ADV	Adverb	only, whenever
CONJ	Conjunction	and, or
DET	Determiner	the, a
NOUN	Noun	market, system
NUM	Numeral	2, two
PRT	Particle	's, off, up
PRON	Pronoun	she, they
PUNC	Punctuation	;; .
VERB	Verb	come, including

Table 6: List of the universal POS tags used in our analysis.

cause they exhibit some simple syntactic characteristics. We use the coarse grained universal POS tags (Petrov et al., 2012) given in Table 6.

To better understand how attention accuracy affects translation quality, we analyse the relationship between attention loss and word prediction loss for individual part-of-speech classes. Figure 3a shows how attention loss differs when generating different POS tags. One can see that attention loss varies substantially across different POS tags. In particular, we focus on the cases of NOUN and VERB which are the most frequent POS tags in the dataset. As shown, the attention of NOUN is the closest to alignments on average. But the average attention loss for VERB is almost two times larger than the loss for NOUN.

Considering this difference and the observations in Section 5.1, a natural follow-up would be to focus on getting the attention of verbs to be closer

to alignments. However, Figure 3b shows that the average word prediction loss for verbs is actually smaller compared to the loss for nouns. In other words, although the attention for verbs is substantially more inconsistent with the word alignments than for nouns, the NMT system translates verbs more accurately than nouns on average.

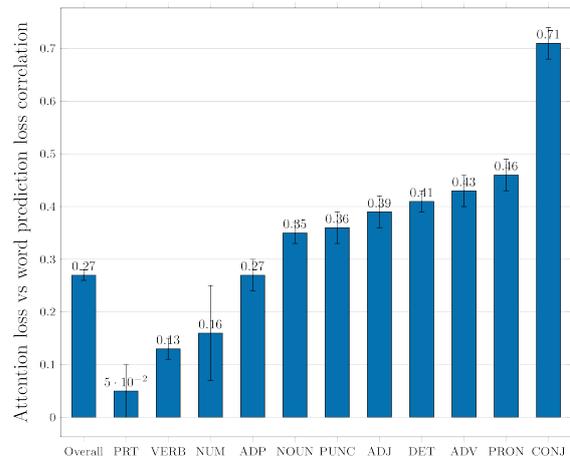

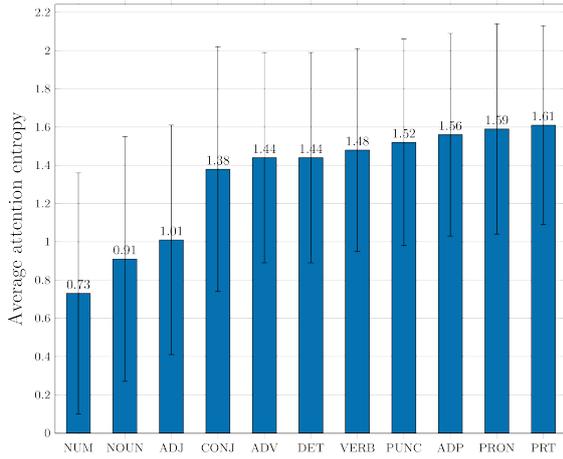

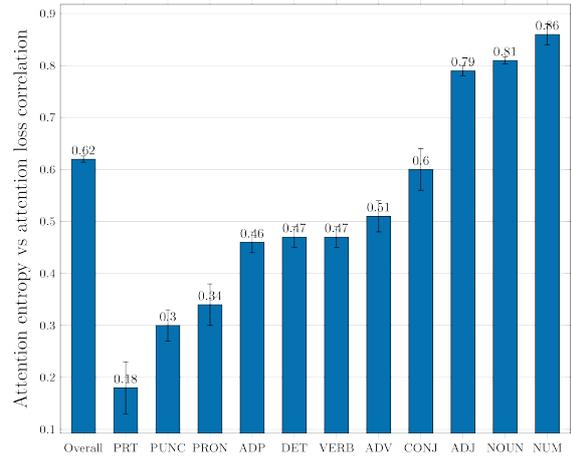

Figure 4: Correlation between word prediction loss and attention loss for the input-feeding model.

To formalize this relationship we compute Spearman’s rank correlation between word prediction loss and attention loss, based on the POS tags of the target side, for the input-feeding model, see Figure 4.

The low correlation for verbs confirms that attention to other parts of source sentence rather than the aligned word is necessary for translating verbs and that attention does not necessarily have to follow alignments. However, the higher correla-

(a) Average attention entropy based on the POS tags.

(b) Correlation between attention entropy and attention loss.

Figure 5: Attention entropy and its correlation with attention loss for the input-feeding system.

tion for nouns means that consistency of attention with alignments is more desirable. This could, in a way, explain the mixed result reported for training attention using alignments (Chen et al., 2016; Liu et al., 2016; Alkhoul et al., 2016). Especially the results by Chen et al. (2016) in which large improvements are achieved for the e-commerce domain which contains many OOV product names and placeholders, but no or very weak improvements were achieved over common domains.

5.3 Attention Concentration

In word alignment, most target words are aligned to one source word. The average number of source words aligned to nouns and verbs is 1.1 and 1.2 respectively. To investigate to what extent this also holds for attention we measure the attention concentration by computing the entropy of the attention distribution, see Equation 11.

Figure 5a shows the average entropy of attention based on POS tags. As shown, nouns have one of the lowest entropies meaning that on average the attention for nouns tends to be concentrated. This also explains the closeness of the attention to alignments for nouns. In addition, the correlation between attention entropy and attention loss in case of nouns is high as shown in Figure 5b. This means that attention entropy can be used as a measure of closeness of attention to alignment in the case of nouns.

The higher attention entropy for verbs, in Figure 5a, shows that the attention is more distributed compared to nouns. The low correlation between attention entropy and word prediction loss (see

Figure 6) shows that attention concentration is not required when translating into verbs. This also confirms that the correct translation of verbs requires the systems to pay attention to different parts of the source sentence.

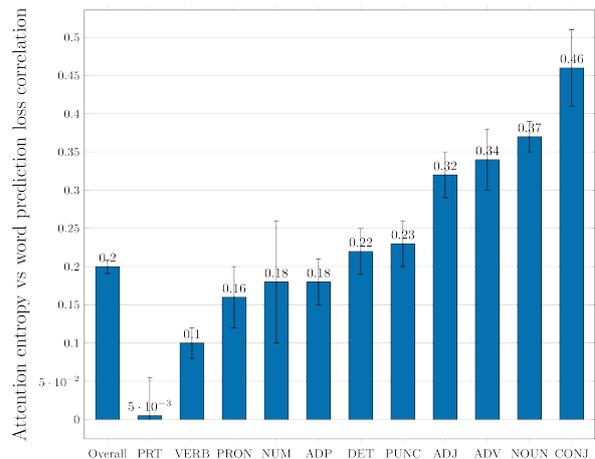

Figure 6: Correlation of attention entropy and word prediction loss for the input-feeding system.

Another interesting observation here is the low correlation for pronouns (PRON) and particles (PRT), see Figure 6. As can be seen in Figure 5a, these tags have more distributed attention comparing to nouns, for example. This could either mean that the attention model does not know where to focus or it deliberately pays attention to multiple, somehow relevant, places to be able to produce a better translation. The latter is supported by the relatively low word prediction losses, shown in the Figure 3b.

POS tag	roles(attention %)	description	
NOUN	punc(16%)	Punctuations ¹	
	pn(12%)	Prepositional complements	
	attr(10%)	Attributive adjectives or numbers	
	det(10%)	Determiners	
VERB	adv(16%)	Adverbial functions including negation	
	punc(14%)		Punctuations
	aux(9%)		Auxiliary verbs
	obj(9%)		Objects ²
	subj(9%)		Subjects
CONJ	punc(28%)	Punctuations	
	adv(11%)	Adverbial functions including negation	
	conj(10%)	All members in a coordination ³	

Table 7: The most attended dependency roles with their received attention percentage from the attention probability mass paid to the words other than the alignment points. Here, we focus on the POS tags discussed earlier.

5.4 Attention Distribution

To further understand under which conditions attention is paid to words other than the aligned words, we study the distribution of attention over the source words. First, we measure how much attention is paid to the aligned words for each POS tag, on average. To this end, we compute the percentage of the probability mass that the attention model has assigned to aligned words for each POS tag, see Table 8.

POS tag	attention to alignment points %	attention to other words %
NUM	73	27
NOUN	68	32
ADJ	66	34
PUNC	55	45
ADV	50	50
CONJ	50	50
VERB	49	51
ADP	47	53
DET	45	55
PRON	45	55
PRT	36	64
Overall	54	46

Table 8: Distribution of attention probability mass (in %) over alignment points and the rest of the words for each POS tag.

One can notice that less than half of the attention is paid to alignment points for most of

¹Punctuations have the role “root” in the parse generated using ParZu. However, we use the pos tag to discriminate them from tokens having the role “root”.

²Attention mass for all different objects are summed up.

³Includes all different types of conjunctions and conjoined elements.

the POS tags. To examine how the rest of attention in each case has been distributed over the source sentence we measure the attention distribution over dependency roles in the source side. We first parse the source side of RWTH data using the ParZu parser (Sennrich et al., 2013). Then we compute how the attention probability mass given to the words other than the alignment points, is distributed over dependency roles. Table 7 gives the most attended roles for each POS tag. Here, we focus on POS tags discussed earlier. One can see that the most attended roles when translating to nouns include adjectives and determiners and in the case of translating to verbs, it includes auxiliary verbs, adverbs (including negation), subjects, and objects.

6 Conclusion

In this paper, we have studied attention in neural machine translation and provided an analysis of the relation between attention and word alignment. We have shown that attention agrees with traditional alignment to a certain extent. However, this differs substantially by attention mechanism and the type of the word being generated. We have shown that attention has different patterns based on the POS tag of the target word. The concentrated pattern of attention and the relatively high correlations for nouns show that training the attention with explicit alignment labels is useful for generating nouns. However, this is not the case for verbs, since the large portion of attention being paid to words other than alignment points, is already capturing other relevant information. Training attention with alignments in this

case will force the attention model to forget these useful information. This explains the mixed results reported when guiding attention to comply with alignments (Chen et al., 2016; Liu et al., 2016; Alkhouli et al., 2016).

Grammatical Error Detection Using Error- and Grammaticality-Specific Word Embeddings

Masahiro Kaneko, Yuya Sakaizawa and Mamoru Komachi

Tokyo Metropolitan University

{kaneko-masahiro@ed, sakaizawa-yuya@ed, komachi@}.tmu.ac.jp

Abstract

In this study, we improve grammatical error detection by learning word embeddings that consider grammaticality and error patterns. Most existing algorithms for learning word embeddings usually model only the syntactic context of words so that classifiers treat erroneous and correct words as similar inputs. We address the problem of contextual information by considering learner errors. Specifically, we propose two models: one model that employs grammatical error patterns and another model that considers grammaticality of the target word. We determine grammaticality of n-gram sequence from the annotated error tags and extract grammatical error patterns for word embeddings from large-scale learner corpora. Experimental results show that a bidirectional long-short term memory model initialized by our word embeddings achieved the state-of-the-art accuracy by a large margin in an English grammatical error detection task on the First Certificate in English dataset.

1 Introduction

Grammatical error detection that can identify the location of errors is useful for second language learners and teachers. It can be seen as a sequence labeling task, which is typically solved by a supervised approach. For example, Rei and Yannakoudakis (2016) achieved the state-of-the-art accuracy in English grammatical error detection using a bidirectional long-short term memory

Phrase pair	W2V	C&W	EWE	GWE	E&GWE
in summer & on summer	0.84	0.75	0.64	0.58	0.54
in summer & in spring	0.84	0.77	0.90	0.80	0.88

on summer & on spring	0.85	0.71	0.82	0.76	0.80

Table 1: Cosine similarity of phrase pairs for each word embedding method.

(Bi-LSTM) neural network. Their approach uses word embeddings learned from a large-scale native corpus to address the data sparseness problem of learner corpora.

However, most of the word embeddings, including the one used by Rei and Yannakoudakis (2016), model only the context of the words from a raw corpus written by native speakers, and do not consider specific grammatical errors of language learners. This leads to the problem wherein the word embeddings of correct and incorrect expressions tend to be similar (Table 1, columns W2V and C&W) so that the classifier must decide grammaticality of a word from contextual information with a similar input vector.

To address this problem, we introduce two methods: 1) error-specific word embeddings (EWE), which employ grammatical error patterns, that is to say the word pairs that learners tend to easily confuse; 2) grammaticality-specific word embeddings (GWE), which consider grammatical correctness of n-grams. In this paper, we use the term grammaticality to refer to the correct or incorrect label of the target word given its surrounding context. We also combine these methods, which we will refer to as error-and grammaticality-specific word embeddings (E&GWE).

Table 1 shows the cosine similarity of phrase

pairs using word2vec (W2V), C&W embeddings (Collobert and Weston, 2008), EWE, GWE, and E&GWE¹. It illustrates that EWE, GWE, and E&GWE are able to distinguish between correct and incorrect phrase pairs while maintaining the contextual relation.

Furthermore, we conducted experiments using the large-scale Lang-8² English learner corpus. The results demonstrated that representation learning is crucial for exploiting a noisy learner corpus for grammatical error detection.

The main contributions of this study are summarized as follows:

- We achieve the state-of-the-art accuracy in grammatical error detection on the First Certificate in English dataset (FCE-public) using a Bi-LSTM model initialized using our word embeddings that consider grammaticality and error patterns extracted from the FCE-public corpora.
- We demonstrate that updating word embeddings using error patterns extracted from the Lang-8 (Mizumoto et al., 2011) in addition to FCE-public corpora greatly improves grammatical error detection.
- The proposed word embeddings can distinguish between correct and incorrect phrase pairs.
- We have released our code and learned word embeddings³.

The rest of this paper is organized as follows: in Section 2, we first give a brief overview of English grammatical error detection; Section 3 describes our grammatical error detection model using error- and grammaticality-specific word embeddings; Section 4 evaluates this model on the FCE-public dataset, and Section 5 presents an analysis of the grammatical error detection model and learned word embeddings; and Section 6 concludes this paper.

2 Related Works

Many studies on grammatical error detection try to address specific types of grammatical errors (Tetreault and Chodorow, 2008; Han et al., 2006; Kochmar and Briscoe, 2014). In contrast, Rei and Yannakoudakis (2016) target all errors using a Bi-

¹The similarity of the phrase pairs was calculated based on the similarity of the mean vector of the word vectors.

²<http://lang-8.com/>

³<https://github.com/kanekomasa/grammatical-error-detection>

LSTM, whose embedding layer is initialized with word2vec. We also address unrestricted grammatical error detection; however, we focus on learning word embeddings that consider a learner’s error pattern and grammaticality of the target word. In this paper, subsequently, our word embeddings give statistically significant improvements over their method using exactly the same training data.

Several studies considering grammatical error patterns in language learning have been performed. For example, Sawai et al. (2013) suggest correction candidates for verbs using the learner error pattern, and Liu et al. (2010) automatically correct verb selection errors in English essays written by Chinese students learning English, based on the error patterns created from a synonym dictionary and an English-Chinese bilingual dictionary. The main difference between these previous studies and ours is that the previous studies focused only on verb selection errors.

As an example of research on learning word embeddings that consider grammaticality, Alikaniotis et al. (2016) proposed a model for constructing word embeddings by considering the importance of each word in predicting a quality score for an English learner’s essay. Their approach learns word embedding from a document-level score using the mean square error whereas we learn word embeddings from a word-level binary error information using the hinge loss.

The use of a large-scale learner corpus on grammatical error correction is described in works such as Xie et al. (2016) and Chollampatt et al. (2016a,b). These studies used the Lang-8 corpus as training data for phrase-based machine translation (Xie et al., 2016) and neural network joint models (Chollampatt et al., 2016a,b). In our study, Lang-8 was used to extract error patterns that were then utilized to learn word embeddings. Our experiments show that Lang-8 cannot be used as a reliable annotation for LSTM-based classifiers. Instead, we need to extract useful information as error patterns to improve the performance of error detection.

3 Grammatical Error Detection Using Error- and Grammaticality-Specific Word Embeddings

In this section, we describe the details of the proposed word embeddings: EWE, GWE, and E&GWE. These models extend an existing word

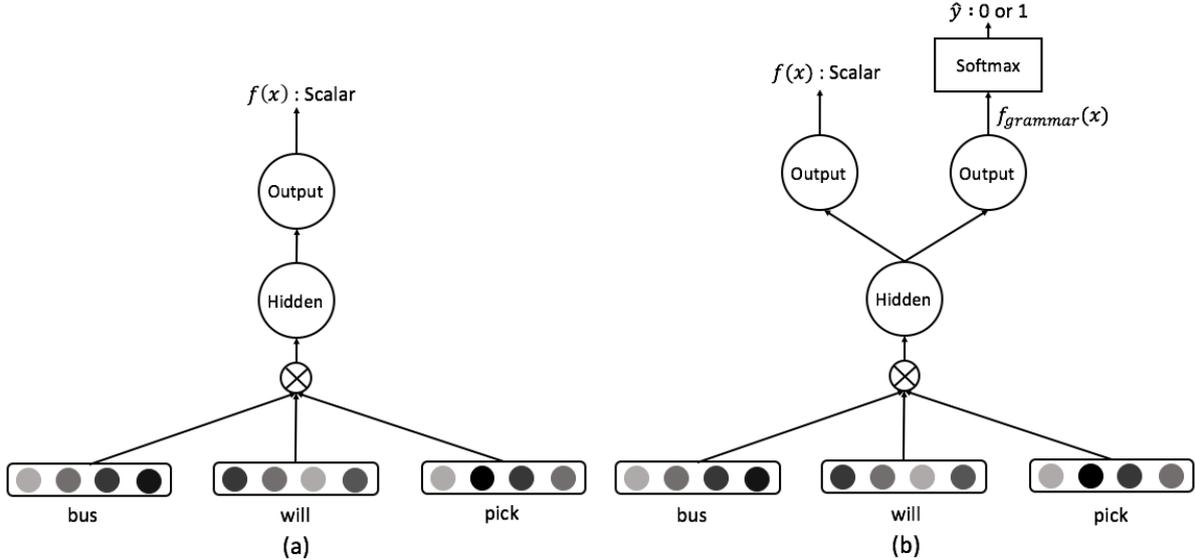

Figure 1: Architecture of our learning methods for word embeddings (a) EWE and (b) GWE. Both models concatenate the word vectors of a sequence for window size and feed them into the hidden layer. Then, EWE outputs a scalar value, and GWE outputs a prediction of the scalar value and the label of the word in the middle of the sequence.

embedding learning algorithm called C&W Embeddings (Collobert and Weston, 2008) and learn word embeddings that consider grammatical error patterns and grammaticality of the target word. We first describe the well-known C&W embeddings, and then explain our extensions. Finally, we introduce how we incorporate the learned word embeddings to the grammatical error detection task using a Bi-LSTM.

3.1 C&W Embeddings

Collobert and Weston (2008; 2011) proposed a window-based neural network model that learns distributed representations of target words based on the local context.

Here, target word w_t is the central word in the window sized sequence of words $S = (w_1, \dots, w_t, \dots, w_n)$. The representation of the target word w_t is compared with the representations of other words that appear in the same sequence ($\forall w_i \in S | w_i \neq w_t$). A negative sample $S' = (w_1, \dots, w_c, \dots, w_n | w_c \sim V)$ is created by replacing the target word w_t with a randomly selected word from the vocabulary V to distinguish between the negative sample S' and the original word sequence S . In their method, the word sequence S and the negative sample S' are converted into vectors in the embedding layer, which are fed as embeddings. They concatenate each converted

vector and treat it as input vector $x \in \mathbb{R}^{n \times D}$, where D is the dimension of the embedding layer. The input vector x is then subjected to a linear transformation (Eq. (1)) to calculate the vector i of the hidden layer. Then, the resulting vector is subjected to another linear transformation (Eq. (2)) to obtain the output $f(x)$.

$$i = \sigma(W_{hx}x + b_h) \quad (1)$$

$$f(x) = W_{oh}i + b_o \quad (2)$$

Here, W_{hx} is the weight matrix between the input vector and the hidden layer, W_{oh} is the weight matrix between the hidden layer and the output layer, b_o and b_h are biases, and σ is an element-wise non-linear function tanh.

This model for word representation learns distributed representations by making the ranking of the original word sequence S higher than that of the negative samples S' , which includes noise due to replaced words. The difference between the original word sequence and the word sequence including noise is optimized to be at least 1.

$$loss_c(S, S') = \max(0, 1 - f(x) + f(x')) \quad (3)$$

Here, x' is a transformed vector at the embedding layer obtained by converting the word w_c of the negative sample S' .

Our proposed models learn distributed representations using the same hinge loss (Eq. (3)) so

the model could distinguish between correct and incorrect phrase pairs.

3.2 Error-Specific Word Embeddings (EWE)

EWE learns word embeddings using the same model as C&W embeddings. However, rather than creating negative samples randomly, we created them by replacing the target word w_t with words w_c that learners tend to easily confuse with the target word w_t . In such a case, w_c is sampled by the conditional probability:

$$P(w_c|w_t) = \frac{|w_c, w_t|}{\sum_{w_{c'}} |w_{c'}, w_t|} \quad (4)$$

where, w_t is a target word, $w_{c'}$ is a set of w_c regarding w_t .

This model learns to distinguish between a correct and an incorrect word by considering error patterns. Replacement candidates, treated as error patterns, are extracted from a learner corpus annotated with correction. Figure 1a represents architecture of EWE.

*The bus will pick you up right at your hotel **entry**/***entrance**.*

The above sentence is a simple example from the test data of FCE-public corpus. In this sentence, the word “entry” is incorrect and the “entrance” is the correct word. In this case, w_t is “entrance” and w_c is “entry”. Note that we use only one-to-one (substitution) error patterns.

Due to the data sparseness problem, the context of infrequent words cannot be properly learned. This problem is solved by using a large corpus to pre-train word2vec. By fine-tuning vectors whose contexts have already been learned, it is possible to learn word embeddings with no or few replacement candidates in a learner corpus.

3.3 Grammaticality-Specific Word Embeddings (GWE)

Similar to the approach of Alikaniotis et al. (2016) for essay score prediction, we extend C&W embeddings to distinguish between correct words and incorrect words by including grammaticality in distributed representations (Figure 1b). For that purpose, we add an additional output layer to predict grammaticality of word sequences, and extend Equation (3) to calculate following two error func-

tions.

$$f_{grammar}(x) = W_{gh}i + b_g \quad (5)$$

$$\hat{y} = softmax(f_{grammar}(x)) \quad (6)$$

$$loss_p(S) = -\sum y \cdot \log(\hat{y}) \quad (7)$$

$$loss(S, S') = \alpha \cdot loss_c(S, S') + (1 - \alpha) \cdot loss_p(S) \quad (8)$$

In Equation (5), $f_{grammar}$ is the predicted label of the original word sequence S . W_{gh} is the weight matrix and b_g is the bias. In Equation (6), the prediction probability \hat{y} is computed using the softmax function for $f_{grammar}$. The error $loss_p$ is computed using the cross-entropy function using the gold label’s vector y of the target word (Eq. (7)). Finally, two errors are combined to calculate $loss$ (Eq. (8)). Here, α is a hyperparameter that determines the weight of the two error functions.

We use the original tag label (0/1) of the FCE-public data as the grammaticality of word sequences for learning. Note that we do not use label information from Lang-8, because the error annotation of Lang-8 error annotations are too noisy to train an error detection model directly from the corpus. Negative examples of GWE are created randomly, that are similar to the case with C&W.

3.4 Error- and Grammaticality-Specific Word Embeddings (E&GWE)

E&GWE is a model that combines EWE and GWE. In particular, E&GWE model creates negative examples using an error pattern as in EWE and outputs score and predicts grammaticality as in GWE.

3.5 Bidirectional LSTM (Bi-LSTM)

We use bidirectional LSTM (Bi-LSTM) (Graves and Schmidhuber, 2005) as a classifier for all our experiments for English grammatical error detection, because Bi-LSTM demonstrates the state-of-the-art accuracy for this task compared to other architectures such as CRF and CNNs (Rei and Yannakoudakis, 2016).

The LSTM calculation is expressed as follows:

$$i_t = \sigma(W_{ie}e_t + W_{ih}h_{t-1} + W_{ic}c_{t-1} + b_i) \quad (9)$$

$$f_t = \sigma(W_{fe}e_t + W_{fh}h_{t-1} + W_{fc}c_{t-1} + b_f) \quad (10)$$

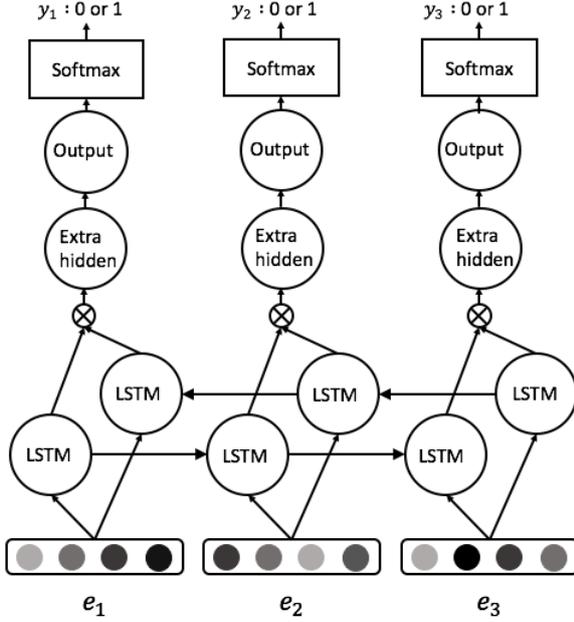

Figure 2: A bidirectional LSTM network. The word vectors e_i enter the hidden layer to predict the labels of each word.

$$c_t = i_t \odot g(W_{ce}e_t + W_{ch}h_{t-1} + b_c) + f_t \odot c_{t-1} \quad (11)$$

$$o_t = \sigma(W_{oe}e_t + W_{oh}h_{t-1} + W_{oc}c_t + b_o) \quad (12)$$

$$h_t = o_t \odot h(c_t) \quad (13)$$

Here, e_t is the word embedding of word w_t , and W_{ie} , W_{fe} , W_{ce} and W_{oe} are weight matrices. Each b_i , b_f , b_c and b_o are biases. An LSTM cell block has an input gate i_t , a memory cell c_t , a forget gate f_t and an output gate o_t to control information flow. In addition, g and h are the sigmoid function and σ is the tanh. \odot is the pointwise multiplication.

We apply a bidirectional extension of LSTM, as shown in Figure 2, to encode the word embedding e_i from both left-to-right and right-to-left directions.

$$y_t = W_{yh}(h_t^L \otimes h_t^R) + b_y \quad (14)$$

The Bi-LSTM model maps each word w_t to a pair of hidden vectors h_t^L and h_t^R , i.e., the hidden vector of the left-to-right LSTM and right-to-left LSTM, respectively. \otimes is the concatenation. W_{yh} is a weight matrix and b_y is a bias. We also added an extra hidden layer for linear transformation between each of the composition function and the output layer, as discussed in the previous study.

4 Experiments

4.1 Settings

We used the FCE-public dataset and the Lang-8 English learner corpus to train classifiers and word embeddings. For this evaluation, we used the test set from the FCE-public dataset (Yannakoudakis et al., 2011) for all experiments.

FCE-public dataset. First, we compared the proposed methods (EWE, GWE, and E&GWE) to previous methods (W2V and C&W) relative to training word embeddings (see Table 2a). For this purpose, we trained our word embeddings and a classifier, which were initialized using pre-trained word embeddings, with the training set from the FCE-public dataset.

This dataset is one of the most famous English learner corpus in grammatical error correction. It contains essays written by English learners. It is annotated with grammatical errors along with error classification. We followed the official split of the data: 30,953 sentences as a training set, 2,720 sentences as a test set, and 2,222 sentences as a development set. In the FCE-public dataset, the number of target words of error patterns is 4,184, the number of tokens of the replacement candidates is 9,834, and the number of types is 6,420. All manually labeled words in the FCE-public dataset were set as the gold target to train the GWE. For a missing word error, an error label is assigned to the word immediately after the missing word (see Table 4 (c)). To prevent overfitting, singleton words in the training data were taken as unknown words.

Lang-8 corpus. Furthermore, we added the large-scale Lang-8 English learner corpus to the FCE-public dataset to train word embeddings (FCE+EWE-L8 and FCE+E&GWE-L8) to explore the effect of a large data on the proposed methods. We used a classifier trained using only the FCE-public dataset whose word embeddings were initialized with the large-scale pre-trained word embeddings to compare the results with those of a classifier trained directly using a noisy large-scale data whose word embeddings were initialized using word2vec (FCE&L8+W2V, see Table 2b).

Lang-8 learner corpus has over 1 million manually annotated English sentences written by ESL learners. Extraction of error patterns from Lang-8 in the process of creating negative samples to train word embeddings was performed as follows:

1. Extract word pairs using the dynamic programming from a correct sentence and an incorrect sentence.
2. If the learner’s word of the extracted word pair is included in the vocabulary created from FCE-public, include it to the error patterns.

In the Lang-8 dataset the number of types of target words of the replacement candidates is 10,372, the number of tokens of the replacement candidates is 272,561, and the number of types is 61,950.

Our experiments on FCE+EWE-L8 and FCE+E&GWE-L8 were conducted by combining error patterns from all of Lang-8 corpus and the training part of FCE-public corpus to train word embeddings. However, since the number of error patterns of Lang-8 is larger than that of FCE-public, we normalized each frequency so that the ratio was 1:1.

We use $F_{0.5}$ as the main evaluation measure, following a previous study (Rei and Yannakoudakis, 2016). This measure was also adopted in the CoNLL-14 shared task on error correction task (Ng et al., 2014). It combines both precision and recall, while assigning twice as much weight to precision because accurate feedback is often more important than coverage in error detection applications (Nagata and Nakatani, 2010). Nagata and Nakatani (2010) presented a precision-oriented error detection system for articles and numbers that demonstrated precision of 0.72 and a recall of 0.25 and achieved a learning effect that is comparable to that of a human tutor.

4.2 Word Embeddings

We set parameters for word embeddings according to the previous study (Rei and Yannakoudakis, 2016). The dimension of the embedding layer of C&W, GWE, EWE and E&GWE is 300 and the dimension of the hidden layer is 200. We used a publicly released word2vec vectors (Chelba et al., 2013) trained on the News crawl from Google news⁴ as pre-trained word embeddings. We set other parameters in our model by running a preliminary experiment in which the window size is 3, the number of negative samples is 600, the linear interpolation α is 0.03, and the optimizer is the ADAM algorithm (Kingma and Ba, 2015)

⁴<https://github.com/mmihaltz/word2vec-GoogleNews-vectors>

with the initial learning rate of 0.001. GWE is initialized randomly and EWE is initialized using pre-trained word2vec.

4.3 Classifier

We use EWE, GWE, and E&GWE word embeddings to initialize the Bi-LSTM neural network, and predict the correctness of the target word in the input sentence. We update initialized weights of embedding layer while training classifiers, since it showed better results. The parameters and settings of the network are the same as in a previous study (Rei and Yannakoudakis, 2016). Specifically, in Bi-LSTM the dimensions of the embedding layer, the first hidden layer, and the second hidden layer are 300, 200, and 50, respectively. The Bi-LSTM model was optimized using the ADAM algorithm (Kingma and Ba, 2015) with an initial learning rate of 0.001, and a batch size of 64 sentences.

4.4 Results

Table 2a shows experimental results comparing Bi-LSTM models trained on FCE-public dataset initialized with two baselines (FCE+W2V and FCE+C&W) and the proposed word embeddings (FCE+EWE, FCE+GWE and FCE+E&GWE) in the error detection task. We used two models for FCE+W2V: FCE+W2V (R&Y 2016) is the experimental result reported in a previous study (Rei and Yannakoudakis, 2016), and FCE+W2V (our reimplementation of (R&Y, 2016)) is the experimental result of our reimplementation of Rei and Yannakoudakis (2016). FCE+E&GWE is a model combining FCE+EWE and FCE+GWE. We conducted Wilcoxon signed rank test ($p \leq 0.05$) 5 times.

Table 2b shows the result of using additional large-scale Lang-8 corpus. Compared to FCE&L8+W2V, FCE+EWE-L8 has better results within the three evaluation metrics. From this result, it can be seen that it is better to extract and use error patterns than simply using Lang-8 corpus as a training data to train a classifier, as it contains noise in the correct sentences. Furthermore, by combining with GWE method, accuracy was improved as in the above experiment.

In terms of precision, recall, and $F_{0.5}$, the methods in our study were ranked as FCE+E&GWE-L8 > FCE+EWE-L8 > FCE+E&GWE > FCE+GWE > FCE+EWE > FCE+W2V > FCE+C&W. Error patterns and grammaticality

Bi-LSTM + embeddings	P	R	$F_{0.5}$
FCE + W2V (R&Y, 2016)	46.1	28.5	41.1
FCE + W2V (our reimplementation of (R&Y, 2016))	45.8±0.1	27.8±0.4	40.5±0.3
FCE + C&W	45.1±0.3	26.7±0.4	39.6±0.3
FCE + EWE	46.1±0.1★	28.0±0.1★	40.8±0.1★
FCE + GWE	46.5±0.1★	28.3±0.4★	41.2±0.2★
FCE + E&GWE	46.7±0.1★	28.6±0.1★	41.4±0.1★

(a) LSTM and word embeddings are trained only using FCE-public.

Bi-LSTM + embeddings	P	R	$F_{0.5}$
FCE&L8 + W2V	12.3±2.6	32.8±2.2	14.0±2.6
FCE + EWE-L8	50.5±3.4★	30.1±1.2★	44.4±2.7★

(b) Either FCE-public and a large-scale Lang-8 corpus are used to train LSTM or word embeddings.

Table 2: Results of grammatical error detection by Bi-LSTM. Asterisks indicate that there is a significant difference for the confidence interval 0.95 for the P, R and $F_{0.5}$ against FCE + W2V (our reimplementation of (R&Y, 2016)).

	Error type	Verb	Missing-article	Noun	Noun type
(a)	FCE + W2V	56	48	26	9
	FCE + C&W	53	46	24	7
(b)	FCE + EWE	60	37	29	12
	FCE + GWE	62	43	29	11
	FCE + E&GWE	64	40	31	14
(c)	FCE + EWE-L8	66	36	37	19
	FCE + E&GWE-L8	67	40	39	18
	Total number of errors	131	112	77	32

Table 3: Numbers of correct instances for typical error types.

consistently improved the accuracy of grammatical error detection, showing that the proposed methods are effective. Also, our proposed method has a statistically significant difference compared with previous research even without using large-scale Lang-8 corpus. It outperformed the preceding state-of-the-art (Rei and Yannakoudakis, 2016) in all evaluation metrics.

5 Discussion

Table 3 shows the number of correct answers of each model for some typical errors. Error types are taken from the gold label of the FCE-public dataset.

First, we analyze verb errors and missing articles, which have the largest differences between the numbers of correct answers of baselines and the proposed methods (see Table 3 (a) and (b)). The proposed methods gave more correct answers for verb errors, whereas FCE+W2V and

FCE+C&W gave more correct answers for missing article errors. A possible explanation is that unigram-based error patterns are too powerful for word embeddings to learn other errors that can be learned from the contextual clues.

Second, we examine the difference made by adding the error patterns extracted from Lang-8 (see Table 3 (b) and (c)): FCE+EWE and FCE+EWE-L8 have the greatest difference in the number of correct answers in noun and noun type errors. FCE+EWE-L8 has more correct answers for noun errors such as *suggestion* and *advice* and noun type errors such as *time* and *times*. The reason is that Lang-8 includes a wide variety of lexical choice errors of nouns while FCE-public covers only a limited number of error variations.

Table 4 demonstrates the examples of error detection of the baseline FCE+W2V and the best proposed method FCE+E&GWE-L8 on the test data. Table 4(a) shows an example of a noun error,

	Bi-LSTM + embeddings	Detection result
(a)	Gold	The bus will pick you up right at your hotel <i>entrance</i> .
	FCE + W2V	The bus will pick you up right at your hotel entry.
	FCE + E&GWE-L8	The bus will pick you up right at your hotel entery .
(b)	Gold	There are shops which <i>sell clothes, food</i> , and books ...
	FCE + W2V	There are shops which sales cloths, foods, and books ...
	FCE + E&GWE-L8	There are shops which sales cloths, foods , and books ...
(c)	Gold	All the buses and <i>the MTR</i> have air-condition.
	FCE + W2V	All the buses and MTR have air-condition.
	FCE + E&GWE-L8	All the buses and MTR have air-condition.

Table 4: Examples of error detection by FCE+W2V and FCE+E&GWE-L8. Gold corrections in *italic*, and detected errors in **bold**.

and as it can be seen, FCE+E&GWE-L8 detected the error in contrast to FCE+W2V. Noun type errors are presented in Table 4(b). Here, FCE+W2V did not detect any error, while FCE+E&GWE-L8 could detect the mass noun error, frequently found in a learner corpus. Detection of “sale” and “cloths” was failed in both models, but they are hard to detect since the former requires syntactic information and the latter involves common knowledge. In Table 4(c), FCE+W2V succeeded in detection of a missing article error, but FCE+E&GWE-L8 did not. Even though proposed word embeddings learn substitution errors effectively, they cannot properly learn insertion and deletion errors. It is our future work to extend word embeddings to include these types of errors and focus on contextual errors that are difficult to deal with the model, for example, missing articles.

Figure 3 visualizes word embeddings (FCE+W2V and FCE+E&GWE-L8) of frequently occurring errors in learning data using t-SNE. We plot prepositions and some typical verbs⁵, where FCE+E&GWE-L8 showed better results compared to FCE+W2V. Proportional to the frequency of errors, the position of the word embeddings of FCE+E&GWE-L8 changes in comparison with that of FCE+W2V. For example, FCE+E&GWE-L8 learned the embeddings of high-frequency words such as *was* and *could* differently from FCE+W2V. On the other hand, low-frequency words such as *under* and *walk* were learned similarly. Also, almost all words shown in this figure move to the upper right. These visualization can be used to analyze errors made by learners.

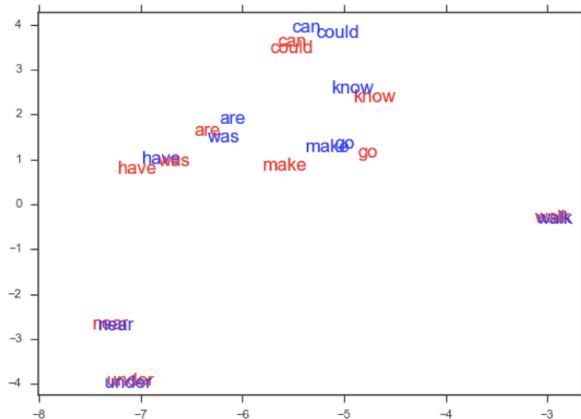

Figure 3: Visualization of word embeddings by FCE+W2V and FCE+E&GWE-L8. The red color represents the word of FCE+W2V and the blue represents FCE+E&GWE-L8.

6 Conclusion

In this study, we proposed word embeddings that can improve grammatical error detection accuracy by considering grammaticality and error patterns. We achieved the state-of-the-art accuracy on the FCE-public dataset using a Bi-LSTM model initialized with the proposed word embeddings. The word embeddings trained on a learner corpus can distinguish between correct and incorrect phrase pairs. In addition, we conducted experiments using a large-scale Lang-8 corpus. As a result, we showed that it is better to extract error patterns from such a corpus to train word embeddings than simply add Lang-8 corpus as a training data to train a classifier. We analyzed the detection results for some typical error types and showed the characteristics of learned word representations. We hope that the learned word embeddings are general enough to be of use to help NLP applications

⁵This dataset includes modal verbs as verb errors.

to language learning.

7 Acknowledgments

We thank Yangyang Xi of Lang-8, Inc. for kindly allowing us to use the Lang-8 learner corpus. We also thank the anonymous reviewers for their insightful comments. This work was partially supported by JSPS Grant-in-Aid for Young Scientists (B) Grant Number JP16K16117.

Abstract

This paper describes and compares two straightforward approaches for dependency parsing with partial annotations (PA). The first approach is based on a forest-based training objective for two CRF parsers, i.e., a biaffine neural network graph-based parser (Biaffine) and a traditional log-linear graph-based parser (LLGPar). The second approach is based on the idea of constrained decoding for three parsers, i.e., a traditional linear graph-based parser (LGPar), a globally normalized neural network transition-based parser (GN3Par) and a traditional linear transition-based parser (LTPar). For the test phase, constrained decoding is also used for completing partial trees. We conduct experiments on Penn Treebank under three different settings for simulating PA, i.e., random, most uncertain, and divergent outputs from the five parsers. The results show that LLGPar is most effective in directly learning from PA, and other parsers can achieve best performance when PAs are completed into full trees by LLGPar.

1 Introduction

Traditional supervised approaches for structural classification assume full annotation (FA), meaning that the training instances have complete manually-labeled structures. In the case of dependency parsing, FA means a complete parse tree is provided for each training sentence. However, recent studies suggest that it is more economic and effective to construct labeled data with partial annotation (PA). A lot of research effort has been attracted to obtain partially-labeled data for different

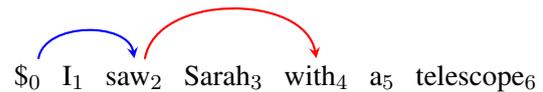

Figure 1: An example partial tree, where only the heads of “saw” and “with” are given.

tasks via active learning (Sassano and Kurohashi, 2010; Mirroshandel and Nasr, 2011; Li et al., 2012; Marcheggiani and Artières, 2014; Flannery and Mori, 2015; Li et al., 2016), cross-lingual syntax projection (Spreyer and Kuhn, 2009; Ganchev et al., 2009; Jiang et al., 2010; Li et al., 2014), or mining natural annotation implicitly encoded in web pages (Jiang et al., 2013; Liu et al., 2014; Nivre et al., 2014; Yang and Vozila, 2014). Figure 1) gives an example sentence partially annotated with two dependencies. However, there still lacks systematic study on how to build dependency parsers with PA. Most previous works listed above rely on ad-hoc strategies designed for only basic dependency parsers. One exception is that Li et al. (2014) convert partial trees into forests and train a traditional log-linear graph-based dependency parser (LLGPar) with PA based on a forest-based objective, showing promising results. Meanwhile, it is still unclear how PAs can be used by other main-stream dependency parsers, such as the traditional linear graph-based parser (LGPar) and transition-based parser (LTPar), and the newly proposed biaffine neural network graph-based parser (Biaffine) (Dozat and Manning, 2017) and globally normalized neural network transition-based parser (GN3Par) (Andor et al., 2016).

This paper aims to thoroughly study this issue and make systematic comparison on different approaches for dependency parsing with PA. In sum-

*Correspondence author

mary, we make the following contributions.

- We present a general framework for directly training GN3Par, LGPar and LTPar with PA based on *constrained decoding*. The basic idea is to use the current feature weights to parse the sentence under the PA-constrained search space, and use the best parse as a pseudo gold-standard reference for feature weight update during perceptron training.
- We also implement the forest-objective based approach of Li et al. (2014) for the two CRF parsers, i.e., LLGPar and Biaffine.
- We have made thorough comparison among different *directly-train* approaches under three different settings for simulating PA, i.e., random dependencies, most uncertain dependencies, and dependencies with divergent outputs from the five parsers. We have also compared the proposed directly-train approaches with the straightforward *complete-then-train* approach.
- Extensive experiments lead to several interesting and clear findings.

2 Dependency Parsing

Given an input sentence $\mathbf{x} = w_0w_1\dots w_n$, a dependency tree comprises a set of dependencies, namely $\mathbf{d} = \{i \curvearrowright j : 0 \leq i \leq n, 1 \leq j \leq n\}$, where $i \curvearrowright j$ is a dependency from a *head* word i to a *modifier* word j . A complete dependency tree contains n dependencies, namely $|\mathbf{d}| = n$, whereas a partial dependency tree contains less than n dependencies, namely $|\mathbf{d}| < n$. Alternatively, FA can be understood as a special form of PA. For clarity, we denote a complete tree as \mathbf{d} and a partial tree as \mathbf{d}^p .

The decoding procedure aims to find an optimal complete tree \mathbf{d}^* :

$$\mathbf{d}^* = \arg \max_{\mathbf{d} \in \mathcal{Y}(\mathbf{x})} \text{Score}(\mathbf{x}, \mathbf{d}; \mathbf{w}) \quad (1)$$

where $\mathcal{Y}(\mathbf{x})$ defines the search space containing all legal trees for \mathbf{x} and \mathbf{w} is the model parameters.

2.1 Graph-based Approach

The graph-based method factorizes the score of a dependency tree into those of small subtrees \mathbf{p} :

$$\text{Score}(\mathbf{x}, \mathbf{d}; \mathbf{w}) = \sum_{\mathbf{p} \subseteq \mathbf{d}} \text{Score}(\mathbf{x}, \mathbf{p}; \mathbf{w}) \quad (2)$$

Dynamic programming based *exact search* are usually applied to find the optimal tree (McDonald et al., 2005; McDonald and Pereira, 2006; Carreras, 2007; Koo and Collins, 2010).

Biaffine belongs to the first-order model and only incorporates scores of single dependencies. In contrast, for LLGPar and LGPar, we follow Li et al. (2014) and adopt the second-order model of McDonald and Pereira (2006) considering scores of single dependencies and adjacent siblings. Biaffine and LLGPar both belong to CRF parser. Please note that the original Biaffine is locally trained on each word. In this work, we follow Ma and Hovy (2017) and add a global CRF loss in the projective case, in order to directly use the proposed approach of Li et al. (2014). In other words, we extend the original Biaffine Parser described in Dozat and Manning (2017) by adding a CRF layer. Under the CRF model, the conditional probability of \mathbf{d} given \mathbf{x} is:

$$p(\mathbf{d}|\mathbf{x}; \mathbf{w}) = \frac{e^{\text{Score}(\mathbf{x}, \mathbf{d}; \mathbf{w})}}{\sum_{\mathbf{d}' \in \mathcal{Y}(\mathbf{x})} e^{\text{Score}(\mathbf{x}, \mathbf{d}'; \mathbf{w})}} \quad (3)$$

For training, \mathbf{w} is optimized using gradient descent to maximize the likelihood of the training data.

Biaffine uses a neural network to compute the score of each dependency. First, the input word and POS tag sequence are fully encoded with two BiLSTM layers. Then, two MLPs are applied to each word position i to obtain two word representations, i.e., \mathbf{r}_i^h (w_i as head) \mathbf{r}_i^m (w_i as modifier). Finally, a biaffine classifier predicts the score of an arbitrary dependency $i \curvearrowright j$.

$$\text{score}(i \curvearrowright j) = \mathbf{r}_i^h \cdot W \cdot \mathbf{r}_j^m + \mathbf{r}_i^h \cdot V \quad (4)$$

where W (matrix) and V (vector) are the biaffine parameters.

LLGPar is a traditional discrete feature based model, which defines the score of a tree as

$$\text{Score}(\mathbf{x}, \mathbf{d}; \mathbf{w}) = \mathbf{w} \cdot \mathbf{f}(\mathbf{x}, \mathbf{d}) \quad (5)$$

$\mathbf{f}(\mathbf{x}, \mathbf{d})$ is a sparse accumulated feature vector corresponding to \mathbf{d} .

LGPar uses perceptron-like online training to directly learn \mathbf{w} . The workflow is similar to Algorithm 1, except that the gold-standard reference \mathbf{d}^+ is directly provided in the training data without the need of constrained decoding in line 7.

Algorithm 1 Perceptron training based on constrained decoding.

```

2.2 Transition-based Approach

The transition-based method builds a dependency by applying sequence of shift/reduce actions \mathbf{a} , and factorizes the score of a tree into the sum of scores of each action in \mathbf{a} (Yamada and Matsumoto, 2003; Nivre, 2003; Zhang and Nivre, 2011):

$$\begin{aligned} \text{Score}(\mathbf{x}, \mathbf{d}; \mathbf{w}) &= \text{Score}(\mathbf{x}, \mathbf{a} \rightarrow \mathbf{d}; \mathbf{w}) \\ &= \sum_{i=1}^{|\mathbf{a}|} \text{Score}(\mathbf{x}, c_i, a_i; \mathbf{w}) \end{aligned} \quad (6)$$

where \mathbf{a}_i is the action taken at step i and c_i is the configuration status after taking action $a_1 \dots a_{i-1}$. Transition-based methods use inexact beam search to find a highest-scoring action sequence.

GN3Par uses a neural network to predict scores of different actions given a state (Chen and Manning, 2014; Andor et al., 2016). First, 48 atomic features are embedded and concatenated as the input layer. Then, two hidden layers are applied to get the scores of all feasible actions. Unlike the traditional perceptron-like training, which only considers the best action sequence in the beam and the gold-standard sequence, their idea of global normalization is to approximately compute the probabilities of all the sequences in the beam to obtain a global CRF-like loss.

LTPar is a traditional discrete feature based model like LLGPar and LGPar, and adopts global perceptron-like training to learn the feature weights \mathbf{w} . We build an arc-eager transition-based dependency parser and features described in Zhang and Nivre (2011).

3 Directly training parsers with PA

As described in Li et al. (2014), CRF parsers such as **LLGPar** and **Biaffine** can naturally learn

from PA based on the idea of ambiguous labeling, which allows a sentence to have multiple parse trees (forest) as its gold-standard reference (Riezler et al., 2002; Dredze et al., 2009; Täckström et al., 2013). First, a partial tree \mathbf{d}^p is converted into a forest by adding all possible dependencies pointing to remaining words without heads, with the constraint that a newly added dependency does not violate existing ones in \mathbf{d}^p . The forest can be formally defined as $\mathcal{F}(\mathbf{x}, \mathbf{d}^p) = \{\mathbf{d} : \mathbf{d} \in \mathcal{Y}(\mathbf{x}), \mathbf{d}^p \subseteq \mathbf{d}\}$, whose conditional probability is the sum of probabilities of all trees that it contains:

$$p(\mathbf{d}^p | \mathbf{x}; \mathbf{w}) = \sum_{\mathbf{d} \in \mathcal{F}(\mathbf{x}, \mathbf{d}^p)} p(\mathbf{d} | \mathbf{x}; \mathbf{w}) \quad (7)$$

Then, we can define a forest-based training objective function to maximize the likelihood of training data as described in Li et al. (2014).

LGPar can be extended to directly learn from PA based on the idea of constrained decoding, as shown in Algorithm 1, which has been previously applied to Chinese word segmentation with partially labeled sequences (Jiang et al., 2010). The idea is using the best tree \mathbf{d}^+ in the constrained search space $\mathcal{Y}(\mathbf{x}_j, \mathbf{d}_j^p)$ (line 7) as a pseudo gold-standard reference for weight update. In traditional perceptron training, \mathbf{d}^+ would be a complete parse tree provided in the training data. It is trivial to implement constrained decoding for graph-based parsers, and we only need to disable some illegal combination operations during dynamic programming.

LTPar can also directly learn from PA in a similar way, as shown in Algorithm 1. Constrained decoding is performed to find a pseudo gold-standard reference (line 8). It is more complicate to design constrained decoding for transition-based parsing

	train-1K	train-39K	dev	test
#Sentence	1,000	38,832	1,700	2,416
#Token	24,358	925,670	40,117	56,684

Table 1: Data Statistics. FA is always used for train-1K, whereas PA is simulated for train-39K.

than graph-based parsing. Fortunately, Nivre et al. (2014) propose a constrained decoding procedure for the arc-eager parsing system. We ignore the details due to the space limitation.

GN3Par learns from PA in a similar manner with LTPar. The difference is that for each sentence, all the sequences in beam are used as negative examples in Line 6, and a^+ obtained in Line 8 as gold-standard. Then, the global loss is computed in the same way with the case of FA.¹ Meanwhile, since GN3Par uses the arc-standard transition system, we also develop a constrained decoding procedure for the arc-standard system, which will be released as supporting documents.

4 Experiments

Data. We conduct experiments on Penn Treebank (PTB), and follow the standard data splitting (sec 2-21 as training, sec 22 as development, and sec 23 as test). Original bracketed structures are converted into dependency structures using Penn2Malt with default head-finding rules. We build a CRF-based bigram part-of-speech (POS) tagger to produce automatic POS tags for all train/dev/test data (10-way jackknifing on training data), with tagging accuracy 97.3% on test data. As suggested by an earlier anonymous reviewer, we further split the training data into two parts. We assume that the first 1K training sentences are provided as a small-scale data with FA, which can be obtained by a small amount of manual annotation or through cross-lingual projection methods. We simulate PA for the remaining 39K sentences. Table 1 shows the data statistics.

Parameter settings. We implement all five parsers from scratch using C++, which will be released publicly in the future. For those who are immediately interested, please contact us. We train LLGPar with stochastic gradient descent (Finkel et al., 2008). For LTPar and GN3Par,

¹ We have also tried to use all sequences in the beam in Line 8 as gold-standard, instead of the best a^+ , considering that there may be many gold-standard references in the case of PA. However, the accuracies become lower.

the beam size is 64 and the standard early update is adopted during training (Collins, 2002). For LGPar and LTPar, averaged perceptron is adopted (Collins, 2002).

For Biaffine, we directly adopt most hyperparameters of the released code of Dozat and Manning (2017), only removing the components related with dependency labels, since we focus on unlabeled dependency parsing in this work. The LSTM (two forward plus two backward) layers all use 300-dimension hidden cells. Dropout with ratio of 0.75 is applied to most layers before output. The two MLPs both have 100-dimension outputs without hidden layer. Adam optimization is adopted with $\alpha_1 = \alpha_2 = 0.9$.

For GN3Par, we follow Daniel et al. (2016), and use two 1024×1024 hidden layers, and adopt momentum (ratio of 0.9) Adam optimization.

For both Biaffine and GN3Par, we set the embedding dimension of both word/tag to 100, and use the GloVe pretrained word embedding for initialization², and randomly initialize embeddings of POS tags.

Since we have two sets of training data, we adopt the simple corpus-weighting strategy of Li et al. (2014). In each iteration, we merge train-1K and a subset of random 10K sentences from train-39K, shuffle them, and then use them for training. For all parsers, training terminates when the peak parsing accuracy on dev data does not improve in 30 consecutive iterations.

For **evaluation metrics**, we use the standard unlabeled attachment score (UAS) excluding punctuation marks.

4.1 Three settings for simulating PA on train-39K

In order to simulate PA for each sentence in train-39K, we only keep $\alpha\%$ gold-standard dependencies (not considering punctuation marks), and remove all other dependencies. We experiment with three simulation settings to fully investigate the capability of different approaches in learning from PA.

Random (30% or 15%):³ For each sentence in train-39K, we randomly select $\alpha\%$ words, and only keep dependencies linking to these words.

²<https://nlp.stanford.edu/projects/glove/>

³ We choose 15% since the parsers achieve about 85% UAS when trained on train-1K (see Table 4). Then 30% aim to find the effect of different levels of supervision.

	Biaffine	LLGPar	LGPar	GN3Par	LTPar	Berkeley	Turbo	Mate-tool	ZPar
on Dev	94.37	93.16	93.00	93.32	92.77	92.84	92.86	92.58	92.42
on Test	94.18	92.42	92.43	93.26	92.01	92.85	92.63	92.48	92.12

Table 2: UAS of different parsers trained on all training data (40K)

	FA(random)			PA(random)		PA(uncertain)		PA(divergence)
	100%	30%	15%	30%	15%	30%	15%	21.33%
Biaffine	94.37	93.06 (-1.31)	92.10 (-2.27)	92.84 (-1.53)	91.92 (-2.45)	93.63 (-0.74)	92.83 (-1.54)	93.58 (-0.79)
LLGPar	93.16	91.93 (-1.23)	91.15 (-2.01)	92.39 (-0.77)	91.66 (-1.50)	93.02 (-0.14)	92.44 (-0.72)	92.83 (-0.33)
LGPar	93.00	91.76 (-1.24)	90.80 (-2.20)	91.63 (-1.37)	90.62 (-2.38)	92.46 (-0.54)	91.64 (-1.36)	92.42 (-0.58)
GN3Par	93.32	91.99 (-1.33)	91.17 (-2.15)	91.43 (-1.89)	90.34 (-2.98)	92.40 (-0.92)	91.80 (-1.52)	92.60 (-0.72)
LTPar	92.77	91.22 (-1.55)	90.35 (-2.42)	91.12 (-1.65)	90.12 (-2.65)	91.35 (-1.42)	90.99 (-1.78)	91.04 (-1.73)

Table 3: UAS on dev data: parsers are directly trained on train-1K with FA and train-39K with PA. “FA (random) $\alpha\%$ ” means randomly selecting $\alpha\%$ sentences with FA from train-39K for training. Numbers in parenthesis are the accuracy gap from the second column “FA (100%)”.

With this setting, we aim to purely study the issue without biasing to certain structures. This setting may be best fit the scenario automatic syntax projection based on bitext, where the projected dependencies tend to be arbitrary (and noisy) due to the errors in automatic source-language parses and word alignments and non-isomorphism syntax between languages.

Uncertain (30% or 15%): In their work of active learning with PA, Li et al. (2016) show that the marginal probabilities from LLGPar is the most effective uncertainty measurement for selecting the most informative words to be annotated. Following their work, we first train LLGPar on train-1K with FA, and then use LLGPar to parse train-39K and select $\alpha\%$ most uncertain words. We use the gold-standard heads of the selected words as PAs for model training.

Following Li et al. (2016), we measure the uncertainty of a word w_i according to the *marginal probability gap* between its two most likely heads h_i^0 and h_i^1 .

$$Uncertainty(\mathbf{x}, i) = p(h_i^0 \curvearrowright i | \mathbf{x}) - p(h_i^1 \curvearrowright i | \mathbf{x}) \quad (8)$$

This setting fits the scenario of active learning, which aims to save annotation effort by only annotating the most useful structures.

Divergence (21.33%): We train all five parsers on train-1K, and use them to parse train-39K. If their output trees do not assign the same head to a word, then we keep the gold-standard dependency pointing to the word, leading to 21.33% remaining dependencies. This setting fits to the tri-training

scenario investigated in Li et al. (2014).

4.2 Results of different parsers trained on FA

We train the five parsers on all the training data with FA. We also employ four publicly available parsers with their default settings. BerkeleyParser (v1.7) is a constituent-structure parser, whose results are converted into dependency structures (Petrov and Klein, 2007). TurboParser (v2.1.0) is a linear graph-based dependency parser using linear programming for inference (Martins et al., 2013). Mate-tool (v3.3) is a linear graph-based dependency parser very similar to our implemented LGPar (Bohnet, 2010). ZPar (v0.6) is a linear transition-based dependency parser very similar to our implemented LTPar (Zhang and Clark, 2011). The results are shown in Table 2.

We can see that the five parsers that we adopt achieve competitive parsing accuracy and serve as strong baselines. Especially, the recently proposed neural network Biaffine outperforms other parser by more than 1%.

4.3 Results of the directly-train approaches

The five parsers are directly trained on train-1K with FA and train-39K with PA based on the methods described in Section 3. Table 3 shows the results.

Comparing the five parsers, we have several clear findings. (1) LLGPar is the most effective in directly learning from PA since its accuracy drop is the smallest over all PA settings compared with FA (100%). (2) Although Biaffine achieves best

Parser for completion	No constraints	PA (random)		PA (uncertain)		PA (divergence)
	0%	30%	15%	30%	15%	21.33%
Biaffine-1K	87.08	92.10 (+5.02)	89.79 (+2.71)	96.78 (+9.70)	93.47 (+6.39)	96.76 (+9.68)
LLGPar-1K	86.67	92.65 (+5.98)	90.02 (+3.35)	97.43 (+10.76)	94.43 (+7.76)	97.07 (+10.40)
LGPar-1K	86.05	92.16 (+6.11)	89.48 (+3.43)	97.30 (+11.25)	94.11 (+8.06)	96.99 (+10.94)
GN3Par-1K	85.86	92.34 (+6.48)	89.54 (+3.68)	97.02 (+11.16)	93.69 (+7.83)	96.56 (+10.70)
LTPar-1K	85.38	91.76 (+6.38)	88.89 (+3.51)	96.90 (+11.52)	93.35 (+7.97)	96.72 (+11.34)
LLGPar-1K+39K	–	95.55	93.37	98.30	96.22	97.69
Biaffine-1K+39K	–	95.77	93.52	98.27	96.17	97.73

Table 4: UAS of full trees in train-39K completed via constrained decoding.

accuracy over all settings, thanks to its strong performance under the basic FA setting, we find that the accuracy gap between LLGPar and Biaffine becomes much smaller with PA than with FA. This also indicates that LLGPar is more effective in directly learning from PA. (3) LTPar achieves the lowest accuracy over all settings, especially on PA under uncertain (30%, 15%) and divergence. It is also clear that the accuracy declines the largest on these three settings, compared with FA (100%).

FA (random) vs. PA (random):⁴ from the results in the two major columns, we can see that LLGPar achieves higher accuracy by about 0.5% when trained on sentences with $\alpha\%$ random dependencies than when trained on $\alpha\%$ random sentences with FA. This is reasonable and can be explained under the assumption that LLGPar can make full use of PA in model training. In fact, in both cases, the training data contains approximately the same number of annotated dependencies. However, from the perspective of model training, given some dependencies in the case of PA, more information about the syntactic structure can be derived.⁵

Taking Figure 1 as an example, “I₁” can only modify “saw₂” due to the single-root and single-head constraints; similarly, “Sarah₃” can only modify either “saw₂” or “with₂”; and so on. More-

⁴ These two settings should give the clearest evidence whether a parser can effectively learn from PAs. Under the same $\alpha\%$, although containing approximately the same number of dependencies, PA certainly provide more syntactic information than FA, since 1) it is more expensive to annotate PA than FA in the terms of annotation time per dependency; 2) in PA, partially annotated dependencies can provide strong constraints on the remaining undecided dependencies. Therefore, we assume that a parser is effectively in learning from PA if it can achieve at least higher accuracy under PA.

⁵Also, as suggested in the work of Li et al. (2016), annotating PA is more time-consuming than annotating FA in terms of averaged time for each dependency, since dependencies in the same sentence are correlated and earlier annotated dependencies usually make later annotation easier.

over, since LLGPar is a second-order model, the presence of certain dependencies can directly affect the choice of other dependencies through the scores of adjacent siblings. Therefore, given the same amount of annotated dependencies, random PA contains more syntactic information than random FA, which explains why LLGPar performs better with PA than FA.

In contrast, all other four parsers achieve lower accuracy with PA than with FA. Biaffine differs from LLGPar in being a first-order model, and thus cannot fully utilize PA by considering sibling scores. The problem of LGPar may lie in the perceptron training with constrained decoding, which only considers a single best tree that complies with the given PA as gold-standard (Line 7 in Algorithm 1), unlike the forest-based objective of LLGPar that consider all trees weighted with probabilities. Both GN3Par and LTPar suffer from the inexact search problem. In other words, the approximate beam search can cause the correct tree drops off the beam too soon due to lower scores for earlier actions, and thus return a bad \mathbf{a}^+ that causes the model be updated to bias to wrong structures (Line 8 in Algorithm 1).

PA (random) vs. PA (uncertain):⁶ we can see that all five parsers achieve much higher accuracy in the latter case.⁷ The annotated dependencies in PA (uncertain) are most uncertain ones for current statistical parser (i.e., LLGPar), and thus are more helpful for training the models than those in PA (random). Another phenomenon is that, in the case of PA (uncertain), increasing $\alpha\% = 15\%$ to

⁶From the idea of active learning, we know that annotating the most informative dependencies as more training data can help models best. So, we select the most uncertain dependencies and compare the result on the setting with randomly-selected dependencies.

⁷The only exception is LTPar with 30% PA, the accuracy increases by only $91.35 - 91.12 = 0.23\%$, which may be caused by the ineffectiveness of LTPar in learning from PA.

30% actually doubles the number of annotated dependencies, but only boost accuracy of LLGPar by $93.02 - 92.44 = 0.58\%$, which indicates that newly added 15% dependencies are much less useful since the model can already well handle these low-uncertainty dependencies.

PA (uncertain, 30%) vs. PA (divergence):⁸ we can see that the all five parsers achieve similar parsing accuracies under the two settings. This indicates that the divergence strategy can find very useful dependencies for all parsers, whereas uncertainty measurement based on LLGPar might be biased towards itself to a certain extent.

In summary, we can conclude from the results that *LLGPar is the most effective in directly learning from PA among all five parsers, due to both the second-order modeling and the forest-based training objective.*

4.4 Results of the complete-then-train methods

The most straight-forward method for learning from PA is the complete-then-learn method (Mirroshandel and Nasr, 2011). The idea is first using an existing parser to complete partial trees in train-39K into full trees based on constrained decoding, and then training the target parser on train-1K with FA and train-39K with completed FA.

Results of completing via constrained decoding: Table 4 reports UAS of the completed trees on train-39K using two different strategies for completion. “No constraints (0%)” means that train-39K has no annotated dependencies and normal decoding without constraints is used. In the remaining columns, each parser performs constrained decoding on PA where $\alpha\%$ dependencies are provided in each sentence.

- **Coarsely-trained-self for completion:** We complete PA into FA using corresponding parsers coarsely trained on only train-1K with FA. We call these parsers *Biaffine-1K*, *LLGPar-1K*, *LGPar-1K*, *GN3Par-1K*, *LTPar-1K* respectively.
- **Fine-trained-LLGPar for completion:** We complete PA into FA using LLGPar fine trained on both train-1K with FA and train-39K with PA. We call this LLGPar

⁸Selecting uncertain dependencies according to LLGPar may cause the resulting data to be biased to LLGPar. Therefore, we consider the divergence among all parsers for selection.

as *LLGPar-1K+39K*. Please note that *LLGPar-1K+39K* actually performs *closed test* in this setting, meaning that it parses its training data. For example, *LLGPar-1K+39K* trained on random (30%) is employed to complete the same data by filling the remaining 70% dependencies.

- **Fine-trained-Biaffine for completion:** This is the same with the case of “Fine-trained-LLGPar”, except that we replace LLGParser with Biaffine. We call the resulting parser as *Biaffine-1K+39K*.

Comparing the five parsers trained on train-1K, we can see that constrained decoding has similar effects on all five parsers, and is able to return much more accurate trees. Numbers in parenthesis show the accuracy gap between unconstrained 0% and constrained decoding. This suggests that constrained decoding itself is not responsible for the ineffectiveness of Algorithm 1 for other parsers, especially LTPar.

Comparing the results of LLGPar-1K and LLGPar-1K+39K, it is obvious that the latter produces much better full trees since the fine-trained LLGPar can make extra use of PA in train-39K during training.

LLGPar-1K+39K and Biaffine-1K+39K achieve similar accuracies. We choose to use the former for completion since LLGPar is the most effective in both learning from PA and completing PA, as indicated by the results in Table 3 and 4.

Results of training on completed FA: Table 5 compares performance of the five parsers trained on train-1K with FA and train-39K with completed FA, from which we can draw several clear and interesting findings. First, different from the case of directly training on PA, the accuracy gaps among the five parsers become much more stable when trained on data with completed FA in both completion settings. Second, *using parsers coarsely-trained on train-1K for completion leads to very bad performance*, which is even much worse than those of the directly-train method in Table 3 except for LTPar with uncertain (30%) and divergence. Third, *using the fine-trained LLGPar-1K+39K for completion makes LGPar and LTPar achieve nearly the same accuracies with LLGPar*, which may be because LLGPar provides complementary effects during completion, analogous to the scenario of co-training.

	Completed by self-1K					Completed by LLGPar-1K+39K				
	PA (random)		PA (uncertain)		PA (divergence)	PA (random)		PA (uncertain)		PA (divergence)

Table 6: UAS on test data: comparison of the directly-train and complete-then-train methods.

4.5 Results on test data: directly-train vs. complete-then-train

Table 6 reports UAS on the test data of parsers directly trained on train-1K with FA and train-39K with PA, and of those trained on train-1K with FA and train-39K with FA completed by fine-trained LLGPar-1K+39K. The results are consistent with the those on dev data in Table 3 and 5. Comparing the two settings, we can draw two interesting findings. First, LLGPar performs slightly better with the directly-train method. Second, the two settings lead to very similar performance on Biaffine, without a clear trend. Third, LGPar performs slightly better with the complete-then-train method in most cases except for uncertain (30%). Four, GN3Par and LTPar perform much better with the complete-then-train method.

5 Related work

In parsing community, most previous works adopt ad-hoc methods to learn from PA. Sassano and Kurohashi (2010), Jiang et al. (2010), and Flanery and Mori (2015) convert partially annotated instances into local dependency/non-dependency classification instances, which may suffer from the lack of non-local correlation between dependencies in a tree.

Mirroshandel and Nasr (2011) and Majidi and Crane (2013) adopt the complete-then-learn method. They use parsers coarsely trained on ex-

isting data with FA for completion via constrained decoding. However, our experiments show that this leads to dramatic decrease in parsing accuracy.

Nivre et al. (2014) present a constrained decoding procedure for arc-eager transition-based parsers. However, their work focuses on allowing their parser to effectively exploit external constraints during the evaluation phase. In this work, we directly employ their method and show that constrained decoding is effective for LTPar and thus irresponsible for its ineffectiveness in learning PA.

Directly learning from PA based on constrained decoding is previously proposed by Jiang et al. (2013) for Chinese word segmentation, which is treated as a character-level sequence labeling problem. In this work, we first apply the idea to LGPar and LTPar for directly learning from PA.

Directly learning from PA based on a forest-based objective in LLGPar is first proposed by Li et al. (2014), inspired by the idea of *ambiguous labeling*. Similar ideas have been extensively explored recently in sequence labeling tasks (Liu et al., 2014; Yang and Vozila, 2014; Marcheggiani and Artières, 2014).

Hwa (1999) pioneers the idea of exploring PA for constituent grammar induction based on a variant Inside-Outside re-estimation algorithm (Pereira and Schabes, 1992). Clark and Curran (2006) propose to train a Combinatorial Categorical Grammar parser using partially labeled data

only containing predicate-argument dependencies. Mielens et al. (2015) propose to impute missing dependencies based on Gibbs sampling in order to enable traditional parsers to learn from partial trees.

6 Conclusions

This paper investigates the problem of dependency parsing with partially labeled data. Particularly, we focus on the realistic scenario where we have a small-scale training dataset with FA and a large-scale training dataset with PA. We experiment with three settings for simulating PA and compare several directly-train and complete-then-train approaches with five mainstream parsers, i.e., Bi-affine, LLGPar, LGPar, GN3Par and LTPar.

Based on this work, we may draw the following conclusions.

- For the complete-then-train approach, using parsers coarsely trained on small-scale data with FA for completion leads to unsatisfactory results.
- LLGPar is the most effective in directly learning from PA due to both its second-order modeling and probabilistic forest-based training objective.
- All other four parsers are less effective in directly learning from PA, but can achieve their best performance with the complete-then-train approach where PAs are completed into FAs by LLGPar fine-trained on all FA+PA data.

However, as our reviewers kindly point out, more extensive experiments and systematic analysis are needed to really understand this interesting issue and provide stronger findings, which we leave for future work.

Acknowledgments

The authors would like to thank the anonymous reviewers for the helpful comments. We are greatly grateful to Jiayuan Chao for her earlier-stage experiments on this work, and to Wenliang Chen for the helpful discussions. Abstract

In this paper, we propose a probabilistic parsing model that defines a proper conditional probability distribution over non-projective dependency trees for a given sentence, using neural representations as inputs. The neural network architecture is based on bi-directional LSTM-CNNs, which automatically benefits from both word- and character-level representations, by using a combination of bi-directional LSTMs and CNNs. On top of the neural network, we introduce a probabilistic structured layer, defining a conditional log-linear model over non-projective trees. By exploiting Kirchhoff's Matrix-Tree Theorem (Tutte, 1984), the partition functions and marginals can be computed efficiently, leading to a straightforward end-to-end model training procedure via back-propagation. We evaluate our model on 17 different datasets, across 14 different languages. Our parser achieves state-of-the-art parsing performance on nine datasets.

1 Introduction

Dependency parsing is one of the first stages in deep language understanding and has gained interest in the natural language processing (NLP) community, due to its usefulness in a wide range of applications. Many NLP systems, such as machine translation (Xie et al., 2011), entity coreference resolution (Ng, 2010; Durrett and Klein, 2013; Ma et al., 2016), low-resource languages processing (McDonald et al., 2013; Ma and Xia, 2014), and word sense disambiguation (Fauceglia et al., 2015), are becoming more sophisticated, in part because of utilizing syntactic knowledge such

as dependency parsing trees.

Dependency trees represent syntactic relationships through labeled directed edges between heads and their dependents (modifiers). In the past few years, several dependency parsing algorithms (Nivre and Scholz, 2004; McDonald et al., 2005b; Koo and Collins, 2010; Ma and Zhao, 2012a,b) have been proposed, whose high performance heavily rely on hand-crafted features and task-specific resources that are costly to develop, making dependency parsing models difficult to adapt to new languages or new domains.

Recently, non-linear neural networks, such as recurrent neural networks (RNNs) with long-short term memory (LSTM) and convolution neural networks (CNNs), with as input distributed word representations, also known as word embeddings, have been broadly applied, with great success, to NLP problems like part-of-speech (POS) tagging (Collobert et al., 2011) and named entity recognition (NER) (Chiu and Nichols, 2016). By utilizing distributed representations as inputs, these systems are capable of learning hidden information representations directly from data instead of manually designing hand-crafted features, yielding end-to-end models (Ma and Hovy, 2016). Previous studies explored the applicability of neural representations to traditional graph-based parsing models. Some work (Kiperwasser and Goldberg, 2016; Wang and Chang, 2016) replaced the linear scoring function of each arc in traditional models with neural networks and used a margin-based objective (McDonald et al., 2005a) for model training. Other work (Zhang et al., 2016; Dozat and Manning, 2016) formalized dependency parsing as independently selecting the head of each word with cross-entropy objective, without the guarantee of a general non-projective tree structure output. Moreover, there have yet been no previous work on deriving a neural prob-

abilistic parsing model to define a proper conditional distribution over non-projective trees for a given sentence.

In this paper, we propose a probabilistic neural network-based model for non-projective dependency parsing. This parsing model uses bi-directional LSTM-CNNs (BLSTM-CNNs) as backbone to learn neural information representations, on top of which a probabilistic structured layer is constructed with a conditional log-linear model, defining a conditional distribution over all non-projective dependency trees. The architecture of BLSTM-CNNs is similar to the one used for sequence labeling tasks (Ma and Hovy, 2016), where CNNs encode character-level information of a word into its character-level representation and BLSTM models context information of each word. Due to the probabilistic structured output layer, we can use negative log-likelihood as the training objective, where the partition function and marginals can be computed via Kirchhoff’s Matrix-Tree Theorem (Tutte, 1984) to process the optimization efficiently by back-propagation. At test time, parsing trees can be decoded with the maximum spanning tree (MST) algorithm (McDonald et al., 2005b). We evaluate our model on 17 treebanks across 14 different languages, achieving state-of-the-art performance on 9 treebanks. The contributions of this work are summarized as: (i) proposing a neural probabilistic model for non-projective dependency parsing. (ii) giving empirical evaluations of this model on benchmark data sets over 14 languages. (iii) achieving state-of-the-art performance with this parser on nine different treebanks.

2 Neural Probabilistic Parsing Model

In this section, we describe the components (layers) of our neural parsing model. We introduce the neural layers in our neural network one-by-one from top to bottom.

2.1 Edge-Factored Parsing Layer

In this paper, we will use the following notation: $\mathbf{x} = \{x_1, \dots, x_n\}$ represents a generic input sentence, where x_i is the i th word. \mathbf{y} represents a generic (possibly non-projective) dependency tree, which represents syntactic relationships through labeled directed edges between heads and their dependents. For example, Figure 1 shows a dependency tree for the sentence, “Economic news had

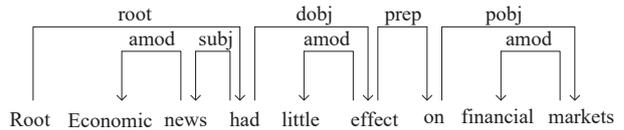

Figure 1: An example labeled dependency tree.

little effect on financial markets”, with the sentence’s root-symbol as its root. $T(\mathbf{x})$ is used to denote the set of possible dependency trees for sentence \mathbf{x} .

The probabilistic model for dependency parsing defines a family of conditional probability $p(\mathbf{y}|\mathbf{x}; \Theta)$ over all \mathbf{y} given sentence \mathbf{x} , with a log-linear form:

$$P(\mathbf{y}|\mathbf{x}; \Theta) = \frac{\exp\left(\sum_{(x_h, x_m) \in \mathbf{y}} \phi(x_h, x_m; \Theta)\right)}{Z(\mathbf{x}; \Theta)}$$

where Θ is the parameter of this model, $s_{hm} = \phi(x_h, x_m; \Theta)$ is the score function of edge from x_h to x_m , and

$$Z(\mathbf{x}; \Theta) = \sum_{\mathbf{y} \in T(\mathbf{x})} \exp\left(\sum_{(x_h, x_m) \in \mathbf{y}} s_{hm}\right)$$

is the partition function.

Bi-Linear Score Function. In our model, we adopt a bi-linear form score function:

$$\phi(x_h, x_m; \Theta) = \varphi(x_h)^T \mathbf{W} \varphi(x_m) + \mathbf{U}^T \varphi(x_h) + \mathbf{V}^T \varphi(x_m) + \mathbf{b}$$

where $\Theta = \{\mathbf{W}, \mathbf{U}, \mathbf{V}, \mathbf{b}\}$, $\varphi(x_i)$ is the representation vector of x_i , $\mathbf{W}, \mathbf{U}, \mathbf{V}$ denote the weight matrix of the bi-linear term and the two weight vectors of the linear terms in ϕ , and \mathbf{b} denotes the bias vector.

As discussed in Dozat and Manning (2016), the bi-linear form of score function is related to the bi-linear attention mechanism (Luong et al., 2015). The bi-linear score function differs from the traditional score function proposed in Kiperwasser and Goldberg (2016) by adding the bi-linear term. A similar score function is proposed in Dozat and Manning (2016). The difference between their and our score function is that they only used the linear term for head words ($\mathbf{U}^T \varphi(x_h)$) while use them for both heads and modifiers.

Matrix-Tree Theorem. In order to train the probabilistic parsing model, as discussed in [Koo et al. \(2007\)](#), we have to compute the *partition function* and the *marginals*, requiring summation over the set $T(\mathbf{x})$:

$$\begin{aligned} Z(\mathbf{x}; \Theta) &= \sum_{\mathbf{y} \in T(\mathbf{x})} \prod_{(x_h, x_m) \in \mathbf{y}} \psi(x_h, x_m; \Theta) \\ \mu_{h,m}(\mathbf{x}; \Theta) &= \sum_{\mathbf{y} \in T(\mathbf{x}): (x_h, x_m) \in \mathbf{y}} P(\mathbf{y} | \mathbf{x}; \Theta) \end{aligned}$$

where $\psi(x_h, x_m; \Theta)$ is the potential function:

$$\psi(x_h, x_m; \Theta) = \exp(\phi(x_h, x_m; \Theta))$$

and $\mu_{h,m}(\mathbf{x}; \Theta)$ is the marginal for edge from h th word to m th word for \mathbf{x} .

Previous studies ([Koo et al., 2007](#); [Smith and Smith, 2007](#)) have presented how a variant of Kirchhoff’s Matrix-Tree Theorem ([Tutte, 1984](#)) can be used to evaluate the partition function and marginals efficiently. In this section, we briefly revisit this method.

For a sentence \mathbf{x} with n words, we denote $\mathbf{x} = \{x_0, x_1, \dots, x_n\}$, where x_0 is the root-symbol. We define a complete graph G on $n + 1$ nodes (including the root-symbol x_0), where each node corresponds to a word in \mathbf{x} and each edge corresponds to a dependency arc between two words. Then, we assign non-negative weights to the edges of this complete graph with $n + 1$ nodes, yielding the weighted adjacency matrix $\mathbf{A}(\Theta) \in \mathbb{R}^{n+1 \times n+1}$, for $h, m = 0, \dots, n$:

$$\mathbf{A}_{h,m}(\Theta) = \psi(x_h, x_m; \Theta)$$

Based on the adjacency matrix $\mathbf{A}(\Theta)$, we have the Laplacian matrix:

$$\mathbf{L}(\Theta) = \mathbf{D}(\Theta) - \mathbf{A}(\Theta)$$

where $\mathbf{D}(\Theta)$ is the weighted degree matrix:

$$\mathbf{D}_{h,m}(\Theta) = \begin{cases} \sum_{h'=0}^n \mathbf{A}_{h',m}(\Theta) & \text{if } h = m \\ 0 & \text{otherwise} \end{cases}$$

Then, according to Theorem 1 in [Koo et al. \(2007\)](#), the partition function is equal to the minor of $\mathbf{L}(\Theta)$ w.r.t row 0 and column 0:

$$Z(\mathbf{x}; \Theta) = \mathbf{L}^{(0,0)}(\Theta)$$

where for a matrix \mathbf{A} , $\mathbf{A}^{(h,m)}$ denotes the *minor* of \mathbf{A} w.r.t row h and column m ; i.e., the determinant

of the submatrix formed by deleting the h th row and m th column.

The marginals can be computed by calculating the matrix inversion of the matrix corresponding to $\mathbf{L}^{(0,0)}(\Theta)$. The time complexity of computing the partition function and marginals is $O(n^3)$.

Labeled Parsing Model. Though it is originally designed for unlabeled parsing, our probabilistic parsing model is easily extended to include dependency labels.

In labeled dependency trees, each edge is represented by a tuple (x_h, x_m, l) , where x_h and x_m are the head word and modifier, respectively, and l is the label of dependency type of this edge. Then we can extend the original model for labeled dependency parsing by extending the score function to include dependency labels:

$$\begin{aligned} \phi(x_h, x_m, l; \Theta) &= \varphi(x_h)^T \mathbf{W}_l \varphi(x_m) \\ &\quad + \mathbf{U}_l^T \varphi(x_h) + \mathbf{V}_l^T \varphi(x_m) \\ &\quad + \mathbf{b}_l \end{aligned}$$

where $\mathbf{W}_l, \mathbf{U}_l, \mathbf{V}_l, \mathbf{b}_l$ are the weights and bias corresponding to dependency label l . Suppose that there are L different dependency labels, it suffices to define the new adjacency matrix by assigning the weight of a edge with the sum of weights over different dependency labels:

$$\mathbf{A}'_{h,m}(\Theta) = \sum_{l=1}^L \psi(x_h, x_m, l; \Theta)$$

The partition function and marginals over labeled dependency trees are obtained by operating on the new adjacency matrix $\mathbf{A}'(\Theta)$. The time complexity becomes $O(n^3 + Ln^2)$. In practice, L is probably large. For English, the number of edge labels in Stanford Basic Dependencies ([De Marneffe et al., 2006](#)) is 45, and the number in the treebank of CoNLL-2008 shared task ([Surdeanu et al., 2008](#)) is 70. While, the average length of sentences in English Penn Treebank ([Marcus et al., 1993](#)) is around 23. Thus, L is not negligible comparing to n .

It should be noticed that in our labeled model, for different dependency label l we use the same vector representation $\varphi(x_i)$ for each word x_i . The dependency labels are distinguished (only) by the parameters (weights and bias) corresponding to each of them. One advantage of this is that it significantly reduces the memory requirement comparing to the model in [Dozat and Manning \(2016\)](#) which distinguishes $\varphi_l(x_i)$ for different label l .

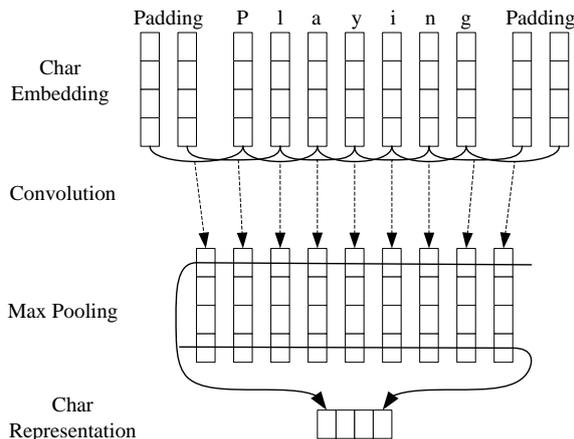

Figure 2: The convolution neural network for extracting character-level representations of words. Dashed arrows indicate a dropout layer applied before character embeddings are input to CNN.

Maximum Spanning Tree Decoding. The decoding problem of this parsing model can be formulated as:

$$\begin{aligned} \mathbf{y}^* &= \operatorname{argmax}_{\mathbf{y} \in T(\mathbf{x})} P(\mathbf{y} | \mathbf{x}; \Theta) \\ &= \operatorname{argmax}_{\mathbf{y} \in T(\mathbf{x})} \sum_{(x_h, x_m) \in \mathbf{y}} \phi(x_h, x_m; \Theta) \end{aligned}$$

which can be solved by using the Maximum Spanning Tree (MST) algorithm described in [McDonald et al. \(2005b\)](#).

2.2 Neural Network for Representation Learning

Now, the remaining question is how to obtain the vector representation of each word with a neural network. In the following subsections, we will describe the architecture of our neural network model for representation learning.

2.2.1 CNNs

Previous work ([Santos and Zadrozny, 2014](#)) have shown that CNNs are an effective approach to extract morphological information (like the prefix or suffix of a word) from characters of words and encode it into neural representations, which has been proven particularly useful on Out-of-Vocabulary words (OOV). The CNN architecture our model uses to extract character-level representation of a given word is the same as the one used in [Ma and Hovy \(2016\)](#). The CNN architecture is shown in Figure 2. Following [Ma and Hovy \(2016\)](#), a dropout layer ([Srivastava et al., 2014](#)) is applied before character embeddings are input to CNN.

2.2.2 Bi-directional LSTM

LSTM Unit. Recurrent neural networks (RNNs) are a powerful family of connectionist models that have been widely applied in NLP tasks, such as language modeling ([Mikolov et al., 2010](#)), sequence labeling ([Ma and Hovy, 2016](#)) and machine translation ([Cho et al., 2014](#)), to capture context information in languages. Though, in theory, RNNs are able to learn long-distance dependencies, in practice, they fail due to the gradient vanishing/exploding problems ([Bengio et al., 1994](#); [Pascanu et al., 2013](#)).

LSTMs ([Hochreiter and Schmidhuber, 1997](#)) are variants of RNNs designed to cope with these gradient vanishing problems. Basically, a LSTM unit is composed of three multiplicative gates which control the proportions of information to pass and to forget on to the next time step.

BLSTM. Many linguistic structure prediction tasks can benefit from having access to both past (left) and future (right) contexts, while the LSTM’s hidden state \mathbf{h}_t takes information only from past, knowing nothing about the future. An elegant solution whose effectiveness has been proven by previous work ([Dyer et al., 2015](#); [Ma and Hovy, 2016](#)) is bi-directional LSTM (BLSTM). The basic idea is to present each sequence forwards and backwards to two separate hidden states to capture past and future information, respectively. Then the two hidden states are concatenated to form the final output. As discussed in [Dozat and Manning \(2016\)](#), there are more than one advantages to apply a multilayer perceptron (MLP) to the output vectors of BLSTM before the score function, eg. reducing the dimensionality and overfitting of the model. We follow this work by using a one-layer perceptron with elu ([Clevert et al., 2015](#)) as activation function.

2.3 BLSTM-CNNs

Finally, we construct our neural network model by feeding the output vectors of BLSTM (after MLP) into the parsing layer. Figure 3 illustrates the architecture of our network in detail.

For each word, the CNN in Figure 2, with character embeddings as inputs, encodes the character-level representation. Then the character-level representation vector is concatenated with the word embedding vector to feed into the BLSTM network. To enrich word-level information, we also use POS embeddings. Finally, the output vec-

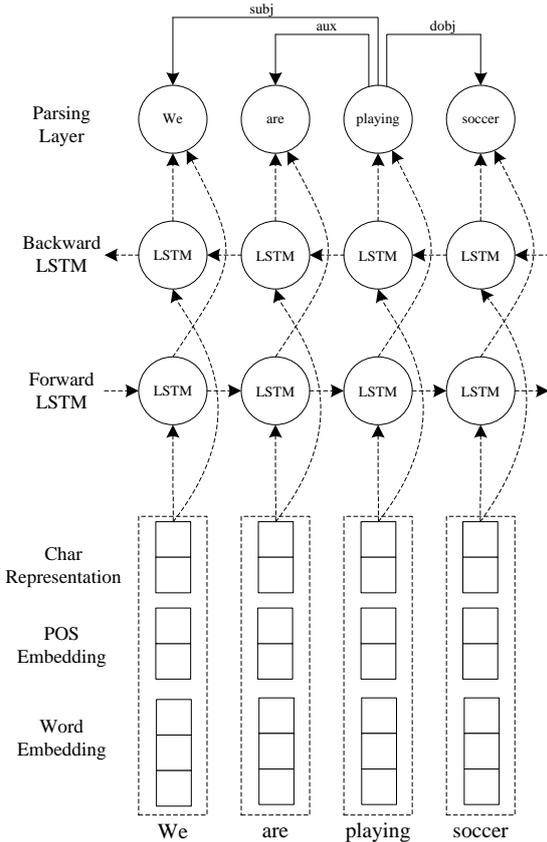

Figure 3: The main architecture of our parsing model. The character representation for each word is computed by the CNN in Figure 2. Then the character representation vector is concatenated with the word and pos embedding before feeding into the BLSTM network. Dashed arrows indicate dropout layers applied on the input, hidden and output vectors of BLSTM.

tors of the neural network are fed to the parsing layer to jointly parse the best (labeled) dependency tree. As shown in Figure 3, dropout layers are applied on the input, hidden and output vectors of BLSTM, using the form of recurrent dropout proposed in Gal and Ghahramani (2016).

3 Network Training

In this section, we provide details about implementing and training the neural parsing model, including parameter initialization, model optimization and hyper parameter selection.

3.1 Parameter Initialization

Word Embeddings. For all the parsing models on different languages, we initialize word vectors with pretrained word embeddings. For Chi-

Layer	Hyper-parameter	Value
CNN	window size	3
	number of filters	50
LSTM	number of layers	2
	state size	256
	initial state	0.0
	peepholes	Hadamard
MLP	number of layers	1
	dimension	100
Dropout	embeddings	0.15
	LSTM hidden states	0.25
	LSTM layers	0.33
Learning	optimizer	Adam
	initial learning rate	0.002
	decay rate	0.5
	gradient clipping	5.0

Table 1: Hyper-parameters for all experiments.

nese, Dutch, English, German and Spanish, we use the structured-skipgram (Ling et al., 2015) embeddings, and for other languages we use the Polyglot (Al-Rfou et al., 2013) embeddings. The dimensions of embeddings are 100 for English, 50 for Chinese and 64 for other languages.

Character Embeddings. Following Ma and Hovy (2016), character embeddings are initialized with uniform samples from $[-\sqrt{\frac{3}{dim}}, +\sqrt{\frac{3}{dim}}]$, where we set $dim = 50$.

POS Embedding. Our model also includes POS embeddings. The same as character embeddings, POS embeddings are also 50-dimensional, initialized uniformly from $[-\sqrt{\frac{3}{dim}}, +\sqrt{\frac{3}{dim}}]$.

Weights Matrices and Bias Vectors. Matrix parameters are randomly initialized with uniform samples from $[-\sqrt{\frac{6}{r+c}}, +\sqrt{\frac{6}{r+c}}]$, where r and c are the number of rows and columns in the structure (Glorot and Bengio, 2010). Bias vectors are initialized to zero, except the bias \mathbf{b}_f for the forget gate in LSTM, which is initialized to 1.0 (Jozefowicz et al., 2015).

3.2 Optimization Algorithm

Parameter optimization is performed with the Adam optimizer (Kingma and Ba, 2014) with $\beta_1 = \beta_2 = 0.9$. We choose an initial learning rate of $\eta_0 = 0.002$. The learning rate η was adapted using a schedule $S = [e_1, e_2, \dots, e_s]$, in which the learning rate η is annealed by

Table 2: Parsing performance (UAS and LAS) of different versions of our model on both the development and test sets for three languages.

multiplying a fixed decay rate $\rho = 0.5$ after $e_i \in S$ epochs respectively. We used $S = [10, 30, 50, 70, 100]$ and trained all networks for a total of 120 epochs. While the Adam optimizer automatically adjusts the global learning rate according to past gradient magnitudes, we find that this additional decay consistently improves model performance across all settings and languages. To reduce the effects of “gradient exploding”, we use a gradient clipping of 5.0 (Pascanu et al., 2013). We explored other optimization algorithms such as stochastic gradient descent (SGD) with momentum, AdaDelta (Zeiler, 2012), or RMSProp (Dauphin et al., 2015), but none of them meaningfully improve upon Adam with learning rate annealing in our preliminary experiments.

Dropout Training. To mitigate overfitting, we apply the dropout method (Srivastava et al., 2014; Ma et al., 2017) to regularize our model. As shown in Figure 2 and 3, we apply dropout on character embeddings before inputting to CNN, and on the input, hidden and output vectors of BLSTM. We apply dropout rate of 0.15 to all the embeddings. For BLSTM, we use the recurrent dropout (Gal and Ghahramani, 2016) with 0.25 dropout rate between hidden states and 0.33 between layers. We found that the model using the new recurrent dropout converged much faster than standard dropout, while achieving similar performance.

3.3 Hyper-Parameter Selection

Table 1 summarizes the chosen hyper-parameters for all experiments. We tune the hyper-parameters on the development sets by random search. We use the same hyper-parameters across the models on different treebanks and languages, due to time constraints. Note that we use 2-layer BLSTM followed with 1-layer MLP. We set the state size of LSTM to 256 and the dimension of MLP to 100. Tuning these two parameters did not significantly impact the performance of our model.

	Dev		Test	
	UAS	LAS	UAS	LAS
cross-entropy	94.10	91.52	93.77	91.57
global-likelihood	94.77	92.66	94.88	92.98

Table 3: Parsing performance on PTB with different training objective functions.

4 Experiments

4.1 Setup

We evaluate our neural probabilistic parser on the same data setup as Kuncoro et al. (2016), namely the English Penn Treebank (PTB version 3.0) (Marcus et al., 1993), the Penn Chinese Treebank (CTB version 5.1) (Xue et al., 2002), and the German CoNLL 2009 corpus (Hajič et al., 2009). Following previous work, all experiments are evaluated on the metrics of unlabeled attachment score (UAS) and Labeled attachment score (LAS).

4.2 Main Results

We first construct experiments to dissect the effectiveness of each input information (embeddings) of our neural network architecture by ablation studies. We compare the performance of four versions of our model with different inputs — Basic, +POS, +Char and Full — where the Basic model utilizes only the pretrained word embeddings as inputs, while the +POS and +Char models augments the basic one with POS embedding and character information, respectively. According to the results shown in Table 2, +Char model obtains better performance than the Basic model on all the three languages, showing that character-level representations are important for dependency parsing. Second, on English and German, +Char and +POS achieves comparable performance, while on Chinese +POS significantly outperforms +Char model. Finally, the Full model achieves the best accuracy on English and German, but on Chinese +POS obtains the best. Thus, we guess that the POS information is more useful

Table 4: UAS and LAS of four versions of our model on test sets for three languages, together with top-performance parsing systems.

for Chinese than English and German.

Table 3 gives the performance on PTB of the parsers trained with two different objective functions — the cross-entropy objective of each word, and our objective based on likelihood for an entire tree. The parser with global likelihood objective outperforms the one with simple cross-entropy objective, demonstrating the effectiveness of the global structured objective.

4.3 Comparison with Previous Work

Table 4 illustrates the results of the four versions of our model on the three languages, together with twelve previous top-performance systems for comparison. Our Full model significantly outperforms the graph-based parser proposed in Kiperwasser and Goldberg (2016) which used similar neural network architecture for representation learning (detailed discussion in Section 5). Moreover, our model achieves better results than the parser distillation method (Kuncoro et al., 2016) on all the three languages. The results of our parser are slightly worse than the scores reported in Dozat and Manning (2016). One possible reason is that, as mentioned in Section 2.1, for labeled dependency parsing Dozat and Manning (2016) used different vectors for different dependency labels to represent each word, making their model require much more memory than ours.

4.4 Experiments on CoNLL Treebanks

Datasets. To make a thorough empirical comparison with previous studies, we also evaluate our system on treebanks from CoNLL shared task on dependency parsing — the English treebank from CoNLL-2008 shared task (Surdeanu et al., 2008) and all 13 treebanks from CoNLL-2006 shared task (Buchholz and Marsi, 2006). For the treebanks from CoNLL-2006 shared task, following Cheng et al. (2016), we randomly select 5% of the training data as the development set. UAS and LAS are evaluated using the official scorer¹ of CoNLL-2006 shared task.

Baselines. We compare our model with the third-order Turbo parser (Martins et al., 2013), the low-rank tensor based model (Tensor) (Lei et al., 2014), the randomized greedy inference based (RGB) model (Zhang et al., 2014), the labeled dependency parser with inner-to-outer greedy decoding algorithm (In-Out) (Ma and Hovy, 2015), and the bi-direction attention based parser (Bi-Att) (Cheng et al., 2016). We also compare our parser against the best published results for individual languages. This comparison includes four additional systems: Koo et al. (2010), Martins et al. (2011), Zhang and McDonald (2014) and Pitler and McDonald (2015).

Table 5: UAS and LAS on 14 treebanks from CoNLL shared tasks, together with several state-of-the-art parsers. “Best Published” includes the most accurate parsers in term of UAS among Koo et al. (2010), Martins et al. (2011), Martins et al. (2013), Lei et al. (2014), Zhang et al. (2014), Zhang and McDonald (2014), Pitler and McDonald (2015), Ma and Hovy (2015), and Cheng et al. (2016).

Results. Table 5 summarizes the results of our model, along with the state-of-the-art baselines. On average across 14 languages, our approach significantly outperforms all the baseline systems. It should be noted that the average UAS of our parser over the 14 languages is better than that of the “best published”, which are from different systems that achieved best results for different languages.

For individual languages, our parser achieves state-of-the-art performance on both UAS and LAS on 8 languages — Bulgarian, Chinese, Czech, Dutch, English, German, Japanese and Spanish. On Arabic, Danish, Portuguese, Slovene and Swedish, our parser obtains the best LAS. Another interesting observation is that the Full model outperforms the +POS model on 13 languages. The only exception is Chinese, which matches the observation in Section 4.2.

5 Related Work

In recent years, several different neural network based models have been proposed and successfully applied to dependency parsing. Among these neural models, there are three approaches most similar to our model — the two graph-based parsers with BLSTM feature representation (Kiperwasser and Goldberg, 2016; Wang and Chang, 2016), and the neural bi-affine attention parser (Dozat and Manning, 2016).

Kiperwasser and Goldberg (2016) proposed a graph-based dependency parser which uses BLSTM for word-level representations. Wang and Chang (2016) used a similar model with a way

to learn sentence segment embedding based on an extra forward LSTM network. Both of these two parsers trained the parsing models by optimizing margin-based objectives. There are three main differences between their models and ours. First, they only used linear form score function, instead of using the bi-linear term between the vectors of heads and modifiers. Second, They did not employ CNNs to model character-level information. Third, we proposed a probabilistic model over non-projective trees on the top of neural representations, while they trained their models with a margin-based objective. Dozat and Manning (2016) proposed neural parsing model using bi-affine score function, which is similar to the bi-linear form score function in our model. Our model mainly differ from this model by using CNN to model character-level information. Moreover, their model formalized dependency parsing as independently selecting the head of each word with cross-entropy objective, while our probabilistic parsing model jointly encodes and decodes parsing trees for given sentences.

6 Conclusion

In this paper, we proposed a neural probabilistic model for non-projective dependency parsing, using the BLSTM-CNNs architecture for representation learning. Experimental results on 17 treebanks across 14 languages show that our parser significantly improves the accuracy of both dependency structures (UAS) and edge labels (LAS), over several previously state-of-the-art systems.

Word Ordering as Unsupervised Learning Towards Syntactically Plausible Word Representations

Noriki Nishida and Hideki Nakayama

Graduate School of Information Science and Technology

The University of Tokyo

{nishida,nakayama}@nlab.ci.i.u-tokyo.ac.jp

Abstract

The research question we explore in this study is how to obtain syntactically plausible word representations without using human annotations. Our underlying hypothesis is that word ordering tests, or linearizations, is suitable for learning syntactic knowledge about words. To verify this hypothesis, we develop a differentiable model called Word Ordering Network (WON) that explicitly learns to recover correct word order while implicitly acquiring word embeddings representing syntactic knowledge. We evaluate the word embeddings produced by the proposed method on downstream syntax-related tasks such as part-of-speech tagging and dependency parsing. The experimental results demonstrate that the WON consistently outperforms both order-insensitive and order-sensitive baselines on these tasks.

1 Introduction

Distributed word representations have been successfully utilized to transfer lexical knowledge to downstream tasks in a semi-supervised manner, and well known to benefit various applications (Turian et al., 2010; Collobert et al., 2011; Socher et al., 2011). As different applications generally require different features, it is crucial to choose representations suitable for target downstream tasks.

The research question we want to explore in this study is how to obtain *syntactically plausible word representations* without human annotations, with a focus on syntax-related tasks (parsing, etc.). Whereas a variety of approaches related to *semantic* word embeddings have been pro-

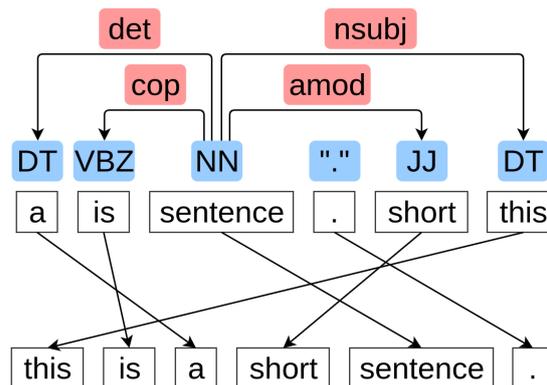

Figure 1: Illustration of the word ordering task. The goal of the word ordering task is to recover an original order given a set of shuffled tokens. The figure shows an example where original sentence is “this is a short sentence.” To correctly reorder the tokens, syntactic knowledge about words (e.g. grammatical classes of words and their possible relations) is indispensable. In this study, we explore how well the word ordering task can be an objective to obtain syntactic word representations.

posed (Mikolov et al., 2013a,b; Pennington et al., 2014), it still remains unclear how we should obtain *syntactic* word embeddings from unannotated corpora.

Word ordering tests, or linearizations, are commonly used to evaluate students’ language proficiency. Suppose that we are given a set of randomly shuffled tokens {“a”, “is,” “sentence,” “short,” “this,” “.”}. In this case we can easily recover the original order: “this is a short sentence.” We consider this doable thanks to our knowledge about grammatical classes (e.g., part-of-speech (POS) tags) of words and their possible relations. We depict the above explanation in Figure 1. Of course, it might not be necessary for machines to mimic exactly the same reasoning pro-

cess in humans. However, syntactic knowledge about words is crucial for both humans and machines to solve the word ordering task.

Inspired by this observation, in this study, we develop an end-to-end model called the Word Ordering Network (WON) that explicitly learns to recover correct word orders while implicitly acquiring word embeddings representing syntactic information. Our underlying hypothesis is that the word ordering task can be an objective for learning syntactic knowledge about words. The WON receives a set of shuffled tokens and first transforms them independently to low-dimensional continuous vectors, which are then aggregated to produce a single summarization vector. We formalize the word ordering task as a sequential prediction problem of a permutation matrix. We use a recurrent neural network (RNN) (Elman, 1990) with long short-term memory (LSTM) units (Hochreiter and Schmidhuber, 1997) and a soft attention mechanism (Bahdanau et al., 2014; Luong et al., 2015) that constructs rows of permutation matrices sequentially conditioned on summarization vectors.

We evaluate the proposed word embeddings on downstream syntax-related tasks such as POS tagging and dependency parsing. The experimental results demonstrate that the WON outperforms both order-insensitive and order-sensitive baselines, and successfully yields the highest performance. In addition, we also evaluate the WON on traditional word-level benchmarks, such as word analogy and word similarity tasks. Combined with semantics-oriented embeddings by a simple fine-tuning technique, the WON gives competitive or better performances than the other baselines. Interestingly, we find that the WON has a potential to refine and improve semantic features. Moreover, we qualitatively analyze the feature space produced by the WON and find that the WON tends to capture not only syntactic but also semantic regularities between words. The source code of this work is available online.¹

2 The Proposed Method

In this section, we formulate the WON which implicitly acquires syntactic word embeddings through learning to solve word ordering problems.

¹<https://github.com/norikinishida/won>

2.1 Embedding Layer

Given a set of shuffled tokens $\mathcal{X} = \{w_1, \dots, w_N\}$, the WON first transforms every single symbol w_c into a low-dimensional continuous vector, i.e.,

$$e_c = F(w_c) \in \mathbb{R}^D, \quad (1)$$

where F is a learnable function. Please note that the number of tokens N in the input \mathcal{X} can vary in the word ordering task.

2.2 Aggregation

To perform reordering on a set of shuffled embeddings $\{e_1, \dots, e_N\}$, we aggregate the embeddings and compute a single summarization vector. The aggregation function is a sum of word embeddings followed by a non-linear transformation:

$$\tilde{e} = \tanh(\mathbf{W}_a \sum_{c=1}^N e_c + \mathbf{b}_a) \in \mathbb{R}^D, \quad (2)$$

where $\mathbf{W}_a \in \mathbb{R}^{D \times D}$ and $\mathbf{b}_a \in \mathbb{R}^D$ are a projection matrix and bias vector, respectively.

2.3 Prediction of a Permutation Matrix

We formalize a reordering problem as a prediction task of a permutation matrix.

A permutation matrix is a square binary matrix and every row and column contains exactly one entry of 1 and 0s elsewhere. The left-multiplication of a matrix $\mathbf{E} \in \mathbb{R}^{N \times D}$ by a permutation matrix $\mathbf{P} \in \mathbb{R}^{N \times N}$ rearranges the rows of the matrix \mathbf{E} , e.g.

$$\begin{pmatrix} e_1^\top \\ e_2^\top \\ e_3^\top \\ e_4^\top \end{pmatrix} = \mathbf{P}\mathbf{E} \quad (3)$$

$$= \begin{pmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{pmatrix} \begin{pmatrix} e_3^\top \\ e_1^\top \\ e_4^\top \\ e_2^\top \end{pmatrix}. \quad (4)$$

Equation 4 gives an example where $\mathbf{E} = (e_3, e_1, e_4, e_2)^\top$, and the original sentence (correct order) is w_1, w_2, w_3, w_4 .

In the word ordering task, one of the issues in predicting permutation matrices is that the number of tokens N changes according to the variable lengths of input sentences. Therefore, it is impossible to define and train learning models that have fixed-dimensional outputs such as multi-layer perceptrons.

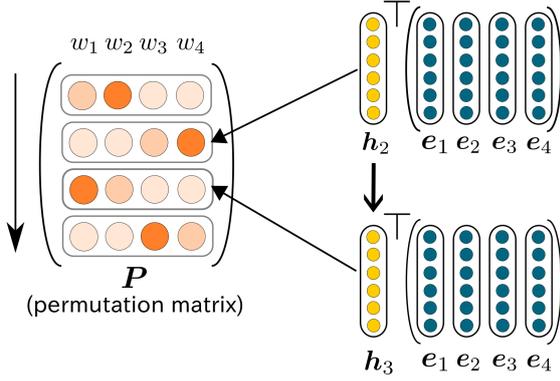

Figure 2: Visualization of our approach to sequentially predict a permutation matrix $\mathbf{P} \in \mathbb{R}^{N \times N}$. In this case, we are given $N = 4$ shuffled tokens (w_1, w_2, w_3, w_4) . We first independently embeds each symbol to dense vectors (e_1, e_2, e_3, e_4) . Then, by using an RNN and a soft attention mechanism, we sequentially constructs the rows of the permutation matrix $\mathbf{P} = (\mathbf{p}_1, \mathbf{p}_2, \mathbf{p}_3, \mathbf{p}_4)^\top$ for N steps through a scoring function. The vector $\mathbf{h}_r \in \mathbb{R}^D$ denotes the r -th hidden state of the RNN. One can interpret \mathbf{p}_r as a selective probability distribution over the input tokens. For simplicity, in this figure, we ignore the projection matrix in the scoring function (Eq. 8).

Recently, Vinyals et al. (2015) proposed the *Pointer Networks* (PtrNets) that were successfully applied to geometric sorting problems. Inspired by the PtrNet, we develop an LSTM (Hochreiter and Schmidhuber, 1997) with a soft attention mechanism (Bahdanau et al., 2014; Luong et al., 2015). The LSTM constructs rows of a permutation matrix $\mathbf{P} = (\mathbf{p}_1, \dots, \mathbf{p}_N)^\top$ conditioned on a set of word embeddings $\{e_1, \dots, e_m\}$ calculated by Equation 1. If $\sum_{c=1}^N p_{r,c} = 1$ holds, one can interpret $p_{r,c}$ as the probability of the token w_c to be placed at r -th position. In Figure 2, we show a visualization of our approach to predict a permutation matrix with the LSTM.

The LSTM’s r -th hidden state $\mathbf{h}_r \in \mathbb{R}^D$ and memory cells $\mathbf{c}_r \in \mathbb{R}^D$ are computed as follows:

$$\mathbf{h}_r, \mathbf{c}_r = \begin{cases} \tilde{e}, \mathbf{0} & (r = 0) \\ F_{\text{LSTM}}(e_{i_{r-1}}, \mathbf{h}_{r-1}, \mathbf{c}_{r-1}) & (1 \leq r \leq N) \end{cases} \quad (5)$$

where the function F_{LSTM} is a state-update function and $i_{r-1} \in \{1, \dots, N\}$ denotes the index of the token $w_{i_{r-1}}$ that is placed at the previous posi-

tion, i.e.,

$$i_{r-1} = \operatorname{argmax}_{c \in \{1, \dots, N\}} p_{r-1,c}. \quad (6)$$

Subsequently, we predict a selective distribution over the input tokens:

$$p_{r,c} = \frac{\exp(\operatorname{score}(\mathbf{h}_r, e_c))}{\sum_{k=1}^N \exp(\operatorname{score}(\mathbf{h}_r, e_k))}, \quad (7)$$

where the scoring function score computes the confidence of placing the token w_c at r -th position. We define the scoring function as a bilinear model as follows

$$\operatorname{score}(\mathbf{u}, \mathbf{v}) = \mathbf{u}^\top \mathbf{W}_s \mathbf{v} \in \mathbb{R}. \quad (8)$$

where $\mathbf{W}_s \in \mathbb{R}^{D \times D}$ denotes a learnable matrix.

2.4 Objective Function

As the WON is designed to be fully differentiable, it can be trained with any gradient descent algorithms, such as RMSProp (Tieleman and Hinton, 2012). Given a set of shuffled tokens $\mathcal{X} = \{w_1, \dots, w_N\}$, we define a loss function as the following negative log likelihood:

$$\mathcal{L}(\mathcal{X}) = \sum_{r=1}^N -\log p_{r,t_r} \quad (9)$$

where $t_r \in \{1, \dots, N\}$ denotes the index of the ground-truth token that appears at r -th position in the original sentence. In other words, an ordered sequence $w_{t_1}, w_{t_2}, \dots, w_{t_N}$ forms the original sentence.

3 Related Work

Among the most popular methods for learning word embeddings are the *skip-gram* (SG) model and the *continuous bag-of-words* (CBOW) of Mikolov et al. (2013a,b), or the GloVe introduced by Pennington et al. (2014). These are formalized as simple log-bilinear models based on the inner product between two word vectors. The core idea is based on the *distributional hypothesis* (Harris, 1954; Firth, 1957), stating that words appearing in similar contexts tend to have similar meanings. For example, SG and CBOW are trained by making predictions of bag-of-words contexts appearing in a fixed-size window around target words, and vice versa. Although word embeddings produced by these models have been

shown to give improvements in a variety of downstream tasks, it still remains difficult for these models to learn syntactic word representations owing to their insensitivity to word order. As a consequence, word embeddings produced by these order-insensitive models are thus suboptimal for syntax-related tasks such as parsing (Andreas and Klein, 2014). In contrast, our method mainly focuses on word order information and utilize it in the learning process.

Ling et al. (2015b) introduced the *structured skip-gram* (SSG) model and the *continuous window* (CWindow) that extend SG and CBOW respectively. Let c be the window size. These models learn $2c$ context-embedding matrices to be aware of relative positions of context words in a window. The recent work of Trask et al. (2015) is also based on the same idea as SSG and CWindow. Ling et al. (2015a) proposed an approach to integrating an order-sensitive attention mechanism into CBOW, which allows for consideration of the contexts of words, and where the context words appear in a window. Bengio et al. (2003) presented a neural network language model (NNLM) where word embeddings are simultaneously learned along with a language model. One of the major shortcomings of these window-based approaches is that it is almost impossible to learn longer dependencies between words than the prefixed window size c . In contrast, the recurrent architecture allows the WON to take into account dependencies over an entire sentence.

Mikolov et al. (2010) applied an RNN for language modeling (RNNLM), and demonstrated that the word embeddings learned by the RNNLM capture both syntactic and semantic regularities. The main shortcoming of the RNNLM is that it is very slow to train unfortunately. This is a consequence of having to predict the probability distribution over an entire vocabulary V , which is generally very large in the real world. In contrast, the WON predicts the probability distribution over entire sentences, whose length N is usually less than $50 \ll |V|$. In our preliminary experiments, we found that the computation time for one iteration (= forward + backward + parameter update) of the WON is about 4 times faster than that of the RNNLM (LSTMLM).

Levy and Goldberg (2014) introduced dependency-based word embeddings. The method applies the *skip-gram with negative*

sampling (SGNS) model (Mikolov et al., 2013b) to *syntactic contexts* derived from dependency parse-trees. Their method heavily relies on pre-trained dependency parsers to produce words’ relations for each sentence in training corpora, thus encountering error propagation problems. In contrast, our method only requires raw corpora, and our aim is to produce word embeddings that improve syntax-related tasks, such as parsing, without using any human annotations.

The WON can be interpreted as a simplification of the recently proposed pointer network (PtrNet) (Vinyals et al., 2015). The main difference between the WON and the PtrNet is the *encoder* part. The PtrNet uses an RNN to encode an unordered set $\mathcal{X} = \{w_1, \dots, w_N\}$ sequentially, i.e.,

$$e_i = \text{RNN}_{\text{enc}}(w_i, e_{i-1}). \quad (10)$$

In contrast, the WON treats each symbol independently (Eq. 1) and aggregates them with a simpler function (Eq. 2). In the word ordering task, the order of $\mathcal{X} = (w_1, \dots, w_N)$ is meaningless because \mathcal{X} is an out-of-order set. Nonetheless, according to Equation 10, the vector e_i depends on the input order of w_1, \dots, w_{i-1} . Vinyals et al. (2015) evaluated the PtrNet on geometric sorting tasks (e.g., Travelling Salesman Problem) where each input w_i forms a continuous vector that represents the cartesian coordinate of the point (e.g., a city). However, in the word ordering task, Equation 10 suffers from the data sparseness problem, as each input w_i forms a high-dimensional discrete symbol.

4 Experimental Setting

4.1 Dataset and Preprocessing

We used the English Wikipedia corpus as the training corpus. We lowercased and tokenized all tokens, and then replaced all digits with “7” (e.g., “ABC2017” → “ABC7777”). We built a vocabulary of the most frequent 300K words and replaced out-of-vocabulary tokens with a special “⟨UNK⟩” symbol. Subsequently, we appended special “⟨EOS⟩” symbols to the end of each sentence. The resulting corpus contains about 97 million sentences with about 2 billion tokens. We randomly extracted 5K sentences as the validation set.

4.2 Hyper Parameters

We set the dimensionality of word embeddings to 300. The dimensionality of the hidden states of the LSTM was 512. The L_2 regularization term (called weight decay) was set to 4×10^{-6} . For the stochastic gradient descent algorithm, we used the SMORMS3 (Func, 2015), and the mini-batch size was set to 180.

4.3 Baselines

For a fair comparison, we trained the following order-insensitive/sensitive baselines on exactly the same pre-processed corpus described in Section 4.1.

- **SGNS** (Mikolov et al., 2013b): We used the `word2vec` implementation in Gensim² to train the Skip-Gram with Negative Sampling (SGNS). We set the window size to 5, and the number of negative samples to 5.
- **GloVe** (Pennington et al., 2014): GloVe’s embeddings are trained by using the original implementation³ provided by the authors. We set the window size to 15. In our preliminary experiments, we found that GloVe with a window size of 15 yields higher performances than that with a window size of 5.
- **SSG, CWindow** (Ling et al., 2015b): We built word embeddings by using the structured skip-gram (SSG) and the continuous window (CWindow). We used the original implementation⁴ developed by the authors. The window size was 5, and the number of negative samples was 5.
- **LSTMLM**: We also compared the proposed method with the RNNLM (Mikolov et al., 2010) with LSTM units (LSTMLM). The hyper parameters were the same with that of the WON except for the mini-batch size. We used a mini-batch size of 100 for the LSTMLM.

5 Evaluation on Part-of-Speech Tagging

In this experiment, we evaluated the learned word embeddings by using them as pre-trained features in supervised POS tagging.

WON	97.04

Table 1: Comparison results on part-of-speech tagging with different word embeddings. The dataset is the Wall Street Journal (WSJ) portion of the Penn Treebank (PTB) corpus. The evaluation metric is accuracy (%).

5.1 Supervised POS Tagger

In POS tagging, every token in a sentence is classified into its POS tag (NN for nouns, VBD for past tense verbs, JJ for adjectives, etc.). We first used the learned word embeddings to project three successive tokens (w_{i-1}, w_i, w_{i+1}) in an input sentence to feature vectors (e_{i-1}, e_i, e_{i+1}) that are then concatenated and fed to a two-layer perceptron followed by a softmax function:

$$P(c|w_{i-1}, w_i, w_{i+1}) = \text{MLP}([e_{i-1}; e_i; e_{i+1}]), \quad (11)$$

where $[\cdot; \cdot; \cdot]$ denotes vector concatenation. The classifier MLP predicts the probability distribution over POS tags of the center token w_i . We put special padding symbols at the beginning and end of each sentence. The dimensionality of the hidden layer of the MLP was 300. The MLP classifier was trained via the SMORMS3 optimizer (Func, 2015) without updating the word embedding layer.

We used the Wall Street Journal (WSJ) portion of the Penn Treebank (PTB) corpus⁵ (Marcus et al., 1993). We followed the standard section partition, which is to use sections 0-18 for training, sections 19-21 for validation, and sections 22-24 for testing. The dataset contains 45 tags. The evaluation metric was the word-level accuracy.

5.2 Results & Discussion

Table 1 presents the comparison of the WON to the other baselines on the test split. The results demonstrate that the WON gives the highest performance, which supports our hypothesis that the word ordering task is effective for acquiring syntactic knowledge about words. We also

⁵We used the LDC99T42 Treebank release 3 version.

observe that the order-sensitive methods (WON, LSTMLM, and SSG) tend to outperform the order-insensitive methods (SGNS and GloVe), which indicates that, as we expect, word order information is crucial for learning syntactic word embeddings.

6 Evaluation on Dependency Parsing

In this experiment, as in Section 5, we evaluated the learned word embeddings on supervised dependency parsing.

6.1 Supervised Dependency Parser

Dependency parsing aims to identify syntactic relations between token pairs in a sentence. We used Stanford’s neural network dependency parser (Chen and Manning, 2014)⁶, whose word embeddings were initialized with the learned word embeddings. We followed all the default settings except for the word embedding size (`embeddingSize = 300`) and the number of training iterations (`maxIter = 6000`).

We used the WSJ portion of the PTB corpus and followed the standard splits of sections 2-21 for training, 22 for validation, and 23 for testing. We converted the treebank corpus to Stanford style dependencies using the Stanford converter. The parsing performances were evaluated in terms of Unlabeled Attachment Score (UAS) and Labeled Attachment Score (LAS).

6.2 Results & Discussion

Table 2 shows the results of the different word embeddings on dependency parsing. First we observe that the WON consistently outperforms

⁶<http://nlp.stanford.edu/software/nndep.shtml>

the baselines on both UAS and LAS. Next, by comparing the unlimited-context models (WON and LSTMLM) with the limited-context models (SGNS, GloVe, SSG, CWindow), we can notice that the former give higher parsing scores than the latter. These results are reasonable because the former can learn arbitrary-length syntactic dependencies between words without constraints from the fixed-size window size based on which the limited-window models are trained.

7 Fusion with Semantic Features

In various NLP tasks, both syntactic and semantic features can benefit performances. To enrich our syntax-oriented word embeddings with semantic information, in this section, we adopt a simple fine-tuning technique and verify its effectiveness. More precisely, we first initialize the word embeddings \mathbf{W} with pre-trained parameters \mathbf{W}_{sem} produced by a semantics-oriented model such as the SGNS. Subsequently we add the following penalty term to the loss function in Equation 9:

$$\lambda \|\mathbf{W} - \mathbf{W}_{\text{sem}}\|_{\mathcal{F}}^2, \quad (12)$$

where $\lambda \in \mathbb{R}$ is a hyper parameter to control the intensity of the penalty term in the learning process, and $\|\cdot\|_{\mathcal{F}}^2$ is the Frobenius norm. This term attempts to keep the word embeddings \mathbf{W} close to the semantic representations \mathbf{W}_{sem} while minimizing the syntax-oriented objective on the word ordering task. In our experiments, we used the SGNS’s embeddings as \mathbf{W}_{sem} and set λ to 1. The SGNS was trained as explained in Section 4.3.

In this section, we quantitatively evaluated the WON with the above fine-tuning technique on two major benchmarks: (1) word analogy task, and (2) word similarity task.

7.1 Word Analogy

The word analogy task has been used in previous work to evaluate the ability of word embeddings to represent semantic and syntactic regularities. In this experiment, we used the word analogy dataset produced by Mikolov et al. (2013a). The dataset consists of questions like “A is to B what C is to ?,” denoted as “A : B :: C : ?.” The dataset contains about 20K such questions, divided into a *syntactic subset* and a *semantic subset*. The syntactic subset contains nine question types, such as *adjective-to-adverb* and *opposite*, while the semantic subset contains five question

Question Types	SGNS	GloVe	SSG	CWindow	LSTMLM	WON
adjective-to-adverb	24.1	23.3	29.9	12.1	4.3	29.9
opposite	36.2	29.9	37.0	11.7	15.0	37.8
comparative	85.7	79.5	88.5	73.5	55.3	88.7
superlative	59.3	49.1	68.7	43.8	22.4	62.8
present-participle	64.9	61.0	73.6	57.4	27.1	71.8
nationality-adjective	89.4	92.2	89.7	87.3	30.5	90.8
past-tense	58.0	52.2	59.0	54.0	33.1	61.4
plural	75.2	83.0	75.2	70.4	26.4	75.4
plural-verbs	78.9	56.0	84.6	64.6	61.0	82.9
capital-common	94.5	95.3	92.5	93.1	53.8	95.5
capital-world	87.8	94.5	84.0	66.6	22.1	82.6
currency	12.8	8.7	14.0	3.7	1.9	10.7
city	66.0	60.7	56.9	61.9	13.6	67.4
family	84.2	77.9	81.8	59.1	62.9	84.2
Total	69.9	68.3	69.7	58.2	27.0	70.6

Table 3: Results on the word analogy task (Mikolov et al., 2013a) with different word embeddings. The first upper block presents the results on nine syntactic question types. In the lower block we show the results on five semantic question types. The last row presents the total score. The evaluation metric is accuracy (%).

types such as `city-in-state` and `family`. Suppose that a vector e_w is a representation of a word w , and is normalized to unit norm. Following a previous work (Mikolov et al., 2013a), we answer an analogy question “A : B :: C : ?” by finding a word w^* that has the closest representation to $(e_B - e_A + e_C)$ in terms of cosine similarity, i.e.,

$$w^* = \operatorname{argmax}_{w \in V \setminus \{A, B, C\}} \frac{(e_B - e_A + e_C)^\top e_w}{\|e_B - e_A + e_C\|}, \quad (13)$$

where V denotes the vocabulary. The evaluation was performed using accuracy, which denotes the percentage of words predicted correctly.

In Table 3, we report the results of the different word embeddings on this task. As can be seen in the Table 3, the WON outperforms the baselines on four out of nine syntactic question types, and tends to yield higher accuracies by a large margin than the baselines except for the SSG. Our method and the SSG totally give the best performances on seven of nine syntactic question types. This tendency, as in Section 5.2, indicates that word order information is crucial to learn syntactic word embeddings. In regard to semantics, the WON achieves the best scores on three out of five semantic question types. Interestingly, on two semantic question types (`capital-common` and `city`), the WON outperforms the SGNS that was used to

	WS-353	MC	RG

initialize our word embeddings. This result implies that the word ordering task has the potential to improve not only syntactic but also semantic features. Our method achieves the highest accuracy on the overall score.

7.2 Word Similarity

The word similarity benchmark is commonly used to evaluate word embeddings in terms of distributional semantic similarity. The word similarity datasets consist of triplets like (w_1, w_2, s) , where $s \in \mathbb{R}$ is a human-annotated similarity score between two words (w_1, w_2) . In this task, we compute cosine similarity between two word embeddings. The evaluation is performed with the Spearman’s rank correlation coefficient between

Query	The 3 most similar words

Table 5: Query words and their most similar words. Cosine similarities are computed between their embeddings produced by the WON.

the human-annotated similarities and the computed similarities.

Table 4 presents the results on three datasets: WordSim-353 (Finkelstein et al., 2001), MC (Miller and Charles, 1991), and RG (Rubenstein and Goodenough, 1965). we observe that the WON gives a slightly higher performance than the baselines on the MC dataset. On the other datasets, the SSG yields the best performances. These results are interesting because the two models rely on word order information while the word similarity task originally focuses on topical semantic similarities between words.

Further investigation into the interaction between syntactic and semantic representations would be interesting and needs to be explored.

8 Qualitative Analysis

In this section, we inspect the learned vector space by computing the similarities between word embeddings.

In this experiment we trained the WON on the BookCorpus (Zhu et al., 2015) that is preprocessed in the same way described in Section 4.1. The BookCorpus consists of a large collection of nov-

els, which results in a grammatically sophisticated text corpus that would be suitable for qualitative analysis. Note that to clearly investigate the word embeddings produced by the WON we neither initialize our word embeddings with other models nor use fine-tuning techniques, as in experiments on downstream syntax-related tasks (Section 5 and Section 6). We choose queries focusing on (1) declension of personal pronouns, (2) singular and plural forms of nouns, (3) verb conjugation, (4) comparative/superlative forms of adjectives, and (5) prepositions.

Table 5 presents some representative queries for (1)-(5) and their respective most similar words in the learned vector space. First we can observe that our word embeddings produce a continuous vector space that successfully captures syntactic regularities. In addition to the syntactic regularities, interestingly, we found that the WON prefers to gather words in terms of those meanings or semantic categories.

9 Conclusion and Future Work

The research question we explored in this study was how to learn *syntactic word embeddings* without using any human annotations. Our underlying hypothesis is that the word ordering task is suitable for obtaining syntactic knowledge about words. To verify this idea, we developed the WON, which implicitly learns syntactic word representations through learning to explicitly solve the word ordering task. The experimental results demonstrate that the WON gives improvements over baselines particularly on syntax-related tasks, such as part-of-speech tagging and dependency parsing. We can also observe that the WON, by combined with a simple fine-tuning technique, has the potential to refine not only syntactic but also semantic features.

It remains unclear how well order-sensitive models like the WON can learn syntactic knowledge about words in languages other than English. Especially, it is interesting to investigate cases on languages with richer morphology and freer word order. We leave this to future work.

Abstract

We present a pointwise mutual information (PMI) based approach for formalizing paraphrasability and propose a variant of PMI, called mutual information based paraphrase acquisition (MIPA), for paraphrase acquisition. Our paraphrase acquisition method first acquires lexical paraphrase pairs by bilingual pivoting and then reranks them by PMI and distributional similarity. The complementary nature of information from bilingual corpora and from monolingual corpora renders the proposed method robust. Experimental results show that the proposed method substantially outperforms bilingual pivoting and distributional similarity themselves in terms of metrics such as mean reciprocal rank, mean average precision, coverage, and Spearman’s correlation.

1 Introduction

Paraphrases are useful for flexible language understanding in many NLP applications. For example, the usefulness of the paraphrase database PPDB (Ganitkevitch et al., 2013; Pavlick et al., 2015), a publicly available large-scale resource for lexical paraphrasing, has been reported for tasks such as learning word embeddings (Yu and Dredze, 2014) and semantic textual similarity (Sultan et al., 2015). In PPDB, paraphrase pairs are acquired via word alignment on a bilingual corpus by a process called bilingual pivoting (Bannard and Callison-Burch, 2005). Figure 1 shows an example of English language paraphrase acquisition using the German language as a pivot.

Although bilingual pivoting is widely used for paraphrase acquisition, it always includes noise

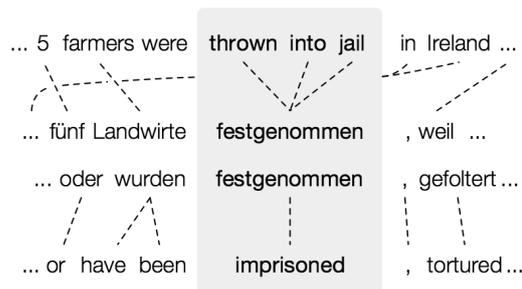

Figure 1: Paraphrase acquisition via bilingual pivoting (Ganitkevitch et al., 2013).

due to unrelated word pairs caused by word alignment errors on the bilingual corpus. Distributional similarity, another well-known method for paraphrase acquisition, is free of alignment errors, but includes noise due to antonym pairs that share the same contexts on the monolingual corpus (Mohammad et al., 2013).

In this study, we formalize the paraphrasability of paraphrase pairs acquired via bilingual pivoting using pointwise mutual information (PMI) and reduce the noise by reranking the pairs using distributional similarity. The proposed method extends Local PMI (Evert, 2005), which is a variant of weighted PMI that aims to avoid low-frequency bias in PMI, for paraphrase acquisition. Since bilingual pivoting and distributional similarity have different advantages and disadvantages, we combine them to construct a complementary paraphrase acquisition method, called mutual information based paraphrase acquisition (MIPA). Experimental results show that MIPA outperforms bilingual pivoting and distributional similarity themselves in terms of metrics such as mean reciprocal rank (MRR), mean average precision (MAP), coverage, and Spearman’s correlation.

The contributions of our study are as follows.

- Bilingual pivoting-based lexical paraphrase acquisition is generalized using PMI.
- Lexical paraphrases are acquired robustly using both bilingual and monolingual corpora.
- We release our lexical paraphrase pairs¹.

2 Bilingual Pivoting

Bilingual pivoting (Bannard and Callison-Burch, 2005) is a method used to acquire large-scale lexical paraphrases by two-level word alignment on a bilingual corpus. Bilingual pivoting employs a conditional paraphrase probability $p(e_2|e_1)$ as a paraphrasability measure, when word alignments exist between an English phrase e_1 and a foreign language phrase f , and between the foreign language phrase f and another English phrase e_2 on a bilingual corpus. It calculates the probability from an English phrase e_1 to another English phrase e_2 using word alignment probabilities $p(f|e_1)$ and $p(e_2|f)$; here, the foreign language phrase f is used as the pivot.

$$\begin{aligned} p(e_2|e_1) &= \sum_f p(e_2|f, e_1) p(f|e_1) \\ &\approx \sum_f p(e_2|f) p(f|e_1) \end{aligned} \quad (1)$$

It assumes conditional independence of e_1 and e_2 given f , so that the equation above can be estimated easily using phrase-based statistical machine translation models. One of its advantages is that it requires only two translation models to acquire paraphrases on a large scale. However, since the conditional probability is asymmetric, it may introduce irrelevant paraphrases that do not hold the same meaning as the original one. In addition, owing to the data sparseness problem in the bilingual corpus, paraphrase probabilities may be overestimated for low-frequency word pairs.

To mitigate this, PPDB (Ganitkevitch et al., 2013) defined the symmetric paraphrase score $s_{bp}(e_1, e_2)$ using bi-directional bilingual pivoting.

$$s_{bp}(e_1, e_2) = -\lambda_1 \log p(e_2|e_1) - \lambda_2 \log p(e_1|e_2) \quad (2)$$

Unlike Equation (1), s_{bp} enforces mutual paraphrasability of e_1 and e_2 . As discussed later, this does not necessarily increase the performance of paraphrase acquisition, because the symmetric constraint may be too strict to allow the extraction of broad-coverage paraphrases. In this study,

¹<https://github.com/tmu-nlp/pmi-ppdb>

without loss of generality, we set² $\lambda_1 = \lambda_2 = -1$.

$$s_{bp}(e_1, e_2) = \log p(e_2|e_1) + \log p(e_1|e_2) \quad (3)$$

Although these paraphrase acquisition methods can extract large-scale paraphrase knowledge, the results may contain many fragments caused by word alignment error.

3 MIPA: Mutual Information Based Paraphrase Acquisition

To mitigate overestimation, we acquire lexical paraphrases with the conditional paraphrase probability by using Kneser-Ney smoothing (Kneser and Ney, 1995) and reranking them using information theoretic measure from a bilingual corpus and distributional similarity calculated from a large-scale monolingual corpus.

3.1 Smoothing of Bilingual Pivoting

Since bilingual pivoting adopts the conditional probability $p(e_2|e_1)$ as paraphrasability, we can mitigate the problem of overestimation by applying a smoothing method.

In the hierarchical Bayesian model, the conditional probability $p(y|x)$ is expressed using the Dirichlet distribution with parameter α_y and maximum likelihood estimation $\hat{p}_{y|x}$ as follows.

$$\begin{aligned} p(y|x) &= \frac{n(y|x) + \alpha_y}{\sum_y (n(y|x) + \alpha_y)} \\ &\simeq \frac{n(y|x)}{n(x) + \sum_y \alpha_y} \quad \because \alpha_y \ll 1 \\ &= \frac{n(x)}{n(x) + \sum_y \alpha_y} \cdot \frac{n(y|x)}{n(x)} \\ &= \frac{n(x)}{n(x) + \sum_y \alpha_y} \cdot \hat{p}_{y|x} \end{aligned} \quad (4)$$

Here, $n(x)$ indicates the frequency of a word x and $n(y|x)$ indicates the co-occurrence frequency of word y following x . As $\sum_y \alpha_y$ is too large to be ignored, especially when the frequency $n(x)$ is small, Equation (4) shows that the maximum likelihood estimation $\hat{p}_{y|x}$ estimates the probability to be excessively large.

Therefore, we propose using Kneser-Ney smoothing (Kneser and Ney, 1995), which is considered to be an extension of the Dirichlet smoothing above, to mitigate overestimation of paraphrase probability in bilingual pivoting.

²PPDB³: $\lambda_1 = \lambda_2 = 1$

³<http://www.cis.upenn.edu/~ccb/ppdb/>

$$\begin{aligned}
p_{\text{KN}}(e_2|e_1) &= \frac{n(e_2|e_1) - \delta}{n(e_1)} + \gamma(e_1)p_{\text{KN}}(e_2) \\
\delta &= \frac{N_1}{N_1 + 2N_2} \\
\gamma(e_1) &= \frac{\delta}{n(e_1)}N(e_1) \\
p_{\text{KN}}(e_2) &= \frac{N(e_2)}{\sum_i N(e_i)}
\end{aligned} \tag{5}$$

Here, N_n indicates the number of types of word pairs of frequency n and $N(e_1)$ indicates the number of types of paraphrase candidates of word e_1 .

3.2 Generalization of Bilingual Pivoting using Mutual Information

The bi-directional bilingual pivoting of PPDB (Ganitkevitch et al., 2013) constrains paraphrase acquisition to be strictly symmetric. However, although it is extremely effective for extracting synonymous expressions, it tends to give high scores to frequent but irrelevant phrases, since bilingual pivoting itself contains noisy phrase pairs because of word alignment errors.

To address the problem of frequent phrases, we smooth paraphrasability by bilingual pivoting in Equation (3) using word probabilities $p(e_1)$ and $p(e_2)$ from a monolingual corpus that is sufficiently larger than the bilingual corpus.

$$\begin{aligned}
s_{pmi}(e_1, e_2) &= \log p(e_2|e_1) + \log p(e_1|e_2) \\
&\quad - \log p(e_1) - \log p(e_2)
\end{aligned} \tag{6}$$

Thus, we can interpret the bi-directional bilingual pivoting as an unsmoothed version of PMI. Since the difference in the logarithms of the numerator and denominator is equal to the logarithm of the quotient, we can transform Equation (6) as

$$\begin{aligned}
s_{pmi}(e_1, e_2) &= \log \frac{p(e_2|e_1)}{p(e_2)} + \log \frac{p(e_1|e_2)}{p(e_1)} \\
&= 2\text{PMI}(e_1, e_2)
\end{aligned} \tag{7}$$

since we can transform PMI into the following forms using Bayes' theorem.

$$\begin{aligned}
\text{PMI}(x, y) &= \log \frac{p(x, y)}{p(x)p(y)} \\
&= \log \frac{p(y|x)p(x)}{p(x)p(y)} = \log \frac{p(y|x)}{p(y)} \\
&= \log \frac{p(x|y)p(y)}{p(x)p(y)} = \log \frac{p(x|y)}{p(x)}
\end{aligned} \tag{8}$$

Plugging Equation (8) into Equation (7), we can interpret PMI as a geometric mean of two models.

$$\begin{aligned}
\text{PMI}(x, y) &= \frac{1}{2}\text{PMI}(x, y) + \frac{1}{2}\text{PMI}(x, y) \\
&= \frac{1}{2} \log \frac{p(y|x)}{p(y)} + \frac{1}{2} \log \frac{p(x|y)}{p(x)} \\
&= \log \left[\left\{ \frac{p(y|x)}{p(y)} \right\}^{\frac{1}{2}} \cdot \left\{ \frac{p(x|y)}{p(x)} \right\}^{\frac{1}{2}} \right]
\end{aligned} \tag{9}$$

Bilingual pivoting in Equation (1) can be regarded as a mixture model that considers only the $e_1 \rightarrow e_2$ direction. However, as shown in Equation (9), our proposed method can be regarded as a product model (Hinton, 2002) that considers both directions. PPDB (Pavlick et al., 2015) also considers the paraphrase probability in both directions, but the authors did not regard it as a product model; instead the paraphrase probability in each direction is treated as one of the features of supervised learning.

3.3 Incorporating Distributional Similarity

In low-frequency word pairs, it is well-known that PMI becomes unreasonably large because of coincidental co-occurrence. In order to avoid this problem, Evert (2005) proposed Local PMI, which assigns weights to PMI depending on the co-occurrence frequency of word pairs.

$$\text{LocalPMI}(x, y) = n(x, y) \cdot \text{PMI}(x, y) \tag{10}$$

In this study, however, it was difficult to directly calculate the weight corresponding to $n(x, y)$ in Equation (10) on the bilingual corpus. Furthermore, our aim was to calculate not the strength of co-occurrence (relation) between words, but the paraphrasability. Therefore, it is not appropriate to count the co-occurrence frequency on a monolingual corpus such as Local PMI.

Alternatively, we use as a weight the distributional similarity, which is frequently used for paraphrase acquisition from a monolingual corpus (Chan et al., 2011; Glavaš and Štajner, 2015).

$$\begin{aligned}
s_{lpmi}(e_1, e_2) &= \cos(e_1, e_2) \cdot s_{pmi}(e_1, e_2) \\
&= \cos(e_1, e_2) \cdot 2\text{PMI}(e_1, e_2)
\end{aligned} \tag{11}$$

Here, $\cos(e_1, e_2)$ indicates cosine similarity between vector representations of word e_1 and word e_2 . Equation (11) simultaneously considers paraphrasability based on the monolingual corpus (distributional similarity) and on the bilingual corpus

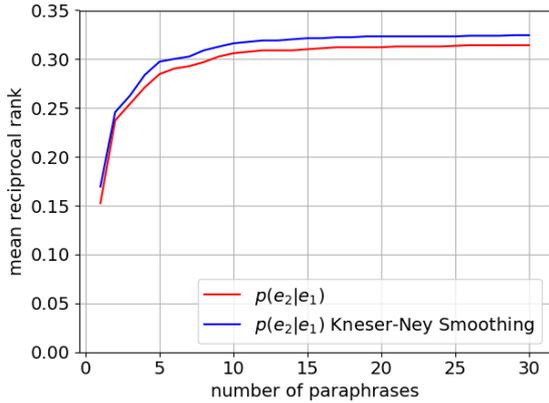

Figure 2: Effectiveness of smoothing of bilingual pivoting evaluated by paraphrase ranking in MRR.

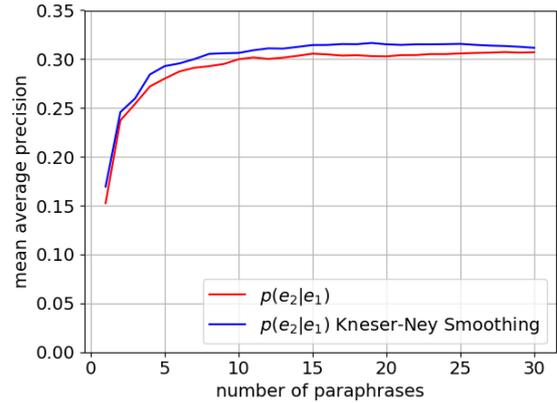

Figure 3: Effectiveness of smoothing of bilingual pivoting evaluated by paraphrase ranking in MAP.

(bilingual pivoting). Distributional similarity, as opposed to bilingual pivoting, is robust against noise associated with unrelated word pairs. Bilingual pivoting is robust against noise arising from antonym pairs, unlike distributional similarity. Therefore, $s_{lpmi}(e_1, e_2)$ can perform paraphrase acquisition robustly by compensating the disadvantages. Hereinafter, we refer to $s_{lpmi}(e_1, e_2)$ as MIPA, mutual information based paraphrase acquisition via bilingual pivoting.

4 Experiments

4.1 Settings

We used French-English parallel data⁴ from Europarl-v7 (Koehn, 2005) and GIZA++ (Och and Ney, 2003) (IBM model 4) to calculate the conditional paraphrase probability $p(e_2|e_1)$ and $p(e_1|e_2)$. We also used the English Gigaword 5th Edition⁵ and KenLM (Heafield, 2011) to calculate the word probability $p(e_1)$ and $p(e_2)$. For $\cos(e_1, e_2)$, we used the CBOW model⁶ of word2vec (Mikolov et al., 2013a). Finally, we acquired paraphrase candidates of 170,682,871 word pairs, excepting the paraphrase of itself ($e_1 = e_2$).

We employed the conditional paraphrase probability of bilingual pivoting given in Equation (1), the symmetric paraphrase score of PPDB given by Equation (3), and distributional similarity as baselines, and compared them with PMI shown in Equation (7) and the MIPA score given in Equation (11). Note that distributional similarity im-

plies that the paraphrase pairs acquired via bilingual pivoting were reranked by distributional similarity rather than by using the top-k distributionally similar words among all the vocabularies.

4.2 Evaluation Datasets and Metrics

For evaluation, we used two datasets included in Human Paraphrase Judgments⁷ published by Pavlick et al. (2015); hereafter, we call these datasets HPJ-Wikipedia and HPJ-PPDB, respectively.

First, Human Paraphrase Judgments includes a paraphrase list of 100 words or phrases randomly extracted from Wikipedia and processed using a five-step manual evaluation for each paraphrase pair (HPJ-Wikipedia). A correct paraphrase is a word that gained three or more evaluations in manual evaluation. We used this dataset to evaluate the acquired paraphrase pairs by MRR and MAP, following Pavlick et al. (2015). Furthermore, we evaluated the coverage of the top-k paraphrase pairs. Function words such as “as” have more than 50,000 types of paraphrase candidates, because they are sensitive to word alignment errors in bilingual pivoting. However, since many of these paraphrase candidates are word pairs that are not in fact paraphrases, we evaluated the coverage in terms of the extent to which they can reduce unnecessary candidates while preserving the correct paraphrases.

Second, Human Paraphrase Judgments also includes a five-step manual evaluation of 26,456 word pairs sampled from PPDB (Ganitkevitch et al., 2013) (HPJ-PPDB)

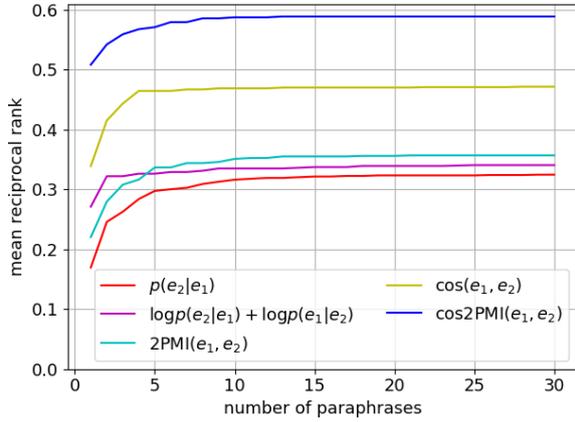

Figure 4: Paraphrase ranking in MRR.

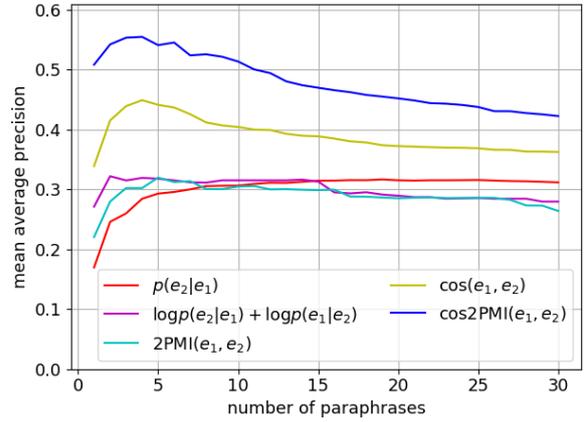

Figure 5: Paraphrase ranking in MAP.

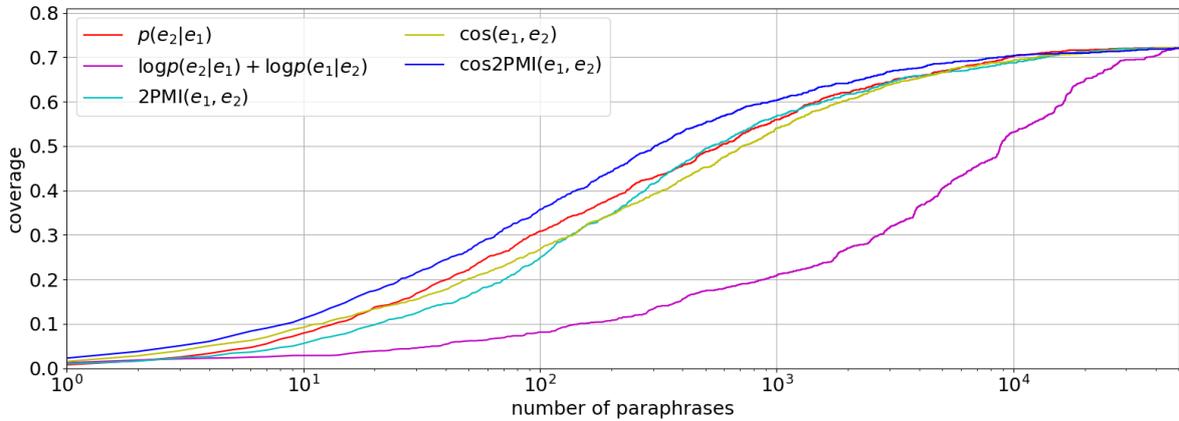

Figure 6: Coverage of the top-k paraphrase pairs.

together with the paraphrase list of 100 words. We used this dataset to evaluate the overall paraphrase ranking based on Spearman’s correlation coefficient, as in Pavlick et al. (2015).

4.3 Results

Figures 2 and 3 show the effectiveness of adopting Kneser-Ney smoothing for bilingual pivoting in terms of MRR and MAP on HPJ-Wikipedia. The horizontal axis of each graph represents the evaluation of the paraphrase up to the top-k of the paraphrase score. The results confirm that the ranking of paraphrases acquired via bilingual pivoting was improved by applying Kneser-Ney smoothing. In the rest of this study, we always applied Kneser-Ney smoothing to conditional paraphrase probability.

Figures 4 and 5 show the comparison of paraphrase rankings in MRR and MAP on HPJ-Wikipedia. The evaluation by MRR, shown in

Figure 4, demonstrates that the ranking performance of paraphrase pairs is improved by making bilingual pivoting symmetric. PMI slightly outperforms the baselines of bilingual pivoting below the top five. Furthermore, MIPA shows the highest performance, because reranking by distributional similarity greatly improves bilingual pivoting.

The evaluation using MAP, shown in Figure 5, also reinforced the same result, i.e., reranking by distribution similarity improved bilingual pivoting, and MIPA showed the highest performance.

Figure 6 shows the coverage of the top-ranked paraphrases on HPJ-Wikipedia. Despite the fact that the symmetric paraphrase score is better than the conditional paraphrase probability in the ranking performance of the top three in MRR and MAP, it shows a poor performance in terms of coverage. Although there is not a significant difference between MIPA and the other methods, MIPA was shown to outperform them.

Table 1: Paraphrase examples of *cultural*. Italicized words are the correct paraphrases.

Figures 7 and 8 show the scatter plots and Spearman’s correlation coefficient of each paraphrase score and manual evaluation (average value of five evaluators) on HPJ-PPDB. As in the previous experimental results, MIPA showed a high correlation. In particular, the noise generated by false positives at the upper left of the scatter plot can be reduced by combining PMI and distributional similarity.

5 Discussion

5.1 Qualitative Analysis

Table 1 shows examples of the top 10 in paraphrase rankings. In the paraphrase examples of *cultural*, conditional paraphrase probability does not score the correct paraphrase as top-ranked words. Although the symmetric paraphrase score ranked the correct paraphrase at the top, words other than the top words are less reliable, as shown by the previous experimental results. PMI is strongly influenced by low-frequency words, and many of the top-ranked words are singleton words in the bilingual corpus. MIPA, in contrast,

mitigates the problem of low-frequency bias, and many of the top-ranked words are correct paraphrases. Distributional similarity-based methods include relatively numerous correct paraphrases at the top, and the other top-ranked words are also strongly related to *cultural*. From the viewpoint of paraphrases, 3 of the top 10 words of the proposed method are incorrect, but these words may also be useful for applications such as learning word embeddings (Yu and Dredze, 2014) and semantic textual similarity (Sultan et al., 2015).

Table 2 shows correct examples of the paraphrase rankings. In the paraphrase examples of *labourers*, there were 20 correct paraphrases that received a rating of 3 or higher in manual evaluation. With respect to the conditional paraphrase probability and PMI, it is necessary to consider up to the 400th place to cover all correct paraphrases. However, distributional similarity-based methods have correct paraphrases of higher rank. In particular, MIPA was able to include 10 words of correct paraphrases in the top 20 words; that is, our method can obtain paraphrases with high coverage by using only the highly ranked paraphrases.

5.2 Quantitative Analysis

Next, we applied the acquired paraphrase pairs to the semantic textual similarity task and evaluated the extent to which the acquired paraphrases improve downstream applications. The semantic textual similarity task deals with calculating the semantic similarity between two sentences. In this study, we conducted the evaluation by applying Pearson’s correlation coefficient with a five-step manual evaluation using five datasets constructed by SemEval (Agirre et al., 2012, 2013, 2014, 2015, 2016). We applied the acquired paraphrase pairs to the unsupervised method of DLC@CU (Sultan et al., 2015), which achieved excellent results using PPDB in the semantic textual similarity task of SemEval-2015 (Agirre et al., 2015). DLS@CU performs word alignment (Sultan et al., 2014) using PPDB, and calculates sentence similarity according to the ratio of aligned words:

$$sts(s_1, s_2) = \frac{n_a(s_1) + n_a(s_2)}{n(s_1) + n(s_2)} \quad (12)$$

Here, $n(s)$ indicates the number of words in sentence s and $n_a(s)$ indicates the number of aligned words. Although DLS@CU targets all the paraphrases of PPDB, we used only the top 10 words of the paraphrase score for each target word and compared the performance of the paraphrase scores.

Table 3 shows the experimental results of the semantic textual similarity task. “ALL” is the weighted mean value of the Pearson’s correlation coefficient over the five datasets. MIPA achieved the highest performance on three out of the five datasets. In other words, the proposed method extracted paraphrase pairs useful for calculating sentence similarity at the top-rank.

5.3 Reranking PPDB 2.0

Finally, we reranked paraphrase pairs from a publicly available state-of-the-art paraphrase database.⁸ PPDB 2.0 (Pavlick et al., 2015) scores paraphrase pairs using supervised learning with

⁸<http://paraphrase.org/>

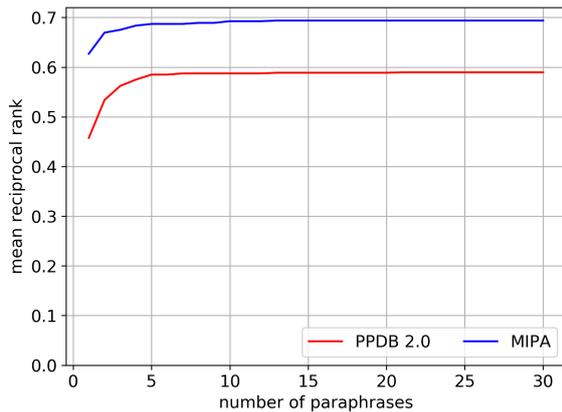

Figure 9: Reranking PPDB 2.0 in MRR.

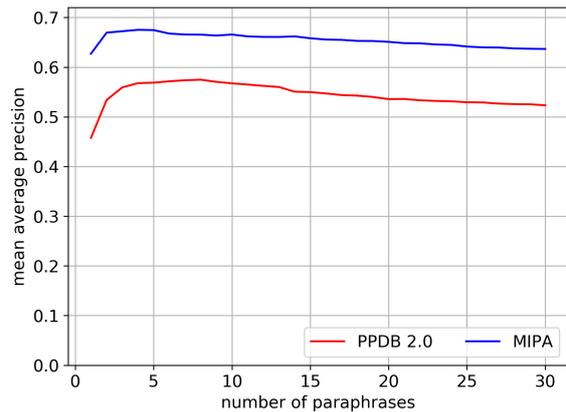

Figure 10: Reranking PPDB 2.0 in MAP.

26,455 labeled data and 209 features. We sorted the paraphrase pairs from PPDB 2.0 using the MIPA instead of the PPDB 2.0 score and used the same evaluation means as described in Section 4. Surprisingly, our unsupervised approach outperformed the paraphrase ranking performance of PPDB 2.0’s supervised approach in terms of MRR (Figure 9) and MAP (Figure 10).

6 Related Work

Levy and Goldberg (2014) explained a well-known representation learning method for word embeddings, the skip-gram with negative-sampling (SGNS) (Mikolov et al., 2013a,b), as a matrix factorization of a word-context co-occurrence matrix with shifted positive PMI. In this paper, we explained a well-known method for paraphrase acquisition, bilingual pivoting (Bannard and Callison-Burch, 2005; Ganitkevitch et al., 2013), as a (weighted) PMI.

Chan et al. (2011) reranked paraphrase pairs acquired via bilingual pivoting using distributional similarity. The main idea of reranking paraphrase pairs using information from a monolingual corpus is similar to ours, but Chan et al.’s method failed to acquire semantically similar paraphrases. We succeeded in acquiring semantically similar paraphrases because we effectively combined information from a bilingual corpus and a monolingual corpus by using weighted PMI.

In addition to English, paraphrase databases are constructed in many languages using bilingual pivoting (Bannard and Callison-Burch, 2005). Ganitkevitch and Callison-Burch (2014) constructed paraphrase databases⁸ in 23 languages, including European languages and Chinese.

Furthermore, Mizukami et al. (2014) constructed the Japanese version⁹. In this study, we improved bilingual pivoting using a monolingual corpus. Since large-scale monolingual corpora are easily available for many languages, our proposed method may improve paraphrase databases in each of these languages.

PPDB (Ganitkevitch et al., 2013) constructed by bilingual pivoting is used in many NLP applications, such as learning word embeddings (Yu and Dredze, 2014), semantic textual similarity (Sultan et al., 2015), machine translation (Mehdizadeh Seraj et al., 2015), sentence compression (Napoles et al., 2016), question answering (Sultan et al., 2016), and text simplification (Xu et al., 2016). Our proposed method may improve the performance of many of these NLP applications supported by PPDB.

7 Conclusion

We proposed a new approach for formalizing lexical paraphrasability based on weighted PMI and acquired paraphrase pairs using information from both a bilingual corpus and a monolingual corpus. Our proposed method, MIPA, uses bilingual pivoting weighted by distributional similarity to acquire paraphrase pairs robustly, as each of the methods complements the other. Experimental results using manually annotated datasets for lexical paraphrase showed that the proposed method outperformed bilingual pivoting and distributional similarity in terms of metrics such as MRR, MAP, coverage, and Spearman’s correlation. We also confirmed the effectiveness of the proposed method

⁹<http://ahclab.naist.jp/resource/jppdb/>

by conducting an extrinsic evaluation on a semantic textual similarity task. In addition to the semantic textual similarity task, we hope to improve the performance of many NLP applications based on the results of this study.

Abstract

Implicit semantic role labeling (iSRL) is the task of predicting the semantic roles of a predicate that do not appear as explicit arguments, but rather regard common sense knowledge or are mentioned earlier in the discourse. We introduce an approach to iSRL based on a predictive recurrent neural semantic frame model (PRNSFM) that uses a large unannotated corpus to learn the probability of a sequence of semantic arguments given a predicate. We leverage the sequence probabilities predicted by the PRNSFM to estimate selectional preferences for predicates and their arguments. On the NomBank iSRL test set, our approach improves state-of-the-art performance on implicit semantic role labeling with less reliance than prior work on manually constructed language resources.

1 Introduction

Semantic role labeling (SRL) has traditionally focused on semantic frames consisting of verbal or nominal predicates and *explicit arguments* that occur *within* the clause or sentence that contains the predicate. However, many predicates, especially nominal ones, may bear arguments that are left implicit because they regard common sense knowledge or because they are mentioned earlier in a discourse (Ruppenhofer et al., 2010; Gerber et al., 2009). These arguments, called *implicit arguments*, are resolved by another semantic task, implicit semantic role labeling (iSRL). Consider a NomBank (Meyers et al., 2004) annotation example:

[_{A0} *The network*] had been expected to have [_{NP} *losses*] [_{A1} *of \$20 million*] ... Those [_{NP} *losses*] may widen because of the short Series.

The predicate *loss* in the first sentence has two arguments annotated explicitly: A0, *the entity losing something*, and A1, *the thing lost*. Meanwhile, the other instance of the same predicate in the second sentence has no associated arguments. However, for a good reader, a reasonable interpretation of the second *loss* should be that it receives the same A0 and A1 as the first instance. These arguments are implicit to the second *loss*.

As an emerging task, implicit semantic role labeling faces a lack of resources. First, hand-crafted implicit role annotations for use as training data are seriously limited: SemEval 2010 Task 10 (Baker et al., 1998) provided FrameNet-style (Baker et al., 1998) annotations for a fairly large number of predicates but with few annotations per predicate, while Gerber and Chai (2010) provided PropBank-style (Palmer et al., 2005) data with many more annotations per predicate but covering just 10 predicates. Second, most existing iSRL systems depend on other systems (explicit semantic role labelers, named entity taggers, lexical resources, etc.), and as a result not only need iSRL annotations to train the iSRL system, but annotations or manually built resources for all of their sub-systems as well.

We propose an iSRL approach that addresses these challenges, requiring no manually annotated iSRL data and only a single sub-system, an explicit semantic role labeler. We introduce a predictive recurrent neural semantic frame model (PRNSFM), which can estimate the probability of a sequence of semantic arguments given a predicate, and can be trained on unannotated data drawn from the Wikipedia, Reuters, and Brown corpora, coupled with the predictions of the MATE (Björkelund et al., 2010) explicit semantic role labeler on these texts. The PRNSFM forms the foundation for our iSRL system, where we use its probability estimates over sequences of semantic arguments to predict *selectional preferences* for associating predicates with

their implicit semantic roles. Our PRNSFM-based iSRL model improves state-of-the-art performance, outperforming the only other system that depends on just an explicit semantic role labeler by 10 % F1, and achieving equal or better F1 score than several other models that require many more lexical resources.

Our work fits today’s interest in natural language understanding, which is hampered by the fact that content in a discourse is often not expressed explicitly because it was mentioned earlier or because it regards common sense or world knowledge that resides in the mind of the communicator or the audience. In contrast, humans easily combine relevant evidence to infer meaning, determine hidden meanings and make explicit what was left implicit in the text, using the *anticipatory power* of the brain that predicts or “imagines” circumstantial situations and outcomes of actions (Friston, 2010; Vernon, 2014) which makes language processing extremely effective and fast (Kurby and Zacks, 2015; Schacter and Madore, 2016). The neural semantic frame representations inferred by our PRNSFM take a first step towards encoding something like anticipatory power for natural language understanding systems.

The remainder of the paper is organized as follows: First, section 2 describes the related work. Second, section 3 proposes the predictive recurrent neural semantic frame model including the formal definition, architecture, and an algorithm to extract selectional preferences from the trained model. Third, in section 4, we introduce the application of our PRNSFM in implicit semantic role labeling. Fourth, the experimental results and discussions are presented in section 5. Finally, we conclude our work and suggest some future work in section 6.

2 Related work

Language Modeling Language models, from n-gram models to continuous space language models (Mikolov et al., 2013; Pennington et al., 2014), provide probability distributions over sequences of words and have shown their usefulness in many natural language processing tasks. However, to our knowledge, they have not yet been used to model semantic frames. Recently, Peng and Roth (2016) developed two distinct models that capture semantic frame chains and discourse information while abstracting over the specific mentions of predicates and entities, but these models focus on discourse

processing tasks, not semantic frame processing.

Semantic Role Labeling In unsupervised SRL, Woodsend and Lapata (2015) and Titov and Khoddam (2015) induce embeddings to represent a predicate and its arguments from unannotated texts, but in their approaches, the arguments are words only, not the semantic role labels, while in our models, both are considered.

Low-resource Implicit Semantic Role Labeling

Several approaches have attempted to address the lack of resources for training iSRL systems. Laparra and Rigau (2013) proposed an approach based on exploiting argument coherence over different instances of a predicate, which did not require any manual iSRL annotations but did require many other manually-constructed resources: an explicit SRL system, WordNet super-senses, a named entity tagger, and a manual categorization of SuperSenseTagger semantic classes. Roth and Frank (2015) generated additional training data for iSRL through comparable texts, but the resulting model performed below the previous state-of-the-art of Laparra and Rigau (2013). Schenk and Chiarcos (2016) proposed an approach to induce prototypical roles using distributed word representations, which required only an explicit SRL system and a large unannotated corpus, but their model performance was almost 10 points lower than the state-of-the-art of Laparra and Rigau (2013). Similar to Schenk and Chiarcos (2016), our model requires only an explicit SRL system and a large unannotated corpus, but we take a very different approach to leveraging these, and as a result improve state-of-the-art performance.

3 Predictive Recurrent Neural Semantic Frame Model

Our goal is to use unlabeled data to acquire selectional preferences that characterize how likely a phrase is to be an argument of a semantic frame. We rely on the fact that current explicit SRL systems achieve high performance on verbal predicates, and run a state-of-the-art explicit SRL system on unlabeled data. We then construct a predictive recurrent neural semantic frame model (PRNSFM) from these explicit frames and roles.

Our PRNSFM views semantic frames as a *sequence*: a predicate, followed by the arguments in their textual order, and terminated by a special EOS symbol. We draw predicates from PropBank

verbal semantic frames, and represent arguments with their nominal/pronominal heads. For example, *Michael Phelps swam at the Olympics* is represented as [swam:PRED, Phelps:A0, Olympics:AM-LOC, EOS], where the predicate is labeled PRED and the arguments *Phelps* and *Olympics* are labeled A0 and AM-LOC, respectively. Our PRNSFM’s task is thus to take a predicate and zero or more arguments, and predict the next argument in the sequence, or EOS if no more arguments will follow.

We choose to model semantic frames as a sequence (rather than, say, a bag of arguments) because in English, there are often fairly strict constraints on the order in which arguments of a verb may appear. A sequential model should thus be able to capture these constraints and use them to improve its probability estimates. Moreover, a sequential model has the ability to learn the interaction between arguments in the same semantic frame. For example, considering a swimming event, if *Phelps* is A0, then *Olympics* is more likely to be the AM-LOC than *lake*.

Formally, for each t^{th} argument of a semantic frame f , we denote its word (e.g., *Phelps*) as $w_{f,t}$, its semantic label (e.g., A0) as $l_{f,t}$, where $w \in \mathbf{V}$, the word vocabulary, and $l \in \mathbf{L} \cup [\text{PRED}]$, the set of semantic labels. We denote the predicate word and label, which are always at the 0^{th} position in the sequence, in the same way as arguments: $w_{f,0}$ and $l_{f,0}$. We denote the sequence $[w_{f,0}, w_{f,1}, \dots, w_{f,t-1}]$ as $w_{f,<t}$, and the sequence $[l_{f,0}, l_{f,1}, \dots, l_{f,t-1}]$ as $l_{f,<t}$. Our model aims to estimate the conditional probability of the occurrence of $w_{f,t}$ as semantic role $l_{f,t}$ given the preceding words and their labels:

$$P(w_{f,t}:l_{f,t}|w_{f,<t}:l_{f,<t})$$

We use a recurrent neural network to learn this probability distribution over sequences of semantic frame arguments. For a semantic frame f with N arguments, at each time step $0 \leq t \leq N$, given the input $w_{f,t}:l_{f,t}$, the model computes the distribution $P(w_{f,t+1}:l_{f,t+1}|w_{f,<t+1}:l_{f,<t+1})$ and predicts the next most likely argument (or EOS). During training, model parameters are optimized by minimizing prediction errors over all time steps.

We consider two versions of this model that differ in input (\mathbf{V}_{in}) and output (\mathbf{V}_{out}) vocabularies.

3.1 Model 1: Joint Embedding LSTM

We adopt the standard recurrent neural network language model (Mikolov et al., 2010), which is a

natural architecture to deal with a sequence prediction problem.

Model 1 consists of three layers (see Figure 1): an embedding layer that learns vector representations for input values; a long short-term memory (LSTM) layer that controls the sequential information receiving the vector representation as input; and a softmax layer to predict the next argument using the output of the LSTM layer as input.

This model treats the word and semantic label as a single unit in both input and output layers. The model, therefore, learns joint embeddings for the word and its corresponding semantic label. For example, if we take “Michael Phelps swam at the Olympics” as training data, the three input values would be *swam:PRED*, *Phelps:A0* and *Olympics:AM-LOC*, and the three expected outputs would be *Phelps:A0*, *Olympics:AM-LOC*, EOS. Since each word:label is considered as a single unit, the embedding layer will learn three vector representations, one for *swam:PRED*, one for *Phelps:A0*, and one for *Olympics:AM-LOC*. As can be seen, an important difference between our problem and the traditional language model is that we have to deal with two different types of information – word and label. By concatenating word and label, the standard recurrent neural network model can be applied directly to our data.

The detail of Model 1 is as following:

Embedding Layer is a matrix of size $|\mathbf{V}_{\text{in}}| \times d$ that maps each unit of input into an d -dimensional vector. The matrix is initialized randomly and updated during network training.

LSTM Layer consists of m standard LSTM units which take as input the output of the embedding layer, x_t , and produce an output h_t by updating at every time step $0 \leq t \leq T$:

$$\begin{aligned} i_t &= \text{sigmoid}(W_i x_t + U_i h_{t-1} + b_i) \\ \hat{C}_t &= \text{tanh}(W_c x_t + U_c h_{t-1} + b_c) \\ f_t &= \text{sigmoid}(W_f x_t + U_f h_{t-1} + b_f) \\ C_t &= i_t * \hat{C}_t + f_t * C_{t-1} \\ o_t &= \text{sigmoid}(W_o x_t + U_o h_{t-1} + b_o) \\ h_t &= o_t * \text{tanh}(C_t) \end{aligned}$$

where W_i, W_c, W_f, W_o are weight matrices of size $d \times m$; U_i, U_c, U_f, U_o are weight matrices of size $m \times m$; b_i, b_c, b_f, b_o are bias vectors of size m ; and $*$ is element-wise multiplication. As per the standard LSTM formulation, $i_t, \hat{C}_t, f_t, C_t, o_t$ represent

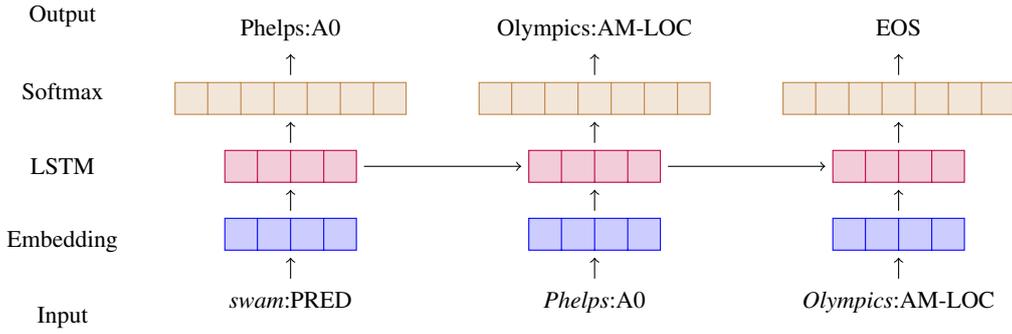

Figure 1: Model 1 – Joint Embedding LSTM

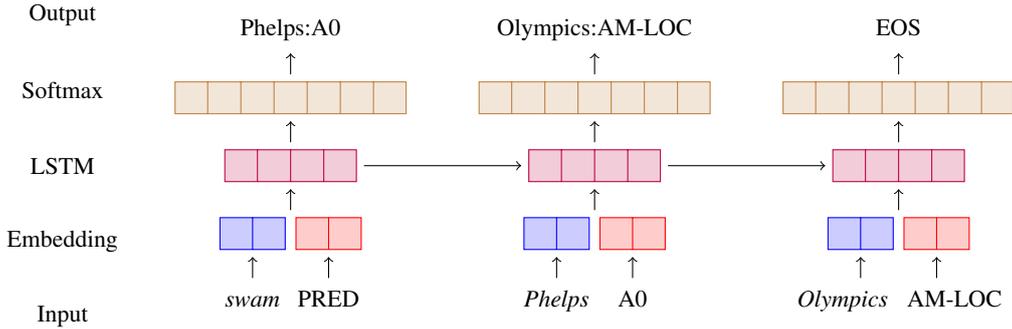

Figure 2: Model 2 – Separate Embedding LSTM

the input gate, states of the memory cells, activation of the memory cells’ forget gates, memory cells’ new state, and output gates’ values, respectively.

Softmax Layer computes the probability distribution of the next argument given the preceding arguments at time step t :

$$P(w_{f,t+1}:l_{f,t+1}|w_{f,<t+1}:l_{f,<t+1}) = \text{softmax}(h_t W + b) \quad (1)$$

where W is a weight matrix of size $m \times |\mathbf{V}_{\text{out}}|$, and b is a bias vector of size $|\mathbf{V}_{\text{out}}|$. The predicted next argument is:

$$\underset{w_{f,t+1}:l_{f,t+1}}{\text{argmax}} P(w_{f,t+1}:l_{f,t+1}|w_{f,<t+1}:l_{f,<t+1})$$

The network is trained using the negative log-likelihood loss function.

3.2 Model 2: Separate Embedding LSTM

Model 2 shares the same basic structure as Model 1, but considers the word and the semantic label as two different units in the input layer. As shown in Figure 2, we use two different embedding layers, one for word values and one for semantic labels, and the two embedding vectors are concatenated before being passed to the LSTM layer. The LSTM

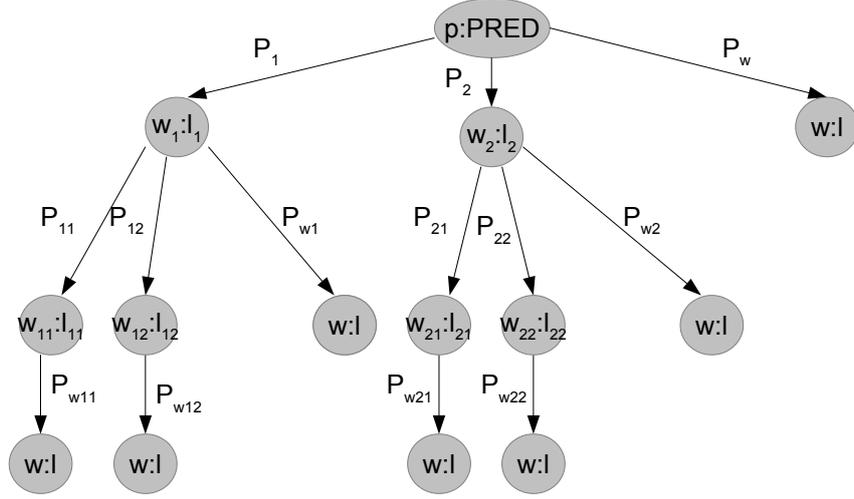

and softmax layers are then the same as in Model 1. For example, if we take “Michael Phelps swam at the Olympics” as training data, the three input words would be *swam*, *Phelps*, and *Olympics*, the three input roles would be PRED, A0 and AM-LOC, and the three expected outputs would be *Phelps:A0*, *Olympics:AM-LOC*, EOS. A total of six different vector representations will be learned: a word embedding for each of *swam*, *Phelps*, and *Olympics*, and a label embedding for each of PRED, A0 and AM-LOC.

In this model, the embedding layer for labels is initialized randomly (as in Model 1), but the embedding layer for word values is initialized with publicly available word embeddings that have been trained on a large dataset (Mikolov et al., 2013).

As compared to the joint-embedding Model 1, the separate-embedding Model 2 gives up a little power to represent the interaction between words and labels, but has a less sparse input vocabulary and gains the ability to incorporate pre-trained word embeddings.

3.3 Selectional Preferences

While the PRNSFM can predict the probability of an argument given the predicate and the preceding arguments, $P(w_{f,t}:l_{f,t}|w_{f,<t}:l_{f,<t})$, an iSRL

Time 0: $S_0 = [[p:PRED]]$

Time 1: $S_1 = [[p:PRED, w_1:l_1], [p:PRED, w_2:l_2]]$

Time 2: $S_2 = [[p:PRED, w_1:l_1, w_{11}:l_{11}], [p:PRED, w_1:l_1, w_{12}:l_{12}], [p:PRED, w_2:l_2, w_{21}:l_{21}], [p:PRED, w_2:l_2, w_{22}:l_{22}]]$

$$P(w:l|p) \sim P_w + P_{w_1} P_1 + P_{w_2} P_2 + P_{w_{11}} P_{11} P_1 + P_{w_{12}} P_{12} P_1 + P_{w_{21}} P_{21} P_2 + P_{w_{22}} P_{22} P_2$$

Figure 3: Selectional Preference Inference example: $k=2, T=3$. The possible sequences are represented as a tree. Each arrow label is the probability of the target node to be predicted given the path from the tree root to the parent of the target node.

system needs a *selectional preference* score representing the probability of a word w being the l argument of predicate p , $P(w:l|p:PRED)$. Thus, to convert our PRNSFM probabilities to selectional preferences, we need to marginalize over the possible argument sequences.

We approximate this marginalization by constructing a tree where the root is the predicate, p , the branches are likely sequences of arguments, and the leaves are the word and label for which we need to estimate a probability, $w:l$. Formally, we define this tree of possible sequences as:

$$S_t = \begin{cases} \{[p:PRED]\} & \text{if } t = 0 \\ \{[q, w_t:l_t] : q \in S_{t-1}, \\ \quad w_t:l_t \in \mathbf{argmax}^k(q)\} & \text{if } 0 < t < T \\ \{[q, w:l] : q \in S_{t-1}\} & \text{if } t = T \end{cases}$$

where $w_{f,0}:l_{f,0} = p:PRED$; k and T are thresholds; and $\mathbf{argmax}^k(q)$ is the k word:label pairs that have the highest probability of being the next argument given the sequence q according to the PRNSFM.

We then estimate $P(w:l|p:PRED)$ as the sum of the probabilities of all the sequences encoded in

the tree. Formally:

$$P(w:l|p:PRED) \approx \sum_{0 \leq t \leq T} P(w:l|w_{f,<t+1}:l_{f,<t+1}) \\ \approx \sum_{0 \leq t \leq T} \sum_{q \in S_t} P(w:l|q) \times P(q)$$

where the probability of an argument sequence q is the product of the PRNSFM's estimates for each step in the sequence:

$$P(q) = P(w_t:l_t|w_{t-1}:l_{t-1}, \dots, p:PRED) \\ \times P(w_{t-1}:l_{t-1}|w_{t-2}:l_{t-2}, \dots, p:PRED) \\ \times \dots \times P(w_1:l_1|p:PRED) \quad (2)$$

An example of the calculation of $P(w:l|p:PRED)$ is shown in Figure 3.

Intuitively, the tree enumerates all possible argument sequences that start with the predicate, have zero or more intervening arguments, and end with the word and label of interest, $w:l$. The probability of $w:l$ given the predicate is the sum of the probabilities of all branches in this tree, i.e., of all possible sequences that end with $w:l$. In reality, we do not have the computational power to explore

all possible sequences, so we must limit the tree somehow. Thus, we only ask the PRNSFM for its top k predictions at each branch point, and we only explore sequences with a maximum length of T .

4 Implicit Semantic Role Labeling

As you will recall from previous sections, implicit semantic role labeling is the task of identifying discourse-level arguments of a semantic frame, which are missed by standard semantic role labeling, which operates on individual sentences. For instance, in “This house has a new owner. The sale was finalized 10 days ago.”, the semantic frame evoked by “sale” in the second sentence should receive “the house” as an implicit A1 semantic role. Humans easily resolve the object of the sale given the candidates (in our example: “house” and “owner”), but for a machine this is more difficult unless it has knowledge on what the likely objects of a sale are. This kind of knowledge of selectional preferences can be extracted from our trained PRNSFM.

The previous section described how to extract selectional preferences from our PRNSFM. However, that model is trained on verbal predicates, and the test data that we use (Gerber and Chai, 2010) contains nominal predicates. Thus, for each triple of a nominal predicate np , a word candidate w , and a label l , we approximate the selectional preference score of w being the implicit argument role l of np as:

$$P(w:l|np) = \max_{p \in V(np)} P(w:l|p:\text{PRED})$$

where $P(w:l|p)$ is the selectional preference score described in Section 3.3, and $V(np)$ is set of verbal forms of np . Here, we use the NomBank lexicon to get verbs associated with each nominal predicate, and then find instances of those verbs in the explicit SRL training data. For example, for the noun *funds*, $V(\textit{funds}) = \{\textit{funds}, \textit{fund}, \textit{funding}, \textit{funded}\}$.

We apply selectional preferences to iSRL following (Laparra and Rigau, 2013). For each nominal predicate np and implicit label l , the current and previous two sentences are designated the *context window*. Each sentence in the context window is annotated with the explicit SRL system. If any instances of np or $V(np)$ in the text have an explicit argument of type l , we deterministically predict the closest such argument as the implicit l argument of np . Otherwise, we run the PRNSFM over each word in the context window, and select the

word with the highest selectional preference score above a threshold s . If all the candidates’ scores are less than s , the system leaves the missing argument unfilled. We optimized this threshold on the development data, resulting in $s = 0.0003$.

As in Laparra and Rigau (2013), we apply a *sentence recency factor* to emphasize recent candidates. The selectional preference score x is updated as $x' = x - z + z \times \alpha^d$ where d is the sentence distance, and α and z are parameters. We set $z = 0.00005$ based on the development set and set $\alpha = 0.5$ as in (Laparra and Rigau, 2013).

5 Experiments

We evaluate the two PRNSFM models on the iSRL task. The tools, resources, and settings we used are as follows:

Semantic Role Labeling We used the full pipeline from MATE (<https://code.google.com/archive/p/mate-tools/>) (Björkelund et al., 2010) as the explicit SRL system, retraining it on just the CoNLL 2009 training portion.

Unannotated Data The unannotated data used in the experiments was drawn from Wikipedia (<http://corpus.byu.edu/wiki/>), Reuters (<http://about.reuters.com/researchandstandards/corpus/>), and Brown (<https://catalog.ldc.upenn.edu/ldc99t42>).

Dataset for PRNSFM The first 15 million short and medium (less than 100 words) sentences from the unannotated data (described above) were annotated automatically by the explicit SRL system. The obtained annotations were then used together with the gold standard CoNLL 2009 SRL training data to train the PRNSFM.

Neural network training and inference Parameters were selected using the CoNLL 2009 development set. We set the dimensions of word and label embeddings in the PRNSFM to 50 and 16, respectively. The hidden sizes of LSTM layers are the same as their input sizes. Word embedding layers are initialized by Skip-gram embeddings learned by training the word2vec tool (Mikolov et al., 2013) on the unannotated data. Our models were trained for 120 epochs using the AdaDelta optimization algorithm (Zeiler, 2012). For fast selectional preference computing, we set $k = 1$ and $T = 4$ ¹.

¹We selected relatively small values for the parameters to reduce the training and prediction time. We tried some larger values of the parameters on a small dataset, but found that the

Evaluation We follow the evaluation setting in Gerber and Chai (2010); Laparra and Rigau (2013); Schenk and Chiarcos (2016)²: the method is evaluated on the evaluation portion of the nominal iSRL data by Dice coefficient metrics. For each missing argument position of a predicate instance, the system is required to either (1) identify a single constituent that fills the missing argument position or (2) make no prediction and leave the missing argument position unfilled. To give partial credit for inexact argument boundaries, predictions are scored by using the Dice coefficient, which is defined as follows:

$$Dice(predicted, true) = \frac{2 |predicted \cap true|}{|predicted| + |true|}$$

Predicted contains the tokens that the model has identified as the filler of the implicit argument position. *True* is the set of tokens from a single annotated constituent that truly fill the missing argument position. The model’s prediction receives a score equal to the maximum Dice overlap across any of the annotated fillers (AF)³:

$$Score(predicted) = \max_{true \in AF} Dice(predicted, true)$$

Precision is equal to the summed prediction scores divided by the number of argument positions filled by the model. Recall is equal to the summed prediction scores divided by the number of argument positions filled in the annotated data.

5.1 Experimental Setup

In the **baseline mode**, instead of using the PRNSFM, we only use the deterministic prediction by the explicit SRL system. We refer to this mode as *Baseline* in Table 1.

In the **main mode**, the joint embedding LSTM model (Model 1) and the separate embedding LSTM model (Model 2) were trained on the same dataset which is a combination of the automatic SRL annotations and the gold standard CoNLL

small values reported in the article achieved similar results with faster processing times.

² Following Schenk and Chiarcos (2016), we do not perform the alternative evaluation of Gerber and Chai (2012) that evaluates systems on the iSRL training set, since the iSRL training set overlaps with the CoNLL 2009 explicit semantic role training set on which MATE is trained.

³For iSRL, one implicit role may receive more than one annotated filler across a coreference chain in the discourse.

2009 training data as described in the previous section. We denote this mode as *gold CoNLL 2009 + unlabeled* in Table 1.

To evaluate how well the system acquires knowledge from unlabeled data, we also train the PRNSFM only on the gold standard CoNLL 2009 training data. We denote this mode as *CoNLL 2009* in Table 1.

In order to compare the performance of our sequential model to a non-sequential model, we train a skip-gram neural language model on the same unlabeled and labeled data as the PRNSFM in the main mode. The skip-gram model treats the predicates and arguments as a bag of labeled words rather than a sequence. The $P(w:l|p)$ is computed at the output layer of the skip-gram model by considering $w:l$ as the context of p . We denote this mode as *Skip-gram* in Table 1.

5.2 Results and Discussion

Table 1 shows the prior state-of-the-art and the performance of the baseline, skip-gram and our PRNSFM-based methods.

Our Model 2 achieves the highest precision and F1 score. This is notable because the first two models require many more language resources than just an explicit SRL system: Gerber and Chai (2010) use WordNet and manually annotated iSRL data, while Laparra and Rigau (2013) use WordNet, named entity annotations, and manual semantic category mappings. Schenk and Chiarcos (2016), like our approach, use only an explicit SRL system, but both our models strongly outperform their results. We assume that the difference here is caused by our proposed neural semantic frame model (PRNSFM). Schenk and Chiarcos (2016) measure the selectional preference of a predicate and a role as a cosine between a standard word2vec embedding for the candidate word, and the average of all word2vec embeddings for all words that appear in that role. Our algorithms are very different: we take a language modeling approach and leverage the sequence of semantic roles, we learn custom word/role embeddings tuned for SRL, and then marginalize over many possible argument sequences. We assume that the learned PRNSFM representations are better informed about semantic frames than simple word embeddings, which only capture knowledge of contextual words.

Table 1 also shows that training on large unlabeled data results in a marked improvement com-

Method	PRNSFM training data	iSRL data	SRL system	WordNet	NER system	P	R	F1
Gerber and Chai (2010)		✓	✓	✓		44.5	40.4	42.3
Laparra and Rigau (2013)			✓	✓	✓	47.9	43.8	45.8
Schenk and Chiarcos (2016)			✓			33.5	39.2	36.1
Baseline			✓			75.3	17.2	28.0
Skip-gram	gold CoNLL 2009 + unlabeled		✓			26.3	32.3	29.0

Table 1: Implicit role labeling evaluation.

pared to training on only the CoNLL 2009 labeled data, providing evidence that the models have acquired linguistic knowledge from the unlabeled data. Although the automatically annotated data used to train the PRNSFM can be noisy, using a large amount of data has smoothed out the noise.

Moreover, the better performance of our models over the standard skip-gram neural language model proves the effectiveness of modeling semantic frames as sequential data. The intuition here is that explicit semantic arguments have typical orderings in which they occur, so a sequential model should be a good fit for this problem. Modeling this sequential aspect of the problem is effective, but requires us to marginalize out positional information to compute selectional preferences, since implicit semantic arguments can occur anywhere in the discourse and do not have a typical position.

Among our two models, Model 2, which learns separate vector representations for words and semantic roles, is better than Model 1, which learns a single vector representation of each (word, semantic role) pair. The separate representation of words and roles means that Model 2 can share information across multiple occurrences of a word even if the semantic roles of that word are different, and this model can use publicly available embeddings pre-trained from even larger unannotated corpora when initializing its embeddings.

Gerber and Chai (2012) report an inter-annotator agreement of 64.3% using Cohen’s kappa measure on the annotated NomBank-based iSRL data. This value is borderline between low and moderate agreement indicating the sheer complexity of the

Predicate	Baseline	2010	2013	2016	2017
sale	36.2	44.2	40.3	37.2	52.8
price	15.4	34.2	53.3	27.3	29.0
investor	9.8	38.4	41.2	33.9	43.1

Table 2: A comparison on F1 scores (%). 2010: (Gerber and Chai, 2010), 2013: (Laparra and Rigau, 2013), 2016: Best model from (Schenk and Chiarcos, 2016), 2017: Our best model (Model 2).

annotation task, and explaining the relatively low performance of the iSRL systems.

In Table 2, we compare the F1 scores over all the ten predicates of our Model 2 to other state-of-the-art systems⁴. Our system obtains relatively high scores (> 50%) on three predicates including “sale”, “plan” and “loss”. These three are the most frequent predicates (among the 10 defined in the nominal iSRL dataset) in the CoNLL 2009 training data – they occur 1016, 318 and 275 times in verbal forms, respectively. In contrast, irregular predicates such as “bid” or “loan” usually have low performance. This is possibly caused by the de-

⁴As an overly conservative estimate, we take a t-test over the 10 predicate-level F1 scores as can be seen in Table 2. Comparing against Model 2, this yields p=0.28 for Gerber and Chai (2010), p=0.46 for Laparra and Rigau (2013), and most importantly p=0.058 for Schenk and Chiarcos (2016).

pendence of our PRNSFM on the performance of the explicit semantic role labeling system on verbal predicates.

It is important to consider how iSRL can be extended beyond the 10 annotated predicates of Gerber and Chai (2010). Our models do not require any handcrafted iSRL annotations for training, and thus can be applied to all predicates observed in large unannotated data on which they are trained.

However, as other work in iSRL, our approach still relies on a resource-heavy SRL system to learn selectional preferences. It would be interesting to investigate in further studies whether this SRL system can be replaced by a low-resource system (Collobert et al., 2011; Connor et al., 2012).

6 Conclusion and Future Work

We have presented recurrent neural semantic frame models for learning probability distributions over semantic argument sequences. By modeling selectional preferences from these probability distributions, we have improved state-of-the-art performance on the NomBank iSRL task while using fewer language resources. In the future, we believe that our semantic frame models are valuable in many language processing tasks that require discourse-level understanding of language, such as summarization, question answering and machine translation.

Abstract

We define a novel textual entailment task that requires inference over multiple premise sentences. We present a new dataset for this task that minimizes trivial lexical inferences, emphasizes knowledge of everyday events, and presents a more challenging setting for textual entailment. We evaluate several strong neural baselines and analyze how the multiple premise task differs from standard textual entailment.

1 Introduction

Standard textual entailment recognition is concerned with deciding whether one statement (the hypothesis) follows from another statement (the premise). However, in some situations, multiple independent descriptions of the same event are available, e.g. multiple news articles describing the same story, social media posts by different people about a single event, or multiple witness reports for a crime. In these cases, we want to use multiple independent reports to infer what really happened.

We therefore introduce a variant of the standard textual entailment task in which the premise text consists of multiple independently written sentences, all describing the same scene (see examples in Figure 1). The task is to decide whether the hypothesis sentence 1) can be used to describe the same scene (entailment), 2) cannot be used to describe the same scene (contradiction), or 3) may or may not describe the same scene (neutral). The main challenge is to infer what happened in the scene from the multiple premise statements, in some cases aggregating information across multiple sentences into a coherent whole.

Premises:

1. Two girls sitting down and looking at a book.
2. A couple laughs together as they read a book on a train.
3. Two travelers on a train or bus reading a book together.
4. A woman wearing glasses and a brown beanie next to a girl with long brown hair holding a book.

Hypothesis:

Women smiling. \Rightarrow ENTAILMENT

Premises:

1. Three men are working construction on top of a building.
2. Three male construction workers on a roof working in the sun.
3. One man is shirtless while the other two men work on construction.
4. Two construction workers working on infrastructure, while one worker takes a break.

Hypothesis:

A man smoking a cigarette. \Rightarrow NEUTRAL

Premises:

1. A group of individuals performed in front of a seated crowd.
2. Woman standing in front of group with black folders in hand.
3. A group of women with black binders stand in front of a group of people.
4. A group of people are standing at the front of the room, preparing to sing.

Hypothesis:

A group having a meeting. \Rightarrow CONTRADICTION

Figure 1: The Multiple Premise Entailment Task

Similar to the SICK and SNLI datasets (Marelli et al., 2014; Bowman et al., 2015), each premise sentence in our data is a single sentence describing everyday events, rather than news paragraphs as in the RTE datasets (Dagan et al., 2006), which require named entity recognition and coreference resolution. Instead of soliciting humans to write new hypotheses, as SNLI did, we use simplified versions of existing image captions, and use a word overlap filter and the structure of the denotation graph of Young et al. (2014) to minimize the presence of trivial lexical relationships.

2 Related Standard Entailment Tasks

In the following datasets, premises are single sentences drawn from image or video caption data

that describe concrete, everyday activities.

The **SICK** dataset (Marelli et al., 2014) consists of 10K sentence pairs. The premise sentences come from the FLICKR8K image caption corpus (Rashtchian et al., 2010) and the MSR Video Paraphrase Corpus (Agirre et al., 2012), while the hypotheses were automatically generated. This process introduced some errors (e.g. “A motorcycle is riding standing up on the seat of the vehicle”) and an uneven distribution of phenomena across entailment classes that is easy to exploit (e.g. negation (Lai and Hockenmaier, 2014)).

The **SNLI** dataset (Bowman et al., 2015) contains over 570K sentence pairs. The premises come from the FLICKR30K image caption corpus (Young et al., 2014) and VisualGenome (Krishna et al., 2016). The hypotheses were written by Mechanical Turk workers who were given the premise and asked to write one definitely true sentence, one possibly true sentence, and one definitely false sentence. The task design prompted workers to write hypotheses that frequently parallel the premise in structure and vocabulary, and therefore the semantic relationships between premise and hypothesis are often limited to synonym/hyponym lexical substitution, replacement of short phrases, or exact word matching.

3 The Multiple Premise Entailment Task

In this paper, we propose a variant of entailment where each hypothesis sentence is paired with an unordered set of independently written premise sentences that describe the same event. The premises may contain overlapping information, but are typically not paraphrases. The majority of our dataset requires consideration of multiple premises, including aggregation of information from multiple sentences.

This Multiple Premise Entailment (MPE) task is inspired by the Approximate Textual Entailment (ATE) task of Young et al. (2014). Each item in the ATE dataset consists of a premise set of four captions from FLICKR30K, and a short phrase as the hypothesis. The ATE data was created automatically, under the assumption that items are positive (approximately entailing) if the hypothesis comes from the same image as the four premises, and negative otherwise. However, Young et al. found that this assumption was only true for just over half of the positive items. For MPE, we also start with four FLICKR30K captions as the premises and a

related/unrelated sentence as the hypothesis, but we restrict the hypothesis to have low word overlap with the premises, and we collect human judgments to label the items as entailing, contradictory, or neutral.

4 The MPE Dataset

The MPE dataset (Figure 1) contains 10,000 items (8,000 training, 1,000 development and 1,000 test), each consisting of four premise sentences (captions from the same FLICKR30K image), one hypothesis sentence (a simplified FLICKR30K caption), and one label (entailment, neutral, or contradiction) that indicates the relationship between the set of four premises and the hypothesis. This label is based on a consensus of five crowdsourced judgments. To analyze the difference between multiple premise and single premise entailment (Section 5.2), we also collected pair label annotations for each individual premise-hypothesis pair in the development data. This section describes how we selected the premise and hypothesis sentences, and how we labeled the items via crowdsourcing.

4.1 Generating the Items

Hypothesis simplification The four premise sentences of each MPE item consist of four original FLICKR30K captions from the same image. Since complete captions are too specific and are likely to introduce new details that are not entailed by the premises, the hypotheses sentences are simplified versions of FLICKR30K captions. Each hypothesis sentence is either a simplified variant of the fifth caption of the same image as the premises, or a simplified variant of one of the captions of a random, unrelated image.

Our simplification process relies on the denotation graph of Young et al. (2014), a subsumption hierarchy over phrases, constructed from the captions in FLICKR30K. They define a set of normalization and reduction rules (e.g. lemmatization, dropping modifiers and prepositional phrases, replacing nouns with their hypernyms, extracting noun phrases) to transform the original captions into shorter, more generic phrases that are still true descriptions of the original image.

To simplify a hypothesis caption, we consider all sentence nodes in the denotation graph that are ancestors (more generic versions) of this caption, but exclude nodes that are also ancestors of

any of the premises. This ensures that the simplified hypothesis cannot be trivially obtained from a premise via the same automatic simplification procedure. Therefore, we avoid some obvious semantic relationships between premises and hypothesis, such as hypernym replacement, dropping modifiers or PPs, etc.

Limiting lexical overlap Given the set of simplified, restricted hypotheses, we further restrict the pool of potential items to contain only pairings where the hypothesis has a word overlap ≤ 0.5 with the premise set. We compute word overlap as the fraction of hypothesis tokens that appear in at least one premise (after stopword removal). This eliminates trivial cases of entailment where the hypothesis is simply a subset of the premise text. Table 1 shows that the mean word overlap for our training data is much lower than SNLI.

Data	SNLI		MPE	
	full	lemma	full	lemma
All	0.44 \pm 0.29	0.48 \pm 0.29	0.28 \pm 0.22	0.33 \pm 0.20
E	0.59 \pm 0.31	0.64 \pm 0.30	0.34 \pm 0.21	0.38 \pm 0.19
N	0.41 \pm 0.24	0.45 \pm 0.24	0.28 \pm 0.21	0.33 \pm 0.19
C	0.33 \pm 0.25	0.36 \pm 0.25	0.23 \pm 0.22	0.30 \pm 0.21

Table 1: Mean word overlap for full training data and each label, original and lemmatized sentences. MPE has much lower word overlap than SNLI.

Data selection From this constrained pool of premises-hypothesis pairings, we randomly sampled 8000 items from the FLICKR30K training split for our training data. For test and development data, we sample 1000 items from FLICKR30K test and 1000 from dev. The hypotheses in the training data must be associated with at least two captions in the FLICKR30K train split, while the hypotheses in dev/test must be associated with at least two captions in the union of the training and dev/test, and with at least one caption in dev/test alone. Since the test and dev splits of FLICKR30K are smaller than the training split, this threshold selects hypotheses that are rare enough to be interesting and frequent enough to be reasonable sentences.

4.2 Assigning Entailment Labels

Crowdsourcing procedure For each item, we solicited five responses from Crowdfunder and Amazon Mechanical Turk as to whether the hypothesis was *entailed*, *contradictory*, or *neither*

given a set of four premises. Instructions are shown in Table 2. We provided labeled examples to illustrate the kinds of assumptions we expected.

Entailment labels We assume three labels (entailment, neutral, contradiction). For entailment, we deliberately asked annotators to judge whether the hypothesis could *very probably* describe the same scene as the premises, rather than specifying that the hypothesis must *definitely* be true, as Bowman et al. (2015) did for SNLI. Our instructions align with the standard definition of textual entailment: “T entails H if humans reading T would typically infer that H is most likely true” (Dagan et al., 2013). We are not only interested in what is logically required for a hypothesis to be true, but also in what human readers assume is true, given their own world knowledge.

Final label assignment Of the 10,000 items for which we collected full label annotations, 90% had a majority label based on the five judgments, including 16% with a 3-2 split between entailment and contradiction. The remaining 10% had a 2-2-1 split across the three classes. We manually adjudicated the latter two cases. As a result, 82% of the final labels in the dataset correspond to a majority vote over the judgments (the remaining 18% differ due to our manual correction). The released dataset contains both our final labels and the crowdsourced judgments for all items.

Image IDs Premises in our dataset have corresponding image IDs from FLICKR30K. We are interested in the information present in linguistic descriptions of a scene, so our labels reflect the textual entailment relationship between the premise text and the hypothesis. Future work could apply multi-modal representations to this task, with the caveat that the image would likely resolve many neutral items to either entailment or contradiction.

5 Data Analysis

5.1 Statistics

The dataset contains 8000 training items, 1000 development items, and 1000 test items. Table 3 shows overall type and token counts and sentence lengths as well as the label distribution.

The mean annotator agreement, i.e. the fraction of annotators who agreed with the final label, is 0.70 for the full dataset, or 0.82 for the entailment

Instructions:

We will show you four caption sentences that describe the same scene, and one proposed sentence. Your task is to decide whether or not the scene described by the four captions can also be described by the proposed sentence.

The four captions were written by four different people. All four people were shown the same image, and then wrote a sentence describing the scene in this image. Therefore, there may be slight disagreements among the captions. The images are photographs from Flickr that show everyday scenes, activities, and events. You will not be given the image that the caption writers saw.

Process:

Read the four caption sentences and then read the proposed sentence.

Choose 1 of 3 possible responses to the question

Can the scene described by the four captions also be described by the proposed sentence?

Yes: The scene described by the captions can definitely (or very probably) be described by the proposed sentence. The proposed sentence may leave out details that are mentioned in the captions. If the proposed sentence describes something that is not mentioned in the captions, it is probably safe to assume the extra information is true, given what you know from the captions. If there are disagreements among the captions about the details of the scene, the proposed sentence is consistent with at least one caption.

Unknown: There is not enough information to decide whether or not the scene described by the captions can be described by the proposed sentence. There may be scenes that can be described by the proposed sentence and the captions, but you don't know whether this is the case here.

No: The scene described by the captions can probably not be described by the proposed sentence. The proposed sentence and the captions either contradict each other or describe what appear to be two completely separate events.

Table 2: The annotation instructions we provided to Crowdfunder and Mechanical Turk annotators.

	SNLI	MPE
#Lexical types	36,616	9,254
#Lexical tokens	12 million	468,524
Mean premise length	14.0 ± 6.0	53.2 ± 12.8
Mean hypothesis length	8.3 ± 3.2	5.3 ± 1.8
Label distribution		
Entailment	33.3%	32.3%
Neutral	33.3%	26.3%
Contradiction	33.3%	41.6%

Table 3: Type and token counts, sentence lengths, and label distributions for training data.

class, 0.42 for neutral, and 0.78 for contradiction. That is, on average, four of the five crowdsourced judgments agree with the final label for the entailment and contradiction items, whereas for the neutral items, only an average of two of the five original annotators assigned the neutral label, and the other three were split between contradiction and entailment.

5.2 MPE vs. Standard Entailment

Multiple premise entailment (MPE) differs from standard single premise entailment (SPE) in that each premise consists of four independently written sentences about the same scene. To understand how MPE differs from SPE, we used crowdsourcing to collect pairwise single-premise entailment labels for each individual premise-hypothesis pair in the development data. Each consensus label is based on three judgments.

In Table 4, we compare the full MPE entailment labels (bold \Rightarrow **E**, \Rightarrow **N**, \Rightarrow **C**), to the four pair

SPE labels (E, N, C). The number of SPE labels that agree with the MPE label yields the five categories in Table 4, ranging from the most difficult case where none of the SPE labels agree with the MPE label (21.8% of the data) to the simplest case where all four SPE labels agree with the MPE label (9.8% of the data).

We observe that a simple majority voting scheme over the gold standard SPE labels would not be sufficient, since it assigns the correct MPE label to only 34.6% of the development items (i.e. those cases where three or four SPE pairs agree with the MPE label). We also evaluate a slightly more sophisticated voting scheme that applies the following heuristic (here, E , N , C are the number of SPE labels of each class):

If $E > C$, predict entailment.
 Else if $C > E$, predict contradiction.
 Otherwise, predict neutral.

This baseline achieves an accuracy of 41.7%. These results indicate that MPE cannot be trivially reduced to SPE. That is, even if a model had access to the correct SPE label for each individual premise (an unrealistic assumption), it would require more than simple voting heuristics to obtain the correct MPE label from these pairwise labels. Table 4 illustrates that the majority of MPE items require aggregation of information about the described entities and events across multiple premises. In the first example, the first premise is consistent with a scene that involves a team of football players, while only the last premise indi-

# pairs agree	% of data	Pair Label	Example Hypothesis and Four Premises
0	21.8	N N N N	A football player in a red uniform is standing in front of other football players in a stadium. A football player facing off against two others. A football player wearing a red shirt. Defensive player waiting for the snap. ⇒E The team waiting.
1	26.9	N C N N	A person is half submerged in water in their yellow kayak. A woman has positioned her kayak nose down in the water. A person in a canoe is rafting in wild waters. A kayaker plunges into the river. ⇒C A man in a boat paddling through waters.
2	16.7	E E N N	A batter playing cricket missed the ball and the person behind him is catching it. A cricket player misses the pitch. The three men are playing cricket. A man struck out playing cricket. ⇒E A man swings a bat.
3	24.8	N N E N	A young gymnast, jumps high in the air, while performing on a balance beam. A gymnast performing on the balance beam in front of an audience. The young gymnast’s supple body soars above the balance beam. A gymnast is performing on the balance beam. ⇒N A woman doing gymnastics.
4	9.8	C C C C	A man with a cowboy hat is riding a horse that is jumping. A cowboy riding on his horse that is jumping in the air. A cowboy balances on his horse in a rodeo. Man wearing a cowboy hat riding a horse. ⇒C Men pulled by animals.

Table 4: MPE examples that illustrate the difference between pair labels and the full label. We include one example for each category, based on the number of pair labels that agree with the full label, and indicate the size of each category as a percentage of the development data.

cates that the team may be waiting. Moreover, the simple majority voting would work on the fourth example but fail on the second example, while the more sophisticated voting scheme would work on the second example and fail on the fourth.

5.3 Semantic Phenomena

We used a random sample of 100 development items to examine the types of semantic phenomena that are useful for inference in this dataset. We categorized each item by type of knowledge or reasoning necessary to predict the correct label for the hypothesis given the premises. An item belongs to a category if at least one premise in that item exhibits that semantic phenomenon in relation to the hypothesis, and an item may belong to multiple categories. For each category, Table 5 contains its frequency, an illustrative example containing the relevant premise, and the distribution over entailment labels. We did our analysis on full items (four premises and the corresponding hypothesis), but the examples in Table 5 have been simplified to a single premise for simplicity.

Word equivalence Items in this category contain a pair of equivalent words (synonyms or paraphrases). The word in the hypothesis can be exchanged for the word in the premise without significantly changing the meaning of the hypothesis.

Word hypernymy These items involve lexical hypernyms: someone who is a man is also a person (entailment), but a person may or may not be a man (neutral), and somebody who is a man is not a child (contradiction).

Phrase equivalence These items involve equivalent phrases, i.e. synonyms or paraphrases. The phrase in the hypothesis can be replaced by the phrase in the premise without significantly changing the meaning of the hypothesis.

Phrase hypernymy Items in this category involve a specific phrase and a general phrase: the more general phrase “doing exercises” can refer to multiple types of exercises in addition to “stretching their legs.”

Mutual exclusion Distinguishing between contradiction and neutral items involves identifying

	#	E	N	C	Example Premise and Hypothesis Pair
Total	100	31	29	40	
Word equivalence	16	12	4	0	A person <i>climbing</i> a rock face. A rock climber scales a cliff. \Rightarrow E
Word hypernymy	19	6	6	7	<i>Girl</i> in a blue sweater painting while looking at a bird in a book. A child painting a picture. \Rightarrow E
Phrase equivalence	7	6	1	0	<i>A couple in their wedding attire</i> stand behind a table with a wedding cake and flowers. Newlyweds standing. \Rightarrow E
Phrase hypernymy	8	6	2	0	A group of young boys wearing track jackets <i>stretch their legs</i> on a gym floor as they sit in a circle. A group doing exercises. \Rightarrow E
Mutual exclusion	25	0	0	25	A woman in a red vest <i>working at a computer</i> . Lady doing yoga. \Rightarrow C
Compatibility	18	0	18	0	<i>Onlookers watch</i> . A girl at bat in a softball game. \Rightarrow N
World knowledge	35	14	9	12	A young woman gives directions to an older woman outside a subway station. Women standing. \Rightarrow E

Table 5: Analysis of 100 random dev items. For each phenomenon, we show the distribution over labels and an example. The label is indicated with E, N, C. We use color and underlining to indicate the relevant comparisons. The indicated span of text is part of the necessary information to predict the correct label, but may not be sufficient on its own.

actions that are mutually exclusive, i.e. cannot be performed simultaneously by the same agent (“Two doctors perform surgery” vs. “Two surgeons are having lunch”).

Compatibility The opposite of mutual exclusion is compatibility: two actions that can be performed simultaneously by the same agent (e.g. “A boy flying a red and white kite” vs. “A boy is smiling”).

World knowledge These items require extra-linguistic knowledge about the relative frequency and co-occurrence of events in the world (not overlapping with the mutual exclusion or compatibility phenomena). A human reader can infer that children in a potato sack race are having fun (while a marathon runner competing in a race might not be described as having fun).

5.4 Combining Information Across Premises

In addition to the semantic phenomena we have just discussed, the data presents the challenge of how to combine information across multiple premises. We examined examples from the development data to analyze the different types of information aggregation present in our dataset.

Coreference resolution This case requires cross-caption coreference resolution of entity mentions from multiple premises and the hypothesis. In this example, a human reader can

recognize that “two men” and “two senior citizens” refer to the same entities, i.e. the “two older men” in the hypothesis. Given that information, the reader can additionally infer that the two older men on the street are likely to be standing.

1. Two men in tan coats exchange looks on the city sidewalk.
2. Two senior citizens talking on a public street.
3. Two men in brown coats on the street.
4. Two men in beige coats, talking.

Two older men stand. \Rightarrow ENTAILMENT

Event resolution This case requires resolving various event descriptions from multiple premises and the hypothesis. In the following example, a human reader recognizes that the man is sitting on scaffolding so that he can repair the building, and therefore he is doing construction work.

1. A man is sitting on a scaffolding in front a white building.
2. A man is sitting on a platform next to a building ledge.
3. A man looks down from his balcony from a stone building.
4. Repairing the front of an old building.

A man doing construction work. \Rightarrow ENTAILMENT

Visual ambiguity resolution This case involves reconciling apparently contradictory information across premises. These discrepancies are largely due to the fact that the premise captions were written to describe an image. Sometimes the image contained visually ambiguous entities or events that are then described by different caption writers. In this example, in order to resolve the discrepancy, the reader must recognize from context

that “woman” and “young child” (also “person”) refer to the same entity.

1. A person in a green jacket and pants appears to be digging in a wooded field with several cars in the background.
2. A young child in a green jacket rakes leaves.
3. A young child rakes leaves in a wooded area.
4. A woman cleaning up a park.

A woman standing in the forest. \Rightarrow ENTAILMENT

Scene resolution These examples require the reader to build a mental representation of the scene from the premises in order to assess the probability that the hypothesis is true. In the first example, specific descriptions – a jumping horse, a cowboy balancing, a rodeo – combine to assign a high probability that the specific event described by the hypothesis is true.

1. A man with a cowboy hat is riding a horse that is jumping.
2. A cowboy riding on his horse that is jumping in the air.
3. A cowboy balances on his horse in a rodeo.
4. Man wearing a cowboy hat riding a horse.

An animal bucking a man. \Rightarrow ENTAILMENT

In the next example, the hypothesis does not contradict any individual premise sentence. However, a reader who understands the generic scene described knows that the very specific hypothesis description is unlikely to go unmentioned. Shirtlessness would be a salient detail in this scene, so the fact that none of the premises mention it means that the hypothesis is likely to be false.

1. A young couple sits in a park eating ice cream as children play and other people enjoy themselves around them.
2. Couple in park eating ice cream cones with three other adults and two children in background.
3. A couple enjoying ice cream outside on a nice day.
4. A couple eats ice cream in the park.

A shirtless man sitting. \Rightarrow CONTRADICTION

In the final example, the premises present a somewhat generic description of the scene. While some premises lean towards entailment (a woman and a man in *discussion* could be having a work meeting) and others lean towards contradiction (two people conversing outdoors at a restaurant are probably not working), none of them contain overwhelming evidence that the scene entails or contradicts the hypothesis. Therefore, the hypothesis is neutral given the premises.

1. A blond woman wearing a gray jacket converses with an older man in a green shirt and glasses while sitting on a restaurant patio.
2. A blond pony-tailed woman and a gray-haired man converse while seated at a restaurant’s outdoor area.
3. A woman with blond hair is sitting at a table and talking to a man with glasses.
4. A woman discusses something with an older man at a table outside a restaurant.

A woman doing work. \Rightarrow NEUTRAL

6 Models

We apply several neural models from the entailment literature to our data. We also present a model designed to handle multiple premises, as this is unique to our dataset.

LSTM In our experiments, we found that the conditional LSTM (Hochreiter and Schmidhuber, 1997) model of Rocktäschel et al. (2016) outperformed a Siamese LSTM network (e.g. Bowman et al. (2015)), so we report results using the conditional LSTM. This model consists of two LSTMs that process the hypothesis conditioned on the premise. The first LSTM reads the premise. Its final cell state is used to initialize the cell state of the second LSTM, which reads the hypothesis. The resulting premise vector and hypothesis vector are concatenated and passed through a hidden layer and a softmax prediction layer. When handling four MPE premise sentences, we concatenate them into a single sequence (in the order of the caption IDs) that we pass to the first LSTM. When we only have a single premise sentence, we simply pass it to the first LSTM.

Word-to-word attention Neural attention models have shown a lot of success on SNLI. We evaluate the word-to-word attention model of Rocktäschel et al. (2016).¹ This model learns a soft alignment of words in the premise and hypothesis. One LSTM reads the premise and produces an output vector after each word. A second LSTM, initialized by the final cell state of the first, reads the hypothesis one word at a time. For each word w_t in the hypothesis, the model produces attention weights α_t over the premise output vectors. The final sentence pair representation is a nonlinear combination of the attention-weighted representation of the premise and the final output vector from the hypothesis LSTM. This final sentence pair representation is passed through a softmax layer to compute the cross-entropy loss. Again, when training on MPE, we concatenate the premise sentences into a single sequence as input to the premise LSTM.

Premise-wise sum of experts (SE) The previous models all assume that the premise is a single sentence, so in order to apply them naively to our dataset, we have to concatenate the four premises.

¹Our experiments use a reimplement of their model https://github.com/junfenglx/reasoning_attention

Training	Class	LSTM	SE	Attention
SNLI only		52.6	55.9	55.0
	E	85.8	71.5	81.7
	N	8.4	21.6	16.4
	C	55.7	62.0	54.5
MPE only		53.5	56.3	53.9
	E	63.1	61.3	48.3
	N	39.2	30.2	30.6
	C	53.5	66.5	71.2
SNLI+MPE		60.4	60.0	64.0
	E	65.1	65.4	75.9
	N	40.9	42.7	32.8
	C	67.2	65.1	71.5

Table 6: Entailment accuracy on MPE (test). SE is best when training only on SNLI or MPE. Attention is best when training on SNLI+MPE.

To capture what distinguishes our task from standard entailment, we also consider a premise-wise sum of experts (SE) model that makes four independent decisions for each premise paired with the hypothesis. This model can adjust how it processes each premise based on the relative predictions of the other premises.

We apply the conditional LSTM repeatedly to read each premise and the hypothesis, producing four premise vectors $p_1 \dots p_4$ and four hypothesis vectors $h_1 \dots h_4$ (conditioned on each premise). Each premise vector p_i is concatenated with its hypothesis vector h_i and passed through a feed-forward layer to produce logit prediction l_i . We sum $l_1 \dots l_4$ to obtain the final prediction, which we use to compute the cross-entropy loss.

When training on SNLI, we apply the conditional LSTM only once to read the premise and hypothesis and produce p_1 and h_1 . We pass the concatenation of p_1 and h_1 through the feed-forward layer to produce l_1 , which we use to compute the cross-entropy loss.

7 Training Details

For the LSTM and SE models, we use 300d GloVe vectors (Pennington et al., 2014) trained on 840B tokens as the input. The attention model uses word2vec vectors (Mikolov et al., 2013) (replacing with GloVe had almost no effect on performance). We use the Adam optimizer (Kingma and Ba, 2014) with the default configuration. We train each model for 10 epochs based on convergence on dev. For joint SNLI+MPE training, we use the same parameters and pretrain for 10 epochs on SNLI, then train for 10 epochs on MPE. This was

the best joint training approach we found.

When training on SNLI, we use the best parameters reported for the word-to-word attention model.² When training on MPE only, we set dropout, learning rate, and LSTM dimensionality as the result of a grid search on dev.³

8 Experimental Results

8.1 Overall Performance

Table 6 contains the test accuracies of the models from Section 6: LSTM, sum of experts (SE), and word-to-word attention under three training regimes: SNLI only, MPE only, and SNLI+MPE.

We train only on SNLI to see whether models can generalize from one entailment task to the other. Interestingly, the attention model’s accuracy on MPE is higher after training only on SNLI than training on MPE, perhaps because it requires much more data to learn reasonable attention weighting parameters.

When training on SNLI or MPE alone, the best model is SE, the only model that handles the four premises. It is not surprising that the LSTM model performs poorly, as it is forced to reduce a very long sequence of words to a single vector. The LSTM performs on par with SE when training on SNLI+MPE, but our analysis (Section 5.3) shows that their errors are quite different.

The attention model trained on SNLI+MPE has the highest accuracy overall. We reason that pre-training on SNLI is necessary to learn reasonable parameters for the attention weights before training on MPE, a smaller dataset where word-to-word inferences may be less obvious. When trained only on MPE, the attention model performs much worse than SE, with particularly low accuracy on entailing items.

We implemented a model that adds attention to the SE model, but it overfit on SNLI and could not match other models’ accuracy, reaching only about 58% on dev compared to 59-63%. Future work will investigate other approaches to combining the benefits of the SE and attention models.

8.2 Performance by Pair Agreement

To get a better understanding of how our task differs from standard entailment, we analyze how

²Dropout: 0.8, learning rate: 0.001, vector dim: 100, batch size: 32

³LSTM: dropout: 0.8, vector dim: 75. SE: dropout: 0.8, vector dim: 100. Attention: dropout: 0.6, vector dim: 100. Learning rate: 0.001 for all models

Accuracy on SPE-MPE agreement subsets					
# pairs agree	0	1	2	3	4
% of data	21.8	26.9	16.7	24.8	9.8
LSTM	57.3	57.6	60.5	67.1	63.3
SE	59.6	58.0	63.3	62.9	66.3
Attention	65.6	57.6	62.9	68.3	70.4

Table 7: Accuracy for each model (trained on SNLI+MPE) on the dev data subsets that have 0–4 SPE labels that match the MPE label (Table 4).

performance is affected by the number of premises whose SPE label agrees with the MPE label. Table 7 shows the accuracy of each SNLI+MPE-trained model on the dev data grouped by SPE-MPE label agreement (as in Table 4).

The attention model has the highest accuracy on three of five categories, including the most difficult category where none of the SPE labels match the MPE label. SE has the highest accuracy in the remaining two categories. The attention model demonstrates large gains in the easiest categories, perhaps because there is less advantage to aggregating individual premise predictions (as SE does) and more cases where attention weighting of individual words is useful. On the other hand, the attention model also does well on the most difficult category, indicating that it may be able to partially aggregate premises by increasing attention weights on phrases from multiple sentences. Attention and SE exhibit complementary strengths that we hope to combine in future work.

8.3 Performance by Semantic Phenomenon

Table 8 shows the performance of the three SNLI+MPE-trained models over semantic phenomena, based on the 100 annotated dev items (see Section 5.3 and Table 5). It may not be informative to analyze performance on smaller classes (e.g. phrase equivalence and phrase hypernymy), but we can still look at other noticeable differences between models.

Although the attention model outperformed both LSTM and SE models in overall accuracy, it is not the best in every category. Both SE and attention have access to the same information, but the attention model does better on items that contain relationships like hypernyms and synonyms for both words and short phrases. The SE model is best at mutual exclusion, compatibility, and world knowledge categories, e.g. knowing that a man who is *resting* is not *kayaking*, and a *bride* is not also a *cheerleader*. In cases that require analy-

Phenomenon	Accuracy			
	LSTM	SE	Att	#
Word equivalence	50.0	56.2	68.8	16
Word hypernymy	52.6	47.4	52.6	19
Phrase equivalence	57.1	57.1	85.7	7
Phrase hypernymy	50.0	50.0	62.5	8
Mutual exclusion	68.0	72.0	60.0	25
Compatibility	50.0	61.1	50.0	18
World knowledge	57.1	62.9	45.7	35

Table 8: Accuracy for each semantic phenomenon on 100 dev items. While attention was the best model overall, it does not have the highest accuracy for all phenomena.

sis of mutually exclusive or compatible events, a model like SE has an advantage since it can reinforce its weighted combination prediction by examining each premise separately.

9 Conclusion

We presented a novel textual entailment task that involves inference over longer premise texts and aggregation of information from multiple independent premise sentences. This task is an important step towards a system that can create a coherent scene representation from longer texts, such as multiple independent reports. We introduced a dataset for this task (<http://nlp.cs.illinois.edu/HockenmaierGroup/data.html>) which presents a more challenging, realistic entailment problem and cannot be solved by majority voting or related heuristics. We presented the results of several strong neural entailment baselines on this dataset, including one model that aggregates information from the predictions of separate premise sentences. Future work will investigate aggregating information at earlier stages to address the cases that require explicit reasoning about the interaction of multiple premises.

Abstract

To learn more knowledge, enabling transitivity is a vital step for lexical inference. However, most of the lexical inference models with good performance are for nouns or noun phrases, which cannot be directly applied to the inference on events or states. In this paper, we construct the largest Chinese verb lexical inference dataset containing 18,029 verb pairs, where for each pair one of four inference relations are annotated. We further build a probabilistic soft logic (PSL) model to infer verb lexicons using the logic language. With PSL, we easily enable transitivity in two layers, the observed layer and the feature layer, which are included in the knowledge base. We further discuss the effect of transitives within and between these layers. Results show the performance of the proposed PSL model can be improved at least 3.5% (relative) when the transitivity is enabled. Furthermore, experiments show that enabling transitivity in the observed layer benefits the most.

1 Introduction

Lexical inference is an important component of natural language understanding for NLP tasks such as textual entailment (Garrette et al., 2011), metaphor detection (Mohler et al., 2013), and text generation (Biran and McKeown, 2013) to acquire implications not explicitly written in context. Given two words, the goal of lexical inferences is to detect whether there is an inference relation between the lexicon pair. For example, the word ‘buy’ entails the word ‘have’. With the help of lexical inference system, we can know “Mom has ap-

ples” from the ground truth “Mom buys apples” to answer the question “Who has apples?” without explicitly mentioning it.

An intuitive solution to this problem is to first represent the sense of words in the lexicon to calculate the confidence of inferences from one sense to another, or to build a classifier to distinguish inference relations from other relations. Most related research is of one of these two types (Szpektor and Dagan, 2008a; Kiela et al., 2015). However, for this problem it is difficult for these models to take into account transitivity. In the framework of a lexical inference system, transitivity can be included in three layers: the observed layer, the feature layer, and the prediction layer. Figure 1 illustrates these layers and the corresponding transitives. The observed layer includes inference relations we already know, e.g., true inferences from the gold labels or ontologies; the feature layer includes the observed features for all lexicon pairs to be predicted, i.e., features for the testing data, and the predicted layer saves the predicted inference pairs, i.e., the relations of pairs in the testing data, predicted by the model. As inference usually involves available knowledge, the knowledge base (KB) is shown in Figure 1 as well. KB contains known information for the models. Therefore, in this system, it includes the observed layer and the feature layer which contain gold relations and the features for the testing data respectively.

There has been several new rising research directions involving lexical inference. The most representative ones are the automatic problem solvers and the open-domain question answering systems, where inferring between events or states like *Some animals grow thick fur* effecting *Some animals stay warm* is critical (Clark et al., 2016). However, many recent works of lexical inference are only designed for or being tested on nouns or noun phrases (Jiang and Conrath, 1997; Kiela et al.,

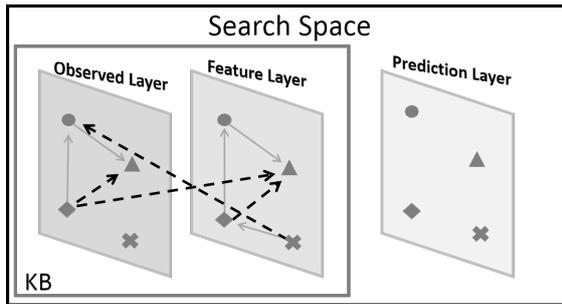

Figure 1: Three-layer lexical inference system. Points of the same shape in each layer are the same verbs; the solid arrow indicates the known inference relation; the dotted arrow indicates the hidden inference relation which can be inferred by the known inference relations.

2015; Schwartz et al., 2016), which makes them limited or not capable for these newly proposed research problems.

In this paper, we adopt the probabilistic soft logic (PSL) model to find lexical inference on Chinese verbs toward the math word problem solver. The contributions of this paper are listed as follows: (1) We build the largest Chinese verb lexical inference dataset with four types of inference relations as a potential testbed in the future. (2) We show that in the proposed PSL model the transitivity is easy to enabled and can benefit the lexical inference on Chinese verbs. (3) We implement and discuss the transitivity inter- and intra- layers and conclude the transitivity within the observed layer brings the most performance gain.

2 Related Work

One mainstream lexical inference extracts either explicit or implicit features from the manually constructed lexical knowledge. Szpektor (2009) constructs a WordNet inference chain through substitution relations (synonyms and hypernyms) defined in WordNet. Aharon (2010) proposed a FrameNet Entailment-rule Derivation (FRED) algorithm to inference on the framework of FrameNet. FrameNet models the semantic argument structure of predicates in terms of prototypical situation, which is called *frames*. Predicates belong to the same *frames* are highly related to a specific situation defined for the frame. Therefore, it is intuitive to acquire lexical inference pairs from predicates in the same frame. However, no matter WordNet or FrameNet was used, the cov-

erage problem was always an issue when leveraging handcraft resources. Moreover, the relations of verbs in WordNet are rather flat compared to nouns, which brings problems when directly adopting approaches utilizing WordNet to detect the inference between verbs.

An unsupervised concept, distributional similarity, for measuring relations between words was proposed to overcome the coverage problem. Distributional similarity related algorithms utilized a large, unstructured corpus to learn lexical entailment relations by assuming that semantically similar lexicons appear with similar context (Harris, 1954). Various implementations were proposed to assess contextual similarity between two lexicons, including (Berant et al., 2010; Lin and Pantel, 2001; Weeds et al., 2004). Lin Similarity, or known as DIRT, is one commonly adopted method to measure the lexical context similarity (Lin and Pantel, 2001). Instead of applying the Distributional Hypothesis to verbs, Lin applied this hypothesis to the paths in dependency trees. They hypothesize that the meaning of two phrases is similar, if their paths tend to link the same sets of words in a dependency tree. Later, Weeds and Weir (2004) proposed a general framework for directional similarity measurement. The measurement examined the coverage of word w_l 's features against those of w_r 's, and more coverage indicated more similarity.

Lin Similarity generates errors as its symmetric structure cannot tell the difference between $w_l \rightarrow w_r$ and $w_r \rightarrow w_l$. That is, it makes errors on non-symmetric examples, like *buy* \rightarrow *take*. Moreover, Weeds' method generates high score when an infrequent lexicon has features similar to those of another lexicon, which harms the performance as it happens a lot for non-entailed lexicons. Therefore, Szpektor and Dagan (2008a) proposed a hybrid method **Balanced-Inclusion, BInc**, and it was proved to outperform methods proposed prior to it. In this paper, we adopt BInc measurement and complement with lexical resource method to construct a hybrid model, which was proved to outperform both methods separately on our dataset.

Recent research is exploiting the effect of transitivity during model training. The intuition is that some implicit entailment relation is difficult to be identified when there is no direct features supporting it. Sometimes previous work could find the

entailment pairs $w_1 \rightarrow w_2$ and $w_2 \rightarrow w_3$, but failed to answer distant entailment relation like $w_1 \rightarrow w_3$. Skeptor and Dagan (2009) first applied transitive chaining in the knowledge provided by the lexical ontology Wordnet (Miller, 1995) in the feature layer. Berant et al. (2011) built a lexical entailment knowledge graph given the predicted results from the base classifier. They used integer linear programming (ILP) to find the latent entailment in the prediction cascade, which transits in the prediction layer. Kloetzer et al. (2015), whose system outperformed Berant et al.’s on their own corpus, further use cascade entailment inference in the feature layer. They applied short transitivity optimization by a two-layered SVM classifier (Kloetzer et al., 2015). A set of candidate transitivity paths were created by concatenating two identified inference pairs from the first SVM classifier, e.g., $w_1 \rightarrow w_2$ and $w_2 \rightarrow w_3$ result in a candidate path $w_1 \rightarrow w_2 \rightarrow w_3$. Then the two-layered SVM classifier re-predicted whether there was an inference relation for the lexical pair $w_1 \rightarrow w_3$. However, none of these models takes into account transitivity in the observed layer or transitivity between two layers.

We select probabilistic soft logic (PSL) to model the lexical inference problem. PSL is a recently proposed alternative framework for probabilistic logic (Bach et al., 2015). It was first applied to the category prediction and similarity propagation on Wikipedia documents to align ontologies on a standard corpus of bibliographic ontology (Brocheler et al., 2012). It has been adopted in social network analysis, including social group modeling (Huang et al., 2012) and social trust analysis (Huang et al., 2013). For natural language processing, recently, Dhanya Sridhar (2014) applied the PSL model to stance classification of on-line debates. Islam Beltagy (2014) approached the textual problem by transforming sentences into their logic representations and applying a PSL model to analyze word-to-word semantic coverage between the hypothesis and the premise. All these show that PSL is good at capturing relations. However, PSL has not been utilized yet in the lexical inference problem, and its power to provide lexical transitivity has not been tested, either. Thus in this paper, we explore its ability on detecting verb lexical inference and on enabling the transitivity.

3 Approach

We start from describing the features for each lexicon pair. To use PSL, we define atoms and design rules to enable the inter- and intra-layer transitives. Finally, PSL will automatically learn the rule weights by MLE to yield the best results.

3.1 Lexicon Pair Features

3.1.1 Lexical ontology features

E-HowNet is a large Chinese lexical resource extended from HowNet (Dong and Dong, 2006). Manually constructed by several linguistic experts, it contains 93,953 Chinese words and 9,197 semantic types (concepts; some are sememes). It was designed as an ontology of semantic types, each is listed in both Chinese and in English. For example, one semantic type is (*Give*|*給*). Each semantic type has some instances which inherit the concept of it. Lexical relations are also defined. In addition to hypernym-hyponym pairs, E-HowNet contains conflation pairs, including preconditions like (*Divorce*|*離婚*) is to (*GetMarried*|*結婚*), consequences like (*Labor*|*臨產*) is to (*Pregnant*|*懷孕*), and same-events like (*Sell*|*賣*) is to (*Buy*|*買*). The hypernym-hyponym relation and the conflation relation are two features that we use to represent a lexicon pair.

3.1.2 Cohesion path score

Given two semantically related words, a key aspect of detecting lexical inference is the generality of the hypothesis compared to the premise. Though we have a lexical ontology to tell us explicitly the hypernym-hyponym relations, a score to estimate the degree of this compared generality is still necessary for model learning. Therefore, We define the cohesion score of a semantic type with E-HowNet to model the generality. For each semantic type $s_i \in S$ which has a set of instantiate words V_{s_i} , the cohesion score of s_i is calculated as

$$Coh(s_i) = \frac{1}{N} \sum_{v_1 \neq v_2} sim(v_1, v_2); \quad (1)$$

$$v_1, v_2 \in V_{s_i}$$

where $sim(v_1, v_2)$ is the word-embedding cosine similarity of words v_1 and v_2 .

We construct a graph by considering hypernym, hyponym, and conflation relations in E-HowNet where nodes are semantic types and instantiate words, and where edges are relations. Given a word pair (v_l, v_r) , a set of paths P from v_l to

v_r can be found by traversing this graph, each of which is denoted as p with edges in the edge set E . Each of these edges in E is represented by the triple $e(n_1, n_2, type_e)$, where node n_2 is of type $type_e$ to node n_1 . Nodes here can be a word or a semantic type. The $PathScore(p)$ is defined as:

$$PathScore(p) = \prod_{e \in E_p} \begin{cases} coh(s_e), type_e = \text{Hyponym} \\ 1, \text{otherwise} \end{cases} \quad (2)$$

The idea of $PathScore(p)$ is to calculate the generality lost, which is caused by hyponym relations, of each step of inference. The hypernym or conflation relation does not lose generality, so the $PathScore(p)$ is always 1.

Empirically, those path p whose length exceed 10 are dropped as the inference chain is too long. Finally, the cohesion path score of word pair (v_1, v_2) is defined as:

$$CohPathScore(v_1, v_2) = \frac{\ln(\max_{p \in P} PathScore(p)) - \ln(m)}{\ln(M) - \ln(m)} \quad (3)$$

while M and m are the Maximum and Minimum PathScore respectively. The cohesion path score also serves as a feature to build the PSL model.

3.1.3 Distributional similarity

Distributional semantics has been used to exploit the semantic similarities of the linguistic items through large language data.

We applied the CKIP parser¹, a well-known Chinese text parser, to raw sentences. Context of words are extracted as features f s of words, according to parsed sentence trees.

Some pre-processing steps are performed. Words appearing only once in the corpus are dropped to reduce Chinese segmentation error. For each Word v , we retrieve all the words that share at least one feature with w and call them candidate words. Drop the candidate word if it shares less than 1 percent features, counted by frequency, with word w . We then calculate the distributional similarity score between w and its candidate words.

Balanced-inclusion (BInc, (Szpektor and Dagan, 2008a)) is a well-known scoring function for

¹CKIP parser : <http://parser.iis.sinica.edu.tw/>

determining lexical entailment. It contains two parts, one is semantic similarity measurement, and one is semantic coverage direction measurement. Given two words w_l, w_r and their feature sets F_l, F_r , the semantic similarity between w_l and w_r is calculated by Lin similarity (Lin and Pantel, 2001):

$$Lin(v_l, v_r) = \frac{\sum_{f \in F_l \cap F_r} [w_{vl}(f) + w_{vr}(f)]}{\sum_{f \in F_l} w_{vl}(f) + \sum_{f \in F_r} w_{vr}(f)} \quad (4)$$

The coverage direction measurement, which provides clues of direction of entailment relation, is calculated by Weed's (Weeds et al., 2004) coverage measurement:

$$weed(v_l, v_r) = \frac{\sum_{f \in F_l \cap F_r} w_{vl}(f)}{\sum_{f \in F_l} w_{vl}(f)} \quad (5)$$

The weight of each feature $w(f)$ is the Point-wise Mutual Information (PMI) between the word v and the feature f :

$$w_v(f) = \log\left[\frac{pr(f|v)}{pr(f)}\right] \quad (6)$$

where $pr(f)$ is probability of feature f . BInc is defined as geometric mean of the above two:

$$BInc(v_l, v_r) = \sqrt{Lin(v_l, v_r) \cdot Weed(v_l, v_r)} \quad (7)$$

To compare BInc's performance to the proposed PSL model and utilize it as a feature, we implemented it on the Chinese experimental dataset to calculate the BInc score of each lexicon pair.

3.1.4 Word Embeddings

Previous work has shown that word embeddings work well on entailment relation recognition of noun-noun pairs and (adj+noun)-noun pairs (Baroni et al., 2012; Roller et al., 2014). We choose glove (Pennington et al., 2014) to train embeddings of each word, and concatenate the embedding of two words to create the embedding for each word pair. This embedding then serves as the feature in the rbf-kernel SVM classifier to predict the entailment relation of the corresponding word pair.

3.2 Probabilistic Soft Logic (PSL)

We use the PSL model to find the latent inference relations by enabling the transitivity of lex-

ical relations. The lexical relations include features described in Section 3.1, and the known inference relations in the observed layer. In PSL, each relation of the lexicon pair v_l, v_r is written as a (ground) atom $a(v_l, v_r)$ in the logic language. The description of the transitivity of atoms $a_i(v_1, v_2), a_j(v_2, v_3)$ and its latent inference relation, $Etl(v_1, v_3)$ is written as a rule in the logic language:

$$a_i(v_1, v_2) \wedge a_j(v_2, v_3) \rightarrow Etl(v_1, v_3) \quad (8)$$

Each rule is assigned a weight to denote the reliability of the hypothesis that given $a_i(v_1, v_2), a_j(v_2, v_3)$ are true, $Etl(v_1, v_3)$ is also true. The PSL model learns the rule weights by the training set. We encode the transitivity inter- ($i = j$) and intra- ($i \neq j$) different types of relations and their resulting latent inference relation to construct the experimental rule set.

Given a set of (ground) atoms $a = \{a_1, \dots, a_n\}$, we denote an *interpretation* the mapping $I : a \rightarrow [0, 1]^n$ from ground atoms to soft truth value. The *distance to satisfaction* of each ground rule is defined as:

$$d(r, I) = \max\{0, I(r_{antecedent}) - I(r_{consequent})\} \quad (9)$$

The PSL model learns the weights λ_r of these rules and optimizes the most probable *interpretation* of entailment relations, through the probability density function f over I :

$$f(I) = \frac{1}{Z} \exp[-\sum_{r \in R} \lambda_r (d(r, I))^p]; \quad (10)$$

where Z is the normalization term, λ_r is the weight of rule r , R is the set of all ground rules, and $p \in \{1, 2\}$. In this paper, we set p to 2, indicating a squared function.

In the following section, we are going to describe the atoms defined in our lexical inference model in Section 3.2.1. Then rules are defined in Section 3.2.2. Last, weight learning is described in Section 3.2.3

3.2.1 Atoms for PSL

Atoms are types of information provided in Knowledge base in PSL model, Table 1 lists all atoms defined in our lexical inference model. Etl denotes the entailment relation serving as the prediction target. It is the only unknown atom. In PSL model the number of prediction target

grows quadratically with the number of the entities (verbs), if no limitation is provided, which is not desired and is time consuming. Thus Cdd indicates canopies (McCallum et al., 2000) over the prediction target. $Hypr$, Con , Coh , and $BInc$ are the hypernym, conflation, cohesion path score, and distributional similarity score $BInc$ features described in Section 3.1. Svm is the prediction of SVM classifier which takes concatenation of word embeddings as feature. Obv represents the knowledge of observed entailment lexical pairs for the training phase. Note that the set of pairs with $Obv = true$ must not overlap with the testing set.

3.2.2 Inference rules for PSL

Having defined the atoms, the five features $Hypr$, Con , $BInc$, Coh , and Svm are used in the design of five basic rules in Eq. 11. We further apply the inference chain by concatenating two atoms to create 25 rules shown as Eq.12 for feature-layer transitivity. For transitivity in the observed layer, we concatenate Obv atoms as shown in Eq.13. Then we concatenate Obv with other features and vice versa to add 10 additional rules shown as in Eq.14,15 for bidirectional transitives between the feature and the observed layers. Finally, the rule $\neg Etl(v_1, v_2)$ states that v_1 does not entail v_2 if the previous rules are not applicable.

$$\begin{aligned} Rel(v_1, v_2) &\rightarrow Etl(v_1, v_2); \\ Rel &\in \{Hypr, Con, BInc, Coh, Svm\} \end{aligned} \quad (11)$$

$$Rel(v_1, v_2) \wedge Rel(v_2, v_3) \rightarrow Etl(v_1, v_3) \quad (12)$$

$$Obv(v_1, v_2) \wedge Obv(v_2, v_3) \rightarrow Etl(v_1, v_3) \quad (13)$$

$$Obv(v_1, v_2) \wedge Rel(v_2, v_3) \rightarrow Etl(v_1, v_3) \quad (14)$$

$$Rel(v_1, v_2) \wedge Obv(v_2, v_3) \rightarrow Etl(v_1, v_3) \quad (15)$$

3.2.3 Learning inference rule weights

The rule weights(λ_r) are determined using maximum-likelihood estimation.

$$\begin{aligned} \frac{\partial}{\partial \lambda_r} \log p(I) &= \\ &= -\sum_{r \in R_i} (d(r, I)) + E \left[\sum_{r \in R_i} (d(r, I)) \right] \end{aligned} \quad (16)$$

Atom Name	Description
$Cdd(v_1, v_2)$	Canopies over prediction target. Return 1 if (v_1, v_2) is the prediction target in the task
$Etl(v_1, v_2)$	Entail statement which is the prediction target.
$Hypr(s_1, s_2)$	Hypernym relation between two semantic concept: s_1 is hypernym of s_2 .
$Con(s_1, s_2)$	Conflation relation between two semantic types.
$Ehow(v_1, v_2)$	E-HowNet algorithm.
$Dis(v_1, v_2)$	BInc between v_1 and v_2 .
$Svm(v_1, v_2)$	Svm prediction featured by word embeddings
$Obv(v_1, v_2)$	Observed entail statement.

Table 1: List of atoms in lexical inference model

The expected value $E[\sum_{r \in R_i} (d(r, I))]$ is intractable. Thus it is approximated via $\sum_{r \in R_i} d_r(I^*)$, where I^* is the most probable interpretation given the current weight (Kimmig et al., 2012).

4 Evaluation

4.1 Experiment Dataset

There are some of entailment dataset open to research utility, but the Chinese Verb entailment dataset (CVED) is special in some way. First, most of the open entailment dataset include the entailment between noun-noun pairs, adjective_noun-noun pairs, and quantity_noun-quantity_noun pairs, but none of them consider the entailment between verb-verb pairs like CVED. Second, in my knowledge, our CVED is the largest Chinese entailment dataset.

To get more verb lexical inference pairs for our experiments, we collected verb pairs from math application problems, which usually contain logical relations in the descriptions for each problem. A total of 995 verbs and 18,029 verb pairs were extracted from 20,000 Chinese elementary math problems, where the verbs in each pair are from the same problem. Few types of verb are discarded, including **V_1**, **V_2**, **VH**, **VI**, **VJ**, **VK** and **VL**, which are adjective² and statement associated verbs defined in CKIP³.

Given a set of verbs extracted from a math problem, every possible directed verb pair was labeled. If there were n verbs, $n \times (n - 1)$ directed verb pairs $(v_i \rightarrow v_j)$ were collected, where v_i is the premise and v_j is the hypothesis. For example, if we extracted “sell”, “buy”, and

“pay” from the descriptions of the problem, we added six directed verb pairs to the annotation set: $\{(sell, buy), (sell, pay), (buy, pay), (buy, sell), (pay, sell), (pay, buy)\}$ We provide four types of entailment label in CVED. One is commonly seen hypernym relation. The same-event relations are verb pairs related to same thing but in different point of view Some examples are (sell, buy) and (give, got). These are used by most earlier research or in small-scale experiments (Szpektor and Dagan, 2008b; Kiela et al., 2015). Another two are casual relations, as premises in the *pre-condition* and *consequence* relations are likely to be true given their hypothesis in our daily life, and because these relations are more useful in real applications, we further consider these relations as entailment relations. These relations are usually selected for web-scale experiments (Aharon et al., 2010; Berant et al., 2011; Kloetzer et al., 2015). Among all experimental verb pairs, 10% were used for testing, 10% were used for developing and the remaining dataset was for training. A five-fold training process was performed to learn the best parameters for the testing model.

4.2 Experiment Setting

To achieve better performance, weights are randomly initialized and retrained 10 times for each fold. The best combination is derived by averaging the five best weight sets obtained in the five-fold cross-validation process. Two baselines are provided for the evaluation of the models with transitivity disabled. Hyper+Conf is the ontology-based baseline. In this setting, verb pairs with hypernym and conflation relations found in E-HowNet are reported as entailment pairs. BInc is the distributional similarity baseline, where we set a best threshold for the development set and apply it

²Adjective words are seen as kind of verbs in CKIP

³http://rocling.iis.sinica.edu.tw/CKIP/tr/9305_2013%20revision.pdf

	Precision	Recall	F1
Hyper+Conf	0.547	0.189	0.281
BInc	0.150	0.098	0.119
PSL	0.270	0.474	0.344

Table 2: Model performance: transitivity disabled.

to the testing set to identify the entailment relation. The 20,000 elementary math problems together with 61,777 sentences from Sinica Treebank⁴ are utilized to calculate the BInc score of each verb pair. A set of 300 dimensional word embedding representation is trained by a hybrid of Sinica Treebank, elementary math problems and Chinese Wikipedia.

To discuss the effect of transitivity within (intra-) and between (inter-) different layers, we build three additional models for PSL. PSL_TrFeat allows transitivity within the feature layer, PSL_TrObv allows transitivity within the observed layer on top of PSL_TrFeat, and PSL_TrFeatObv allows transitivity between the observed layer and the feature layer on top of PSL_TrObv. Here we set the degree of transitivity to 2, and leave the determination of the best transitivity degree as future work. For comparison, we implement a SVM baseline, the state-of-the-art entailment classifier (Kloetzer(base)), and its transitivity framework (Kloetzer(TrFeatPred)) (Kloetzer et al., 2015). We use rbf-kernel SVM and the other hyper-parameters are selected from the 5-fold training.

4.3 Results and Discussion

Table 2 shows the performance of the proposed PSL model when transitivity is disabled (PSL). Unsurprisingly, Hyper+Conf achieves the highest precision as the relations found in E-HowNet are built manually. False alarms come from pairs that contain various unknown Chinese compound words that E-HowNet does not include, e.g., 分給(distribute to) is composed of 分(issue) and 給(give). We attempt to find its head to determine its sense, which sometimes causes errors. Compared to BInc, though in general distributional approaches may outperform ontology-based approaches at least in recall, Hyper+Conf still performs much better. We think the reason is that E-HowNet already contains a large number of words

⁴sinica treeback: <http://rocling.iis.sinica.edu.tw/CKIP/engversion/treebank.htm>

and adopting the heuristic of finding the head for compound words which could mitigate the coverage problem.

Table 3 shows the performance of various PSL models when transitivity is enabled. We conduct a SVM baseline, SVM(w2v), by concatenating the word embeddings of two verbs as the features of the verb pair and it performs comparably well, indicating word embeddings are strong features. Therefore, we discuss the effect of the strong and the weak base settings here. The strong base setting involves the prediction of SVM by word embeddings (relation SVM), while the weak base setting involves the rest relations *Hypr*, *Con*, *BInc* and *Coh*. The SVM model from Kloetzer serves as the second baseline. It involves more than 100 features but does not include word embeddings, and hence we compare it with the PSL models of the weak base setting. For the weak base setting, the performance of PSL cannot beat that of Kloetzer’s SVM in the very beginning, as SVM is generally considered a more powerful classifier and the Kloetzer’s SVM model involves comparably more features. Surprisingly, this state-of-the-art model from Kloetzer does not improve its F1 score after enabling the transitivity in the feature layer by their transitivity framework. (Kloetzer(TrFeatPred) vs. Kloetzer(base): they report a 2% improvement in average precision in their paper.) For the proposed PSL models, enabling transitivity in the feature layer (PSL(TrFeat) vs. PSL(base)) does improve the F1 score from the gain of recall. The reason for this could be that the transivities of Kloetzer’s features depend on the transivities of the prediction results. If the predictions don’t indicate a path to transit, their features will not be combined together for the next prediction. Therefore, their transitivity framework may involve the noise from the first prediction. On the contrary, in our PSL models, all possible feature-layered transivities between pairs are explored. Hence, our feature-layered transitivity models have the capabilities to improve the recall.

A significant improvement comes from enabling transitivity in the observed layer, that is, if we know $w_1 \rightarrow w_2$ and $w_2 \rightarrow w_3$, we add $w_1 \rightarrow w_3$ to the gold labels. As the relations in the observed layer constitute prior knowledge (known from the training data and saved in the PSL knowledge base), inferring from one relation to the other involves less uncertainty. Therefore, compared to

	Precision	Recall	F1
SVM(w2v)	0.850	0.500	0.630
PSL(WeakBase)	0.314	0.570	0.405
PSL(WeakBase_TrFeat)	0.348	0.645	0.452
PSL(WeakBase_TrObv)	0.675	0.577	0.622
PSL(WeakBase_TrFeatObv)	0.544	0.613	0.577
Kloetzer(base)	0.390	0.590	0.469
Kloetzer(TrFeatPred)	0.385	0.604	0.470
PSL(StrongBase)	0.670	0.649	0.660
PSL(StrongBase_TrFeat)	0.667	0.649	0.658
PSL(StrongBase_TrObv)	0.624	0.757	0.684
PSL(StrongBase_TrFeatObv)	0.612	0.764	0.680

Table 3: Model performance: transitivity enabled. PSL(StrongBase_TrObv) is significantly better than all the other models with p-value < 0.001.

PSL(WeakBase_TrFeat), PSL(WeakBase_TrObv) shows a great improvement in both precision and F1. For recall, the feature-layer transitivity (PSL(WeakBase_TrFeat)) enables the model to reach more words for a better recall, while the enrichment of the prior knowledge in PSL(WeakBase_TrObv) helps to eliminate uncertainty but decreases recall. If we go further to enable transitivity between the observed layer and the feature layer using model PSL(WeakBase_TrFeatObv), it begins to suffer from the lower precision caused by longer transitivity. Overall, PSL(WeakBase_TrObv) achieves best among all PSL(WeakBase) models, with improvements of 21.7% over the transitivity-disabled PSL model.

Compared to the models of the weak base setting, the PSL model of the strong base setting without transitivity enabled has achieved good performance in the very beginning (F1=0.66). Its performance is better than 3 baselines, SVM(w2v), Kloetzer(base) and Kloetzer(TrFeatPred). It also performs better than the best PSL model of the weak base setting, PSL(WeakBase_TrObv). The great thing is, enabling transitivity achieves even better performance in PSL(StrongBase_TrObv) and PSL(StrongBase_TrFeatObv). For all models of the strong base settings, only enabling the transitivity in the feature layer does not benefit the performance as this decreases the precision.

From all the experiment results, we can conclude the followings. First, enabling transivities help to find more inference pairs no matter the initial model is strong or weak. Second, for

a general model, transivities inter- or intra- layers both help it become stronger; however, for a strong model, only the transivities intra- or inter the observed layer, i.e., involving the gold labels, contribute to the performance gain. In other words, only solid knowledge can make a strong model even stronger through transivities.

5 Conclusion

We have proposed a PSL model to explore the power of transitivity. In this process, the easy and straightforward nature of PSL in considering transitives for lexical inference is demonstrated. Results show that the best PSL model achieves the F1 score 0.684. Moreover, the proposed base PSL model has already achieved well and models with transitivity enabled achieve even better, which confirms the power of transitivity for solving the lexical inference problem on verbs. We will release the current experimental dataset. Future goals include enlarging our dataset by including web word pairs and applied the predicted results in textual entailment tasks. The constructed CVED dataset can be found in the NLPSA lab webpage⁵.

Abstract

In this work, we explore multiple neural architectures adapted for the task of automatic post-editing of machine translation output. We focus on neural end-to-end models that combine both inputs *mt* (raw MT output) and *src* (source language input) in a single neural architecture, modeling $\{mt, src\} \rightarrow pe$ directly. Apart from that, we investigate the influence of hard-attention models which seem to be well-suited for monolingual tasks, as well as combinations of both ideas. We report results on data sets provided during the WMT-2016 shared task on automatic post-editing and can demonstrate that dual-attention models that incorporate all available data in the APE scenario in a single model improve on the best shared task system and on all other published results after the shared task. Dual-attention models that are combined with hard attention remain competitive despite applying fewer changes to the input.

1 Introduction

Given the raw output of a (possibly unknown) machine translation system from language *src* to language *mt*, Automatic Post-Editing (APE) is the process of automatic correction of raw MT output (*mt*), so that a closer resemblance to human post-edited MT output (*pe*) is achieved. While APE systems that only model $mt \rightarrow pe$ yield good results, the field has always strived towards methods that also integrate *src* in various forms.

With neural encoder-decoder models, and multi-source models in particular, this can be now achieved in more natural ways than for previously popular phrase-based statistical machine transla-

tion (PB-SMT) systems. Despite this, previously reported results for multi-source or dual-source models in APE scenarios are unsatisfying in terms of performance.

In this work, we explore a number of single-source and dual-source neural architectures which we believe to be better fits to the APE task than vanilla encoder-decoder models with soft attention. We focus on neural end-to-end models that combine both inputs *mt* and *src* in a single neural architecture, modeling $\{mt, src\} \rightarrow pe$ directly. Apart from that, we investigate the influence of hard-attention models, which seem to be well-suited for monolingual tasks. Finally, we create combinations of both architectures.

We report results on data sets provided during the WMT-2016 shared task on automatic post-editing (Bojar et al., 2016) and compare our performance against the shared task winner, the system submitted by the Adam Mickiewicz University (AMU) team (Junczys-Dowmunt and Grundkiewicz, 2016), and a more recent system by Pal et al. (2017) with the previously best published results on the same test set.

Our main contributions are: (1) we perform a thorough comparison of end-to-end neural approaches to APE during which (2) we demonstrate that dual-attention models that incorporate all available data in the APE scenario in a single model achieve the best reported results for the WMT-2016 APE task, and (3) show that models with a hard-attention mechanism reach competitive results although they execute fewer edits than models relying only on soft attention.

The remainder of the paper is organized as follows: Previous relevant work is described in Section 2. Section 3 summarizes the basic encoder-decoder with attention architecture that is further extended with multiple non-standard attention mechanisms in Section 4. These attention mecha-

nisms are: hard-attention in Section 4.1, a combination of hard attention and soft attention in Section 4.2, dual soft attention in Section 4.3 and a combination of hard attention and dual soft attention in Section 4.4. We describe experiments and results in Section 5 and conclude in Section 7.

2 Previous work

Before the application of neural sequence-to-sequence models to APE, most APE systems would rely on phrase-based SMT following a monolingual approach first introduced by Simard et al. (2007). Béchara et al. (2011) proposed a “source-context aware” variant of this approach where automatically created word alignments were used to create a new source language which consisted of joined MT output and source token pairs. The inclusion of source-language information in that form was shown to improve the automatic post-editing results (Béchara et al., 2012; Chatterjee et al., 2015). The quality of the used word alignments plays an important role for this methods, as demonstrated for instance by Pal et al. (2015).

During the WMT-2016 APE shared task two systems relied on neural models, the CUNI system (Libovický et al., 2016) and the shared task winner, the system submitted by the AMU team (Junczys-Dowmunt and Grundkiewicz, 2016). This submission explored the application of neural translation models to the APE problem and achieved good results by treating different models as components in a log-linear model, allowing for multiple inputs (the source *src* and the translated sentence *mt*) that were decoded to the same target language (post-edited translation *pe*). Two systems were considered, one using *src* as the input (*src* \rightarrow *pe*) and another using *mt* as the input (*mt* \rightarrow *pe*). A simple string-matching penalty integrated within the log-linear model was used to control for higher faithfulness with regard to the raw MT output. The penalty fired if the APE system proposed a word in its output that had not been seen in *mt*. The influence of the components on the final result was tuned with Minimum Error Rate Training (Och, 2003) with regard to the task metric TER.

Following the WMT-2016 APE shared task, Pal et al. (2017) published work on another neural APE system that integrated precomputed word-alignment features into the neural structure and en-

forced symmetric attention during the neural training process. The result was the best reported single neural model for the WMT-2016 APE test set prior to this work. With n-best list re-ranking and combination with phrase-based post-editing systems, the authors improved their results even further. None of their systems, however, integrated information from *src*, all modeled *mt* \rightarrow *pe*.

3 Attentional Encoder-Decoder

Implementations of all models explored in this paper are available in the Marian¹ toolkit (Junczys-Dowmunt et al., 2016). The attentional encoder-decoder model in Marian is a re-implementation of the NMT model in Nematus (Sennrich et al., 2017). The model differs from the standard model introduced by Bahdanau et al. (2015) by several aspects, the most important being the conditional GRU with attention. The summary provided in this section is based on the description in Sennrich et al. (2017).

Given the raw MT output sequence (x_1, \dots, x_{T_x}) of length T_x and its manually post-edited equivalent (y_1, \dots, y_{T_y}) of length T_y , we construct the encoder-decoder model using the following formulations.

Encoder context A single forward encoder state $\vec{\mathbf{h}}_i$ is calculated as:

$$\vec{\mathbf{h}}_i = \text{GRU}(\vec{\mathbf{h}}_{i-1}, \mathbf{F}[x_i]),$$

where \mathbf{F} is the encoder embeddings matrix. The GRU RNN cell (Cho et al., 2014) is defined as:

$$\begin{aligned} \text{GRU}(\mathbf{s}, \mathbf{x}) &= (1 - \mathbf{z}) \odot \underline{\mathbf{s}} + \mathbf{z} \odot \mathbf{s}, & (1) \\ \underline{\mathbf{s}} &= \tanh(\mathbf{W}\mathbf{x} + \mathbf{r} \odot \mathbf{U}\mathbf{s}), \\ \mathbf{r} &= \sigma(\mathbf{W}_r\mathbf{x} + \mathbf{U}_r\mathbf{s}), \\ \mathbf{z} &= \sigma(\mathbf{W}_z\mathbf{x} + \mathbf{U}_z\mathbf{s}), \end{aligned}$$

where \mathbf{x} is the cell input; \mathbf{s} is the previous recurrent state; \mathbf{W} , \mathbf{U} , \mathbf{W}_r , \mathbf{U}_r , \mathbf{W}_z , \mathbf{U}_z are trained model parameters²; σ is the logistic sigmoid activation function. The backward encoder state is calculated analogously over a reversed input sequence with its own set of trained parameters.

Let \mathbf{h}_i be the annotation of the source symbol at position i , obtained by concatenating the forward and backward encoder RNN hidden states, $\mathbf{h}_i = [\vec{\mathbf{h}}_i; \overleftarrow{\mathbf{h}}_i]$, the set of encoder states $\mathbf{C} = \{\mathbf{h}_1, \dots, \mathbf{h}_{T_x}\}$ then forms the encoder context.

¹<https://github.com/marian-nmt/marian>

²Biases have been omitted.

Decoder initialization The decoder is initialized with start state s_0 , computed as the average over all encoder states:

$$s_0 = \tanh \left(\mathbf{W}_{init} \frac{\sum_{i=1}^{T_x} \mathbf{h}_i}{T_x} \right).$$

Conditional GRU with attention We follow the Nematus implementation of the conditional GRU with attention, cGRU_{att}:

$$\mathbf{s}_j = \text{cGRU}_{\text{att}}(\mathbf{s}_{j-1}, \mathbf{E}[y_{j-1}], \mathbf{C}), \quad (2)$$

where \mathbf{s}_j is the newly computed hidden state, \mathbf{s}_{j-1} is the previous hidden state, \mathbf{C} the source context and $\mathbf{E}[y_{j-1}]$ is the embedding of the previously decoded symbol y_{j-1} .

The conditional GRU cell with attention, cGRU_{att}, has a complex internal structure, consisting of three parts: two GRU layers and an intermediate attention mechanism ATT.

Layer GRU₁ generates an intermediate representation \mathbf{s}'_j from the previous hidden state \mathbf{s}_{j-1} and the embedding of the previous decoded symbol $\mathbf{E}[y_{j-1}]$:

$$\mathbf{s}'_j = \text{GRU}_1(\mathbf{s}_{j-1}, \mathbf{E}[y_{j-1}]).$$

The attention mechanism, ATT, inputs the entire context set \mathbf{C} along with intermediate hidden state \mathbf{s}'_j in order to compute the context vector \mathbf{c}_j as follows:

$$\begin{aligned} \mathbf{c}_j &= \text{ATT}(\mathbf{C}, \mathbf{s}'_j) = \sum_i \alpha_{ij} \mathbf{h}_i, \\ \alpha_{ij} &= \frac{\exp(e_{ij})}{\sum_{k=1}^{T_x} \exp(e_{kj})}, \\ e_{ij} &= \mathbf{v}_a^T \tanh(\mathbf{U}_a \mathbf{s}'_j + \mathbf{W}_a \mathbf{h}_i), \end{aligned}$$

where α_{ij} is the normalized alignment weight between source symbol at position i and target symbol at position j , and $\mathbf{v}_a, \mathbf{U}_a, \mathbf{W}_a$ are trained model parameters.

Layer GRU₂ generates \mathbf{s}_j , the hidden state of the cGRU_{att}, from the intermediate representation \mathbf{s}'_j and context vector \mathbf{c}_j :

$$\mathbf{s}_j = \text{GRU}_2(\mathbf{s}'_j, \mathbf{c}_j).$$

Deep output Finally, given \mathbf{s}_j, y_{j-1} , and \mathbf{c}_j , the output probability $p(y_j | \mathbf{s}_j, y_{j-1}, \mathbf{c}_j)$ is computed by a softmax activation as follows:

$$\begin{aligned} p(y_j | \mathbf{s}_j, y_{j-1}, \mathbf{c}_j) &= \text{softmax}(\mathbf{t}_j \mathbf{W}_o), \\ \mathbf{t}_j &= \tanh(\mathbf{s}_j \mathbf{W}_{t_1} + \mathbf{E}[y_{j-1}] \mathbf{W}_{t_2} + \mathbf{c}_j \mathbf{W}_{t_3}). \end{aligned}$$

$\mathbf{W}_{t_1}, \mathbf{W}_{t_2}, \mathbf{W}_{t_3}, \mathbf{W}_o$ are the trained model parameters.

This rather standard encoder-decoder model with attention is our baseline and denoted as cGRU.

4 Encoder-Decoder Models with APE-specific Attention Models

The following models reuse most parts of the architecture described above wherever possible, most differences occur in the decoder RNN cell and the attention mechanism. The encoders are identical, so are the deep output layers.

4.1 Hard Monotonic Attention

Aharoni and Goldberg (2016) introduce a simple model for monolingual morphological reinflection with hard monotonic attention. This model looks at one encoder state at a time, starting with the left-most encoder state and progressing to the right until all encoder states have been processed.

The target word vocabulary V_y is extended with a special step symbol ($V'_y = V_y \cup \{\langle \text{STEP} \rangle\}$) and whenever $\langle \text{STEP} \rangle$ is predicted as the output symbol, the hard attention is moved to the next encoder state. Formally, the hard attention mechanism is represented as a precomputed monotonic sequence (a_1, \dots, a_{T_y}) which can be inferred from the target sequence (y_1, \dots, y_{T_y}) (containing original target symbols and T_x step symbols) as follows:

$$\begin{aligned} a_1 &= 1, \\ a_j &= \begin{cases} a_{j-1} + 1 & \text{if } y_{j-1} = \langle \text{STEP} \rangle \\ a_{j-1} & \text{otherwise.} \end{cases} \end{aligned}$$

For a given context $\mathbf{C} = \{\mathbf{h}_1, \dots, \mathbf{h}_{T_x}\}$, the attended context vector at time step j is simply \mathbf{h}_{a_j} .

Following the description by Aharoni and Goldberg (2016) for their LSTM-based model, we adapt the previously described encoder-decoder model to incorporate hard attention. Given the sequence of attention indices (a_1, \dots, a_{T_y}) , the conditional GRU cell (Eq. 2) used for hidden state updates of the decoder is replaced with a simple GRU cell (Eq. 1) (thus removing the soft-attention mechanism):

$$\mathbf{s}_j = \text{GRU}(\mathbf{s}_{j-1}, [\mathbf{E}[y_{j-1}]; \mathbf{h}_{a_j}]), \quad (3)$$

where the cell input is now a concatenation of the embedding of the previous target symbol $\mathbf{E}[y_{j-1}]$

and the currently attended encoder state \mathbf{h}_{a_j} . This model is labeled GRU-HARD.

We find this architecture compelling for monolingual tasks that might require higher faithfulness with regard to the input. With hard monotonic attention, the translation algorithm can enforce certain constraints:

1. The end-of-sentence symbol can only be generated if the hard attention mechanism has reached the end of the input sequence, enforcing full coverage;
2. The $\langle \text{STEP} \rangle$ symbol cannot be generated once the end-of-sentence position in the source has been reached. It is however still possible to generate content tokens.

This model requires a target sequence with correctly inserted $\langle \text{STEP} \rangle$ symbols. For the described APE task, using the Longest Common Subsequence algorithm (Hirschberg, 1977), we first generate a sequence of match, delete and insert operations which transform the raw MT output (x_1, \dots, x_{T_x}) into the corrected post-edited sequence (y_1, \dots, y_{T_y}) ³. Next, we map these operations to the final sequence of steps and target tokens according to the following rules:

- For each matched pair of tokens x, y we produce symbols: $\langle \text{STEP} \rangle y$;
- For each inserted target token y we produce the same token y ;
- For each deleted source token x we produce $\langle \text{STEP} \rangle$;
- Since at initialization of the model $a_1 = 1$, i.e. the first encoder state is already attended to, we discard the first symbol in the new sequence if it is a $\langle \text{STEP} \rangle$ symbol.

4.2 Hard and Soft Attention

While the hard attention model can be used to enforce faithfulness to the original input, we would also like the model to be able to look at information anywhere in the source sequence which is a property of the soft attention model.

By re-introducing the conditional GRU cell with soft attention into the GRU-HARD model while also inputting the hard-attended encoder

³Similar to GNU `wdiff`.

state h_{a_j} , we can try to take advantage of both attention mechanisms. Combining Eq. 2 and Eq. 3, we get:

$$\mathbf{s}_j = \text{cGRU}_{\text{att}}(\mathbf{s}_{j-1}, [\mathbf{E}[y_{j-1}]; \mathbf{h}_{a_j}], \mathbf{C}). \quad (4)$$

The rest of the model is unchanged; the translation process is the same as before and we use the same target step/token sequence for training. This model is called CGRU-HARD.

4.3 Soft Dual-Attention

Neural multi-source models (Zoph and Knight, 2016) seem to be a natural fit for the APE task as raw MT output and original source language input are available. Although applications to the APE problem have been reported (Libovický and Helcl, 2017), state-of-the-art results seem to be missing.

In this section we give details about our dual-source model implementation. We rename the existing encoder \mathbf{C} to \mathbf{C}^{mt} to signal that the first encoder consumes the raw MT output and introduce a structurally identical second encoder $\mathbf{C}^{src} = \{\mathbf{h}_1^{src}, \dots, \mathbf{h}_{T_{src}}^{src}\}$ over the source language. To compute the decoder start state s_0 for the multi-encoder model we concatenate the averaged encoder contexts before mapping them into the decoder state space:

$$\mathbf{s}_0 = \tanh \left(\mathbf{W}_{init} \left[\frac{\sum_{i=1}^{T_{mt}} \mathbf{h}_i^{mt}}{T_{mt}}; \frac{\sum_{i=1}^{T_{src}} \mathbf{h}_i^{src}}{T_{src}} \right] \right).$$

In the decoder, we replace the conditional GRU with attention, with a doubly-attentive cGRU cell (Calixto et al., 2017) over contexts \mathbf{C}^{mt} and \mathbf{C}^{src} :

$$\mathbf{s}_j = \text{cGRU}_{2\text{-att}}(\mathbf{s}_{j-1}, \mathbf{E}[y_{j-1}], \mathbf{C}^{mt}, \mathbf{C}^{src}). \quad (5)$$

The procedure is similar to the original cGRU, differing only in that in order to compute the context vector \mathbf{c}_j , we first calculate contexts vectors \mathbf{c}_j^{mt} and \mathbf{c}_j^{src} for each context and then concatenate⁴ the results:

⁴Calixto et al. (2017) combine their two attention models by modifying their GRU cell to include another set of parameters that is multiplied with the additional context vector and summed in the GRU-components. Formally, both approaches give identical results, as for concatenation the original parameters have to grow in size to match the now longer input vector dimensions. The GRU cell itself does not need to be modified.

$$\begin{aligned}
\mathbf{s}'_j &= \text{GRU}_1(\mathbf{s}_{j-1}, \mathbf{E}[y_{j-1}]), \\
\mathbf{c}_j^{mt} &= \text{ATT}(\mathbf{C}^{mt}, \mathbf{s}'_j) = \sum_i^{T_{mt}} \alpha_{ij} \mathbf{h}_i^{mt}, \\
\mathbf{c}_j^{src} &= \text{ATT}(\mathbf{C}^{src}, \mathbf{s}'_j) = \sum_i^{T_{src}} \alpha_{ij} \mathbf{h}_i^{src}, \\
\mathbf{c}_j &= [\mathbf{c}_j^{mt}; \mathbf{c}_j^{src}], \\
\mathbf{s}_j &= \text{GRU}_2(\mathbf{s}'_j, \mathbf{c}_j).
\end{aligned}$$

This could be easily extended to an arbitrary number of encoders with different architectures. During training, this model is fed with a tri-parallel corpus, and during translation both input sequences are processed simultaneously to produce the corrected output. This model is denoted as M-CGRU.

4.4 Hard Attention with Soft Dual-Attention

Analogously to the procedure described in section 4.2, we can extend the doubly-attentive cGRU to take the hard-attended encoder context as additional input:

$$\mathbf{s}_j = \text{cGRU}_{2\text{-att}}(\mathbf{s}_{j-1}, [\mathbf{E}[y_{j-1}]; \mathbf{h}_{a_j}^{mt}], \mathbf{C}^{mt}, \mathbf{C}^{src}).$$

In this formulation, only the first encoder context \mathbf{C}^{mt} is attended to by the hard monotonic attention mechanism. The target training data consists of the step/token sequences used for all previous hard-attention models. We call this model M-CGRU-HARD.

5 Experiments and Results

5.1 Training, Development, and Test Data

We perform all our experiments⁵ with the official WMT-2016 (Bojar et al., 2016) automatic post-editing data and the respective development and test sets. The training data consists of a small set of 12,000 post-editing triplets (src, mt, pe), where src is the original English text, mt is the raw MT output generated by an English-to-German system, and pe is the human post-edited MT output. The MT system used to produce the raw MT output is unknown, so is the original training data. The task consists of automatically correcting the MT output so that it resembles human

⁵All experiments in this sections can be reproduced following the instructions on <https://marian-nmt.github.io/examples/exploration/>.

Data set	Sentences	TER
training set	12,000	26.22
development set	1,000	24.81
test set	2,000	–
artificial-large	4,335,715	36.63
artificial-small	531,839	25.28

Table 1: Statistics for artificial data sets in comparison to official training and development data. Adapted from Junczys-Dowmunt and Grundkiewicz (2016).

post-edited data. The main task metric is TER (Snover et al., 2006) — the lower the better — with BLEU (Papineni et al., 2002) as a secondary metric.

To overcome the problem of too little training data, Junczys-Dowmunt and Grundkiewicz (2016) — the authors of the best WMT-2016 APE shared task system — generated large amounts of artificial data via round-trip translations. The artificial data has been filtered to match the HTER statistics of the training and development data for the shared task and was made available for download⁶. Table 1 summarizes the data sets used in this work.

To produce our final training data set we over-sample the original training data 20 times and add both artificial data sets. This results in a total of slightly more than 5M training triplets. We validate on the development set for early stopping and report results on the WMT-2016 test set. The data is already tokenized. Additionally we true-case all files and apply segmentation into BPE subword units (Sennrich et al., 2016). We reuse the subword units distributed with the artificial data set. For the hard-attention models, we create target training and development files following the LCS-based procedure outlined in section 4.1.

5.2 Training parameters

All models are trained on the same training data. Models with single input encoders take only the raw MT output (mt) as input, dual-encoder models use raw MT output (mt) and the original source (pe). The training procedures and model settings are the same whenever possible:

⁶The artificial filtered data has been made available at <https://github.com/emjotde/amanmt/wiki/AmuNMT-for-Automatic-Post-Editing>.

Model	dev 2016		test 2016	
	TER↓	BLEU↑	TER↓	BLEU↑
WMT-2016 BASELINE-1 (Bojar et al., 2016)	25.14	62.92	24.76	62.11
WMT-2016 BASELINE-2 (Bojar et al., 2016)	–	–	24.64	63.47
Junczys-Dowmunt and Grundkiewicz (2016)	21.46	68.94	21.52	67.65
Pal et al. (2017) SYMMETRIC	–	–	21.07	67.87
Pal et al. (2017) RERANKING	–	–	20.70	69.90

Table 2: Results from the literature for the WMT-2016 APE development and test set.

Model	dev 2016		test 2016	
	TER↓	BLEU↑	TER↓	BLEU↑
CGRU	22.01	68.11	22.27	66.90
GRU-HARD	22.72	66.82	22.72	65.86
CGRU-HARD	22.11	67.82	22.10	67.15
M-CGRU	20.79	69.28	20.69	68.56
M-CGRU × 4	20.10	70.24	19.92	69.40
M-CGRU-HARD	20.83	69.02	20.87	68.14
M-CGRU-HARD × 4	20.08	70.05	20.34	68.96

Table 3: Results for models explored in this work. Models with × 4 are ensembles of four models. The main WMT 2016 APE shared task metric was TER (the lower the better).

- All embedding vectors consist of 512 units; the RNN states use 1024 units. We choose a vocabulary size of 40,000 for all inputs and outputs. When hard attention models are trained the maximum sentence length is 100 to accommodate the additional step symbols, otherwise 50.
- To avoid overfitting, we use pervasive dropout (Gal and Ghahramani, 2016) over GRU steps and input embeddings, with dropout probabilities 0.2, and over source and target words with probabilities 0.2.
- We use Adam (Kingma and Ba, 2014) as our optimizer, with a mini-batch size of 64. All models are trained with Asynchronous SGD (Adam) on three to four GPUs.
- We train all models until convergence (early-stopping with a patience of 10 based on development set cross-entropy cost), saving model checkpoints every 10,000 mini-batches. For different models we observed early stopping to be triggered between 600,000 and 900,000 mini-batch updates or between 8 and 11 epochs.
- The best eight model checkpoints w.r.t. development set cross-entropy of each training run are averaged element-wise (Junczys-Dowmunt et al., 2016) resulting in new single models with generally improved performance.
- For the multi-source models we repeat the mentioned procedure four times with different randomly initialized weights.

Training time for one model on four NVIDIA GTX 1080 GPUs or NVIDIA TITAN X (Pascal) GPUs is between one and two days, depending on model complexity. The M-CGRU-HARD model is the most complex and trains longest.

5.3 Evaluation

Table 2 contains relevant results for the WMT-2016 APE shared task — during the task and afterwards. WMT-2016 BASELINE-1 is the raw uncorrected MT output. BASELINE-2 is the result of a vanilla phrase-based Moses system (Koehn et al., 2007) trained only on the official 12,000 sentences. Junczys-Dowmunt and Grundkiewicz (2016) is the best system at the shared task. Pal

Model	TER- <i>pe</i>	TER- <i>mt</i>
CGRU	22.27	12.01
GRU-HARD	22.72	9.48
CGRU-HARD	22.10	11.57
M-CGRU	20.69	15.98
M-CGRU \times 4	19.92	15.41
M-CGRU-HARD	20.87	13.62
M-CGRU-HARD \times 4	20.34	13.34

Table 4: TER w.r.t. the reference compared to TER w.r.t. the input on test 2016. Lower results for TER-*mt* indicate greater similarity to the input.

et al. (2017) SYMMETRIC is the currently best reported result on the WMT-2016 APE test set for a single neural model (single source), whereas Pal et al. (2017) RERANKING — the overall best reported result on the test set — is a system combination of Pal et al. (2017) SYMMETRIC with phrase-based models via n-best list re-ranking.

In Table 3 we present the results for the models discussed in this work. Unsurprisingly, none of the single attention models can compete with the better systems reported in the literature. The encoder-decoder model with only hard monotonic attention (GRU-HARD) is the clear loser, while the comparison between CGRU and CGRU-HARD remains inconclusive. CGRU-HARD seems to generalize slightly better, but would not have been chosen based on the development set performance.

The dual-attention models each outperform the best WMT-2016 system and the currently reported best single-model Pal et al. (2017) SYMMETRIC. The ensembles also beat the system combination Pal et al. (2017) RERANKING in terms of TER (not in terms of BLEU though). The simpler dual-attention model with no hard-attention M-CGRU reaches slightly better results on the test set than its counterpart with added hard attention M-CGRU-HARD, but the situation would have been less clear if only the development set were used to determine the best model. The hard-attention model with dual soft-attention benefits less from ensembling.

6 Analysis

6.1 Faithfulness and Errors

We postulated that the hard-attention models might have a potential for higher faithfulness. Since the APE task is a mostly monolingual task,

Model	Mod.	Imp.	Det.
CGRU	1575	871	399
GRU-HARD	1479	783	362
CGRU-HARD	1564	897	371
M-CGRU	1668	1020	379
M-CGRU \times 4	1612	1037	322
M-CGRU-HARD	1688	1044	388
M-CGRU-HARD \times 4	1672	1074	341

Table 5: Number of test set sentences modified, improved and deteriorated by each model.

we can verify this by comparing TER scores with regard to the reference post-edition (TER-*pe*) and TER scores with regard to the raw MT output (TER-*mt*). The lower the TER-*mt* score the fewer changes have been made to the input to arrive at the output, thus resulting in higher faithfulness. Table 4 contains this comparison for the WMT-2016 APE test set. The hard-attention models indeed make fewer changes than their soft-attention counterparts. This difference is especially dramatic for M-CGRU and M-CGRU-HARD, where only small differences in TER-*pe* occur, but a gap of more than two TER points for TER-*mt*. This shows that hard-attention models can reach similar TER scores to soft-attention models while performing fewer changes. It might also explain why ensembling has a lower impact on the hard-attention models: higher faithfulness means less variety which results in smaller benefits from ensembles.

Table 5 compares the number of modified, improved and deteriorated test set sentences (2000 in total) for all models. The majority of sentences is being modified. While the number of deteriorated sentences is comparable between models, the number of improved sentences increases for the dual-source architectures. Ensembles lower the number of deteriorated sentences rather than increasing the number of improved sentences.

6.2 Visualization of Attention Types

Figures 1 and 2 visualize the behavior of the presented attention variants examined in this work for the example sentences in Table 6.

For this sentence, the unseen MT system mistranslated the word “Set” as “festlegen”. The monolingual *mt* \rightarrow *pe* systems cannot easily correct the error as the original meaning is lost, but

<i>mt</i>	Wählen Sie einen Tastaturbefehlssatz im Menü festlegen .
<i>src</i>	Select a shortcut set in the Set menu .
CGRU	Wählen Sie einen Tastaturbefehlssatz im Menü aus .
GRU-HARD	Wählen Sie einen Tastaturbefehlssatz im Menü aus .
CGRU-HARD	Wählen Sie einen Tastaturbefehlssatz im Menü aus .
M-CGRU	Wählen Sie einen Tastaturbefehlssatz im Menü " Satz " aus .
M-CGRU-HARD	Wählen Sie einen Tastaturbefehlssatz im Menü " Satz . "
<i>pe</i>	Wählen Sie einen Tastaturbefehlssatz im Menü " Satz . "

Table 6: Example corrections for different models. Only the multi-source models manage to restore the missing translation for “Set” and insert quotes. The added particle “aus” does not appear in the reference, but is grammatically correct as well.

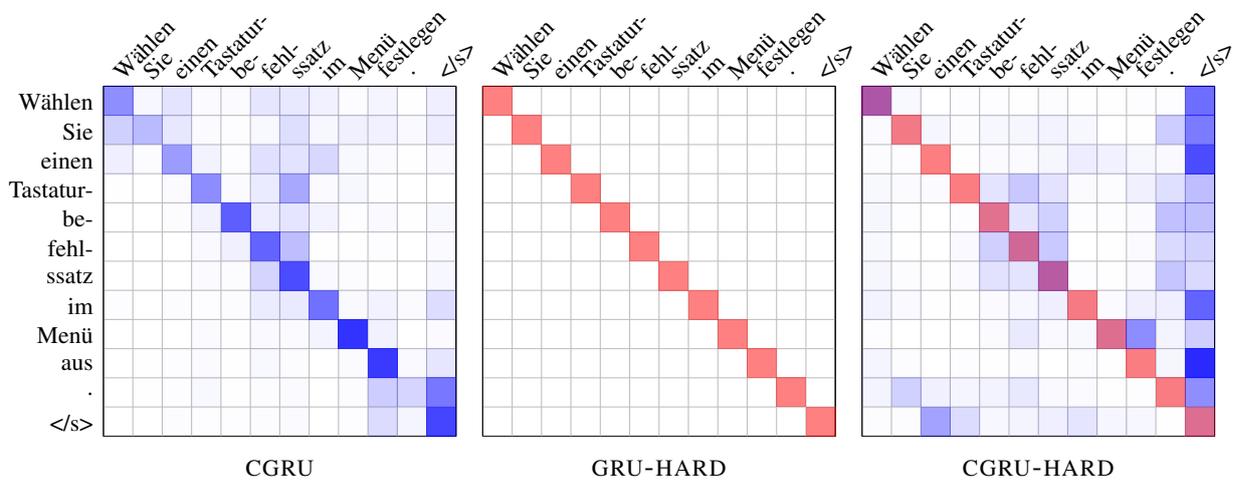

Figure 1: Behavior of different monolingual attention models (best viewed in color).

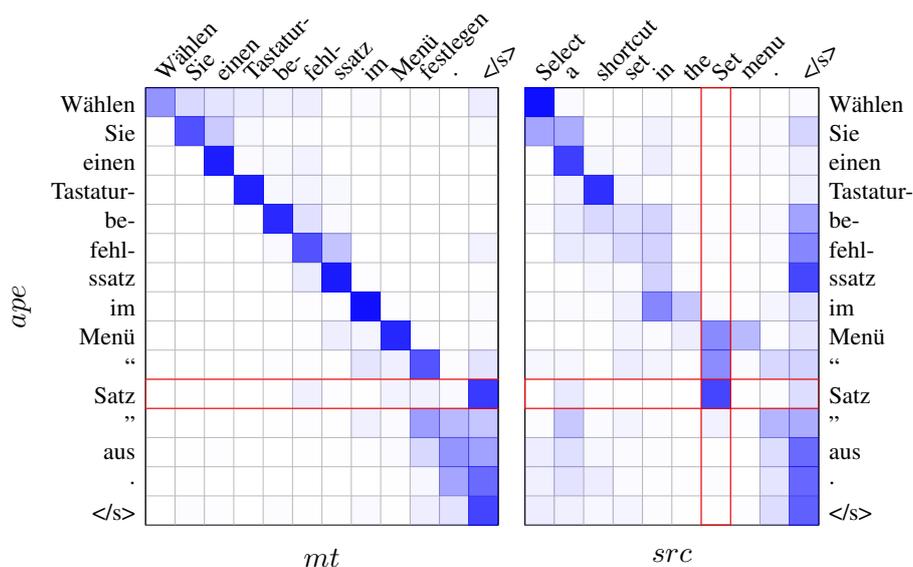

Figure 2: Attention matrices for dual-soft-attention model M-CGRU (best viewed in color).

they improve grammaticality. In Figure 1, we see how the soft attention model (CGRU) follows the input roughly monotonically. The monotonic hard attention model (GRU-HARD) does this naturally. For CGRU-HARD, it is interesting to see how the monotonic attention now allows the soft attention mechanism to look around the input sentence more freely or to remain inactive instead of following the monotonic path.

Both $\{mt, src\} \rightarrow pe$ systems take advantage of the *src* information and improve the input. The proposed modifications could be accepted as correct; one matches the reference. The highlighted rows and columns in Figure 2 show how the original source was used to reconstruct the missing word “Satz” and how both attention mechanisms interact. The attention over *src* seems to spend most time in a “parking” position at the sentence end unless it can provide useful information; the attention over *mt* follows the input closely.

7 Conclusions and Future Work

In this paper we presented several neural APE models that are equipped with non-standard attention mechanisms and combinations thereof. Among these, hard attention models have been applied to APE for the first time, whereas dual-soft attention models have been proposed before for APE tasks, but with non-conclusive results.

This is the first work to report state-of-the-art results for dual-attention models that integrate full post-edition triplets into a single end-to-end model. The ensembles of dual-attention models provide more than 1.52 TER points improvement over the best WMT-2016 system and 0.7 TER improvement over the best reported system combination for the same test set.

We also demonstrated that while hard-attention models yield similar results to pure soft-attention models, they do so by performing fewer changes to the input. This might be a useful property in scenarios where conservative edits are preferred.

Abstract

We decompose multimodal translation into two sub-tasks: learning to translate and learning visually grounded representations. In a multitask learning framework, translations are learned in an attention-based encoder-decoder, and grounded representations are learned through image representation prediction. Our approach improves translation performance compared to the state of the art on the Multi30K dataset. Furthermore, it is equally effective if we train the image prediction task on the external MS COCO dataset, and we find improvements if we train the translation model on the external News Commentary parallel text.

1 Introduction

Multimodal machine translation is the task of translating sentences in context, such as images paired with a parallel text (Specia et al., 2016). This is an emerging task in the area of multilingual multimodal natural language processing. Progress on this task may prove useful for translating the captions of the images illustrating online news articles, and for multilingual closed captioning in international television and cinema.

Initial efforts have not convincingly demonstrated that visual context can improve translation quality. In the results of the First Multimodal Translation Shared Task, only three systems outperformed an off-the-shelf text-only phrase-based machine translation model, and the best performing system was equally effective with or without the visual features (Specia et al., 2016). There remains an open question about how translation models should take advantage of visual context.

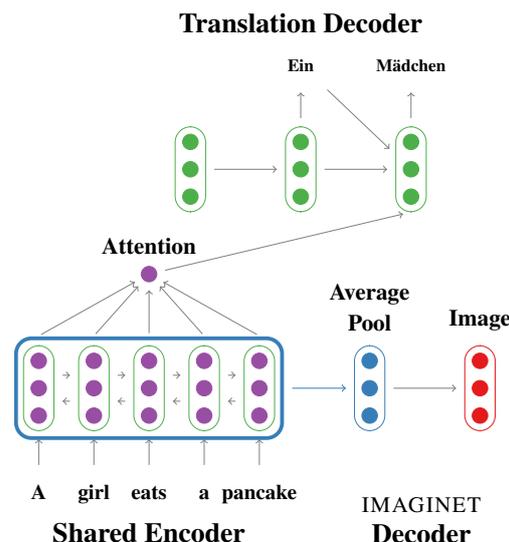

Figure 1: The Imagination model learns visually-grounded representations by sharing the encoder network between the Translation Decoder with image prediction in the IMAGINET Decoder.

We present a multitask learning model that decomposes multimodal translation into learning a translation model and learning visually grounded representations. This decomposition means that our model can be trained over external datasets of parallel text or described images, making it possible to take advantage of existing resources. Figure 1 presents an overview of our model, Imagination, in which source language representations are shared between tasks through the Shared Encoder. The translation decoder is an attention-based neural machine translation model (Bahdanau et al., 2015), and the image prediction decoder is trained to predict a global feature vector of an image that is associated with a sentence (Chrupała et al., 2015, IMAGINET). This decomposition encourages grounded learning in the shared encoder because the IMAGINET decoder is trained to imagine

the image associated with a sentence. It has been shown that grounded representations are qualitatively different from their text-only counterparts (Kádár et al., 2016) and correlate better with human similarity judgements (Chrupała et al., 2015). We assess the success of the grounded learning by evaluating the image prediction model on an image–sentence ranking task to determine if the shared representations are useful for image retrieval (Hodosh et al., 2013). In contrast with most previous work, our model does not take images as input at translation time, rather it learns grounded representations in the shared encoder.

We evaluate Imagination on the Multi30K dataset (Elliott et al., 2016) using a combination of in-domain and out-of-domain data. In the in-domain experiments, we find that multitasking translation with image prediction is competitive with the state of the art. Our model achieves 55.8 Meteor as a single model trained on multimodal in-domain data, and 57.6 Meteor as an ensemble.

In the experiments with out-of-domain resources, we find that the improvement in translation quality holds when training the IMAGINET decoder on the MS COCO dataset of described images (Chen et al., 2015). Furthermore, if we significantly improve our text-only baseline using out-of-domain parallel text from the News Commentary corpus (Tiedemann, 2012), we still find improvements in translation quality from the auxiliary image prediction task. Finally, we report a state-of-the-art result of 59.3 Meteor on the Multi30K corpus when ensembling models trained on in- and out-of-domain resources.

The main contributions of this paper are:

- We show how to apply multitask learning to multimodal translation. This makes it possible to train models for this task using external resources alongside the expensive triple-aligned source-target-image data.
- We decompose multimodal translation into two tasks: learning to translate and learning grounded representations. We show that each task can be trained on large-scale external resources, e.g. parallel news text or images described in a single language.
- We present a model that achieves state of the art results without using images as an input. Instead, our model learns visually grounded source language representations using an

auxiliary image prediction objective. Our model does not need any additional parameters to translate unseen sentences.

2 Problem Formulation

Multimodal translation is the task of producing target language translation y , given the source language sentence x and additional context, such as an image v (Specia et al., 2016). Let x be a source language sentence consisting of N tokens: x_1, x_2, \dots, x_n and let y be a target language sentence consisting of M tokens: y_1, y_2, \dots, y_m . The training data consists of tuples $\mathcal{D} \in (x, y, v)$, where x is a description of image v , and y is a translation of x .

Multimodal translation has previously been framed as minimising the negative log-likelihood of a translation model that is additionally conditioned on the image, i.e. $J(\theta) = -\sum_j \log p(y_j | y_{<j}, x, v)$. Here, we decompose the problem into learning to translate and learning visually grounded representations. The decomposition is based on sharing parameters θ between these two tasks, and learning task-specific parameters ϕ . We learn the parameters in a multitask model with shared parameters in the source language encoder. The translation model has task-specific parameters ϕ^t in the attention-based decoder, which are optimized through the translation loss $J_T(\theta, \phi^t)$. Grounded representations are learned through an image prediction model with task-specific parameters ϕ^g in the image-prediction decoder by minimizing $J_G(\theta, \phi^g)$. The joint objective is given by mixing the translation and image prediction tasks with the parameter w :

$$J(\theta, \phi) = wJ_T(\theta, \phi^t) + (1 - w)J_G(\theta, \phi^g) \quad (1)$$

Our decomposition of the problem makes it straightforward to optimise this objective without paired tuples, e.g. where we have an external dataset of described images $\mathcal{D}_{image} \in (x, v)$ or an external parallel corpus $\mathcal{D}_{text} \in (x, y)$.

We train our multitask model following the approach of Luong et al. (2016). We define a primary task and an auxiliary task, and a set of parameters θ to be shared between the tasks. A minibatch of updates is performed for the primary task with probability w , and for the auxiliary task with $1-w$. The primary task is trained until convergence and weight w determines the frequency of parameter updates for the auxiliary task.

3 Imagination Model

3.1 Shared Encoder

The encoder network of our model learns a representation of a sequence of N tokens $x_{1\dots n}$ in the source language with a bidirectional recurrent neural network (Schuster and Paliwal, 1997). This representation is shared between the different tasks. Each token is represented by a one-hot vector \mathbf{x}_i , which is mapped into an embedding \mathbf{e}_i through a learned matrix \mathbf{E} :

$$\mathbf{e}_i = \mathbf{x}_i \cdot \mathbf{E} \quad (2)$$

A sentence is processed by a pair of recurrent neural networks, where one captures the sequence left-to-right (forward), and the other captures the sequence right-to-left (backward). The initial state of the encoder \mathbf{h}_{-1} is a learned parameter:

$$\vec{\mathbf{h}}_i = \overrightarrow{\text{RNN}}(\overrightarrow{\mathbf{h}}_{i-1}, \mathbf{e}_i) \quad (3)$$

$$\overleftarrow{\mathbf{h}}_i = \overleftarrow{\text{RNN}}(\overleftarrow{\mathbf{h}}_{i-1}, \mathbf{e}_i) \quad (4)$$

Each token in the source language input sequence is represented by a concatenation of the forward and backward hidden state vectors:

$$\mathbf{h}_i = [\vec{\mathbf{h}}_i; \overleftarrow{\mathbf{h}}_i] \quad (5)$$

3.2 Neural Machine Translation Decoder

The translation model decoder is an attention-based recurrent neural network (Bahdanau et al., 2015). Tokens in the decoder are represented by a one-hot vector \mathbf{y}_j , which is mapped into an embedding \mathbf{e}_j through a learned matrix \mathbf{E}_y :

$$\mathbf{e}_j = \mathbf{y}_j \cdot \mathbf{E}_y \quad (6)$$

The inputs to the decoder are the previously predicted token \mathbf{y}_{j-1} , the previous decoder state \mathbf{d}_{j-1} , and a timestep-dependent context vector \mathbf{c}_j calculated over the encoder hidden states:

$$\mathbf{d}_j = \text{RNN}(\mathbf{d}_{j-1}, \mathbf{y}_{j-1}, \mathbf{e}_j) \quad (7)$$

The initial state of the decoder \mathbf{d}_{-1} is a nonlinear transform of the mean of the encoder states, where \mathbf{W}_{init} is a learned parameter:

$$\mathbf{d}_{-1} = \tanh(\mathbf{W}_{init} \cdot \frac{1}{N} \sum_i \mathbf{h}_i) \quad (8)$$

The context vector \mathbf{c}_j is a weighted sum over the encoder hidden states, where N denotes the length of the source sentence:

$$\mathbf{c}_j = \sum_{i=1}^N \alpha_{ji} \mathbf{h}_i \quad (9)$$

The α_{ji} values are the proportion of which the encoder hidden state vectors $\mathbf{h}_{1\dots n}$ contribute to the decoder hidden state when producing the j th token in the translation. They are computed by a feed-forward neural network, where \mathbf{v}_a , \mathbf{W}_a and \mathbf{U}_a are learned parameters:

$$\alpha_{ji} = \frac{\exp(e_{ji})}{\sum_{l=1}^N \exp(e_{li})} \quad (10)$$

$$e_{ji} = \mathbf{v}_a \cdot \tanh(\mathbf{W}_a \cdot \mathbf{d}_{j-1} + \mathbf{U}_a \cdot \mathbf{h}_i) \quad (11)$$

From the hidden state \mathbf{d}_j the network predicts the conditional distribution of the next token y_j , given a target language embedding \mathbf{e}_{j-1} of the previous token, the current hidden state \mathbf{d}_j , and the calculated context vector \mathbf{c}_j . Note that at training time, y_{j-1} is the true observed token; whereas for unseen data we use the inferred token \hat{y}_{j-1} sampled from the output of the softmax:

$$p(y_j | y_{<j}, c) = \text{softmax}(\tanh(\mathbf{e}_{j-1} + \mathbf{d}_j + \mathbf{c}_j)) \quad (12)$$

The translation model is trained to minimise the negative log likelihood of predicting the target language output:

$$J_{NLL}(\theta, \phi^t) = - \sum_j \log p(y_j | y_{<j}, x) \quad (13)$$

3.3 Imaginet Decoder

The image prediction decoder is trained to predict the visual feature vector of the image associated with a sentence (Chrupała et al., 2015). It encourages the shared encoder to learn grounded representations for the source language.

A source language sentence is encoded using the Shared Encoder, as described in Section 3.1. Then we transform the shared encoder representation into a single vector by taking the mean pool over the hidden state annotations, the same way we initialise the hidden state of the translation decoder (Eqn. 8). This sentence representation is the input to a feed-forward neural network that predicts the visual feature vector $\hat{\mathbf{v}}$ associated with a

	Size	Tokens	Types	Images

sentence with parameters \mathbf{W}_{vis} :

$$\hat{\mathbf{v}} = \tanh(\mathbf{W}_{\text{vis}} \cdot \frac{1}{N} \sum_i^N \mathbf{h}_i) \quad (14)$$

This decoder is trained to predict the true image vector \mathbf{v} with a margin-based objective, parameterised by the minimum margin α , and the cosine distance $d(\cdot, \cdot)$. A margin-based objective has previously been used in grounded representation learning (Vendrov et al., 2016; Chrupała et al., 2017). The contrastive examples \mathbf{v}' are drawn from the other instances in a minibatch:

$$J_{MAR}(\theta, \phi^t) = \sum_{\mathbf{v}' \neq \mathbf{v}} \max\{0, \alpha - d(\hat{\mathbf{v}}, \mathbf{v}) + d(\hat{\mathbf{v}}, \mathbf{v}')\} \quad (15)$$

4 Data

We evaluate our model using the benchmark Multi30K dataset (Elliott et al., 2016), which is the largest collection of images paired with sentences in multiple languages. This dataset contains 31,014 images paired with an English language sentence and a German language translation: 29,000 instances are reserved for training, 1,014 for development, and 1,000 for evaluation.¹

The English and German sentences are pre-processed by normalising the punctuation, lowercasing and tokenizing the text using the Moses toolkit. We additionally decompound the German text using Zmorge (Sennrich and Kunz, 2014).

¹The Multi30K dataset also contains 155K independently collected descriptions in German and English. In order to make our experiments more comparable with previous work, we do not make use of this data.

This results in vocabulary sizes of 10,214 types for English and 16,022 for German.

We also use two external datasets to evaluate our model: the MS COCO dataset of English described images (Chen et al., 2015), and the English-German News Commentary parallel corpus (Tiedemann, 2012). When we perform experiments with the News Commentary corpus, we first calculate a 17,597 sub-word vocabulary using SentencePiece (Schuster and Nakajima, 2012) over the concatenation of the Multi30K and News Commentary datasets. This gives us a shared vocabulary for the external data that reduces the number of out-of-vocabulary tokens.

Images are represented by 2048D vectors extracted from the ‘pool5/7x7_s1’ layer of the GoogLeNet v3 CNN (Szegedy et al., 2015).

5 Experiments

We evaluate our multitasking approach with in- and out-of-domain resources. We start by reporting results of models trained using only the Multi30K dataset. We also report the results of training the IMAGINET decoder with the COCO dataset. Finally, we report results on incorporating the external News Commentary parallel text into our model. Throughout, we report performance of the En→De translation using Meteor (Denkowski and Lavie, 2014) and BLEU (Papineni et al., 2002) against lowercased tokenized references.

5.1 Hyperparameters

The encoder is a 1000D Gated Recurrent Unit bidirectional recurrent neural network (Cho et al., 2014, GRU) with 620D embeddings. We share all of the encoder parameters between the primary and auxiliary task. The translation decoder is a 1000D GRU recurrent neural network, with a 2000D context vector over the encoder states, and 620D word embeddings (Sennrich et al., 2017). The Imaginet decoder is a single-layer feed-forward network, where we learn the parameters $\mathbf{W}_{\text{vis}} \in \mathbb{R}^{2048 \times 2000}$ to predict the true image vector with $\alpha = 0.1$ for the Imaginet objective (Equation 15). The models are trained using the Adam optimiser with the default hyperparameters (Kingma and Ba, 2015) in minibatches of 80 instances. The translation task is defined as the primary task and convergence is reached when BLEU has not increased for five epochs on the validation data. Gradients are clipped when their norm ex-

ceeds 1.0. Dropout is set to 0.2 for the embeddings and the recurrent connections in both tasks (Gal and Ghahramani, 2016). Translations are decoded using beam search with 12 hypotheses.

5.2 In-domain experiments

We start by presenting the results of our multitask model trained using only the Multi30K dataset. We compare against state-of-the-art approaches and text-only baselines. Moses is the phrase-based machine translation model (Koehn et al., 2007) reported in (Specia et al., 2016). NMT is a text-only neural machine translation model. Calixto et al. (2017) is a double-attention model over the source language and the image. Calixto and Liu (2017) is a multimodal translation model that conditions the decoder on semantic image vector extracted from the VGG-19 CNN. Hitschler et al. (2016) uses visual features in a target-side retrieval model for translation. Toyama et al. (2016) is most comparable to our approach: it is a multimodal variational NMT model that infers latent variables to represent the source language semantics from the image and linguistic data.

Table 2 shows the results of this experiment. We can see that the combination of the attention-based translation model and the image prediction model is a 1.8 Meteor point improvement over the NMT baseline, but it is 1.1 Meteor points worse than the strong Moses baseline. Our approach is competitive with previous approaches that use visual features as inputs to the decoder and the target-side reranking model. It also competitive with

+ Imagination (COCO)	57.1 ± 0.2	37.8 ± 0.7
Calixto et al. (2017)	56.8	39.0

Table 4: Translation results with out-of-domain parallel text and described images. We find further improvements when we multitask with the News Commentary (NC) and COCO datasets.

Toyama et al. (2016), which also only uses images for training. These results confirm that our multitasking approach uses the image prediction task to improve the encoder of the translation model.

5.3 External described image data

Recall from Section 2 that we are interested in scenarios where x , y , and v are drawn from different sources. We now experiment with separating the translation data from the described image data using \mathcal{D}_{image} : MS COCO dataset of 83K described images² and \mathcal{D}_{text} : Multi30K parallel text.

Table 3 shows the results of this experiment. We find that there is no significant difference between training the IMAGINET decoder on in-domain (Multi30K) or out-of-domain data (COCO). This result confirms that we can separate the parallel text from the described images.

5.4 External parallel text data

We now experiment with training our model on a combination of the Multi30K and the News Commentary English-German data. In these experiments, we concatenate the Multi30K and News

²Due to differences in the vocabularies of the respective datasets, we do not train on examples where more than 10% of the tokens are out-of-vocabulary in the Multi30K dataset.

	Parallel text		Described images		Meteor	BLEU
	Multi30K	News Commentary	Multi30K	COCO		
Zmorph	✓				56.2	37.8
	✓		✓		57.6	39.0
Sub-word	✓				54.4	35.0
	✓				58.6	39.4
	✓	✓			59.0	39.5
	✓	✓	✓	✓	59.3	40.2

Table 5: Ensemble decoding results. Zmorph denotes models trained with decomposed German words; Sub-word denotes joint SentencePiece word splitting (see Section 4 for more details).

Commentary datasets into a single D_{text} training dataset, similar to Freitag and Al-Onaizan (2016). We compare our model against Calixto et al. (2017), who pre-train their model on the WMT’15 English-German parallel text and back-translate (Sennrich et al., 2016) additional sentences from the bilingual independent descriptions in the Multi30K dataset (Footnote 2).

Table 4 presents the results. The text-only NMT model using sub-words is 1.2 Meteor points lower than decomposing the German text. Nevertheless, the model trained over a concatenation of the parallel texts is a 2.7 Meteor point improvement over this baseline (+ NC) and matches the performance of our Multitasking model that uses only in-domain data (Section 5.2). We do not see an additive improvement for the multitasking model with the concatenated parallel text and the in-domain data (+ Imagination) using a training objective interpolation of $w = 0.89$ (the ratio of the training dataset sizes). This may be because we are essentially learning a translation model and the updates from the IMAGINET decoder are forgotten. Therefore, we experiment with multitasking the concatenated parallel text and the COCO dataset ($w = 0.5$). We find that balancing the datasets improves over the concatenated text model by 0.4 Meteor (+ Imagination (COCO)). Our multitasking approach improves upon Calixto et al. by 0.3 Meteor points. Our model can be trained in 48 hours using 240K parallel sentences and 414K described images from out-of-domain datasets. Furthermore, recall that our model does not use images as an input for translating unseen data, which results in 6.2% fewer parameters compared to using the 2048D Inception-V3 visual features to initialise the hidden state of the decoder.

5.5 Ensemble results

Table 5 presents the results of ensembling different randomly initialised models. We achieve a start-of-the-art result of 57.6 Meteor for a model trained on only in-domain data. The improvements are more pronounced for the models trained using sub-words and out-of-domain data. An ensemble of baselines trained on sub-words is initially worse than an ensemble trained on Zmorph decomposed words. However, we always see an improvement from ensembling models trained on in- and out-of-domain data. Our best ensemble is trained on Multi30K parallel text, the News Commentary parallel text, and the COCO descriptions to set a new state-of-the-art result of 59.3 Meteor.

5.6 Multi30K 2017 results

We also evaluate our approach against 16 submissions to the WMT Shared Task on Multimodal Translation and Multilingual Image Description (Elliott et al., 2017). This shared task features a new evaluation dataset: Multi30K Test 2017 (Elliott et al., 2017), which contains 1,000 new evaluation images. The shared task submissions are evaluated with Meteor and human direct assessment (Graham et al., 2017). We submitted two systems, based on whether they used only the Multi30K dataset (constrained) or used additional external resources (unconstrained). Our constrained submission is an ensemble of three Imagination models trained over only the Multi30K training data. This achieves a Meteor score of 51.2, and a joint 3rd place ranking according to human assessment. Our unconstrained submission is an ensemble of three Imagination models trained with the Multi30K, News Commentary, and MS COCO datasets. It achieves a Meteor score of

53.5, and 2nd place in the human assessment.

5.7 Qualitative examples

Table 6 shows examples of where the multitasking model improves or worsens translation performance compared to the baseline model³. The first example shows that the baseline model makes a significant error in translating the pose of the children, translating “on their stomachs” as “on their faces”). The middle example demonstrates that the baseline model translates the dog as walking (“läuft”) and then makes grammatical and sense errors after the clause marker. Both models neglect to translate the word “dangling”, which is a low-frequency word in the training data. There are instances where the baseline produces better translations than the multitask model: In the bottom example, our model translates a bird flying through the water (“durch”) instead of “over” the water.

6 Discussion

6.1 Does the model learn grounded representations?

A natural question to ask is whether the multitask model is actually learning representations that are relevant for the images. We answer this question by evaluating the Imagenet decoder in an image-sentence ranking task. Here the input is a source language sentence, from which we predict its im-

³We used MT-ComparEval (Klejšch et al., 2015)

age vector \hat{v} . The predicted vector \hat{v} can be compared against the true image vectors v in the evaluation data using the cosine distance to produce a ranked order of the images. Our model returns a median rank of 11.0 for the true image compared to the predicted image vector. Figure 2 shows examples of the nearest neighbours of the images predicted by our multitask model. We can see that the combination of the multitask source language representations and IMAGENET decoder leads to the prediction of relevant images. This confirms that the shared encoder is indeed learning visually grounded representations.

6.2 The effect of visual feature vectors

We now study the effect of varying the Convolutional Neural Network used to extract the visual features used in the Imagenet decoder. It has previously been shown that the choice of visual features can affect the performance of vision and language models (Jabri et al., 2016; Kiela et al., 2016). We compare the effect of training the IMAGENET decoder to predict different types of image features, namely: 4096D features extracted from the ‘fc7’ layer of the VGG-19 model (Simonyan and Zisserman, 2015), 2048D features extracted from the ‘pool5/7x7_s1’ layer of InceptionNet V3 (Szegedy et al., 2015), and 2048D features extracted from ‘avg_pool’ layer of ResNet-50 (He et al., 2016). Table 7 shows the results of this experiment. There is a clear difference between predicting the 2048D

(a) Nearest neighbours for “a native woman is working on a craft project .”

(b) Nearest neighbours for “there is a cafe on the street corner with an oval painting on the side of the building .”

Figure 2: We can interpret the IMAGINET Decoder by visualising the predictions made by our model.

	Meteor	Median Rank
Inception-V3	56.0 ± 0.1	11.0 ± 0.0
Resnet-50	54.7 ± 0.4	11.7 ± 0.5
VGG-19	53.6 ± 1.8	13.0 ± 0.0

Table 7: The type of visual features predicted by the IMAGINET Decoder has a strong impact on the Multitask model performance.

vectors (Inception-V3 and ResNet-50) compared to the 4096D vector from VGG-19). This difference is reflected in both the translation Meteor score and the Median rank of the images in the validation dataset. This is likely because it is easier to learn the parameters of the image prediction model that has fewer parameters (8.192 million for VGG-19 vs. 4.096 million for Inception-V3 and ResNet-50). However, it is not clear why there is such a pronounced difference between the Inception-V3 and ResNet-50 models⁴.

7 Related work

Initial work on multimodal translation used semantic or spatially-preserving image features as inputs to a translation model. Semantic image features are typically extracted from the final layer of a pre-trained object recognition CNN, e.g. ‘pool5/7x7_s1’ in GoogLeNet (Szegedy et al., 2015). This type of vector has been used as input to the encoder (Elliott et al., 2015; Huang

⁴We used pre-trained CNNs (<https://github.com/fchollet/deep-learning-models>), which claim equal ILSVRC object recognition performance for both models: 7.8% top-5 error with a single-model and single-crop.

et al., 2016), the decoder (Libovický et al., 2016), or as features in a phrase-based translation model (Shah et al., 2016; HITSCHLER et al., 2016). Spatially-preserving image features are extracted from deeper inside a CNN, where the position of a feature is related to its position in the image. These features have been used in “double-attention models”, which calculate independent context vectors for the source language and a convolutional image features (Calixto et al., 2016; Caglayan et al., 2016; Calixto et al., 2017). We use an attention-based translation model but our multitask model does not use images for translation.

More related to our work is an extension of Variational Neural Machine Translation to infer latent variables to *explicitly* model the semantics of source sentences from visual and linguistic information (Toyama et al., 2016). They report improvements on the Multi30K data set but their model needs additional parameters in the “neural inferrer” modules. In our model, the grounded semantics are represented *implicitly* in the shared encoder. They assume Source-Target-Image training data, whereas our approach achieves equally good results if we train on separate Source-Image and Source-Target datasets. Saha et al. (2016) study cross-lingual image description where the task is to generate a sentence in language L_1 given the image, using only Image- L_2 and L_1 - L_2 training corpora. They propose a Correlational Encoder-Decoder to model the Image- L_2 and L_1 - L_2 data, which learns correlated representations for paired Image- L_2 data and decodes L_1 from the joint representation. Similar to our work, the encoder is trained by minimizing two loss functions: the Image- L_2 correlation loss, and the L_1 decoding

cross-entropy loss. Nakayama and Nishida (2017) consider a zero-resource problem, where the task is to translate from L_1 to L_2 with only Image- L_1 and Image- L_2 corpora. Their model embeds the image, L_1 , and L_2 in a joint multimodal space learned by minimizing a multi-task ranking loss between both pairs of examples. In this paper, we focus on *enriching* source language representations with visual information instead of zero-resource learning.

Multitask Learning improves the generalisability of a model by requiring it to be useful for more than one task (Caruana, 1997). This approach has recently been used to improve the performance of sentence compression using eye gaze as an auxiliary task (Klerke et al., 2016), and to improve shallow parsing accuracy through the auxiliary task of predicting keystrokes in an out-of-domain corpus (Plank, 2016). More recently, Bingel and Søgaard (2017) analysed the beneficial relationships between primary and auxiliary sequential prediction tasks. In the translation literature, multitask learning has been used to learn a one-to-many languages translation model (Dong et al., 2015), a multi-lingual translation model with a single attention mechanism shared across multiple languages (Firat et al., 2016), and in multitask sequence-to-sequence learning without an attention-based decoder (Luong et al., 2016). We explore the benefits of grounded learning in the specific case of multimodal translation. We combine sequence prediction with continuous (image) vector prediction, compared to previous work which multitasks different sequence prediction tasks.

Visual representation prediction has been studied using static images or videos. Lin and Parikh (2015) use a conditional random field to imagine the composition of a clip-art scene for visual paraphrasing and fill-in-the-blank tasks. Chrupała et al. (2015) predict the image vector associated with a sentence using an L2 loss; they found this improves multi-modal word similarity compared to text-only baselines. Gelderloos and Chrupała (2016) predict the image vector associated with a sequence of phonemes using a max-margin loss, similar to our image prediction objective. Collell et al. (2017) learn to predict the visual feature vector associated with a word for word similarity and relatedness tasks. As a video reconstruction problem, Srivastava et al. (2015) propose an LSTM Autoencoder to predict video frames as a

reconstruction task or as a future prediction task. Pasunuru and Bansal (2017) propose a multitask model for video description that combines unsupervised video reconstruction, lexical entailment, and video description. They find improvements from using out-of-domain resources for entailment and video prediction, similar to the improvements we find from using out-of-domain parallel text and described images.

8 Conclusion

We decompose multimodal translation into two sub-problems: learning to translate and learning visually grounded representations. In a multitask learning framework, we show how these sub-problems can be addressed by sharing an encoder between a translation model and an image prediction model⁵. Our approach achieves state-of-the-art results on the Multi30K dataset without using images for translation. We show that training on separate parallel text and described image datasets does not hurt performance, encouraging future research on multitasking with diverse sources of data. Furthermore, we still find improvements from image prediction when we improve our text-only baseline with the out-of-domain parallel text. Future work includes adapting our decomposition to other NLP tasks that may benefit from out-of-domain resources, such as semantic role labelling, dependency parsing, and question-answering; exploring methods for inputting the (predicted) image into the translation model; experimenting with different image prediction architectures; multitasking different translation languages into a single shared encoder; and multitasking in both the encoder and decoder(s).

Acknowledgments

We are grateful to the anonymous reviewers for their feedback. We thank Joost Bastings for sharing his multitasking Nematus model, Wilker Aziz for discussions about formulating the problem, Stella Frank for finding and explaining the qualitative examples to us, and Afra Alishahi, Grzegorz Chrupała, and Philip Schulz for feedback on earlier drafts of the paper. Abstract

End-to-end training makes the neural machine translation (NMT) architecture simpler, yet elegant compared to traditional statistical machine translation (SMT). However, little is known about linguistic patterns of morphology, syntax and semantics learned during the training of NMT systems, and more importantly, which parts of the architecture are responsible for learning each of these phenomena. In this paper we i) analyze how much morphology an NMT decoder learns, and ii) investigate whether injecting target morphology into the decoder helps it produce better translations. To this end we present three methods: i) joint generation, ii) joint-data learning, and iii) multi-task learning. Our results show that explicit morphological information helps the decoder learn target language morphology and improves the translation quality by 0.2–0.6 BLEU points.

1 Introduction

Neural machine translation (NMT) offers an elegant end-to-end architecture, improving translation quality compared to traditional phrase-based machine translation. These improvements are attributed to more fluent output (Toral and Sánchez-Cartagena, 2017) and better handling of morphology and long-range dependencies (Bentivogli et al., 2016). However, systematic studies are required to understand what kinds of linguistic phenomena (morphology, syntax, semantics, etc.) are learned by these models and more importantly, which of the components is responsible for each phenomenon.

A few attempts have been made to understand

what NMT models learn about morphology (Belinkov et al., 2017a), syntax (Shi et al., 2016) and semantics (Belinkov et al., 2017b). Shi et al. (2016) used activations at various layers from the NMT encoder to predict syntactic properties on the source-side, while Belinkov et al. (2017a) and Belinkov et al. (2017b) used a similar approach to investigate the quality of word representations on the task of morphological and semantic tagging.

Belinkov et al. (2017a) found that word representations learned from the encoder are rich in morphological information, while representations learned from the decoder are significantly poorer. However, the paper does not present a convincing explanation for this finding. Our first contribution in this work is to provide a more comprehensive analysis of morphological learning on the decoder side. We hypothesize that other components of the NMT architecture – specifically the encoder and the attention mechanism, learn enough information about the target language morphology for the decoder to perform reasonably well, without incorporating high levels of morphological knowledge into the decoder. To probe this hypothesis, we investigate the following questions:

- What is the effect of attention on the performance of the decoder?
- How much does the encoder help the decoder in predicting the correct morphological variant of the word it generates?

To answer these questions, we train NMT models for different language pairs, involving morphologically rich languages such as German and Czech. We then use the trained models to extract features from the decoder for words in the language of interest. Finally we train a classifier using the extracted features to predict the morphological tag of the words. The accuracy of this ex-

ternal classifier gives us a quantitative measure of how well the NMT model learned features that are relevant to morphology. Our results indicate that both the encoder and the attention mechanism aid the decoder in generating correct morphological forms, and thus limit the need of the decoder to learn target morphology.

Motivated by these findings, we hypothesize that it may be possible to force the decoder to learn more about morphology by injecting the morphological information during training which can in turn improve the overall translation quality. In order to test this hypothesis, we experiment with three possible solutions:

1. *Joint Generation*: An NMT model is trained on the concatenation of words and morphological tags on the target side.
2. *Joint-data learning*: An NMT model is trained where each source sequence is used twice with an artificial token to either predict target words or morphological tags.
3. *Multi-task learning*: A multi-task NMT system with two objective functions is trained to jointly learn translation and morphological tagging.

Our experiments show that word representations learned after explicitly injecting target morphology improve morphological tagging accuracy of the decoder by 3% and also improves the translation quality by up to 0.6 BLEU points.

The remainder of this paper is organized as follows. Section 2 describes our experimental setup. Section 3 shows an analysis of the decoder. Section 4 describes the three proposed methods to integrate morphology into the decoder. Section 5 presents the results. Section 6 gives an account of related work and Section 7 concludes the paper.

2 Experimental Design

Parallel Data

We used the German-English and Czech-English datasets from the WIT³ TED corpus (Cettolo, 2016) made available for IWSLT 2016. We used the official training sets to analyze and evaluate the proposed methods for integrating morphology. The corpus also provides four test sets, test-11 through test-14. We used test-11 for tuning, and the other test sets for evaluation. The statistics for the sets are provided in Table 1.

Language-pair	Sentences	tok _{de/cz}	tok _{en}
De↔En	210K	4M	4.2M
Cz↔En	122K	2.1M	2.5M

Table 1: Statistics for the data used for training, tuning and testing

Morphological Annotations

In order to train and evaluate the external classifier on the extracted features, we required data annotated with morphological tags. We used the following tools recommended on the Moses website¹ to annotate the data: LoPar (Schmid, 2000) for German, Tree-tagger (Schmid, 1994) for Czech and MXPOST (Ratnaparkhi, 1998) for English. The number of tags produced by these taggers is 214 for German and 368 for Czech.

Data preprocessing

We used the standard MT pre-processing pipeline of tokenizing and truecasing the data using Moses (Koehn et al., 2007) scripts. We did not apply byte-pair encoding (BPE) (Sennrich et al., 2016b), which has recently become a common part of the NMT pipeline, because both our analysis and the annotation tools are word level.² However, experimenting with BPE and other representations such as character-based models (Kim et al., 2015) would be interesting.³

NMT Systems

We used the seq2seq-attn implementation (Kim, 2016) with the following default settings: word embeddings and LSTM states with 500 dimensions, SGD with an initial learning rate of 1.0 and decay rate of 0.5 (after the 9th epoch), and dropout rate of 0.3. We use two uni-directional hidden layers for both the encoder and the decoder.

¹These have been used frequently to annotate data in the previous evaluation campaigns (Birch et al., 2014; Durrani et al., 2014a).

²The difficulty with using these is that it is not straightforward to derive word representations out of a decoder that processes BPE-ed text, because the original words are split into subwords. We considered aggregating the representations of BPE subword units, but the choice of aggregation strategy may have an undesired impact on the analysis. For this reason we decided to leave exploration of BPE for future work.

³Character-based models are becoming increasingly popular in Neural MT, for addressing the rare word problem – and they have been used previously also to benefit MT for morphologically rich (Luong et al., 2010; Belinkov and Glass, 2016; Costa-jussà and Fonollosa, 2016) and closely related languages (Durrani et al., 2010; Sajjad et al., 2013).

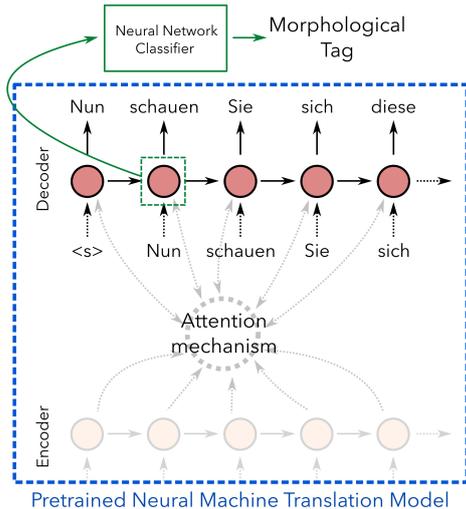

Figure 1: Features for the word *Nun* (DEC_{t_1}) are extracted from the decoder of a pre-trained NMT system and provided to the classifier for training

The NMT system is trained for 13 epochs, and the model with the best validation loss is used for extracting features for the external classifier. We use a vocabulary size of 50000 on both the source and target side.

Classifier Settings

For the classification task, we used a feed-forward network with one hidden layer, dropout ($\rho = 0.5$), a ReLU non-linearity, and an output layer mapping to the tag set (followed by a Softmax). The size of the hidden layer is set to be identical to the size of the NMT decoder’s hidden state (500 dimensions). The classifier has no explicit access to context other than the hidden representation generated by the NMT system, which allows us to focus on the quality of the representation. We use Adam (Kingma and Ba, 2014) with default parameters to minimize the cross-entropy objective.

3 Decoder Analysis

3.1 Methodology

We follow a process similar to Shi et al. (2016) and Belinkov et al. (2017a) to analyze the NMT systems but with a focus on the decoder component of the architecture. Formally, given a source sentence $s = \{s_1, s_2, \dots, s_N\}$ and a target sentence $t = \{t_1, t_2, \dots, t_M\}$, we first use the encoder (Equation 1) to compute a set of hidden states $h = \{h_1, h_2, \dots, h_N\}$. We then use an attention mechanism (Bahdanau et al., 2014) to compute a

weighted average of these hidden states from the previous decoder state (d_{i-1}), known as the context vector c_i (Equation 2). The context vector is a real valued vector of k dimensions, which is set to be the same as the hidden states in our case. The attention model computes a weight w_{h_i} for each hidden state of the encoder, thus giving soft alignment for each target word. The context vector is then used by the decoder (Equation 3) to generate the next word in the target sequence:

$$\text{ENC} : s = \{s_1, \dots, s_N\} \mapsto h = \{h_1, \dots, h_N\} \quad (1)$$

$$\text{ATTN}_i : h, d_{i-1}, t_{i-1} \mapsto c_i \in \mathbb{R}^k (1 \leq i \leq M) \quad (2)$$

$$\text{DEC} : \{c_1, \dots, c_M\} \mapsto t = \{t_1, t_2, \dots, t_M\} \quad (3)$$

After training the NMT system, we freeze the parameters of the network and use the encoder or the decoder as a feature extractor to generate vectors representing words in the sentence. Let ENC_{s_i} denote the representation of a source word s_i . We use ENC_{s_i} to train the external classifier that for predicting the morphological tag for s_i and evaluate the quality of the representation based on our ability to train a good classifier. For word representations on the target side, we feed our word of interest t_i as the previously predicted word, and extract the representation DEC_{t_i} from the higher layers (See Figure 1 for illustration).

Note that in the decoder, the target word representations DEC_{t_i} are not learned for predicting the word t_i , but the next word (t_{i+1}). Hence, it is arguable that DEC_{t_i} actually captures morphological information about t_{i+1} rather than t_i , which can also explain the poorer decoder accuracies. To test this argument, we also trained our systems assuming that DEC_{t_i} encodes morphological information about the next word t_{i+1} . In this case, the decoder performance dropped by almost 15%. DEC_{t_i} probably encodes morphological information about both the current word (t_i) and the next word (t_{i+1}). However, we leave this exploration for future work, and work with the assumption that DEC_{t_i} encodes information about word t_i .

3.2 Analysis

Before diving into the decoder’s performance, we first compare the performance of encoder versus decoder by training $\text{De} \leftrightarrow \text{En}^4$ and $\text{Cz} \leftrightarrow \text{En}$ NMT models. We use the $\text{De} \rightarrow \text{En}/\text{Cz} \rightarrow \text{En}$ models to extract encoder representations, and the

⁴By $\text{De} \leftrightarrow \text{En}$, we mean independently trained German-to-English and English-to-German models.

Baseline	ENC _{s_i}	DEC _{t_i}
De↔En	89.5	44.55
Cz↔En	77.0	36.35

Table 2: Comparison of morphological accuracy for the encoder and decoder representations

En→De/En→Cz models to extract decoder representations. We then feed these representations to our classifier to predict morphological tags for German and Czech words. Table 2 shows that German and Czech representations learned on the encoder-side (using the De→En/Cz→En models) give much better accuracy compared to the ones learned on the decoder-side (using the En→De/En→Cz models).

Given this difference in performance between the two components in our NMT system, we analyze the decoder further in various settings: comparing the performance i) with and without the attention mechanism, and ii) augmenting the decoder representation with the representation of the most attended source word. The baseline NMT models were trained with an attention mechanism. In an attempt to probe what effect the attention mechanism has on the decoder’s performance in the context of learning target language morphology, we trained NMT models without attention. Next we tried to take our baseline model (with attention) and augment its decoder representations with the encoder hidden state corresponding to the maximum attention (hereby denoted as ENC_{t_i}). Our hypothesis is that since the decoder focuses on this hidden state to output the next target word, it may also encode some useful information about target morphology. Lastly, we also train a classifier on ENC_{t_i} alone in order to compare the ability of the encoder and decoder in learning *target* language morphology.

Table 3 summarizes the results of these experiments. Comparing systems with (DEC_{t_i}) and without attention (w/o-ATTN), we see that the accuracy on the morphological tagging task goes up when no attention is used. This can be explained by the fact that in the case of no attention, the decoder only receives a single context vector from the encoder and it has to learn more information about each target word to make accurate predictions. It is difficult for the encoder to transfer information about each target word using the same context vector cleanly, causing the decoder

	DEC _{t_i}	w/o-ATTN	DEC _{t_i} +ENC _{t_i}	ENC _{t_i}
En→De	44.55	50.26	60.34	43.43
En→Cz	36.35	42.09	48.64	36.36

Table 3: Morphological Tagging accuracy of the Decoder with and without attention, and effect of considering the most attended source word (ENC_{t_i})

to learn more, resulting in better decoder performance in regards to the morphological information learned.

The second part of the table presents results involving encoder representations to aid morphological analysis of target words. There is a significant boost in the classifier’s performance when the decoder representation for a target word t_i is concatenated with the encoder representation of the most attended source word (DEC_{t_i}+ENC_{t_i}). This hints towards several hypotheses: i) because the source and target words are translations, they share some morphological properties (e.g. nouns get translated to nouns, etc.), ii) the encoder also learns and stores information about the target language, so that the attention mechanism can make use of this information while deciding which word to focus on next. To ensure that the encoder and decoder indeed learn different information, we also tried to classify the morphological tag of a given word t_i based on the encoder representation of the most attended source word alone (ENC_{t_i}). We see a drop in accuracy, showing that both encoder and decoder learned different things about the same target word and are complementary representations. We can also see that the accuracy of the combined representation (DEC_{t_i}+ENC_{t_i}) still lags behind the encoder’s performance in predicting source morphology (Table 2). This indicates that there is still room for improvement in the NMT model’s ability to learn target side morphology.

In this section, we showed that the encoder and decoder learn different amounts of morphology due to the varying nature of their tasks within NMT architecture. The decoder depends on the encoder and attention mechanism to generate the correct morphological variant of a target word.

4 Morphology-aware Decoder

Motivated by the result that the decoder learns considerably less amount of morphology than the

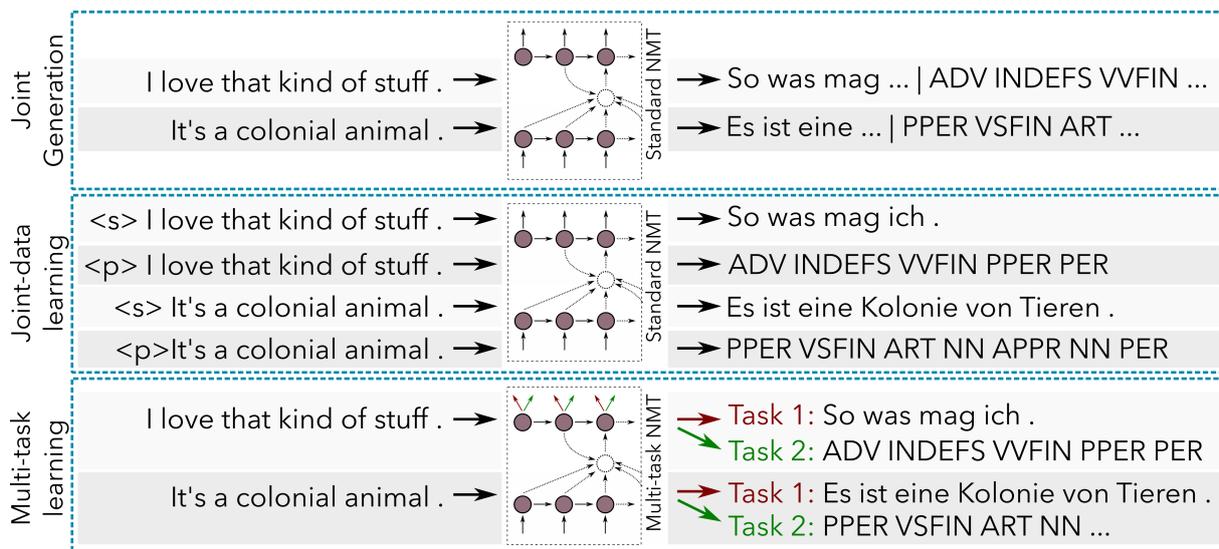

Figure 2: Various approaches to inject morphological knowledge into the decoder

encoder (Table 2) and the overall system does not learn as much about target morphology as source morphology, we investigated three ways to directly inject target morphology into the decoder, namely: i) Joint Generation, ii) Joint-data Learning, iii) Multi-task Learning. Figure 2 illustrates the approaches.

4.1 Joint Generation

As our first approach, we considered a solution that uses the standard NMT architecture, but is trained on a modified dataset. To incorporate morphological information, we modify the target sentence by appending the morphological tag sequence to it. The NMT system trained on this data learns to produce both words and morphological tags simultaneously. Formally, given a source sentence $s = \{s_1, \dots, s_N\}$, target sentence $t = \{t_1, \dots, t_M\}$ and its morphological sequence $m = \{m_1, \dots, m_M\}$, we train an NMT system on (s', t') pairs, where $s' = s$ and $t' = t + m$. Although this model is quite weak and the (word and morphological) bases are quite far away, we posit that the attention mechanism might be able to attend to the same source word twice. Given this, the decoder gets a similar representation from which it has to predict a word in the first instance, and a tag in the second - thus helping in common learning for the two tasks.

4.2 Joint-data Learning

Given the drawbacks of the first approach, we considered another data augmentation technique

inspired by multilingual NMT systems (Johnson et al., 2016). Instead of having multiple source and target languages, we used one source language and two target language variations. The training data consists of sequences of source→target words and source→target morphological tags. We added an artificial token in the beginning of each source sentence indicating whether we want to generate target words or morphological tags. Using an artificial token in the source sentence has been explored and shown to work well to control the style of the target language (Sennrich et al., 2016a). The objective function is the same as the one in usual sequence-to-sequence models, and is hence shared to minimize both morphological and translation error given the mixed data.

4.3 Multi-task Learning

In this final method, we decided to follow a more principled approach and modified the standard sequence-to-sequence for multi-task learning. The goal in multi-task training is to learn several tasks simultaneously such that each task can benefit from the mutual information learned (Collobert and Weston, 2008).⁵ With this motivation, we modified the NMT decoder to predict not only a word but also its corresponding tag. All of the layers below the output layers are shared. We have two output layers in parallel – the first to predict the target word, and the second to predict the morphological tag of the target word. Both output lay-

⁵For example, Eriguchi et al. (2017) jointly learned the tasks of parsing and translation.

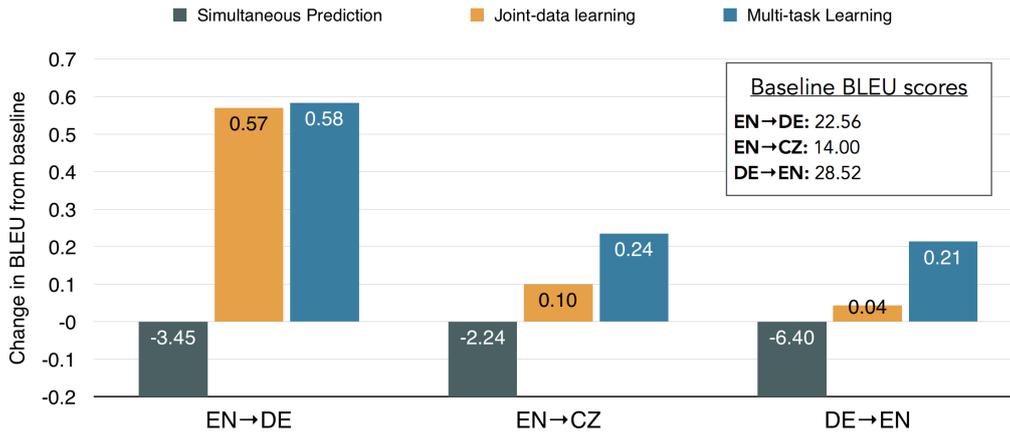

Figure 3: Improvements from adding morphology. A y-value of zero represents the baseline

ers have their own separate loss function. While training, we combine the losses from both output layers to jointly train the system. This is different from the Joint-data learning technique, where we predict entire sequences of words or tags without any dependence on each other.

Formally, given a set of N tasks, sequence-to-sequence multi-task learning involves an objective function minimizing the overall loss, which is a weighted combination of the N individual task losses. In our scenario, the training corpus consisted of a multi-target corpus: source→target words and source→target morphological tags, i.e. $N = 2$. Hence, given a set of training examples $D = \{ \langle s^{(n)}, t^{(n)}, m^{(n)} \rangle \}_{n=1}^N$, where s is the source sentence, t is the target sentence and m is the target morphological tag sequence, the new objective function to maximize is as follows:

$$\mathcal{L} = (1 - \lambda) \sum_{n=1}^N \log P(t^{(n)} | s^{(n)}; \theta) + \lambda \sum_{n=1}^N \log P(m^{(n)} | s^{(n)}; \theta)$$

Where λ is a hyper-parameter used to shift focus towards translation or the morphological tagging.⁶

5 Results and Discussion

Our results show that the multi-task learning approach performed the best among the three approaches, while the Joint Generation method has the poorest performance. Figure 3 summarizes the results for different language pairs. The joint generation method degrades overall translation performance, as expected, given its weakness from

⁶We tuned the weight parameter on held-out data.

a modeling perspective. It is possible that even though the attention mechanism is able to focus on the source sequence in two passes, the parts of the network that predict words and tags are not tightly coupled enough to learn from each other.

The BLEU scores improved when using the other two methods. We achieved an improvement of up to 0.6 BLEU points and 3% (in tagging accuracy). The best improvements were obtained in the En→De direction, while we observed lesser gains in the De→En. This is perhaps because English is morphologically poorer, and the baseline system was able to learn the required amount of morphological information from the text itself. Improvements were also obtained for the En→Cz direction, although not as much as in German. This could be due to data sparsity: Czech is much richer in morphology,⁷ and the available TED En↔Cz data was 40% less than the En↔De data.

Joint-data vs. Multi-task Learning

Both Joint-data learning and Multi-task learning improved overall translation performance. In the case of En→De, the performance of both approaches is very similar. However, each has its own pros and cons. While the joint-data learning method is a simple approach that allows to add morphology and other linguistic information without needing to change the architecture, the multi-task learning approach is a more principled and powerful way of integrating the same information into the decoder. Having separate objective functions in multi-task learning also allows us to adjust the balance between the two tasks, which can

⁷The number of morphological tags in Czech are 368 versus 214 in German.

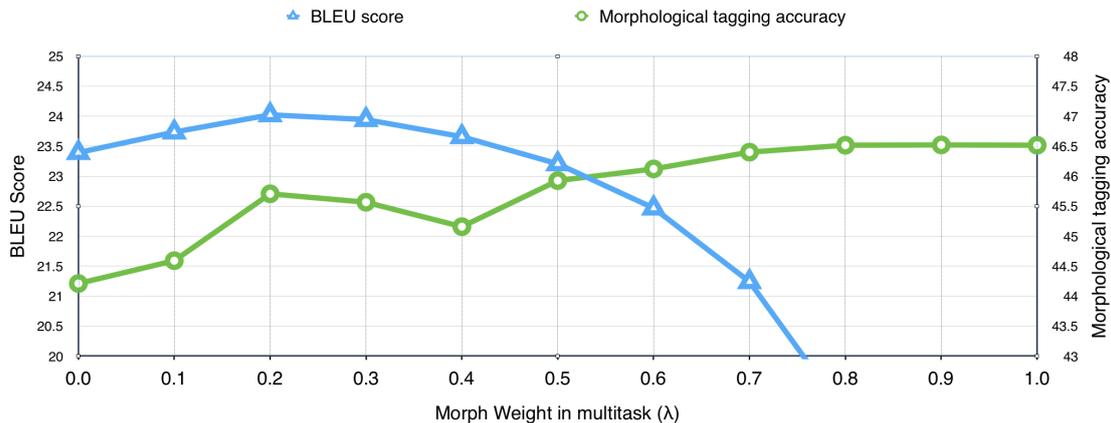

Figure 4: Multi-task learning: Translation vs. Morphological Tagging weight for En→De model

be handy if the morphological information quality is not very high. On the flip side, this additional explicit weight adjustment can also be viewed as a potential constraint that is not present in the joint-data learning approach.

Multi-task Weight Hyper-Parameter

As discussed, the multi-task learning approach has an additional weight hyper-parameter λ that adjusts the balance between word and tag prediction. Figure 4 shows the result of varying λ from no morphological information ($\lambda = 0$) to only morphological information ($\lambda = 1$) on test-11 set. The left y-axis presents the BLEU score and the right y-axis presents the morphological accuracy. The best morphological accuracy is achieved at $\lambda = 1$ which does not correspond to best translation quality since at that point the model is only minimizing the tag objective function. Similarly at $\lambda = 0$, the model falls back to the baseline model with a single objective function minimizing translation error. For all language pairs, we consistently achieved the best BLEU score at $\lambda = 0.2$. The parameter was tuned on a separate held out development set (test-11), and the results shown in Figure 3 are on blind test sets (test-12,13). Averages are reported in the figure.

6 Related Work

The related work to this paper can be broken into two groups:

Analysis Several approaches have been devised to analyze MT models and the linguistic properties that are learned during training. A common approach has been to use activations from a trained model to train an external classifier to predict some

relevant information about the input. Köhn (2015) and Qian et al. (2016b) analyzed linguistic information learned in word embeddings, while Qian et al. (2016a) went further and analyzed linguistic properties in the hidden states of a recurrent neural network. Adi et al. (2016) looked at the overall information learned in a sentence summary vector generated by an RNN using a similar approach. Our approach closely aligns with that of Shi et al. (2016) and Belinkov et al. (2017a), where the activations from various layers in a trained NMT system are used to predict linguistic properties.

Integrating Morphology Some work has also been done in injecting morphological or more general linguistic knowledge into an NMT system. Sennrich and Haddow (2016) proposed a factored model that incorporates linguistic features on the source side as additional factors. An embedding is learned for each factor, just like a source word, and then the word and factor embeddings are combined before being passed on to the encoder. Aharoni and Goldberg (2017) proposed a method to predict the target sentence along with its syntactic tree. They linearize the tree in order to use the existing sequence-to-sequence model. Nadejde et al. (2017) also evaluated several methods of incorporating syntactic knowledge on both the source and target. While they used factors on the source side, their best method for the target side was to linearize the information and interleave it between the target words. García-Martínez et al. (2016) used a neural MT model with multiple outputs, like in our case of *Multi-task learning*. Their model predicts two properties at every step, the lemma of the target word and its morphological information. They then use an external tool to use

this information to generate the actual target word. Dong et al. (2015) presented multi-task learning to translate a language into multiple target languages, and Luong et al. (2015) did experiments involving several levels of source and target language information. There have been previous efforts to integrate morphology into MT systems by learning factored models (Koehn and Hoang, 2007; Durrani et al., 2014b) over POS and morphological tags.

7 Conclusion

In this paper we analyzed and investigated ways to improve morphological learning in the NMT decoder. We carried a series of experiments to understand why the decoder learns considerably less morphology than the encoder in the NMT architecture. We found that the decoder needs assistance from the encoder and the attention mechanism to generate correct target morphology. Additionally we explored three ways to explicitly inject morphology in the decoder: joint generation, joint-data learning, and multi-task learning. We found multi-task learning to outperform the other two methods. The simpler joint-data learning method also gave decent improvements. The code for the experiments and the modified framework is available at <https://github.com/fdalvi/seq2seq-attn-multitask>.

Abstract

Compared to traditional statistical machine translation (SMT), neural machine translation (NMT) often sacrifices adequacy for the sake of fluency. We propose a method to combine the advantages of traditional SMT and NMT by exploiting an existing phrase-based SMT model to compute the phrase-based decoding cost for an NMT output and then using this cost to rerank the n -best NMT outputs. The main challenge in implementing this approach is that NMT outputs may not be in the search space of the standard phrase-based decoding algorithm, because the search space of phrase-based SMT is limited by the phrase-based translation rule table. We propose a soft forced decoding algorithm, which can always successfully find a decoding path for any NMT output. We show that using the forced decoding cost to rerank the NMT outputs can successfully improve translation quality on four different language pairs.

1 Introduction

Neural machine translation (NMT), which uses a single large neural network to model the entire translation process, has recently been shown to outperform traditional statistical machine translation (SMT) such as phrase-based machine translation (PBMT) on several translation tasks (Koehn et al., 2003; Bahdanau et al., 2015; Sennrich et al., 2016a). Compared to traditional SMT, NMT generally produces more fluent translations, but often sacrifices adequacy, such as translating source words into completely unrelated target words, over-translation or under-translation (Koehn and Knowles, 2017).

There are a number of methods that combine the two paradigms to address their respective weaknesses. For example, it is possible to incorporate neural features into traditional SMT models to disambiguate hypotheses (Neubig et al., 2015; Stahlberg et al., 2016). However, the search space of traditional SMT is usually limited by translation rule tables, reducing the ability of these models to generate hypotheses on the same level of fluency as NMT, even after reranking. There are also methods that incorporate knowledge from traditional SMT into NMT, such as lexical translation probabilities (Arthur et al., 2016; He et al., 2016), phrase memory (Tang et al., 2016; Zhang et al., 2017), and n -gram posterior probabilities based on traditional SMT translation lattices (Stahlberg et al., 2017). These improve the adequacy of NMT outputs, but do not impose hard alignment constraints like traditional SMT systems and therefore cannot effectively solve all over-translation or under-translation problems.

In this paper, we propose a method that exploits an existing phrase-based translation model to compute the phrase-based decoding cost for a given NMT translation.¹ That is, we force a phrase-based translation system to take in the source sentence and generate an NMT translation. Then we use the cost of this phrase-based forced decoding to rerank the NMT outputs. The phrase-based decoding cost will heavily punish completely unrelated translations, over-translations, and under-translations, as they will not be able to be found in the translation phrase table.

One challenge in implementing this method is that the NMT output may not be in the search space of the phrase-based translation model, which is limited by the phrase-based translation

¹In fact, our method can take in the output of *any* upstream system, but we experiment exclusively with using it to rerank NMT output.

rule table. To solve this problem, we propose a soft forced decoding algorithm, which is based on the standard phrase-based decoding algorithm and integrates new types of translation rules (deleting a source word or inserting a target word). The proposed forced decoding algorithm can always successfully find a decoding path and compute a phrase-based decoding cost for any NMT output. Another challenge is that we need a diverse NMT n -best list for reranking. Because beam search for NMT often lacks diversity in the beam – candidates only have slight differences, with most of the words overlapping – we use a random sampling method to obtain a more diverse n -best list.

We test the proposed method on English-to-Chinese, English-to-Japanese, English-to-German and English-to-French translation tasks, obtaining large improvements over a strong NMT baseline that already incorporates discrete lexicon features.

2 Attentional NMT

Our baseline NMT model is similar to the attentional model of Bahdanau et al. (2015), which includes an encoder, a decoder and an attention (alignment) model. Given a source sentence $F = \{f_1, \dots, f_J\}$, the encoder learns an annotation $h_j = [\vec{h}_j; \overleftarrow{h}_j]$ for f_j using a bi-directional recurrent neural network.

The decoder generates the target translation from left to right. The probability of generating next word e_i is,²

$$P_{NMT}(e_i | e_1^{i-1}, F) = \text{softmax}(g(e_{i-1}, t_i, s_i)) \quad (1)$$

where t_i is a decoding state for time step i , computed by,

$$t_i = f(t_{i-1}, e_{i-1}, s_i) \quad (2)$$

s_i is a source representation for time i , calculated as,

$$s_i = \sum_{j=1}^J \alpha_{i,j} \cdot h_j \quad (3)$$

where $\alpha_{i,j}$ scores how well the inputs around position j and the output at position i match, computed as,

$$\alpha_{i,j} = \frac{\exp(a(t_{i-1}, h_j))}{\sum_{k=1}^J \exp(a(t_{i-1}, h_k))} \quad (4)$$

² g , f and a in Equation 1, 2 and 4 are nonlinear, potentially multi-layered, functions.

As we can see, NMT only learns an attention (alignment) distribution for each target word over all source words and does not provides exact mutually-exclusive word or phrase level alignments. As a result, it is known that attentional NMT systems make mistakes in over- or under-translation (Cohn et al., 2016; Mi et al., 2016).

3 Phrase-based Forced Decoding for NMT

3.1 Phrase-based SMT

In phrase-based SMT (Koehn et al., 2003), a phrase-based translation rule r includes a source phrase, a target phrase and a translation score $S(r)$. Phrase-based translation rules can be extracted from the word-aligned training set and then used to translate new sentences. Word alignments for the training set can be obtained by IBM models (Brown et al., 1993).

Phrase-based decoding uses a list of translation rules to translate source phrases in the input sentence and generate target phrases from left to right. A basic concept in phrase-based decoding is hypotheses. As shown in Figure 1, the hypothesis H_1 consists of two rules r_1 and r_2 . The score of a hypothesis $S(H)$ can be calculated as the product of the scores of all applied rules.³ An existing hypothesis can be expanded into a new hypothesis by applying a new rule. As shown in Figure 1, H_1 can be expanded into H_2 , H_3 and H_4 . H_2 cannot be further expanded, because it covers all source words, while H_3 and H_4 can (and must) be further expanded. The decoder starts with an initial empty hypothesis H_0 and selects the hypothesis with the highest score from all completed hypotheses.

During decoding, hypotheses are stored in stacks. For a source sentence with J words, the decoder builds J stacks. The hypotheses that cover j source words are stored in stack s_j . The decoder expands hypotheses in s_1, s_2, \dots, s_J in turn as shown in Algorithm 1. Here, $\text{EXPAND}(H)$ is expanding H to get new hypotheses and putting the new hypotheses into corresponding stacks. For each stack, a beam of the best n hypotheses is kept to speed up the decoding process.

³In actual phrase-based decoding it is common to integrate reordering probabilities in the forced decoding score defined in Equation 9. However, because NMT generally produces more properly ordered sentences than traditional SMT, in this work we do not consider reordering probabilities in our forced decoding algorithm.

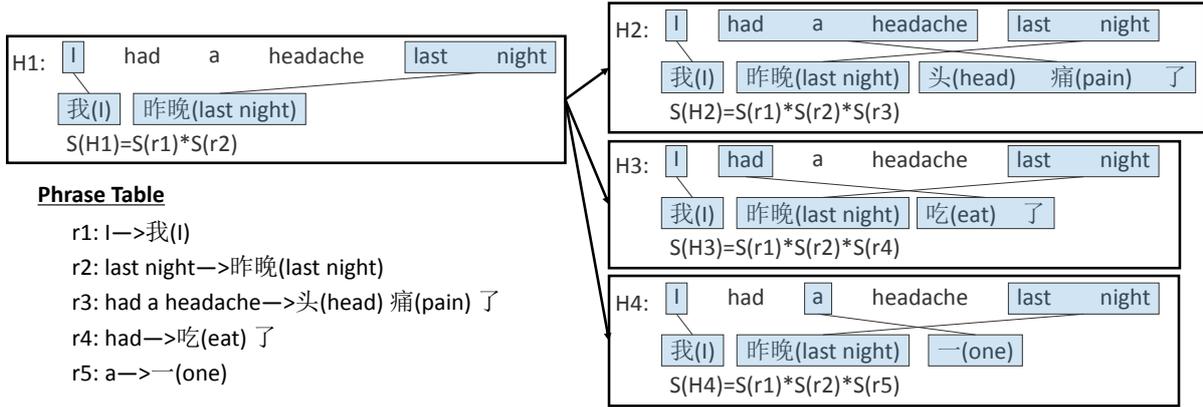

Figure 1: An example of phrase-based decoding.

Algorithm 1 Standard phrase-based decoding.

 EXPAND(H_{jk})

 select best hypothesis in s_j

3.2 Forced Decoding for NMT

As stated in the introduction, our goal is not to generate new hypotheses with phrase-based SMT, but instead use the phrase-based model to calculate scores for NMT output. In order to do so, we can perform *forced decoding*, which is very similar to the algorithm in the previous section but discards all partial hypotheses that do not match the NMT output. However, the NMT output is not limited by the phrase-based rule table, so there may be no decoding path that completely matches the NMT output when using only the phrase-based rules.

To remedy this problem, inspired by previous work in forced decoding for training phrase-based SMT systems (Wuebker et al., 2010, 2012) we propose a soft forced decoding algorithm that can always successfully find a decoding path for a source sentence F and an NMT translation E .

First, we introduce two new types of rules R_1 and R_2 .

R_1 A source word f can be translated into a special word `null`. This corresponds to deleting f during translation. The score of deleting f is cal-

culated as,

$$s(f \rightarrow \text{null}) = \frac{\text{unalign}(f)}{|\mathcal{T}|} \quad (5)$$

where $\text{unalign}(f)$ is how many times f is unaligned in the word-aligned training set \mathcal{T} and $|\mathcal{T}|$ is the number of sentence pairs in \mathcal{T} .

R_2 A target word e can be translated from a special word `null`, which corresponds to inserting e during translation. The score of inserting e is calculated as,

$$s(\text{null} \rightarrow e) = \frac{\text{unalign}(e)}{|\mathcal{T}|} \quad (6)$$

where $\text{unalign}(e)$ is how many times e is unaligned in \mathcal{T} .

One motivation for Equations 5 and 6 is that function words usually have high frequencies, but do not have as clear a correspondence with a word in the other language as content words. As a result, in the training set function words are more often unaligned than content words. As an example, Table 1 and Table 2 show how many times different words occur and how many times they are unaligned in the word-aligned training set of English-to-Chinese and English-to-French tasks in our experiments. As we can see, generally there are less unaligned words in the English-to-French task, however, function words are more likely to be unaligned in both tasks. Based on Equation 5 and Equation 6, the scores of deleting or inserting “of” and “a” will be higher.

In our forced decoding, we choose to model the score of each translation rule that exists in the phrase table as the product of direct and inverse phrase translation probabilities. To make sure that

Words	of	a	practice	water
Occur	1.3M	1.0M	2.2K	29K
Unaligned	0.51M	0.41M	0.25K	3.5K

Table 1: The number of times that words occur in the English-to-Chinese training corpus and the number of times that they are unaligned.

Words	of	a	practice	water
Occur	1.7M	0.83M	8.8K	7.4K
Unaligned	0.16M	0.12M	0.38K	0.19K

Table 2: The number of times that words occur in the English-to-French training corpus and the number of times that they are unaligned.

the scale of the scores for R_1 and R_2 match the other phrase (which are the product of two probabilities), we use the square of the score in Equation 5/6 as the rule score for R_1/R_2 .

Algorithm 2 shows the forced decoding algorithm that integrates the new rules. Because the translation E is given for the forced decoding algorithm, the proposed forced decoding algorithm keeps I stacks, where I is the length of E . In other words, the stack size is corresponding to the target word size during forced decoding while the stack size is corresponding to the source word size during standard phrase-based decoding. The stack s'_i in Algorithm 2 contains all hypotheses in which the first i target words have been generated. We expand hypotheses in s'_1, s'_2, \dots, s'_I in turn. When expanding a hypothesis H_{old} in s'_i , besides expanding it using the original rule table $\text{EXPAND}(H_{old})$,⁴ we also expand H_{old} by inserting the next target word e_{i+1} at the end of H_{old} to get an additional hypothesis H_{new} and put H_{new} into s'_{i+1} . For a final hypothesis in stack s'_I , it may not cover all source words. We update its score by translating uncovered words into `null`.

Because different decoding paths can generate the same final translation, there can be different decoding paths that fit the NMT translation E . We use the score of the single decoding path with the highest decoding score as the forced decoding score for E .

⁴The new introduced word inserting/deleting rules are not used when performing $\text{EXPAND}(H_{old})$.

Algorithm 2 Forced phrase-based decoding.

Require: Source sentence F with length J and translation E with length I

Ensure: Decoding path D

initialize H_0 and s'_1, s'_2, \dots, s'_I

for each hypothesis H_{Ik} in s'_I **do**

 update $S(H_{Ik})$ for uncovered source words

 select best hypothesis in s'_I

4 Reranking NMT Outputs with Phrase-based Decoding Score

We rerank the n -best NMT outputs using the phrase-based forced decoding score according to Equation 7.

$$\log P(E|F) = w_1 \cdot \log P_n(E|F) + w_2 \cdot \log S_d(E|F) \quad (7)$$

where $P_n(E|F)$ is the original NMT translation probability as calculated by Equation 1;

$$P_n(E|F) = \prod_{i=1}^I P_{NMT}(e_i | e_1^{i-1}, F) \quad (8)$$

$S_d(E|F)$ is the forced decoding score, which is the score of the decoding path \hat{D} with the highest decoding score as described above;

$$S_d(E|F) = \prod_{r \in \hat{D}} S(r) \quad (9)$$

w_1 and w_2 are weights that can be tuned on the n -best list of the development set.

The easiest way to get an n -best list for NMT is by using the n -best translations from beam search, which is the standard decoding algorithm for NMT. While beam search is likely to find the highest-scoring hypothesis, it often lacks diversity in the beam: candidates only have slight differences, with most of the words overlapping. In order to obtain a more diverse list of hypotheses for reranking, we additionally augment the 1-best hypothesis discovered by beam search with translations sampled from the NMT conditional probability distribution.

The standard method for sampling hypotheses in NMT is ancestral sampling, where we randomly select a word from the vocabulary according to

$P_{NMT}(e_i|e_1^{i-1}, F)$ (Shen et al., 2016). This will make a diverse list of hypotheses, but may reduce the probability of selecting a highly scoring hypothesis, and the whole n -best list may not contain any candidate with better translation quality than the standard beam search output.

Instead, we take an alternative approach that proved empirically better in our experiments: at each time step i , we use sampling to randomly select the next word from e' and e'' according to Equation 10. Here, e' and e'' are the two target words with the highest probability according to Equation 1.

$$P_{rdm}(e') = \frac{P_{NMT}(e'|e_1^{i-1}, F)}{P_{NMT}(e'|e_1^{i-1}, F) + P_{NMT}(e''|e_1^{i-1}, F)}$$

$$P_{rdm}(e'') = \frac{P_{NMT}(e''|e_1^{i-1}, F)}{P_{NMT}(e'|e_1^{i-1}, F) + P_{NMT}(e''|e_1^{i-1}, F)} \quad (10)$$

The sampling process ends when $\langle /s \rangle$ is selected as the next word.

We repeat the decoding process 1,000 times to sample 1,000 outputs for each source sentence. We additionally add the 1-best output of standard beam search, making the size of the list used for reranking to be 1,001.

5 Experiments

5.1 Settings

We evaluated the proposed approach for English-to-Chinese (en-zh), English-to-Japanese (en-ja), English-to-German (en-de) and English-to-French (en-fr) translation tasks. For the en-zh and en-ja tasks, we used datasets provided for the patent machine translation task at NTCIR-9 (Goto et al., 2011).⁵ For the en-de and en-fr tasks, we used version 7 of the Europarl corpus as training data, WMT 2014 test sets as our development sets and WMT 2015 test sets as our test sets. The detailed statistics for training, development and test sets are given in Table 3. The word segmentation was done by BaseSeg (Zhao et al., 2006) for Chinese and Mecab⁶ for Japanese.

We built attentional NMT systems with Lamtram⁷. Word embedding size and hidden layer size

⁵Note that NTCIR-9 only contained a Chinese-to-English translation task, we used English as the source language in our experiments. In NTCIR-9, the development and test sets were both provided for the zh-en task while only the test set was provided for the en-ja task. We used the sentences from the NTCIR-8 en-ja and ja-en test sets as the development set in our experiments.

Table 3: Data sets.

are both 512. We used Byte-pair encoding (BPE) (Sennrich et al., 2016b) and set the vocabulary size to be 50K. We used the Adam algorithm for optimization.

To obtain a phrase-based translation rule table for our forced decoding algorithm, we used GIZA++ (Och and Ney, 2003) and *grow-diag-final-and* heuristic to obtain symmetric word alignments for the training set. Then we extracted the rule table using Moses (Koehn et al., 2007).

5.2 Results and Analysis

Table 4 shows results of the phrase-based SMT system⁸, the baseline NMT system, the lexicon integration method (Arthur et al., 2016) and the proposed reranking method. We tested three features for reranking: the NMT score P_n , the forced decoding score S_d and a word penalty (WP) feature, which is the length of the translation. The best NMT system and the systems that have no significant difference from the best NMT system at the $p < 0.05$ level using bootstrap resampling (Koehn, 2004) are shown in bold font.

As we can see, integrating lexical translation probabilities improved the baseline NMT system

⁸We used the default Moses settings for phrase-based SMT.

Table 6: Ratio of translation length to reference length for different system outputs in Table 4.

and reranking with the three features all together achieved further improvements for all four language pairs. Even on English-to-Chinese and English-to-Japanese tasks, where the NMT system outperformed the phrase-based SMT system by 7-8 BLEU scores, using the forced decoding score for reranking NMT outputs can still achieve significant improvements. With or without the word penalty feature, using both P_n and S_d for reranking gave better results than only using P_n or S_d alone. We also show METEOR and chrF scores on the test sets in Table 5. Our reranking method improved both METEOR and chrF significantly.

The Word Penalty Feature The word penalty feature generally improved the reranking results, especially when only the NMT score P_n was used for reranking. As we can see, using only P_n for reranking decreased the translation quality com-

pared to the standard beam search result of NMT. Because the search spaces of beam search and random sampling are quite different, the best beam search output does not necessarily have the highest NMT score compared to random sampling outputs. Therefore, even the P_n reranking results do have higher NMT scores, but have lower BLEU scores according to Table 4. To explain why this happened, we show the ratio of translation length to reference length in Table 6. As we can see, the P_n reranking outputs are much shorter. This is because NMT generally prefers shorter translations, since Equation 8 multiplies all target word probabilities together. So the word penalty feature can improve the P_n reranking results considerably, by preferring longer sentences. Because the forced decoding score S_d as shown in Equation 9 does not obviously prefer shorter or longer sentences, when S_d was used for reranking, the word penalty

Table 7: An example of improving inaccurate rare word translation by using S_d for reranking.

feature became less helpful. When both P_n and S_d were used for reranking, the word penalty feature only achieved further significant improvement on the English-to-Japanese task.

Table 7 gives translation examples of our reranking method from the English-to-Chinese task. The source English word “hypophysectomized” is an unknown word which does not occur in the training set. By employing BPE, this word is split into “hypop”, “hy”, “sec”, “to” and “mized”. The correct translation for “hypophysectomized” is “去(remove) 垂体(hypophysis)” as shown in the reference sentence. The original attentional NMT translated it into incorrect translation “过(pass) 盲肠(cecum)”. After integrating lexicons, the NMT system translated it into “低(low) 酪(cheese) 蛋白(protein) 切除(remove)”. The last word “切除(remove)” is correct, but the rest of the translation is still wrong. Only by using the forced decoding score S_d for reranking, we get the more accurate translation “垂体(hypophysis) 在(is) 切除(remove)”.

To further demonstrate how the reranking method works, Table 9 shows translation rules and their log-scores contained in the forced decoding paths found for T_1 , the NMT translation without reranking and T_2 , the NMT translation using both P_n and S_d for reranking. As we can see, the four rules r_a , r_b , r_c and r_d used for T_1 have low scores. r_a is an unlikely translation. In r_b , r_c and r_d , “酪(cheese)”, “蛋白(protein)” and “hypop” are content words, which are unlikely to be deleted or inserted during translation. Table 9 also shows that the translation of function words is very flexible. The score of inserting a function word “的(of)” is very high. The translation rule “the \rightarrow 在(is)” used for T_2 is incorrect, but its score is relatively high, because function words are often

Table 8: An example of improving under-translation and over-translation by using S_d for reranking.

incorrectly aligned in the training set. The reason why function words are more likely to be incorrectly aligned to each other is that they usually have high frequencies and do not have clear correspondences between different languages.

In T_1 , “hypophysectomized (hypop hy sec to mized)” is incorrectly translated into “低(low) 酪(cheese) 蛋白(protein) 切除(remove)”. However, from Table 9, we can see that the forced decoding algorithm learns it as unlikely translation (hy→低(low)), over-translation (null→酪(cheese), null→蛋白(protein)) and under-translation (hypop→null, sec→null), because there is no translation rule between “hypop” “sec” and “酪(cheese)” “蛋白(protein)”. Because content words are unlikely to be deleted or inserted during translation, they have low forced decoding scores. So using the forced decoding score for reranking NMT outputs can naturally improve over-translation or under-translation as shown in Table 8. As we can see, without using S_d for reranking, NMT under-translated “temperature” and over-translated “ph” twice, which will be assigned low scores by forced decoding. By using S_d for reranking, the correct translation was selected.

We did human evaluation on 100 sentences randomly selected from the English-to-Chinese test set to test the effectiveness of our forced decoding

method. We compared the outputs of two systems:

- NMT+lex+rerank(P_n +WP)
- NMT+lex+rerank(P_n + S_d +WP)

For each source sentence, we compared the two system outputs. Table 10 shows the numbers of sentences that our forced decoding feature helped to reduce completely unrelated translation, over-translation and under-translation. The last line of Table 10 means that for 73 source sentences, our forced decoding feature neither reduced nor caused more unrelated/over/under translation. That is our forced decoding feature never caused more unrelated/over/under translation for the sampled 100 sentences, which shows that our method is very robust for improving unrelated/over/under translation.

	both under- and over- translation	2
Reduce	under-translation	11
	over-translation	10
	unrelated translation	4
No difference		73

Table 10: Human evaluation results.

Reranking PBMT Outputs with NMT We also did experiments that use the NMT score as an additional feature to rerank PBMT outputs (unique 1,000-best list). The results are shown

in Table 11. We also copy results of baseline PBMT and NMT from Table 4 for direct comparison. As we can see, using NMT to rerank PBMT outputs achieved improvements over the baseline PBMT system. However, when the baseline NMT system is significantly better than the baseline PBMT system (en-zh, en-ja), even using NMT to rerank PBMT outputs still achieved lower translation quality compared to the baseline NMT system.

6 Related Work

Wuebker et al. (2010, 2012) applied forced decoding on the training set to improve the training process of phrase-based SMT and prune the phrase-based rule table. They also used word insertions and deletions for forced decoding, but they used a high penalty for all insertions and deletions. In contrast, our soft forced decoding algorithm for NMT outputs uses a small penalty for function words and a high penalty for content words, because function words are usually translated very flexibly and more likely to be inserted or deleted compared to content words. For example, the under-translation of a content word can hurt the adequacy of the translation heavily. But function words may naturally disappear during translation (e.g. the English word “the” disappears in Chinese). By assigning a high penalty to words that should not be deleted or inserted during translation, our soft forced decoding method aims to improve the adequacy of NMT, which is very different from previous forced decoding methods that are used to improve general SMT training (Yu et al., 2013; Xiao et al., 2016).

A major difference of traditional SMT and NMT is that the alignment model in traditional SMT provides exact word or phrase level alignments between the source and target sentences while the attention model in NMT only computes an alignment probability distribution for each target word over all source words, which is the main

reason why NMT is more likely to produce completely unrelated translations, over-translation or under-translation compared to traditional SMT. To relieve NMT of these problems, there are methods that modify the NMT neural network structure (Tu et al., 2016; Meng et al., 2016; Alkhouli et al., 2016) while we rerank NMT outputs by exploiting knowledge from traditional SMT.

There are also existing methods that rerank NMT outputs by using target-bidirectional NMT models (Liu et al., 2016; Sennrich et al., 2016a). Their reranking method aims to overcome the issue of unbalanced accuracy in NMT outputs while our reranking method aims to solve the inadequacy problem of NMT.

7 Conclusion

In this paper, we propose to exploit an existing phrase-based SMT model to compute the phrase-based decoding cost for NMT outputs and then use the phrase-based decoding cost to rerank the n -best NMT outputs, so we can combine the advantages of both PBMT and NMT. Because an NMT output may not be in the search space of standard phrase-based SMT, we propose a forced decoding algorithm, which can always successfully find a decoding path for any NMT output by deleting source words and inserting target words. Results show that using the forced decoding cost to rerank NMT outputs improved translation accuracy on four different language pairs.

Abstract

Character-based sequence labeling framework is flexible and efficient for Chinese word segmentation (CWS). Recently, many character-based neural models have been applied to CWS. While they obtain good performance, they have two obvious weaknesses. The first is that they heavily rely on manually designed bigram feature, i.e. they are not good at capturing n -gram features automatically. The second is that they make no use of full word information. For the first weakness, we propose a convolutional neural model, which is able to capture rich n -gram features without any feature engineering. For the second one, we propose an effective approach to integrate the proposed model with word embeddings. We evaluate the model on two benchmark datasets: PKU and MSR. Without any feature engineering, the model obtains competitive performance — 95.7% on PKU and 97.3% on MSR. Armed with word embeddings, the model achieves state-of-the-art performance on both datasets — 96.5% on PKU and 98.0% on MSR, without using any external labeled resource.

1 Introduction

Unlike English and other western languages, most east Asian languages, including Chinese, are written without explicit word delimiters. However, most natural language processing (NLP) applications are word-based. Therefore, word segmentation is an essential step for processing those languages. CWS is often treated as a character-based sequence labeling task (Xue et al., 2003; Peng et al., 2004). Figure 1 gives an intuitive

Figure 1: Chinese word segmentation as a sequence labeling task. This figure presents the common *BMES* (Beginning, Middle, End, Singleton) tagging scheme.

explanation. Linear models, such as Maximum Entropy (ME) (Berger et al., 1996) and Conditional Random Fields (CRF) (Lafferty et al., 2001), have been widely used for sequence labeling tasks. However, they often depend heavily on well-designed hand-crafted features.

Recently, neural networks have been widely used for NLP tasks. Collobert et al. (2011) proposed a unified neural architecture for various sequence labeling tasks. Instead of exploiting hand-crafted input features carefully optimized for each task, their system learns internal representations automatically. As for CWS, there are a series of works, which share the main idea with Collobert et al. (2011) but vary in the network architecture. In particular, feed-forward neural network (Zheng et al., 2013), tensor neural network (Pei et al., 2014), recursive neural network (Chen et al., 2015a), long-short term memory (LSTM) (Chen et al., 2015b), as well as the combination of LSTM and recursive neural network (Xu and Sun, 2016) have been used to derive contextual representations from input character sequences, which are then fed to a prediction layer.

Despite of the great success of above models, they have two weaknesses. The first is that they are not good at capturing n -gram features automatically. Experimental results show that their models perform badly when no bigram feature is explicitly used. One of the strengths of neural networks is the ability to learn features automatically. However, this strength has not been well exploited in

their works. The second is that they make no use of full word information. Full word information has shown its effectiveness in word-based CWS systems (Andrew, 2006; Zhang and Clark, 2007; Sun et al., 2009). Recently, Liu et al. (2016); Zhang et al. (2016) utilized word embeddings to boost performance of word-based CWS models. However, for character-based CWS models, word information is not easy to be integrated.

For the first weakness, we propose a convolutional neural model, which is also character-based. Previous works have shown that convolutional layers have the ability to capture rich n -gram features (Kim et al., 2016). We use stacked convolutional layers to derive contextual representations from input sequence, which are then fed into a CRF layer for sequence-level prediction. For the second weakness, we propose an effective approach to incorporate word embeddings into the proposed model. The word embeddings are learned from large auto-segmented data. Hence, this approach belongs to the category of semi-supervised learning.

We evaluate our model on two benchmark datasets: PKU and MSR. Experimental results show that even without the help of explicit n -gram feature, our model is capable of capturing rich n -gram information automatically, and obtains competitive performance — 95.7% on PKU and 97.3% on MSR (F score). Furthermore, armed with word embeddings, our model achieves state-of-the-art performance on both datasets — 96.5% on PKU and 98.0% on MSR, without using any external labeled resource.¹

2 Architecture

In this section, we introduce the architecture from bottom to top.

2.1 Lookup Table

The first step to process a sentence by deep neural networks is often to transform words or characters into embeddings (Bengio et al., 2003; Collobert et al., 2011). This transformation is done by lookup table operation. A character lookup table $M_{char} \in \mathbb{R}^{|V_{char}| \times d}$ (where $|V_{char}|$ denotes the size of the character vocabulary and d denotes the dimension of embeddings) is associated with all

¹The tensorflow (Abadi et al., 2016) implementation and related resources can be found at <https://github.com/chqiwang/convseg>.

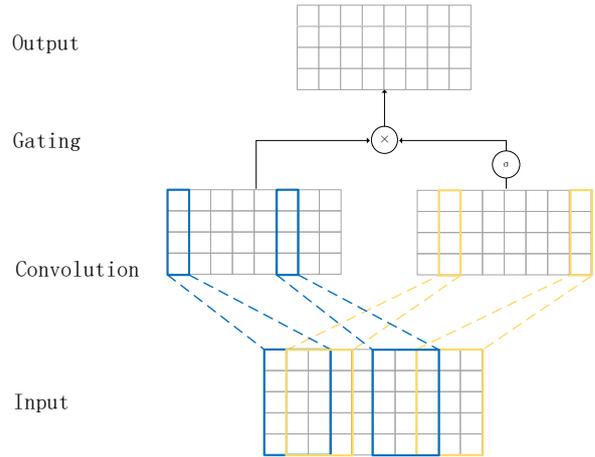

Figure 2: Structure of a convolutional layer with GLU. There are five input channels and four output channels in this figure.

characters. Given a sentence $\mathcal{S} = (c_1, c_2, \dots, c_L)$, after the lookup table operation, we obtain a matrix $X \in \mathbb{R}^{L \times d}$ where the i 'th row is the character embedding of c_i .

Besides the character, other features can be easily incorporated into the model (we shall see word feature in section 3). We associate to each feature a lookup table (some features may share the same lookup table) and the final representation is calculated as the concatenation of all corresponding feature embeddings.

2.2 Convolutional Layer

Many neural network models have been explored for CWS. However, experimental results show that they are not able to capture n -gram information automatically (Pei et al., 2014; Chen et al., 2015a,b). To achieve good performance, n -gram feature must be used explicitly. To overcome this weakness, we use convolutional layers (Waibel et al., 1989) to encode contextual information. Convolutional neural networks (CNNs) have shown its great effectiveness in computer vision tasks (Krizhevsky et al., 2012; Simonyan and Zisserman, 2014; He et al., 2016). Recently, Zhang et al. (2015) applied character-level CNNs to text classification task. They showed that CNNs tend to outperform traditional n -gram models as the dataset goes larger. Kim et al. (2016) also observed that character-level CNN learns to differentiate between different types of n -grams — prefixes, suffixes and others, automatically.

Our network is quite simple — only convolutional layers is used (no pooling layer). Gated lin-

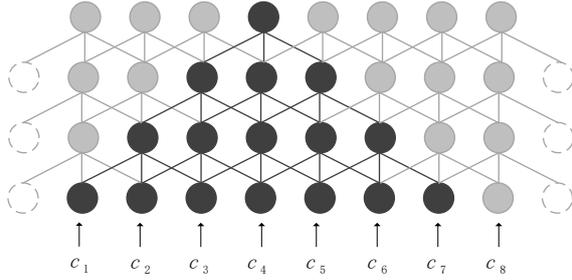

Figure 3: Stacked convolutional layers. There is one input layer on the bottom and three convolutional layers on the top. Dashed white circles denote paddings. Black circles and lines mark the pyramid in the perspective of c_4 .

ear unit (GLU) (Dauphin et al., 2016) is used as the non-linear unit in our convolutional layer, which has been shown to surpass rectified linear unit (ReLU) on the language modeling task. For simplicity, GLU can also be easily replaced by ReLU with performance slightly hurt (with roughly the same number of network parameters). Figure 2 shows the structure of a convolutional layer with GLU. Formally, we define the number of input channels as N , the number of output channels as M , the length of input as L and kernel width as k . The convolutional layer can be written as

$$F(X) = (X * W + b) \otimes \sigma(X * V + c)$$

where $*$ denotes one dimensional convolution operation, $X \in \mathbb{R}^{L \times N}$ is the input of this layer, $W \in \mathbb{R}^{k \times N \times M}$, $b \in \mathbb{R}^M$, $V \in \mathbb{R}^{k \times N \times M}$, $c \in \mathbb{R}^M$ are parameters to be learned, σ is the sigmoid function and \otimes represents element-wise product. We make $F(X) \in \mathbb{R}^{L \times M}$ by augmenting the input X with paddings.

A succession of convolutional layers are stacked to capture long distance information. From the perspective of each character, information flows in a pyramid. Figure 3 shows a network with three convolutional layers stacked. On the topmost layer, a linear transformation is used to transform the output of this layer to unnormalized label scores $E \in \mathbb{R}^{L \times C}$, where C is the number of label types.

2.3 CRF Layer

For sequence labeling tasks, it is often beneficial to explicitly consider the correlations between adjacent labels (Collobert et al., 2011).

Correlations between adjacent labels can be modeled as a transition matrix $T \in \mathbb{R}^{C \times C}$. Given

a sentence $\mathcal{S} = (c_1, c_2, \dots, c_L)$, we have corresponding scores $E \in \mathbb{R}^{L \times C}$ given by the convolutional layers. For a label sequence $y = (y_1, y_2, \dots, y_L)$, we define its unnormalized score to be

$$s(\mathcal{S}, y) = \sum_{i=1}^L E_{i, y_i} + \sum_{i=1}^{L-1} T_{y_i, y_{i+1}}.$$

then the probability of the label sequence is defined as

$$P(y|\mathcal{S}) = \frac{e^{s(\mathcal{S}, y)}}{\sum_{y' \in \mathcal{Y}} e^{s(\mathcal{S}, y')}}.$$

where \mathcal{Y} is the set of all valid label sequences. This actually takes the form of linear chain CRF (Lafferty et al., 2001). Then the final loss of the proposed model is defined as the negative log-likelihood of the ground-truth label sequence y^*

$$\mathcal{L}(\mathcal{S}, y^*) = -\log P(y^*|\mathcal{S}).$$

During training, the loss function is minimized by back propagation. During test, Viterbi algorithm is applied to quickly find the label sequence with maximum probability.

3 Integration with Word Embeddings

Character-based CWS models have the superiority of being flexible and efficient. However, full word information is not easy to be incorporated. There is another type of CWS models: the word-based models. Models belong to this category utilize not only character-level information, but also word-level (Zhang and Clark, 2007; Andrew, 2006; Sun et al., 2009). Recent works have shown that word embeddings learned from large auto-segmented data lead to great improvements in word-based CWS systems (Liu et al., 2016; Zhang et al., 2016). We propose an effective approach to integrate word embeddings with our character-based model. The integration brings two benefits. On the one hand, full word information can be used. On the other hand, large unlabeled data can be better exploited.

To use word embeddings, we design a set of word features, which are listed in Table 1. We associate to the word features a lookup table M_{word} . Then the final representation of c_i is defined as

$$\begin{aligned} R(c_i) = & M_{char}[c_i] \oplus \\ & M_{word}[c_i] \oplus M_{word}[c_{i-1}c_i] \oplus \dots \oplus \\ & M_{word}[c_i c_{i+1} c_{i+2} c_{i+3}] \end{aligned}$$

Length	Features
1	c_i
2	$c_{i-1}\underline{c}_i$ $\underline{c}_i c_{i+1}$
3	$c_{i-2}c_{i-1}\underline{c}_i$ $c_{i-1}\underline{c}_i c_{i+1}$ $\underline{c}_i c_{i+1} c_{i+2}$
4	$c_{i-3}c_{i-2}c_{i-1}\underline{c}_i$ $c_{i-2}c_{i-1}\underline{c}_i c_{i+1}$ $c_{i-1}\underline{c}_i c_{i+1} c_{i+2}$ $\underline{c}_i c_{i+1} c_{i+2} c_{i+3}$

Table 1: Word features at position i given a sentence $S = (c_1, c_2, \dots, c_L)$. Only the words that include the current character c_i (marked with underline) are considered as word feature. Hence, the number of features can be controlled in a reasonable range. We also restrict the max length of words to 4 since few words contain more than 4 characters in Chinese. Note that the feature space is still tremendous ($O(N^4)$, where N is the number of characters).

where \oplus denotes the concatenation operation. Note that the max length of word features is set to 4, therefore the feature space is extremely large ($O(N^4)$). A key step is to shrink the feature space so that the memory cost can be confined within a feasible scope. In the meanwhile, the problem of data sparsity can be eased. The solution is as following. Given the unlabeled data \mathcal{D}_{un} and a teacher CWS model, we segment \mathcal{D}_{un} with the teacher model and get the auto-segmented data \mathcal{D}'_{un} . A vocabulary V_{word} is generated from \mathcal{D}'_{un} where low frequency words are discarded². We replace $M_{word}[*]$ with $M_{word}[UNK]$ if $* \notin V_{word}$ (UNK denotes the unknown words).

To better exploit the auto-segmented data \mathcal{D}'_{un} , we adopt an off-the-self tool *word2vec*³ (Mikolov et al., 2013) to pretrain the word embeddings. The whole procedure is summarized as following steps:

1. Train a *teacher* model that does not rely on word feature.
2. Segment unlabeled data \mathcal{D} with the *teacher* model and get the auto-segmented data \mathcal{D}' .
3. Build a vocabulary V_{word} from \mathcal{D}' . Replace all words not appear in V_{word} with UNK .
4. Pretrain word embeddings on \mathcal{D}' using *word2vec*.
5. Train the *student* model with word feature using the pretrained word embeddings.

Note that no external labeled data is used in this procedure.

²The threshold of frequency is set to 5, which is the default setting of *word2vec*.

4 Experiments

4.1 Settings

Datasets We evaluate our model on two benchmark datasets, PKU and MSR, from the second International Chinese Word Segmentation Bake-off (Emerson, 2005). Both datasets are commonly used by previous state-of-the-art models. For both datasets, last 10% of the training data are used as development set. The unlabeled data used in this work is news data collected by *Sogou*⁴.

We do not perform any preprocessing for these datasets, such as replacing continuous digits and English characters with a single token.

Dropout Dropout (Srivastava et al., 2014) is a very efficient method for preventing overfit, especially when the dataset is small. We apply dropout to our model on all convolutional layers and embedding layers. The dropout rate is fixed to 0.2.

Hyper-parameters For both datasets, we use the same set of hyper-parameters, which are presented in Table 2. For all convolutional layers, we just use the same number of channels. Following the practice of designing very deep CNN in computer vision (Simonyan and Zisserman, 2014), we use a small kernel width, i.e. 3, for all convolutional layers. To avoid computational inefficiency, we use a relatively small dimension, i.e. 50, for word embeddings.

Pretraining Character embeddings and word embeddings are pretrained on unlabeled or auto-segmented data by *word2vec*. Since the pretrained embeddings are not task-oriented, they are fine-tuned during supervised training by normal back-propagation.⁵

Optimization Adam algorithm (Kingma and Ba, 2014) is applied to optimize our model. We use default parameters given in the original paper

⁴<http://www.sogou.com/labs/resource/ca.php>

⁵We also try to use fixed word embeddings as Zhang et al. (2016) do but no significant difference is observed.

Table 3: Performance of our models and previous state-of-the-art models. Note that (Chen et al., 2015a,b; Xu and Sun, 2016) used an external Chinese idiom dictionary. To make the comparison fair, we mark them with *. Chen et al. (2015a,b); Cai and Zhao (2016); Xu and Sun (2016) also preprocessed the datasets by replacing the continuous English character and digits with a unique token. We mark them with [◇].

and we set batch size to 100. For both datasets, we train no more than 100 epochs. The final models are chosen by their performance on the development set.

Weight normalization (Salimans and Kingma, 2016) is applied for all convolutional layers to accelerate the training procedure and obvious acceleration is observed.

4.2 Main Results

Table 3 gives the performances of our models, as well as previous state-of-the-art models. Two proposed models are shown in the table:

- **CONV-SEG** It is our preliminary model without word embeddings. Character embeddings are pretrained on large unlabeled data.
- **WE-CONV-SEG** On the basis of CONV-SEG, word embeddings are used. We use CONV-SEG as the teacher model (see section 3).

Our preliminary model CONV-SEG achieves competitive performance without any feature engineering. Armed with word embeddings, WE-CONV-SEG obtains state-of-the-art performance on both PKU and MSR datasets without using any external labeled data. WE-CONV-SEG outperforms state-of-the-art neural model (Zhang et al., 2016) in a large margin (+0.8 on PKU and +0.3 in MSR). Chen et al. (2015b) preprocessed all datasets by replacing Chinese idioms with a sin-

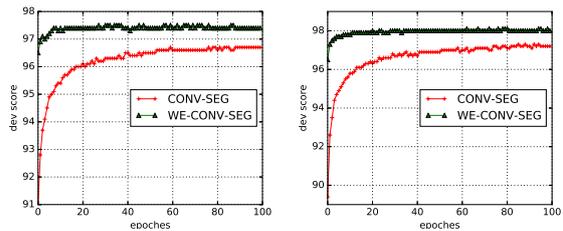

Figure 4: Learning curves (dev scores) of our models on PKU (left) and MSR (right).

gle token and thus their model obtains excellent score on PKU dataset. However, WE-CONV-SEG achieves the same performance on PKU and outperforms their model on MSR, without any data preprocessing.

We also observe that WE-CONV-SEG converges much faster compared to CONV-SEG. Figure 4 presents the learning curves of the two models. It takes 10 to 20 epochs for WE-CONV-SEG to converge while it takes more than 60 epochs for CONV-SEG to converge.

4.3 Network Depth

Network depth shows great influence on the performance of deep neural networks. A too shallow network may not fit the training data very well while a too deep network may overfit or is hard to train. We evaluate the performance of the proposed model with varying depth. Figure 5 shows

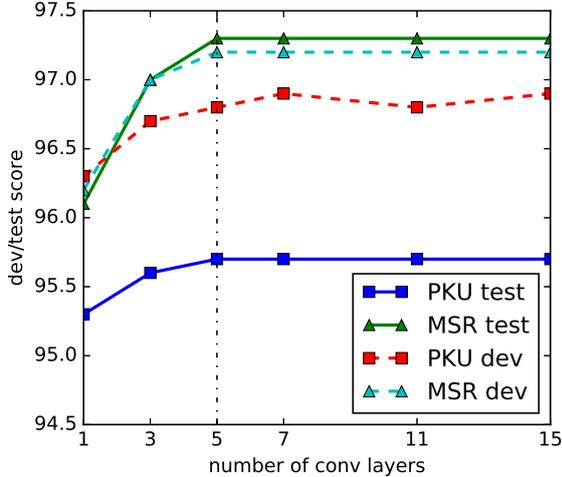

Figure 5: Scores on dev set and test set with respect to the number of convolutional layers. The vertical dashed line marks the depth we choose.

Model Options	PKU	MSR
without pretraining	94.7	96.7
with pretraining	95.7	97.3

Table 4: Test performances with or without pretraining character embeddings. “without pretraining” means that the character embeddings are randomly initialized.

the results. It is obvious that five convolutional layers is a good choice for both datasets. When we increase the depth from 1 to 5, the performance is improved significantly. However, when we increase depth from 5 to 7, even to 11 and 15, the performance is almost unchanged. This phenomenon implies that CWS rarely relies on context larger than 11⁶. With more training data, deeper networks may perform better.

4.4 Pretraining Character Embeddings

Previous works have shown that pretraining character embeddings boost the performance of neural CWS models significantly (Pei et al., 2014; Chen et al., 2015a,b; Cai and Zhao, 2016). We verify this and get a consistent conclusion. Table 4 shows the performances with or without pretraining. Our model obtains significant improvements (+1.0 on PKU and +0.6 on MSR) with pretrained character embeddings.

Results with * used external dictionary. Results with [†] come from Cai and Zhao (2016). Results with [‡] come from Pei et al. (2014). [◊] marks word-based models.

4.5 N-gram Features

In this section, we test the ability of our model in capturing n -gram features. Since unigram is indispensable and trigram is beyond memory limit, we only consider bigram.

Bigram feature has shown to play a vital role in character-based neural CWS models (Pei et al., 2014; Chen et al., 2015a,b). Without bigram feature, previous models perform badly. Table 5 gives a summarization. Without bigram feature, our model outperforms previous character-based models in a large margin (+0.9 on PKU and +1.7 on MSR). Compared with word-based model (Cai and Zhao, 2016), the improvements are also significant (+0.2 on PKU and +0.8 on MSR).

Then we arm our model with bigram feature. The bigram feature we use is the same with Pei et al. (2014); Chen et al. (2015a,b). The dimension of bigram embedding is set to 50. Following Pei et al. (2014); Chen et al. (2015a,b), the bigram embeddings are initialized by the average of corresponding pretrained character embeddings. The result model is named AVEBE-CONV-SEG and the performance is shown in Table 5. Unexpectedly, the performance of AVEBE-CONV-SEG is worse than the preliminary model CONV-SEG that uses no bigram feature (-0.3 on PKU and -0.2

⁶Context size is calculated by $(k - 1) \times d + 1$, where k and d denotes the kernel size and the number of convolutional layers, respectively.

on MSR). This result is dramatically inconsistent with previous works, in which the performance is significantly improved by the method. We also observe that the training cost of AVEBE-CONV-SEG is much lower than CONV-SEG. Hence we can conclude that the inconsistency is caused by overfitting. A reasonable conjecture is that the model CONV-SEG already capture abundant bigram feature automatically, therefore the model is tend to overfit when bigram feature is explicitly added.

A practicable way to overcome overfitting is to introduce priori knowledge. We introduce priori knowledge by using bigram embeddings directly pretrained on large unlabeled data, which is simillar with (Mansur et al., 2013). We convert the unlabeled text to bigram sequence and then apply *word2vec* to pretrain the bigram embeddings directly. The result model is named W2VBE-CONV-SEG, and the performance is also shown in Table 5. This method leads to substantial improvements (+0.5 on PKU and +0.4 MSR) over AVEBE-CONV-SEG. However, compared to CONV-SEG, there are only slight gains (+0.2 on PKU and MSR).

All above observations verify that our proposed network has considerable superiority in capturing n -gram, at least bigram features automatically.

4.6 Word Embeddings

Word embeddings lead to significant improvements over the strong baseline model CONV-SEG. The improvements come from the teacher model and the large unlabeled data. A natural question is how much unlabeled data can lead to significant improvements. We study this by halving the unlabeled data. Figure 6 presents the results. As the unlabeled data becomes smaller, the performance remains unchanged at the beginning and then becomes worse. This demonstrates that the mass of unlabeled data is a key factor to achieve high performance. However, even with only 68MB unlabeled data, we can still observe remarkable improvements (+0.4 on PKU and MSR). We also observe that MSR dataset is more robust to the size of unlabeled data than PKU dataset. We conjecture that this is because MSR training set is larger than PKU training set⁷.

We also study how the teacher’s performance influence the student. We train other two mod-

⁷There are 2M words in MSR training set but only 1M words in PKU training set.

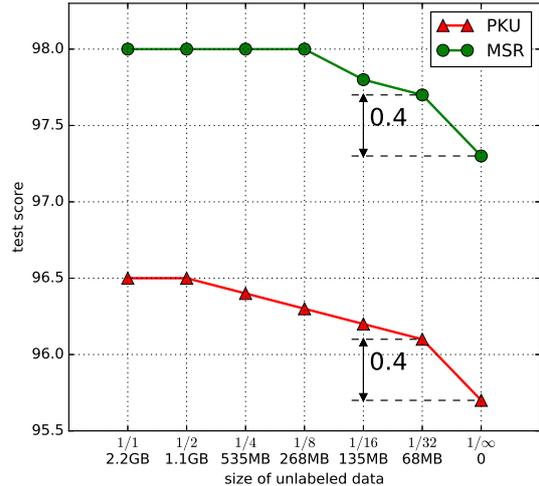

Figure 6: Test performances with varying size of unlabeled data for pretraining word embeddings. With full size, the model is WE-CONV-SEG. With the 0 size, the model degenerates to CONV-SEG.

Models	teacher		student	
	PKU	MSR	PKU	MSR
WE-CONV-SEG	95.7	97.4	96.5	98.0
worse teacher	95.4	97.1	96.4	97.9
better teacher	96.5	98.0	96.5	98.0

Table 6: Performances of student models and teacher models. A previous trained model maybe reused in following so that there are some

els that use different teacher models. One of them uses a worse teacher and the other uses a better teacher. The results are shown in Table 6. As expected, the worse teacher indeed creates a worse student, but the effect is marginal (-0.1 on PKU and MSR). And the better teacher brings no improvements. These facts demonstrate that the student’s performance is relatively insensitive to the teacher’s ability as long as the teacher is not too weak.

Not only the pretrained word embeddings, we also build a vocabulary V_{word} from the large auto-segmented data. Both of them should have positive impacts on the improvements. To figure out their contributions quantitatively, we train a contrast model, where the pretrained word embeddings are not used but the word features and the vocabulary are persisted, i.e. the word embeddings are randomly initialized. The results are shown in Table 7. According to the results, we conclude that the pretrained word embeddings and the vocabulary have roughly equal contributions to the final

improvements.

5 Related Work

CWS has been studied with considerable efforts in NLP community. [Xue et al. \(2003\)](#) firstly modeled CWS as a character-based sequence labeling problem. They used a sliding-window maximum entropy classifier to tag Chinese characters into one of four position tags, and then converted these tags into a segmentation using rules. Following their work, [Peng et al. \(2004\)](#) applied CRF to the problem for sequence-level prediction. Recently, under the sequence labeling framework, various neural models have been explored for CWS. [Zheng et al. \(2013\)](#) firstly applied a feed-forward neural network for CWS. [Pei et al. \(2014\)](#) improved upon [Zheng et al. \(2013\)](#) by explicitly modeling the interactions between local context and previous tag. [Chen et al. \(2015a\)](#) proposed a gated recursive neural network (GRNN) to model the combinations of context characters. [Chen et al. \(2015b\)](#) utilized Long short-term memory (LSTM) to capture long distant dependencies. [Xu and Sun \(2016\)](#) combined LSTM and GRNN to efficiently integrate local and long-distance features.

Our proposed model is also a neural sequence labeling model. The difference from above models lies in that CNN is used to encode contextual information. CNNs have been successfully applied in many NLP tasks, such as text classification ([Kalchbrenner et al., 2014](#); [Kim, 2014](#); [Zhang et al., 2015](#); [Conneau et al., 2016](#)), language modeling ([Kim et al., 2016](#); [Pham et al., 2016](#); [Dauphin et al., 2016](#)), machine translation ([Meng et al., 2015](#); [Kalchbrenner et al., 2016](#); [Gehring et al., 2016](#)). Experimental results show that the convolutional layers are capable to capture more n -gram features than previous introduced networks. [Collobert et al. \(2011\)](#) also proposed a CNN based sequence labeling model. However, our model

is significantly different from theirs since theirs adopt max-pooling to encode the whole sentence into a fixed size vector and use position embeddings to demonstrate which word to be tagged while ours does not. Our model is more efficient due to the sharing structure in lower layers. Contemporary to this work, [Strubell et al. \(2017\)](#) applied dilated CNN to named entity recognition.

The integration with word embeddings is inspired by word-based CWS models ([Andrew, 2006](#); [Zhang and Clark, 2007](#); [Sun et al., 2009](#)). Most recently, [Zhang et al. \(2016\)](#); [Liu et al. \(2016\)](#); [Cai and Zhao \(2016\)](#) proposed word-based neural models for CWS. Particularly, [Zhang et al. \(2016\)](#); [Liu et al. \(2016\)](#) utilized word embeddings learned from large auto-segmented data, which leads to significant improvements. Different from their word-based models, we integrate word embeddings with the proposed character-based model.

Similar to this work, [Wang et al. \(2011\)](#) and [Zhang et al. \(2013\)](#) also enhanced character-based CWS systems by utilizing auto-segmented data. However, they didn’t use word embeddings, but only used statistics features. [Sun \(2010\)](#) and [Wang et al. \(2014\)](#) combined character-based and word-based CWS model via bagging and dual decomposition respectively and achieved better performance than single model.

6 Conclusion

In this paper, we address the weaknesses of character-based CWS models. We propose a novel neural model for CWS. The model utilizes stacked convolutional layers to derive contextual representations from input sequence, which are then fed to a CRF layer for prediction. The model is capable to capture rich n -gram features automatically. Furthermore, we propose an effective approach to integrate the proposed model with word embeddings, which are pretrained on large auto-segmented data. Evaluation on two benchmark datasets shows that without any feature engineering, much better performance than previous models (also without feature engineering) is obtained. Armed with word embeddings, our model achieves state-of-the-art performance on both datasets, without using any external labeled data.

Abstract

We present a character-based model for joint segmentation and POS tagging for Chinese. The bidirectional RNN-CRF architecture for general sequence tagging is adapted and applied with novel vector representations of Chinese characters that capture rich contextual information and sub-character level features. The proposed model is extensively evaluated and compared with a state-of-the-art tagger respectively on CTB5, CTB9 and UD Chinese. The experimental results indicate that our model is accurate and robust across datasets in different sizes, genres and annotation schemes. We obtain state-of-the-art performance on CTB5, achieving 94.38 F1-score for joint segmentation and POS tagging.

1 Introduction

Word segmentation and part-of-speech (POS) tagging are core steps for higher-level natural language processing (NLP) tasks. Given the raw text, segmentation is applied at the very first step and POS tagging is performed on top afterwards. As by convention the words in Chinese are not delimited by spaces, segmentation is non-trivial, but its accuracy has a significant impact on POS tagging. Moreover, POS tags provide useful information for word segmentation. Thus, modelling word segmentation and POS tagging jointly can outperform the pipeline models (Ng and Low, 2004; Zhang and Clark, 2008).

POS tagging is a typical sequence tagging problem over segmented words, while segmentation also can be modelled as a character-level tagging problem via predicting the labels that identify the word boundaries. Ng and Low (2004) propose a

joint model which predicts the combinatory labels of segmentation boundaries and POS tags at the character level. Joint segmentation and POS tagging becomes a standard character-based sequence tagging problem and therefore the general machine learning algorithms for structured prediction can be applied.

The bidirectional recurrent neural network (RNN) using conditional random fields (CRF) (Lafferty et al., 2001) as the output interface for sentence-level optimisation (BiRNN-CRF) achieves state-of-the-art accuracies on various sequence tagging tasks (Huang et al., 2015; Ma and Hovy, 2016) and outperforms the traditional linear statistical models. RNNs with gated recurrent cells, such as long-short term memory (LSTM) (Hochreiter and Schmidhuber, 1997) and gated recurrent units (GRU) (Cho et al., 2014) are capable of capturing long dependencies and retrieving rich global information. The sequential CRF on top of the recurrent layers ensures that the optimal sequence of tags over the entire sentence is obtained.

In this paper, we model joint segmentation and POS tagging as a fully character-based sequence tagging problem via predicting the combinatory labels. The BiRNN-CRF architecture is adapted and applied. The Chinese characters are fed into the neural networks as vector representations. In addition to utilising the pre-trained character embeddings, we propose a concatenated n-gram-representation of the characters. Furthermore, sub-character level information, namely radicals and orthographical features extracted by convolutional neural networks (CNNs), are also incorporated and tested. Three datasets of different sizes, genres and with different annotation schemes are employed for evaluation. Our model is thoroughly evaluated and compared with the joint segmentation and POS tagging model in ZPar

(Zhang and Clark, 2010), which is a state-of-the-art joint tagger using structured perceptron and beam decoding. According to the experimental results, our proposed model outperforms ZPar on all the datasets in terms of accuracy.

The main contributions of this work include: 1. We apply the BiRNN-CRF model for general sequence tagging to joint segmentation and POS tagging for Chinese and achieve state-of-the-art accuracy. The experimental results show that our tagger is robust and accurate across datasets of different sizes, genres and annotation schemes. 2. We propose a novel approach for vector representations of characters that leads to substantial improvements over the baseline model. 3. Additional improvements are obtained via exploring the feasibility of utilising sub-character level information. 4. We provide an open-source implementation of our method along with pre-trained character embeddings.¹

2 Model

2.1 Neural Network Architecture

Our baseline model is an adaptation of BiRNN-CRF. As illustrated in Figure 1, the Chinese characters are represented as vectors and fed into the bidirectional recurrent layers. The character representations will be described in detail in the following sections. For the recurrent layer, we employ GRU as the basic recurrent unit as it has similar functionalities but fewer parameters compared to LSTM (Chung et al., 2014). Dropout (Srivastava et al., 2014) is applied to the outputs of the bidirectional recurrent layers. The outputs are concatenated and passed to the first-order chain CRF layer. The optimal sequence of the combinatory labels is predicted at the end. There is a post processing step to retrieve both segmentation and POS tags from the combinatory tags.

2.2 Tagging Scheme

Following the work of Kruengkrai et al. (2009a), the employed tags indicating the word boundaries are B, I, E, S representing a character at the beginning, inside, end of a word or as a single-character word. The CRF layer models conditional scores over all possible combinatory labels given the input characters. Incorporating the transition scores between the successive labels, the op-

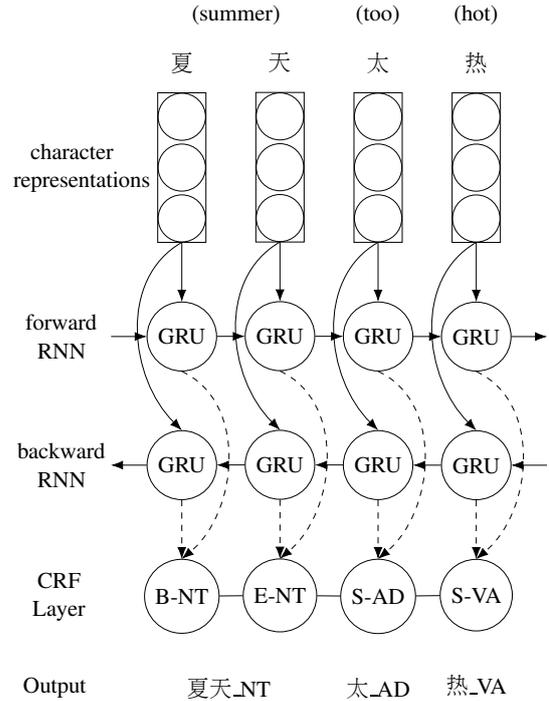

Figure 1: The BiRNN-CRF model for joint Chinese segmentation and POS tagging. The dashed arrows indicate that dropout layers are applied to the outputs of the recurrent layers.

timal sequence can be obtained efficiently via the Viterbi algorithm both for training and decoding.

The time complexity for the Viterbi algorithm is linear with respect to the sentence length n as $\mathcal{O}(k^2n)$, where k is constant and equals to the total number of combinatory labels. The efficiency can be improved if we reduce k . For some POS tags, combining them with the full boundary tags is redundant. For instance, only the functional word 的 can be tagged as DEG in Chinese Treebank (Xue et al., 2005). Since it is a single-character word, combinatory tags of B-DEG, I-DEG, and E-DEG never occur in the experimental data and should therefore be pruned to reduce the search space. Similarly, if the maximum length of words under a given POS tag is two in the training data, we prune the corresponding label.

2.3 Character Representations

We propose three different approaches to effectively represent Chinese characters as vectors for the neural network.

2.3.1 Concatenated N-gram

The prevalent character-based neural models assume that larger spans of text, such as words and

¹ <https://github.com/yanshao9798/tagger>

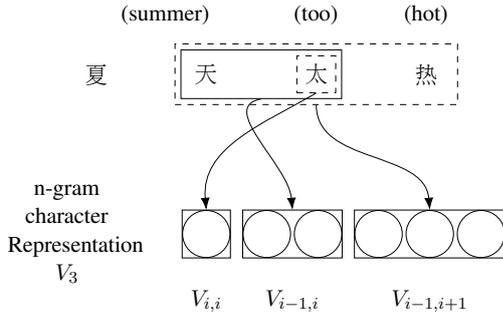

Figure 2: Vector representations of the Chinese characters as incrementally concatenated n-gram vectors in a given context.

n-grams, can be represented by the sequence of characters that they consist of. For example, the vector representation $V_{m,n}$ of a span $c_{m,n}$ is obtained by passing the vector representations v_i of the characters c_i to a function f as:

$$V_{m,n} = f(v_m, v_{m+1}, \dots, v_n) \quad (1)$$

where f is usually an RNN (Ling et al., 2015) or a CNN (dos Santos and Zadrozny, 2014).

In this paper, instead of completely relying on the BiRNN to extract contextual features from context-free character representations, we encode rich local information in the character vectors via employing the incrementally concatenated n-gram representation as demonstrated in Figure 2. In the example, the vector representation of the pivot character 太 in the given context is the concatenation of the context-free vector representation $V_{i,i}$ of 太 itself along with $V_{i-1,i}$ of the bigram 天太 as well as $V_{i-1,i+1}$ of the trigram 天太热.

Instead of constructing the vector representation $V_{m,n}$ of an n-gram $c_{m,n}$ from the character representations as in Equation 1, $V_{m,n}$ in different orders, such as $V_{i,i}$, $V_{i-1,i}$, and $V_{i-1,i+1}$, are randomly initialised separately. We use a single special vector to represent all the unknown n-grams per order. The n-grams in different orders are then concatenated incrementally to form up the vector representations of a Chinese character in the given context, which is passed further to the recurrent layers. As shown in Figure 2, the neighbouring characters on both sides of the pivot character are taken into account.

2.3.2 Radicals and Orthographical Features

Chinese characters are logograms. As opposed to alphabetical languages, there is rich information

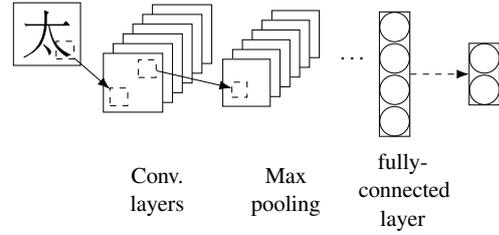

Figure 3: Convolutional Neural Networks for orthographical feature extraction. Only the first convolutional layer and its following max-pooling layer are presented.

encrypted in the graphical components. For instance, the Chinese characters that share the same part 钅 (gold) are all somewhat related to metals, such as 银 (silver), 铁 (iron), 针 (needle) and so on. The shared part 钅 is known as the radical, which functions as a semantic indicator. Hence, we investigate the effectiveness of using the information below the character level for our task.

Radicals are first represented as randomly initialised vectors and concatenated as parts of the character representations. Radicals are traditionally used as indices in Chinese dictionaries. In our approach, they are retrieved via the unicode representation of Chinese characters as the characters that share the same radical are grouped together. They are organised in consistent with the categorisation in Kangxi Dictionary (康熙字典), in which all the Chinese characters are grouped under 214 different radicals. We only employ the radicals of the common characters in the unicode range of (U+4E00, U+9FFF). For the characters out of the range and the non-Chinese characters, we use a single special vector as their radical representations.

Additionally, instead of presuming that only radicals encode sub-character level information, we use convolutional neural networks (CNNs) to extract graphical features from scratch by regarding the Chinese characters as pictures and feed their pixels as the input. As illustrated in Figure 3, there are two convolutional layers, both followed by a max-pooling layer. The output of the second max-pooling layer is reshaped and passed to a regular fully-connected layer. Dropout is applied to the output of the fully-connected layer. The output is then concatenated as parts of the character representation. The CNNs are trained jointly with the main network.

2.3.3 Pre-trained Character Embeddings

The context-free vector representations of single characters introduced in section 2.3.1 can be replaced by pre-trained character embeddings retrieved from large corpora. We employ GloVe (Pennington et al., 2014) to train our character embeddings on Wikipedia² and the freely available Sogou News Corpora (SogouCS).³ We use randomly initialised vectors as the representations of the characters that are not in the embedding vocabulary. Pre-trained embeddings for higher-order n-grams are not employed in this paper.

2.4 Ensemble Decoding

At the final decoding phase, we use ensemble decoding, a simple averaging technique, to mitigate the deviations led by random weight initialisation of the neural network. For the chain CRF decoder, the final sequence of the combinatory tags y is obtained via the conditional scores $S(y_i|x_i)$ and the transition scores $T(y_i, y_j)$ given the input sequence x . Instead of computing the optimal sequence with respect to the scores returned by a single model, both the conditional scores and transition scores are averaged over four models with identical parameter settings that are trained independently:

$$y^* = \operatorname{argmax}_{y \in L(x)} p(y|x; \{\bar{S}\}, \{\bar{T}\}) \quad (2)$$

Ensemble decoding is only applied to the best performing model according to the feature experiments at the final testing phase in this paper.

3 Implementation

Our neural networks are implemented using the TensorFlow 1.2.0 library (Abadi et al., 2016). We group the sentences with similar lengths into the same buckets and the sentences in the same bucket are padded to the same length accordingly. We construct sub-computational graphs respectively for each bucket. The training and tagging speed of our neural network on GPU devices can be drastically improved thanks to the bucket model. The training time is proportional to both the size of the training set and the number of POS tags.

Table 1 shows the adopted hyper-parameters. We use one set of parameters for all the experiments on different datasets. The weights of the

Char. embedding size	64

Batch size	10

Table 1: Hyper-parameters.

neural networks, including the randomly initialised embeddings, are initialised using the scheme introduced in Glorot and Bengio (2010). The network is trained with the error back-propagation algorithm. All the embeddings are fine-tuned during training by back-propagating gradients. Adagrad (Duchi et al., 2011) with mini-batches is employed for optimisation with the initial learning rate $\eta_0 = 0.1$, which is updated with a decay rate $\rho = 0.05$ as $\eta_t = \frac{\eta_0}{\rho^{(t-1)+1}}$, where t is the index of the current epoch.

The model is optimised with respect to the performance on the development sets. F1-scores of both segmentation ($F1_{Seg}$) and joint POS tagging ($F1_{Seg\&Tag}$) are employed as $F1_{Seg} * F1_{Seg\&Tag}$ to measure the performance of the model after each epoch during training. In our experiments, the models are trained for 30 epochs. To ensure that the weights are well optimised, we only adopt the best epoch after the model is trained at least for 5 epochs.

4 Experiments

4.1 Datasets

We employ three different datasets for our experiments, namely Chinese Treebank (Xue et al., 2005) 5.0 (CTB5) and 9.0 (CTB9) along with the Chinese section in Universal Dependencies (UD Chinese) (Nivre et al., 2016) of version 1.4.

CTB5 is the most employed dataset for joint segmentation and POS tagging in previous research. It is composed of newswire data. We follow the conventional split of the dataset as in Jiang et al. (2008); Kruengkrai et al. (2009a);

²<https://dumps.wikimedia.org/>

³<http://www.sogou.com/labs/resource/cs.php>

Zhang and Clark (2010). CTB9 consists of source texts in various genres, CTB5 is a subset of it. We split CTB9 by referring to the partition of CTB7 in Wang et al. (2011). We extend the training, development and test sets from CTB5 by adding 80% of the new data in CTB9 to training and 10% each to development and test. The double-checked files are all placed in the test set. The detailed splitting information can be found in Table 10 in Appendix. UD Chinese has both universal and language-specific POS tags. They are not predicted jointly in this paper. For the sake of convenience, we refer the universal tags as UD1 and the language-specific ones as UD2 in the following sessions. To make the model benefit from the pre-trained character embeddings, we convert the texts in UD Chinese from traditional Chinese into simplified Chinese.

Table 2 shows brief statistics of the employed datasets in numbers of words. The out-of-vocabulary (OOV) words are counted regardless of the POS tags. We can see that the size of UD Chinese is much smaller and it has a notably higher OOV rate than the two CTB datasets.

	CTB5	CTB9	UD Chinese
Train	493,935	1,696,322	98,608
Dev	6,821	136,468	12,663
Test	8,008	242,317	12,012
OOV rate (dev)	8.11	2.93	12.13
OOV rate (test)	3.47	3.13	12.46

Table 2: Statistics of the employed datasets in numbers of words.

4.2 Experimental Results

Both segmentation (Seg) and joint segmentation and POS tagging (Seg&Tag) are evaluated in our experiments.⁴ We employ word-level recall (R), precision (P) and F1-score (F) as the evaluation metrics. A series of feature experiments are carried out on the development sets to evaluate the effectiveness of the proposed approaches for vector representations of the characters. Finally, the best performing model according to the feature experiment is applied to the test sets in the forms of single as well as ensemble and compared with ZPar.

⁴The evaluation script is downloaded from: http://people.sutd.edu.sg/yue.zhang/doc/doc/joint_files/evaluate.py

4.2.1 Feature Experiments

Table 3 shows the evaluation results of using concatenated n-grams up to different orders as the character representations. By introducing 2-grams, we can obtain vast improvements over solely using the conventional character embeddings, which indicates that not all the local information can be effectively captured by the BiRNN using context-free character representations. Utilising the concatenated n-grams ensures that the same character has different but yet closely related representations in different contexts, which is an effective way to encode contextual features.

From the table, we see that notable improvements can be achieved further via employing 3-grams. 4-grams still help but only to CTB9 while adding 5-grams achieves almost no improvement on any of the datasets. The results imply that concatenating higher-order n-grams can be detrimental, especially on datasets in smaller sizes due to the fact that higher-order n-grams are more sparse in the training data and their vector representations cannot be trained well enough. Besides, adopting higher-order n-grams also substantially increases the numbers of weights and therefore both training and decoding become less efficient. Under the circumstances, we consider that 3-gram model is optimal for our task and it is employed in the following experiments for all the datasets.

The concatenated n-grams have a bigger size compared to the basic character representation. We conduct one additional experiment using a basic 1-gram character model with a larger character vector size of 300. The evaluation scores are similar to the basic character model with the size of 64, which shows that the improvements obtained by the n-gram model are not matched by enlarging the size of the vector representation.

The evaluation scores of the sub-character level features are reported in Table 4. The relevant features are added on top of the 3-gram model. Employing radicals and graphical features achieves similar improvements for segmentation while utilising radicals obtains better results for joint POS tagging on CTB5. However, radicals are not a very effective feature on CTB9, UD1 and UD2 whereas a notable enhancement is observed when employing graphical features on UD1. Using CNNs to extract graphical features is computationally much more expensive than simply adopting radicals via a lookup table, especially when GPU is not avail-

Table 5: Evaluation of the pre-trained character embeddings on the development sets in F1-scores.

able.

From Table 5, we can learn that employing pre-trained embeddings as initial vector representations for the characters achieves improvements in general, whereas the improvements are comparatively smaller if the concatenated n-gram representations and the radicals are added. Additionally, the improvements obtained on UD Chinese are more significant than on CTBs, which indicates that the pre-trained character embeddings are more beneficial to the datasets in smaller sizes.

In general, the feature experiments indicate that the proposed Chinese character representations are all sensitive to dataset size. Using higher-order n-grams requires more data for training. On the other hand, the pre-trained embeddings are more vital if the dataset is small. In addition, the different representations are sensitive to tagging schemes as the evaluation results on UD1 and UD2 are quite diverse. Taking both robustness and efficiency into consideration, we select 3-grams along with radicals and pre-trained character embeddings as the best setting for final evaluation.

4.2.2 Final Results

Table 6 shows the final scores on the test sets. The complete evaluation results in precision, re-

call and F1-scores are contained in Table 11 and Table 12 in Appendix. Our system is compared with ZPar. We retrained a ZPar model on CTB5 that reproduces the evaluation scores reported in Zhang and Clark (2010). We also modified the source code so that it is applicable to CTB9 and UD Chinese. In addition, we perform the mid- p McNemar’s test (Fagerland et al., 2013) to examine the statistical significances.

As shown in Table 6, the single model is worse than the ensemble model but still outperforms ZPar on all the tested datasets. ZPar incorporates discrete local features at both character and word levels and employs structured perceptron for global optimisation, whereas we encode rich local information in the character representations and employ BiRNN to effectively extract global features and capture long term dependencies. The chain CRF layer is used for sentence-level optimisation, which functions similarly to structured perceptron. As opposed to the taggers built with traditional machine learning algorithms, our model avoids heavy feature engineering and benefits from large plain texts via utilising pre-trained character embeddings. It is also very flexible to add sub-character level features as parts of the character representations. The model

	Single	78.78	69.78	74.16	62.58	81.36	67.40	81.16	66.73
	Ensemble	77.34	70.50	75.52	64.14	82.16	68.14	81.56	68.00

Table 6: Evaluations of the best model on the final test sets in F1-scores as well as the recalls of out-of-vocabulary words. Significance tests for Single are in comparison to ZPar, while tests for Ensemble are in comparison to Single (** $p < 0.01$, * $p < 0.05$)

performs very well despite being fully character based. Moreover, it has clear advantages when applied to smaller datasets like UD Chinese, while the prevalence is much smaller on CTB5.

Both our model and ZPar segment OOV words in UD Chinese with higher accuracies than the ones in CTBs despite that UD Chinese is notably smaller and the overall OOV rate is higher. Compared to CTB, the words in UD Chinese are more fine-grained and the average word length is shorter, which makes it easier for the tagger to correctly segment the OOV words as Zhang et al. (2016) show that the longer words are more difficult to be segmented correctly. For joint POS tagging for OOV words, the two systems both perform significantly better on CTB5 as it is only composed of news text.

In general, our model is more robust to OOV words than ZPar, except that ZPar yields better result for segmentation by a small margin on CTB9. ZPar also obtains higher accuracy for joint POS tagging than the single model on CTB9. The differences between ZPar and our model for both segmentation and POS tagging are more substantial on UD Chinese, which indicates that our model is relatively more advantageous for handling OOV words when the training sets are small, whereas ZPar is able to perform equally well when substantial amount of training data is available as they achieve similar results on the CTB sets.

The single model is further improved by ensemble-averaging four independently trained models. The improvements are not drastic but they are observed systematically across all the datasets. In general, ensemble decoding is beneficial to handling OOV words as well except that a small drop for segmentation on CTB5 is observed.

Table 7 displays the evaluation of the ensemble model and ZPar on the decomposed test sets

	Ensemble		ZPar

of CTB9 in different genres. Our model surpasses ZPar on all the genres in both segmentation and joint POS tagging. The differences are subtle on the genres in which the texts are normalised, such as News and Broadcast News. This, to a very large extent, explains why our model is only marginally better than ZPar on CTB5, whereas the experimental results reveal that our model is substantially better at processing non-standard text as it yields significantly higher scores on Conversations, Short Messages and Weblogs. The evaluation results of both our model and ZPar vary substantially across different genres as some genres are fundamentally more challenging to process.

Our models are compared with the previous best-performing systems on CTB5 in Table 8. Our models are not optimised particularly with respect to CTB5 but still yield competitive results, especially for joint POS tagging. We are the first to report evaluation scores on CTB9 and UD Chinese.

4.3 Tagging Speed

Our joint segmentation and POS tagger is very efficient with GPU devices and can be practically

Single	97.89	94.07
Ensemble	98.02	94.38

Table 8: Result comparisons on CTB5 in F1-scores.

used for processing very large files. The memory demand of decoding is drastically milder compared to training, a large batch size therefore can be employed. The tagger takes constant time to build the sub-computational graphs and load the weights.

With bucket size of 10 and batch size of 500, Table 9 shows the tagging speed of the tagger using a single Tesla K80 GPU card and the pre-trained model on CTB5. The tagging speed of ZPar is also presented for comparison. GPU devices are not supported by ZPar and therefore the tagging speed is calculated using an Intel Core i7 CPU.

	Init. Time (s)	Sentence/s	Chars/s

5 Related Work

The fundamental BiRNN-CRF architecture is task-independent and has been applied to many sequence tagging problems on Chinese. Peng and Dredze (2016) adopt the model for Chinese segmentation and named entity recognition in the context of multi-task and multi-domain learning. Dong et al. (2016) employ a character level BiLSTM-CRF model that utilises radical-level information for Chinese named entity recognition. Ma and Sun (2016) use a similar architecture but feed the Chinese characters pairwise as edge embeddings instead. Their model is applied respectively to chunking, segmentation and POS tagging.

Zheng et al. (2013) model joint Chinese segmentation and POS tagging via predicting the combinatory segmentation and POS tags. They

employ the adaptation of the feed forward neural network introduced in Collobert et al. (2011) that only extracts local features in a context window. A perceptron-style training algorithm is employed for sentence level optimisation, which is the same as the training algorithm of the BiRNN-CRF model. Their proposed model is not evaluated on CTB5 and therefore difficult to be compared with our system. Kong et al. (2015) apply segmental recurrent neural networks to joint segmentation and POS tagging but the evaluation results are substantially below the state-of-the-art on CTB5.

Bojanowski et al. (2016) retrieve word embeddings via representing words as a bag of character n-grams for morphologically rich languages. A similar character n-gram model is proposed by Wieting et al. (2016). Sun et al. (2014) attempt to encode radical information into the conventional character embeddings. The radical-enhanced embeddings are employed and evaluated for Chinese segmentation. The results show that radical-enhanced embeddings outperform both skip-ngram and continues bag-of-word (Mikolov et al., 2013) in word2vec.

6 Conclusion

We adapt and apply the BiRNN-CRF model for sequence tagging in NLP to joint Chinese segmentation and POS tagging via predicting the combinatory tags of word boundaries and POS tags. Concatenated n-grams as well as sub-character features are employed along with the conventional pre-trained character embeddings as the vector representations for Chinese characters. The feature experiments indicate that concatenated n-grams contribute substantially. However, both radicals and graphical features as sub-character level information are less effective. How to incorporate the sub-character level information more effectively will be further explored in the future.

The proposed model is extensively evaluated on CTB5, CTB9 and UD Chinese. Despite the fact that different character representation approaches are sensitive to data size and tagging schemes, we use one set of hyper-parameters and universal feature settings so that the model is robust across datasets. The experimental results on the test sets show that our model outperforms ZPar which is built on structured perceptron on all the datasets. We obtain state-of-the-art performances on CTB5.

The results on UD Chinese and CTB9 also reveal that our model has great advantages in processing non-standard text, such as weblogs, forum text and short messages. Moreover, the implemented tagger is very efficient with GPU devices and therefore can be applied to tagging very large files.

Abstract

Boundary features are widely used in traditional Chinese Word Segmentation (CWS) methods as they can utilize unlabeled data to help improve the Out-of-Vocabulary (OOV) word recognition performance. Although various neural network methods for CWS have achieved performance competitive with state-of-the-art systems, these methods, constrained by the domain and size of the training corpus, do not work well in domain adaptation. In this paper, we propose a novel BLSTM-based neural network model which incorporates a global recurrent structure designed for modeling boundary features dynamically. Experiments show that the proposed structure can effectively boost the performance of Chinese Word Segmentation, especially OOV-Recall, which brings benefits to domain adaptation. We achieved state-of-the-art results on 6 domains of CNKI articles, and competitive results to the best reported on the 4 domains of SIGHAN Bakeoff 2010 data.

1 Introduction

Since Chinese writing system does not have explicit word delimiters, word segmentation becomes an essential first step for further Chinese language processing. In recent years, Chinese Word Segmentation (CWS) has experienced great advancement. One mainstream method is to regard word segmentation task as a sequence labeling problem (Xue, 2003; Peng et al., 2004) where each character is assigned a tag indicating its position in the word. This method has been proved

effective as it turns word segmentation into a structured discriminative learning task which can be handled by supervised learning algorithms such as Maximum Entropy (ME) (Berger et al., 1996) and Conditional Random Fields (CRF) (Lafferty et al., 2001). Furthermore, rich features can be incorporated into these systems to improve their performances and most state-of-the-art systems are still based on feature-based models.

Recently, neural network models are drawing increasing attention in Natural Language Processing (NLP) tasks. They significantly reduced feature engineering effort and achieved competitive or state-of-the-art results in many NLP tasks. Collobert et al. (2011) developed a general neural network architecture for sequence labeling tasks. Following this work, many neural network models (Zheng et al., 2013; Pei et al., 2014; Chen et al., 2015a,b) have been applied to CWS and some approached state-of-the-art performance.

However, these neural network models, as well as other supervised methods, do not work well in domain adaptation. In recent years, manually annotated training corpus mostly come from the news domain. When it shifts to other domains such as literature or medicine, where there are many domain-related words that rarely appear in other domains, Out-of-Vocabulary (OOV) word recognition becomes an important problem. Moreover, different domains means different language usages and contexts. Therefore, the In-Vocabulary (IV) word segmentation performance is also affected. As a result, CWS accuracies can drop gravely on cross-domain corpora. For example, consider a sentence “三聚氰胺(melamine) / 致(lead to) / 婴幼儿(baby) / 泌尿系(urinary tract) / 结石(stones)”. Here the word “三聚氰胺(melamine)” is a chemical that often appears in medicine-related domains while seldom appears in other domains. It is a four-Chinese-character word

*Corresponding author

where each character stands for ‘three’, ‘gather’, ‘cyanide’ and ‘amine’. The four characters are totally irrelevant. A supervised CWS system trained on news domain corpus would face great challenges on segmenting this word correctly

Several approaches have been proposed to address the domain adaption problem for CWS. One major family proposed to compose boundary features by fitting the relevance of consecutive characters using Accessor Variety (AV) (Feng et al., 2004a,b), or Chi-square Statistics (Chi2) (Chang and Han, 2010). Combining the boundary features with other hand-crafted features, these methods were shown to achieve better performance on OOV words.

Inspired by these models, we propose a novel BLSTM-based neural network model which incorporates a global recurrent structure designed to model boundary features dynamically. This structure can learn to utilize the target domain corpus and extract the correlation or irrelevance between characters, which is a reminiscence of the discrete boundary features such as Accessor Variety (AV).

The contributions of this paper are two folds:

- First, we propose a global recurrent structure and incorporate it in the BLSTM-based neural network model for CWS. The structure can capture correlations between characters, and thus is especially efficient for segmenting OOV words and enhancing the performance of CWS on non-news domains.
- We obtain competitive results comparing to the best reported in the literature on the SIGHAN Bakeoff 2010 data, which is a benchmark dataset for cross-domain CWS.

2 BLSTM Architecture for Chinese Word Segmentation

We regard Chinese word segmentation task as a character-based sequence labeling problem, by labeling each character a tag from $\{S, B, E, M\}$. These tags indicate the position of the character in the segmented word. B, E, M represents *Begin*, *Middle*, *End* of a multi-character segmentation respectively, while S represents a single-character segmentation.

Figure 1 illustrates the general BLSTM architecture for Chinese word segmentation.

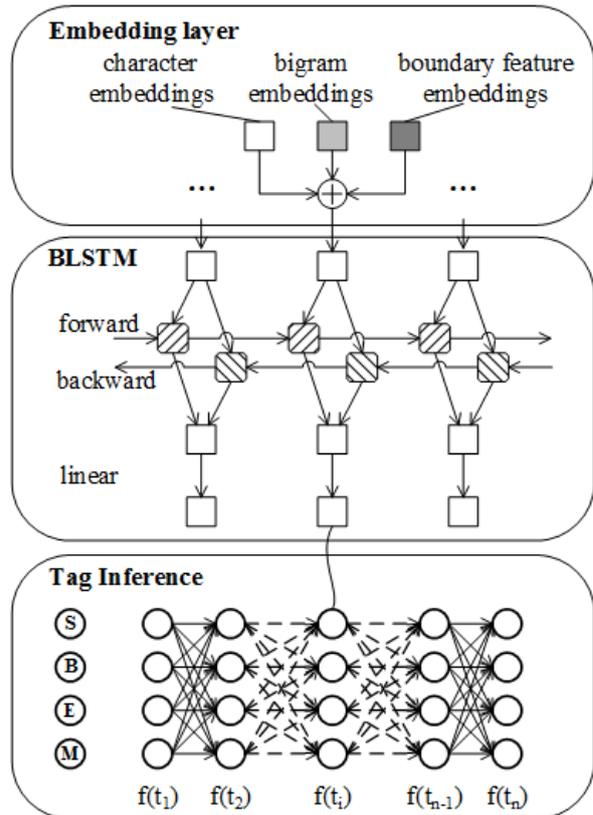

Figure 1: General architecture for Chinese word segmentation.

2.1 Embeddings

The outputs of the embedding layer is a concatenation of three parts: character embeddings, bigram embeddings and boundary feature embeddings.

We adopt the the local window approach which assumes that the tag of a character largely depends on its neighboring characters. For each character c_i in a given input sentence $c_{[1:n]}$, the context characters $c_{[i-w/2:i+w/2]}$ and their corresponding bigrams are chosen to be fed into the networks, where w is the context window size. As most CWS methods do, we will set $w = 5$ in our experiments.

Given a character set V of size $|V|$, each character $c \in V$ will be mapped into a d -dimensional embedding space as $Emb_c(c) \in \mathbb{R}^d$ by a lookup table $M_c \in \mathbb{R}^{d \times |V|}$. Similarly, each bigram $b \in \{c_1 c_2 | c_1 \in V, c_2 \in V\}$ will be mapped into a d -dimensional embedding space as $Emb_b(b) \in \mathbb{R}^d$ by a lookup table $M_b \in \mathbb{R}^{d \times |V| \times |V|}$.

The boundary feature embeddings are hidden vectors computed from the current bigrams and the whole bigram history, which will be explained in detail in Section 3.

Three kinds of embeddings of the context characters $c_{[i-2:i+2]}$ and their corresponding bigrams are then concatenated into a single vector $x_i \in \mathbb{R}^{H_1}$, where $H_1 = 5d + 4d + 4d_{bf}$. d_{bf} is the number of hidden units output by the boundary feature embeddings. Then, this vector x_i is fed into the BLSTM layer.

2.2 Bidirectional LSTM Network

Following the embedding layer is an one-layer BLSTM network (Graves and Schmidhuber, 2005). By combining hidden states from two separate LSTM layers, it can incorporate long periods of contextual information from both directions. The LSTM cell is implemented as follows (Graves et al., 2013):

$$\begin{aligned} i_t &= \sigma(W_{xi}x_t + W_{hi}h_{t-1} + W_{ci}c_{t-1} + b_i) \\ f_t &= \sigma(W_{xf}x_t + W_{hf}h_{t-1} + W_{cf}c_{t-1} + b_f) \\ c_t &= f_t c_{t-1} + i_t \tanh(W_{xc}x_t + W_{hc}h_{t-1} + b_c) \\ o_t &= \sigma(W_{xo}x_t + W_{ho}h_{t-1} + W_{co}c_t + b_o) \\ h_t &= o_t \tanh(c_t) \end{aligned} \quad (1)$$

where σ is the logistic sigmoid function, and i , f , o and c are the input gate, forget gate, output gate and the cell respectively, all of which are the same dimension as the hidden output h . The subscripts of the weight matrix describe the meaning as the name suggests. For instance, W_{xi} is the input gate weight matrix for input x .

The outputs of the BLSTM layer are the concatenation of a forward hidden sequence \vec{h} and a backward hidden sequence \overleftarrow{h} which will be fed to the decoding layer that contains a linear transformation with no non-linear function:

$$f(t_i | c_{[i-w/2:i+w/2]}) = W_d(\vec{h}_i \oplus \overleftarrow{h}_i) + b_d \quad (2)$$

where $W_d \in \mathbb{R}^{|T| \times H_2}$, $b_d \in \mathbb{R}^{|T|}$. H_2 is the number of hidden units of the outputs for the BLSTM layer. $f(t_i | c_{[i-w/2:i+w/2]}) \in \mathbb{R}^{|T|}$ is the score vector for each possible tag. Here in Chinese word segmentation, we set $T = \{S, B, E, M\}$.

2.3 Tag Inference

To model the correlations between tags in neighborhoods and jointly decode the best chain of tags for a given sentence, a transition score A_{ij} is introduced to measure the probability of jumping from

tag $i \in T$ to tag $j \in T$ (Collobert et al., 2011). For an input sentence $c_{[1:n]}$ with a tag sequence $t_{[1:n]}$, a sentence-level score can be formulated as follows:

$$s(c_{[1:n]}, t_{[1:n]}, \theta) = \sum_{i=1}^n (A_{t_{i-1}t_i} + f_\theta(t_i | c_{[i-2:i+2]})) \quad (3)$$

where $f_\theta(t_i | c_{[i-2:i+2]})$ indicates the score output for the i th tag computed by the neural network described above with parameters θ .

3 Global Recurrent Structure

Chinese word segmentation is essentially a task of resolving the relevance of consecutive characters. Lacking knowledge of such relevance, recognizing out-of-domain words has been the bottleneck of domain adaption in CWS. However, Boundary features such as Accessor Variety (AV) (Feng et al., 2004a,b), Mutual Information (Sun and Xu, 2011) and Chi-square Statistics (Chi2) (Chang and Han, 2010) are features designed to fit such relevance. A significant advantage of boundary features is that they can compute the correlation of characters from a large scale corpora, annotated or not, to boost the OOV word recognition performance. As a result, they are especially effective for cross-domain CWS.

In this paper, we propose 5 novel global recurrent structures to generate embeddings that mimic the boundary features for further computing, which needs minimal pre-processing and feature engineering. The structures are designed to capture the intuition that nearby sentences in a single-domain corpus often share certain words. Thus the correlation of characters within or across certain words can be learned, and those involving OOV words notably enhance domain adaption for CWS. **GRS-1** The basic structure (GRS-1) is illustrated in Figure 2. It looks like LSTM-2 (Chen et al., 2015b) when incorporated into the BLSTM model. However, the difference is that common recurrent networks will reset the hidden states every time they process a new sentence in NLP problems while the hidden states in our structure are never reset.

$$h_{k+1,0}, c_{k+1,0} = h_{k,n_k}, c_{k,n_k} \quad (4)$$

where $h_{k,i}$ and $c_{k,i}$ are the hidden state and cell vector of the k th sentence at the i th step, n_k is the

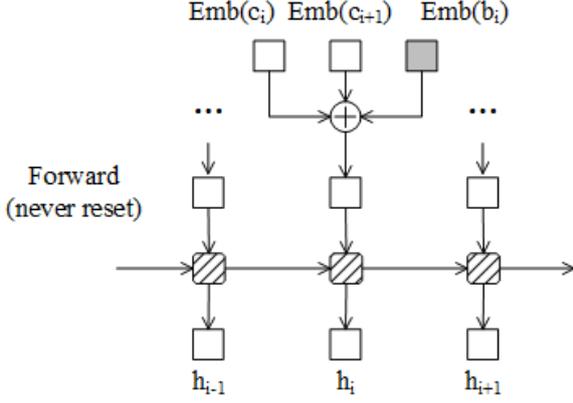

Figure 2: Global recurrent structure.

length of the k th sentence. For simplicity, in the following part we will ignore the subscript k and always indicate the current sentence.

As a result of such warm start mechanism, our structure can to some extent record the history information in recent sentences. And some information may last long in the structure.

Here we choose the LSTM cell as it can learn to keep relatively long term memory. We follow the equations (1) to implement it and directly take h_i as the boundary feature embeddings for the bigram $b_i = c_i c_{i+1}$ in the basic structure, where the input is the concatenation of embeddings of a bigram and its corresponding characters $Emb_b(b_i) \oplus Emb_c(c_i) \oplus Emb_c(c_{i+1})$.

$$Emb_{bf}(b_i) = h_i \quad (5)$$

where h_i is the output of the recurrent network at the i th step.

We also propose four more variants of the structure that are shown in Figure 3.

GRS-2 To better fit the boundary features, we add a full-connection hidden layer following the recurrent network. The boundary feature embeddings are calculated as follows:

$$Emb_{bf}(b_i) = \sigma(W_{bf}h_i + b_{bf}) \quad (6)$$

where σ is the logistic sigmoid function.

GRS-3 Considering the hidden states are noisy and contains much information of other words, we want the hidden values more relevant to the current bigram, so a gate is introduced to the structure. The boundary feature embeddings are calculated

as follows:

$$\begin{aligned} E_i &= Emb_c(c_i) \oplus Emb_c(c_{i+1}) \oplus Emb_b(b_i) \\ g(b_i) &= \sigma(W_g E_i + b_g) \\ Emb_{bf}(b_i) &= g(b_i)h_i \end{aligned} \quad (7)$$

where \oplus is the symbol for concatenation.

GRS-4 GRS-4 is a combination version of GRS-2 and GRS-3 by adding a full-connection hidden layer following the gated output.

GRS-5 GRS-5 is a more complicated version which tries to mimic the **Accessor Variety(AV)** criterion. AV criterion is a feature describing the number of distinct characters that precede or succeed a certain string s . For simplicity, we only focus on strings with $length = 2$, in other words, bigrams. Therefore, we substitute the input of GRS-4 with a bigram and its preceding character to fit its left AV and similarly with a bigram and its succeeding character to fit its right AV. At last, we simply concatenate the two embeddings as the final boundary feature embeddings (Actually they are trigram boundary feature embeddings):

$$\begin{aligned} E_i^L &= Emb_c(c_{i-1}) \oplus Emb_b(b_i) \\ E_i^R &= Emb_c(c_{i+1}) \oplus Emb_b(b_{i-1}) \\ g^L(tri_i) &= \sigma(W_g^L E_i^L + b_g^L) \\ g^R(tri_i) &= \sigma(W_g^R E_i^R + b_g^R) \\ Emb_{bf}^L(tri_i) &= \sigma(W_{bf}^L g^L(tri_i)h_i^L + b_{bf}^L) \\ Emb_{bf}^R(tri_i) &= \sigma(W_{bf}^R g^R(tri_i)h_i^R + b_{bf}^R) \\ Emb_{bf}(tri_i) &= Emb_{bf}^L(tri_i) \oplus Emb_{bf}^R(tri_i) \end{aligned} \quad (8)$$

where $tri_i = c_{i-1}c_i c_{i+1}$ and other values have the same meanings as above.

4 Training

Instead of using the Max-Margin criterion (Taskar et al., 2005) adopted by previous neural network models for CWS (Zheng et al., 2013; Pei et al., 2014; Chen et al., 2015a,b), we try to directly maximize the log-probability of the correct tag sequence following Lample et al. (2016):

$$\begin{aligned} \log(p(y|X)) &= s(X, y) - \log\left(\sum_{\tilde{y} \in Y_X} e^{s(X, \tilde{y})}\right) \\ &= s(X, y) - \text{logadd}_{\tilde{y} \in Y_X} s(X, \tilde{y}) \end{aligned} \quad (9)$$

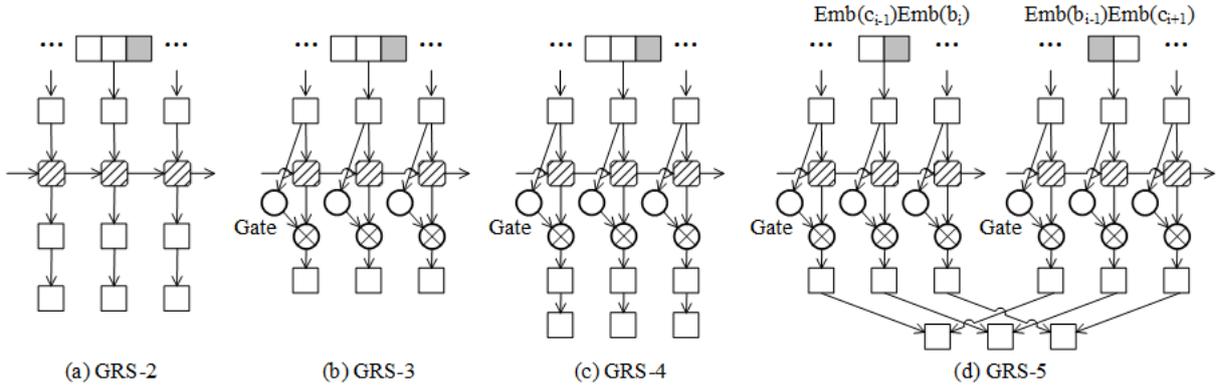

Figure 3: Four variants of the global recurrent structure.

where Y_X represents all possible tag sequences for a sentence X . While decoding, we predict the output sequence which obtains the maximum score as follows:

$$y^* = \underset{\tilde{y} \in Y_X}{\operatorname{argmax}} s(X, \tilde{y}) \quad (10)$$

The optimal sequence can be computed using dynamic programming. We use Adam (Kingma and Ba, 2014) to maximize the objective function.

5 Experiments

5.1 Experimental Setup

Data. We use the PKU corpus drawn from news domain for the source-domain training. The PKU dataset is provided by SIGHAN Bakeoff 2005 (Emerson, 2005). We regard the random 90% sentences of the training data as training set and the rest 10% sentences as development set. We also use the test part of the PKU dataset to measure the in-domain segmentation ability of our models. Following Liu et al. (2014)’s settings, our domain adaption experiments are performed on the four testing sets from the SIGHAN Bakeoff 2010 (Zhao and Liu, 2010) whose domains cover finance, computer, medicine and literature. In addition, we manually annotate six more corpora from non-news domains as testing sets, including finance, medicine, geology, agriculture, material and weather domains, which are extracted from abstracts of papers in CNKI¹. These data are annotated following the guideline proposed by Yu et al. (2001). The OOV rate of these data are relatively high because they are more academic. Statistics

¹<http://www.cnki.net/>

of the training and testing data are shown in the Table 1.

All datasets are pre-processed by replacing the Chinese idioms and the continuous English letters and digits with a unique token.

Embeddings. We use *word2vec*² to pre-train character embeddings on the training corpus. The bigram embeddings are initialized with the average of the corresponding two characters’ embeddings.

Discrete Boundary Features. The discrete boundary features which will be used in Section 5.3 are extracted from the datasets mentioned above and the Chinese Gigaword corpus³, following methods in Sun and Xu (2011)’s paper.

Hyper-parameters. The hyper-parameters are tuned according to the experimental results. The detailed values are shown in Table 2.

Character & bigram embedding size	100
Boundary feature embedding size	100
Hidden unit number(cell in GRS)	300
Hidden unit number(cell in BLSTM)	300

mains from the **CNKI** dataset. The results are shown in Table 3. The BLSTM+GRS-4 model with a gate and an additional full-connection hidden layer achieves the best performances among all domains. Surprisingly, the most delicate structure GRS-5 seems to be of no help to the CWS task.

To examine whether OOV recognition can benefit from GRS, we also look into the IV and OOV recalls of the PKU dataset respectively. Table 4 and Table 5 show that the proposed GRS can effectively improve the segmentation performance on OOV words, which empirically proves its domain adaption ability. BSLTM-2, similar to LSTM-2 (Chen et al., 2015b), is an architecture comprised of two stacking bidirectional LSTM hidden layers. GRS-4 is short for BLSTM+GRS-4 model.

5.3 Final Results

In this section, We compare our BLSTM+GRS-4 model with previous state-of-the-art methods.

Experimental results on the four test domains from SIGHAN Bakeoff 2010 are shown in Ta-

ble 6. We also attempt to integrate discrete boundary features into the models. In our experiments, we choose the **Accessor Variety(AV)** (Feng et al., 2004a,b) which is a feature widely used in traditional Chinese word segmentation. Our F-scores and OOV recalls are competitive to those reported by Liu et al. (2014) and Jiang et al. (2013). However, following Liu et al. (2014)’s setting, we choose the PKU dataset as the training corpus while Jiang et al. (2013)’s model is trained on a different corpus. The results are not directly comparable. The results prove the incredible effectiveness of the global recurrent structure on OOV recognition and overall segmentation, comparable to the BLSTM model that directly incorporates discrete AV features. Adding discrete AV features into our model seem not to be a notable improvement, which also confirms that our model already has certain domain adaption ability.

ous neural models, which is shown in Table 7. The baseline BLSTM model with no modification or augmentation can achieve comparative results while the GRS does little help to the in-domain Chinese word segmentation task.

5.4 Error Analysis

We collect and analyze the errors on the Medicine corpus from Sighan Bakeoff 2010 in light of the fact that the results are the worst among the four domains. We calculate accuracies of individual OOV words, where accuracies are simply treated as 0 or 1 for further counting, and categorize them according to their frequencies in the testing corpus. Statistics are shown in Figure 4. From the trendlines we can infer that in our proposed GRS more occurrences yield higher accuracy while common BLSTM models can rarely benefit from this. That conforms to the intuition of our model that can utilize correlation information of testing corpora. Our model thereupon performs better with the increase of the size of testing corpus as long as the OOV words appear more.

Although the trendline of our model is promising, there are some OOV words that occurs frequently but are wrongly segmented. Some examples are listed in Table 8. Errors involving

“肾脏”(kidney) and “维生素C”(vitamin C) are typical examples of the Combination Ambiguity, where there are some words containing “肾脏” such as “肾脏病学”(nephrology). Likewise, “维生素”(vitamin) is a frequent word that confuses our model. “甲型H1N1流感”(influenza A(H1N1)) reveals another severe problem that most CWS systems confront when processing the mix of Chinese characters and digits, punctuation-s or letters from other languages. The commonly used methods by treating consecutive digits or letters as one indeed boost the performance on corpora where most characters are Chinese. However, with the increase of characters other than Chinese, it is becoming a problem that should be reconsidered carefully.

OOV Word	English	Correct	Total
肾脏	kidney	15	39
甲型H1N1流感	influenza A (H1N1)	0	30
维生素C	vitamin C	2	23

6 Related Work

Word segmentation has been pursued with considerable efforts in the Chinese NLP community. One mainstream method is regarding word segmentation task as a sequence labeling problem (Xue, 2003; Peng et al., 2004). Recently, researchers have tended to explore neural network based approaches (Collobert et al., 2011; Zheng et al., 2013; Qi et al., 2014) to reduce efforts of feature engineering. Pei et al. (2014) used a neural tensor model to capture the complicated interactions between tags and context characters. Experiments in his paper also show that bigram embeddings are of great benefit. To incorporate complicated combinations and long-term dependency information of the context characters, gated recursive model (Chen et al., 2015a) and LSTM model (Chen et al., 2015b) were used respectively. Moreover, Xu and Sun (2016) proposed a dependency-based gated recursive model which merges the benefits of the two models above. Coincidentally, Cai and Zhao (2016) and Zhang et al. (2016) both addressed the problem of lacking word-based features that previous neural CWS models have. Cai and Zhao (2016) proposed a novel gated combination neural network which thoroughly eliminates context windows and can utilize complete segmentation history. Zhang et al. (2016) proposed a transition-based neural model which replaces manually designed discrete features with neural features.

Domain adaption for Chinese word segmentation has been widely exploited before neural CWS models are proposed. Jiang et al. (2013) utilized the web text(160K Wikipedia) to improves seg-

mentation accuracies on several domains. Zhang et al. (2014) studied type-supervised domain adaptation for Chinese segmentation by making use of domain-specific tag dictionaries and only unlabeled target domain data. Liu et al. (2014) proposed a variant CRF model to leverage both fully and partially annotated data transformed from different sources of free annotations consistently.

Some researches which focus on making use of unlabeled data for word segmentation also do help to domain adaption. Zhao and Kit (2008) and Zhang et al. (2013a) improved segmentation performance by mutual information between characters, collected from large unlabeled data. Li and Sun (2009) used punctuation information in a large raw corpus to learn a segmentation model, and achieve better recognition of OOV words. Sun and Xu (2011) explored several statistical features derived from both unlabeled data to help improve character-based word segmentation. Zhang et al. (2013b) proposed a semi-supervised approach that dynamically extracts representations of label distributions from both in-domain corpora and out-of-domain corpora.

7 Conclusion and Perspectives

In this paper, we propose a novel global recurrent structure to model dynamic boundary features and incorporate it in the BLSTM-based neural network model for Chinese Word Segmentation. The structure can capture correlations between characters, and thus is especially effective for segmenting OOV words and enhancing the performance of CWS on non-news domains.

The proposed global recurrent structure is not limited to the Chinese word segmentation task. It

can be easily adapted to other sequence labeling problems that may benefit from the history information carried in the structure.

Although the structure is effective in this task, it's admittedly hard to train a stable model. As our future work, we would like to try some pre-training methods to handle this problem. And we plan to apply our method to other natural language processing tasks, such as Name Entity Recognition (NER). Also, the hybrid model is a great idea to try and we will do it later.

Abstract

We present a novel technique for segmenting chat conversations using the information bottleneck method (Tishby et al., 2000), augmented with sequential continuity constraints. Furthermore, we utilize critical non-textual clues such as time between two consecutive posts and people mentions within the posts. To ascertain the effectiveness of the proposed method, we have collected data from public Slack conversations and Fresco, a proprietary platform deployed inside our organization. Experiments demonstrate that the proposed method yields an absolute (relative) improvement of as high as 3.23% (11.25%). To facilitate future research, we are releasing manual annotations for segmentation on public Slack conversations.

1 Introduction

The prolific upsurge in the amount of chat conversations has notably influenced the way people wield languages for conversations. Moreover, conversation platforms have now become prevalent for both personal and professional usage. For instance, in a large enterprise scenario, project managers can utilize these platforms for various tasks such as decision auditing and dynamic responsibility allocation (Joty et al., 2013). Logs of such conversations offer potentially valuable information for various other applications such as automatic assessment of possible collaborative work among people (Rebedea et al., 2011).

* indicates that both authors contributed equally. \$ indicates that the author was at TCS Research New-Delhi during the course of this work.

It is thus vital to invent effective segmentation methods that can separate discussions into small granules of independent conversational snippets. By 'independent', we meant a segment should as much as possible be self-contained and discussing the same topic, such that a segment can be suggested if any similar conversation occurs again. As an outcome of this, various short text similarity methods can be employed directly. Segmentation can also potentially act as an empowering preprocessing step for various down-streaming tasks such as automatic summarization (Dias et al., 2007), text generation (Barzilay and Lee, 2004), information extraction (Allan, 2012), and conversation visualization (Liu et al., 2012). It is worth noting that chat segmentation presents a number of gruelling challenges such as, the informal nature of the text, the frequently short length of the posts and a significant proportion of irrelevant interspersed text (Schmidt and Stone).

Research in text segmentation has a long history going back to the earliest attempt of Kozima (1993). Since then many methods, including but not limited to, Texttiling (Hearst, 1997), Choi's segmentation (Choi, 2000), representation learning based on semantic embeddings (Alemi and Ginsparg, 2015), and topic models (Du et al., 2015a) have been presented. Albeit, very little research effort has been proposed for segmenting informal chat text. For instance, Schmidt and Stone have attempted to highlight the challenges with chat text segmentation, though they have not presented any algorithm specific to chat text.

The Information Bottleneck (IB) method has been successfully applied to clustering in the NLP domain (Slonim and Tishby, 2000). Specifically, IB attempts to balance the trade-off between accuracy and compression (or complexity) while clustering the target variable, given a joint probability distribution between the target variable and an ob-

served relevant variable. Similar to clustering, this paper interprets the task of text segmentation as a compression task with a constraint that allows only contiguous text snippets to be in a group.

The focus of this paper is to develop text segmentation methods for chat text utilizing the IB framework. In the process, this paper makes the following major contributions:

- (i) We introduce an IB inspired objective function for the task of text segmentation.
- (ii) We develop an agglomerative algorithm to optimize the proposed objective function that also respects the necessary sequential continuity constraint for text segmentation.
- (iii) To the best of our knowledge, this paper is a first attempt that addresses segmentation for chat text and incorporates non-textual clues.
- (iv) We have created a chat text segmentation dataset and releasing it for future research.

The remainder of this paper is organized as follows: we present a review of related literature in Section 2. Then, we formulate the text segmentation problem and define necessary notations in Section 3. Following this, we explain the proposed methodology in Section 4. Section 5 presents experiments and provides details on the dataset, experimental set-up, baselines, results, and effect of parameters. Finally, conclusions and potential directions for future work are outlined in Section 6.

2 Related Work

The IB method (Tishby et al., 2000) was originally introduced as a generalization of rate distortion theory which balances the tradeoff between the preservation of information about a relevance variable and the distortion of the target variable. Later on, similar to this work, a greedy bottom-up (agglomerative) IB based approach (Slonim and Tishby, 1999, 2000) has been successfully applied to NLP tasks such as document clustering.

Furthermore, the IB method has been widely studied for multiple machine learning tasks, including but not limited to, speech diarization (Vijayasenan et al., 2009), image segmentation (Bardera et al., 2009), image clustering (Gordon et al., 2003), and visualization (Kamimura, 2010). Particularly, similar to this paper, image segmentation has considered segmentation as the compres-

sion part of the IB based method. But, image segmentation does not involve continuity constraints as their application can abolish the exploitation of similarity within the image. Yet another similar attempt that utilizes information theoretic terms as an objective (only the first term of the IB approach) has been made for the task of text segmentation and alignment (Sun et al., 2006).

Broadly stating, a typical text segmentation method comprises of a method that: (a) consumes text representations for every independent text snippet, and (b) applies a search procedure for segmentation boundaries while optimizing objectives for segmentation. Here, we review literature of text segmentation by organizing them into 3 categories based on their focus: *Category1* - (a), *Category2* - (b), and *Category3* - both (a) and (b).

Category1 approaches utilize or benefit from a great amount of effort put in developing robust topic models that can model discourse in natural language texts (Brants et al., 2002). Recently, Du et al. (2013, 2015b) have proposed a hierarchical Bayesian model for unsupervised topic segmentation that integrates a point-wise boundary sampling algorithm used in Bayesian segmentation into a structured (ordering-based) topic model. For a more comprehensive view of classical work on topic models for text segmentation, we refer to Misra et al. (2009); Riedl and Biemann (2012). This work does not explore topic models and is left as a direction for future research.

Category2 approaches comprise of different search procedures proposed for the task of text segmentation, including but not limited to, divisive hierarchical clustering (Choi, 2000), dynamic programming (Kehagias et al., 2003), and graph based clustering (Pourvali and Abadeh, 2012; Glavas et al., 2016; Utiyama and Isahara, 2001). This work proposes an agglomerative IB based hierarchical clustering algorithm - an addition to the arsenal of the approaches that falls in this category.

Similar to the proposed method, *Category3* cuts across both of the above introduced dimensions of segmentation. Alemi and Ginsparg (2015) have proposed the use of semantic word embeddings and a relaxed dynamic programming procedure. We have also argued to utilize chat clues and introduced an IB based approach augmented with sequential continuity constraints. Yet another similar attempt has been made by Joty et al. (2013) in which they use topical and conversa-

tional clues and introduce an unsupervised random walk model for the task of text segmentation.

Beyond the above mentioned categorization, a significant amount of research effort has been put up in studying the evaluation metric for text segmentation (Pevzner and Hearst, 2002; Scaiano and Inkpen, 2012). Here, we make use of the classical and most widely utilized metric introduced by Beeferman et al. (1999). Also, there have been attempts to track topic boundaries for thread discussions (Zhu et al., 2008; Wang et al., 2008). While these methods look similar to the proposed method, they differ as they attempt to recover thread structure with respect to the topic level view of the discussions within a thread community.

The most similar direction of research to this work is on conversation trees (Louis and Cohen, 2015) and disentangling chat conversations (Elsner and Charniak, 2010). Both of these directions cluster independent posts leading to topic labelling and segmentation of these posts simultaneously. It is important to note that these methods do not have a sequential continuity constraint and consider lexical similarity even between long distant posts (Elsner and Charniak, 2011). Moreover, if these methods are applied only for segmentation then they are very likely to produce segments with relatively very smaller durations; as reflected in the ground truth annotations of correspondingly released dataset (Elsner and Charniak, 2008). It is worth noting that Elsner and Charniak (2010) have also advocated to utilize time gap and people mentions similar to the proposed method of this work.

3 Problem Description And Notations

Let C be an input chat text sequence $C = \{c_1, \dots, c_i, \dots, c_{|t|}\}$ of length $|C|$, where c_i is a text snippet such as a sentence or a post from chat text. In a chat scenario, text post c_i will have a corresponding time-stamp c_i^t . A segment or a subsequence can be represented as $C_{a:b} = \{c_a, \dots, c_b\}$. A segmentation of C is defined as a segment sequence $S = \{s_1, \dots, s_p\}$, where $s_j = C_{a_j:b_j}$ and $b_j + 1 = a_{j+1}$. Given an input text sequence C , the segmentation is defined as the task of finding the most probable segment sequence S .

4 Proposed Methodology

This section firstly presents the proposed IB inspired method for text segmentation that conforms to the necessary constraint of sequential continu-

ity, in Section 4.1. Next, in Section 4.2, the proposed IB inspired method is augmented to incorporate important non-textual clues that arise in a chat scenario. More specifically, the time between two consecutive posts and people mentions within the posts are integrated into the proposed IB inspired approach for the text segmentation task.

4.1 IB Inspired Text Segmentation Algorithm

The IB introduces a set of relevance variables R which encapsulate meaningful information about C while compressing the data points (Slonim and Tishby, 2000). Similarly, we propose that a segment sequence S should also contain as much information as possible about R (i.e., maximize $I(R, S)$), constrained by mutual information between S and C (i.e., minimize $I(S, C)$). Here, C is a chat text sequence, following the notation introduced in the previous section. The IB objective can be achieved by maximizing the following:

$$F = I(R, S) - \frac{1}{\beta} \times I(S, C) \quad (1)$$

In other words, the above IB objective function attempts to balance a trade-off between the most informative segmentation of R and the most compact representation of C ; where β is a constant parameter to control the relative importance.

Similar to Tishby et al. (2000), we model R as word clusters and optimize F in an agglomerative fashion, as explained in Algorithm 1. In simple words, the maximization of F boils down to agglomeratively merging an adjacent pair of posts that correspond to least value of d . In Algorithm 1, $p(\bar{s})$ is equal to $p(s_i) + p(s_{i+1})$ and $d(s_i, s_{i+1})$ is computed using the following definition:

$$d(s_i, s_{i+1}) = JSD[p(R|s_i), p(R|s_{i+1})] - \frac{1}{\beta} \times JSD[p(C|s_i), p(C|s_{i+1})] \quad (2)$$

Here, JSD indicates Jensen-Shannon-Divergence. The computation of R and $p(R, C)$ is explained later in Section 5.2. Stopping criterion for Algorithm 1 is $SC > \theta$, where SC is computed as follows:

$$SC = \frac{I(R, S)}{I(R, C)} \quad (3)$$

The value of SC is expected to decrease due to a relatively large dip in the value of $I(R, S)$ when

Algorithm 1: IB inspired text segmentation

Input : Joint distribution: $p(R, C)$,
Tradeoff parameter: β
Output : Segmentation sequence: S
Initialization: $S \leftarrow C$
Calculate $\Delta F(s_i, s_{i+1}) = p(\bar{s}) \times d(s_i, s_{i+1}) \forall s_i \in S$
1 **while** *Stopping criterion is false* **do**
2 | $\{i\} = \operatorname{argmin}_{i'} \Delta F(s_{i'}, s_{i'+1})$;
3 | Merge $\{s_i, s_{i+1}\} \Rightarrow \bar{s} \in S$;
4 | Update $\Delta F(\bar{s}, s_{i-1})$ and $\Delta F(\bar{s}, s_{i+2})$;
5 **end**

more dissimilar clusters are merged. Therefore, SC provides strong clues to terminate the proposed IB approach. The inspiration behind this specific computation of SC has come from the fact that it has produced stable results when experimented with a similar task of speaker diarization (Vijayasenan et al., 2009). The value of θ is tuned by optimizing the performance over a validation dataset just like other hyper-parameters.

The IB inspired text segmentation algorithm (Algorithm 1) respects the sequential continuity constraint, as it considers merging only adjacent pairs (see step 2, 3, and 4 of Algorithm 1) while optimizing F ; unlike the agglomerative IB clustering (Slonim and Tishby, 2000). As a result of this, the proposed IB based approach requires a limited number of involved computations, more precisely, linear in terms of number of text snippets.

4.2 Incorporating Non-Textual Clues

As mentioned above, we submit that non-textual clues (such as time between two consecutive posts and people mentions within the posts) are critical for segmenting chat text. To incorporate these two important clues, we augment Algorithm 1, developed in the previous section. More precisely, we modify d of Equation 2 to \bar{d} as follows:

$$\bar{d}(s_i, s_{i+1}) = w_1 \times d(s_i, s_{i+1}) + w_2 \times (c_{a_{i+1}}^t - c_{b_i}^t) + w_3 \times \|s_i^p - s_{i+1}^p\| \quad (4)$$

Here, $c_{a_{i+1}}^t$, $c_{b_i}^t$ and s_i^p represent time-stamp of the first post of segment s_{i+1} , time-stamp of last post of segment s_i , and representation for poster information embedded in segment s_i , respectively. The s_i^p representation is computed as a bag of posters counting all the people mentioned in the

posts and posters themselves in a segment. w_1, w_2, w_3 are weights indicating the relative importance of distance terms computed for all three different clues. $\|\cdot\|$ in Equation 4 indicates euclidean norm.

It is important to note that Algorithm 1 utilizes d of Equation 2 to represent textual dissimilarity between a pair of posts in order to achieve the optimal segment sequence S . Following the same intuition, \bar{d} in Equation 4 measures weighted distances based not only on textual similarity but also based on information in time-stamps, posters and people mentioned. The intuition behind the second distance term in \bar{d} is that if the time difference between two posts is small then they are likely to be in the same segment. Additionally, the third distance term in \bar{d} is intended to merge segments that involve a higher number of common posters and people mentions. Following the same intuition, in addition to the changes in \bar{d} , we modify the stopping criterion as well while the rest stays the same as in Algorithm 1. The stopping criterion is defined as $SC > \theta$, where SC is as follows:

$$SC = w_1 \times \frac{I(R, S)}{I(R, C)} + w_2 \times \left(1 - \frac{G(S)}{G_{max}}\right) + w_3 \times \frac{H(S)}{H_{max}} \quad (5)$$

Here, the $G(S)$ and $H(S)$ mentioned in Equation 5 are computed as follows:

$$G(S) = \sum_{s_i \in S} c_{b_i}^t - c_{a_i}^t \quad (6)$$

$$H(S) = \sum_{i=1}^{|S|} \|s_i^p - s_{i+1}^p\| \quad (7)$$

The first term in SC in Equation 5 is taken from the stopping criterion of Algorithm 1 and the remaining second and third terms are similarly derived. Both the second and third terms decrease as the cardinality of S is decreased and reflect analogous behaviour to the two introduced important clues. The first term computes the fraction of information contained in S about R , normalized by the information contained in C about R ; similarly, the second term computes the fraction of time duration between segments normalized by total duration of chat text sequence (i.e. 1 - fraction of durations of all segments normalized by total duration), and the third term computes the sum of

inter segment distances in terms of poster information normalized by the maximum distance of similar terms (i.e. when each post is a segment).

5 Experiments

This section starts with a description of the datasets collected from the real world conversation platforms in Subsection 5.1. Later in Subsection 5.2, we explain the evaluation metric utilized in our experiments. Subsection 5.3 describes the meaningful baselines developed for a fair comparison with the proposed IB approach. Next in Subsections 5.4 and 5.5, we discuss the performance accomplished by the proposed approach on both of the collected datasets. Lastly, we analyse the stability of the proposed IB approach with respect to parameters β and θ in Subsection 5.6.

5.1 Dataset Description

We have collected chat text datasets, namely, *Slack* and *Fresco*, respectively from <http://slackarchive.io/> and <http://talk.fresco.me/>. After that, we have manually annotated them for the text segmentation task. We have utilized the annotations done by 3 workers with problematic cases resolved by consensus. Datasets’ statistics is mentioned in Table 1. The collected raw data was in the form of threads, which was later divided into segments. Further, we have created multiple documents where each document contains N continuous segments from the original threads. N was selected randomly between 5 and 15. 60% of these documents were used for tuning hyper-parameters which include weights (w_1, w_2, w_3) , θ , and β ; and the remaining were used for testing.

A small portion of one of the documents from the *Slack* dataset is depicted in Figure 1(a). Here, manual annotations are marked by a bold black horizontal line, and also enumerated as 1), 2), and 3). Every text line is a post made by one of the users on the *Slack* platform during conversations. As mentioned above, in a chat scenario, every post has following three integral components:

- 1) poster (indicated by corresponding identity in Figure 1, from beginning till ‘-=[*says’),
- 2) time-stamp (between ‘-=[*’ and ‘*]=’), and
- 3) textual content (after ‘*]=-:: ’ till end).

One must also notice that some of the posts also have people mentions within the posts (indicated as ‘<@USERID>’ in Figure 1).

To validate the differences between the collected chat datasets and traditional datasets such as Choi’s dataset (Choi, 2000), we computed the fraction of words occurring with a frequency less than a given word frequency, as shown in Figure 2. It is clearly evident from the Figure 2 that chat segmentation datasets have a significantly high proportion of less frequent words in comparison to the traditional text segmentation datasets. The presence of large infrequent words makes it hard for textual similarity methods to succeed as it will increase the proportion of out of vocabulary words (Gulcehre et al., 2016). Therefore, it becomes even more critical to utilize the non-textual clues while processing chat text.

5.2 Evaluation and Setup

For performance evaluation, we have employed P_k metric (Beeferman et al., 1999) which is widely utilized for evaluating the text segmentation task. A sliding window of fixed size k (usually half of the average of length of all the segments in the document) slides over the entire document from top to bottom. Both inter and intra segment errors for all posts k apart is calculated by comparing inferred and annotated boundaries.

We model the set of relevance variables R as word clusters estimated by utilizing agglomerative IB based document clustering (Slonim and Tishby, 2000) where posts are treated as relevance variables. Consequently, R comprises of informative word clusters about posts. Thus, each entry $p(r_i, c_j)$ in matrix $p(R, C)$ represents the joint probability of getting a word cluster r_i in post c_j . We calculate $p(r_i, c_j)$ simply by counting the common words in r_i and c_j and then normalizing.

5.3 Baseline Approaches

For comparisons, we have developed multiple baselines. In *Random*, 5 to 15 boundaries are inserted randomly. In case of *No Boundary*, the entire document is labelled as one segment. Next, we implemented *C-99* and *Dynamic Programming*, which are classical benchmarks for the text segmentation task. Another very simple and yet effec-

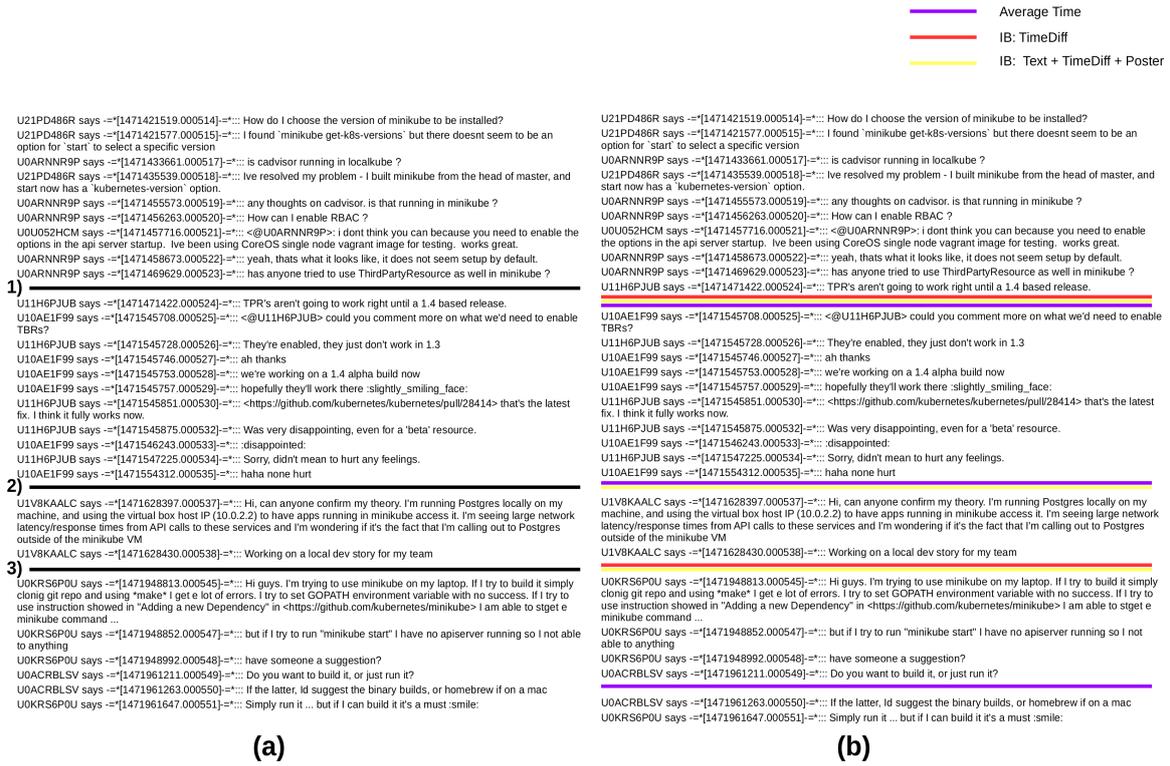

Figure 1: (a) Manually created ground truth for *Slack* public conversations. Black color lines represents segmentation boundaries. (b) Results obtained for multiple approaches. Text best read magnified.

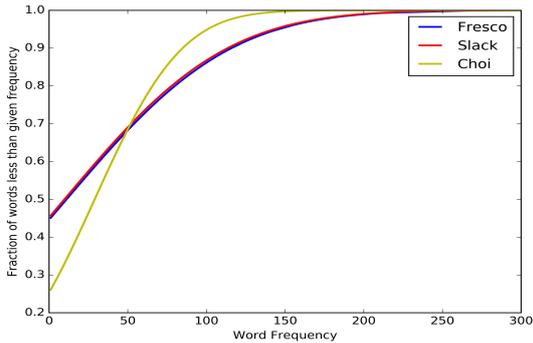

Figure 2: Fraction of words less than a given word frequency.

tive baseline *Average Time* is prepared, in which boundaries are inserted after a fixed amount of time has elapsed. Fixed time is calculated from a certain separate portion of our annotated dataset.

Next baseline utilized in our experiments is *Encoder-Decoder Distance*. In this approach, we have trained a sequence to sequence RNN encoder-decoder (Sutskever et al., 2014) utilizing 1.5 million posts from the publicly available *Slack* dataset excluding the labelled portion. The network comprises of 2 hidden layers and the hidden state dimension was set to 256 for each. The encoded representation was utilized and greedily merged in an agglomerative fashion using Euclidean distance. The stopping criterion for this approach was similar to the third term in Equation 5 corresponding to poster information. The optimization of hidden state dimension was computationally demanding hence left for further exploration in future. Similar to *Encoder-Decoder Distance*, we have developed *LDA Distance* where representations have come from a topic model (Blei et al., 2003) having 100 topics.

5.4 Quantitative Results

The results for all prepared baselines and variants of IB on both *Slack* and *Fresco* datasets are mentioned in Table 2. For both *Slack* and *Fresco* datasets, multiple variants of IB yield superior performance when compared against all the developed baselines. More precisely, for *Slack* dataset, 4 different variants of the proposed IB based method achieve higher performance with an absolute improvement of as high as **3.23%** and a relative improvement of **11.25%**, when compared against the baselines. In case of *Fresco* dataset, 3

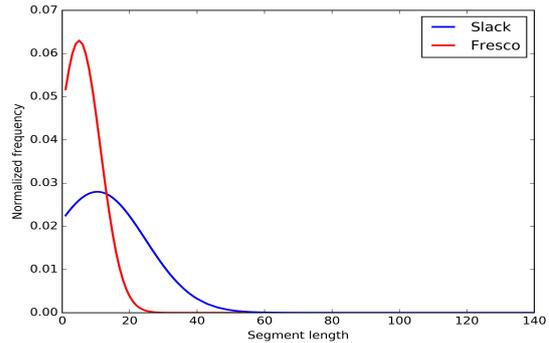

Figure 3: Normalized frequency distribution of segment length for both the collected chat datasets.

different variants of the proposed method achieve superior performance but not as significantly in terms of absolute P_k value, as they do for the *Slack* dataset. We hypothesize that such a behaviour is potentially because of the lesser value of posts per segment for *Fresco* ($5000/800=6.25$) in comparison to *Slack* ($9000/900=10$). Also, note that just the time clue in IB framework performs best on *Fresco* dataset indicating that the relative importance of time clue will be higher for a dataset with smaller lengths of segments (i.e. low value of posts per segment). To validate our hypothesis further, we estimate the normalized frequency distribution of segment length (number of posts per segment) for both datasets, as shown in Figure 3.

It is worth noting that the obtained empirical results support the major hypothesis of this work. As variants of IB yield superior performance on both the datasets. Also, on incorporation of individual non-textual clues, superior improvements of 3.23% and 7.32% are observed from *Text* to *Text+TimeDiff* for *Slack* and *Fresco*, respectively; similarly, from *Text* to *Text+Poster* improvements of 4.43% and 3.79% are observed for *Slack* and *Fresco*, respectively. Further, the best performance is achieved for both the datasets on fusing both the non-textual clues indicating that clues are complementary as well.

5.5 Qualitative Results

Results obtained for multiple approaches, namely, *Average Time*, *IB:TimeDiff*, and *IB:Text+TimeDiff+Poster*, corresponding to a small portion of chat text placed in part (a) of Figure 1 are presented in part (b) of Figure 1. *Average Time* baseline (indicated by purple)

managed to find three boundaries, albeit one of the boundary is significantly off, potentially due to the constraint of fixed time duration.

Similarly, the next *IB:TimeDiff* approach also manages to find first two boundaries correctly but fails to recover the third boundary. Results seem to indicate that the time clue is not very effective to reconstruct segmentation boundaries when segment length varies a lot within the document. Interestingly, the combination of all three clues as happens in the *IB:Text+TimeDiff+Poster* approach, yielded the best results as all of three segmentation boundaries in ground truth are recovered with high precision. Therefore, we submit that the incorporation of non-textual clues is critical to achieve superior results to segment chat text.

5.6 Effect Of Parameters

To analyse the behaviour of the proposed IB based methods, we compute the average performance metric P_k of *IB:Text* with respect to β and θ , over the test set of *Slack* dataset. Also, to facilitate the reproduction of results, we mention optimal values of all the parameters for all the variants of the proposed IB approach in Table 5.5.

Figure 4 shows the behaviour of the average of performance evaluation metric P_k over the test set of *Slack* dataset with respect to hyper-parameter β . As mentioned above also, the parameter β represents a trade-off between the preserved amount of information and the level of compression. It is clearly observable that the optimal value of β does not lie on extremes indicating the importance of both the terms (as in Equation 1) of the proposed IB method. The coefficient of the second term (i.e. $\frac{1}{\beta}$ equals to 10^{-3}) is smaller. One could interpret the behaviour of the second term as a regularization term because $\frac{1}{\beta}$ controls the complexity of the learnt segment sequence S . Furthermore, optimal values in Table 5.5 for variants with fusion of two or more clues indicate complementary and relative importance of the studied non-textual clues.

The average performance evaluation metric P_k over test set of the *Slack* dataset with respect to hyper-parameter θ is depicted in Figure 5. Figure 5 makes the appropriateness of the stopping criterion clearly evident. Initially, the average of P_k value decreases as more coherent posts are merged and continues to decrease till it is less than a particular value of θ . After that, the average of P_k value starts increasing potentially due to the merging of

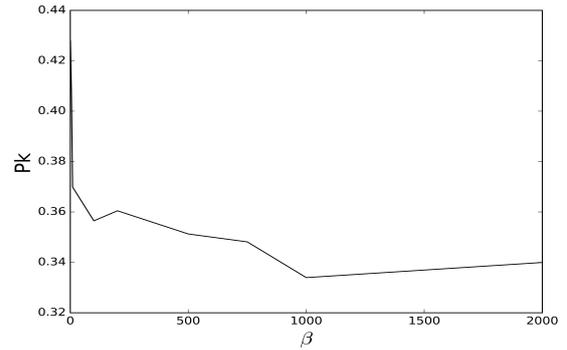

Figure 4: Average evaluation metric P_k over *Slack* dataset with respect to hyper-parameter β .

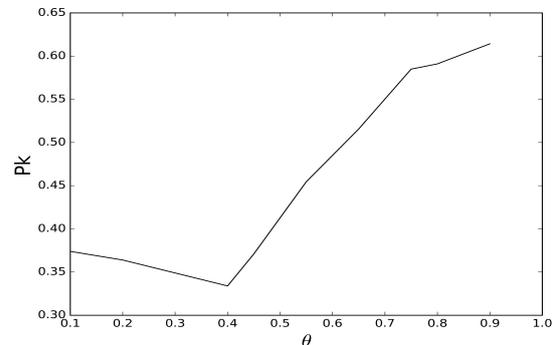

Figure 5: Average evaluation metric P_k over *Slack* dataset with respect to hyper-parameter θ .

more dissimilar segments. The optimal values of θ varies significantly from one variant to another requiring a mandatory tuning over the validation dataset, as mentioned in Table 5.5, for all *IB* variants proposed in this work.

6 Discussion And Future Work

We started by highlighting the increasing importance of efficient methods to process chat text, in particular for text segmentation. We have collected and introduced datasets for the same. Our introduction of chat text datasets has enabled us to explore segmentation approaches that are specific to chat text. Further, our results demonstrate that the proposed IB method yields an absolute improvement of as high as **3.23%**. Also, a significant boost (**3.79%-7.32%**) in performance is observed on incorporation of non-textual clues indicating their criticality. In future, it will be interesting to investigate the possibility of incorporat-

IB Variants:	Slack			Fresco

Distributional Modeling on a Diet: One-shot Word Learning from Text Only

Abstract

We test whether distributional models can do one-shot learning of definitional properties from text only. Using Bayesian models, we find that first learning overarching structure in the known data, regularities in textual contexts and in properties, helps one-shot learning, and that individual context items can be highly informative. Our experiments show that our model can learn properties from a single exposure when given an informative utterance.

1 Introduction

When humans encounter an unknown word in text, even with a single instance, they can often infer approximately what it means, as in this example from Lazaridou et al. (2014):

We found a cute, hairy *wampimuk* sleeping behind the tree.

People who hear this sentence typically guess that a *wampimuk* is an animal, or even that it is a mammal. Distributional models, which describe the meaning of a word in terms of its observed contexts (Turney and Pantel, 2010), have been suggested as a model for how humans learn word meanings (Landauer and Dumais, 1997). However, distributional models typically need hundreds of instances of a word to derive a high-quality representation for it, while humans can often infer a passable meaning approximation from one sentence only (as in the above example). This phenomenon is known as *fast mapping* (Carey and Bartlett, 1978). Our primary modeling objective in this paper is to explore a plausible model for fast-mapping learning from textual context.

While there is preliminary evidence that fast mapping can be modeled distributionally (Lazaridou et al., 2016), it is unclear what enables it.

How do humans infer word meanings from so little data? This question has been studied for *grounded* word learning, when the learner perceives an object in non-linguistic context that corresponds to the unknown word. The literature emphasizes the importance of learning general knowledge or overarching structure, which we define as the information that is learned by accumulation across concepts (e.g. regularities in property co-occurrence), across all concepts (Kemp et al., 2007). In grounded word learning, overarching structure that has been proposed includes knowledge about which properties. For example knowledge about which properties are most important to object naming (Smith et al., 2002; Colunga and Smith, 2005), or a taxonomy of concepts (Xu and Tenenbaum, 2007).

In this paper we study models for fast mapping in word learning¹ from textual context alone, using probabilistic distributional models. Our task differs from the grounded case in that we do not perceive any object labeled by the unknown word. In that context, learning *word meaning* means learning the associated definitional properties and their weights (see Section 3). For the sake of interpretability, we focus on learning definitional properties. We ask what kinds of overarching structure in distributional contexts and in properties will be helpful for one-shot word learning.

We focus on learning from syntactic context. Distributional representations of syntactic context are directly interpretable as selectional constraints, which in manually created resources are typically characterized through high-level taxonomy classes (Kipper-Schuler, 2005; Fillmore et al., 2003). So they should provide good evidence for

¹In this paper, we interchangeably use the terms *unknown word* and *unknown concept*, as we learn properties, and properties belong to concepts rather than words, and we learn them from text, where we observe words rather than concepts.

the meaning of role fillers. Also, it has been shown that selectional constraints can be learned distributionally (Erk et al., 2010; Ó Séaghdha and Korhonen, 2014; Ritter et al., 2010). However, our point will not be that syntax is needed for fast word learning, but that it helps to observe overarching structure, with syntactic context providing a clear test bed.

We test two types of overarching structure for their usefulness in fast mapping. First, we hypothesize that it is helpful to learn about commonalities among context items, which enables mapping from contexts to properties. For example the syntactic contexts *eat-dobj* and *cook-dobj* should prefer similar targets: things that are cooked are also things that are eaten (Hypothesis **H1**).

The second hypothesis is that it will be useful to learn co-occurrence patterns between properties. That is, we hypothesize that in learning an entity is a *mammal*, we may also infer it is *four-legged* (Hypothesis **H2**).

We do not intent to make *strong* cognitive claims, for which additional experimentation will be in order, and we leave this for future work. This work sets its goal on building a plausible computational model that models human fast-mapping in learning (i) well from limited grounded data, (ii) effectively from only one instance.

2 Background

Fast mapping and textual context. Fast mapping (Carey and Bartlett, 1978) is the human ability to construct provisional word meaning representations after one or few exposures. An important reason for why humans can do fast mapping is that they acquire overarching structure that constrains learning (Smith et al., 2002; Colunga and Smith, 2005; Kemp et al., 2007; Xu and Tenenbaum, 2007; Maas and Kemp, 2009). In this paper, we ask what forms of overarching structure will be useful for text-based word learning.

Lazaridou et al. (2014) consider fast mapping for grounded word learning, mapping image data to distributional representations, which is in a way the mirror image of our task. Lazaridou et al. (2016) were the first to explore fast mapping for text-based word learning, using an extension to word2vec with both textual and visual features. However, they model the unknown word simply by averaging the vectors of known words in the sentence, and do not explore what types of knowl-

edge enable fast mapping.

Definitional properties. Feature norms are definitional properties collected from human participants. Feature norm datasets are available from McRae et al. (2005) and Vigliocco et al. (2004). In this paper we use feature norms as our target representations of word meaning. There are several recent approaches that learn to map distributional representations to feature norms (Johns and Jones, 2012; Rubinstein et al., 2015; Făgărășan et al., 2015; Herbelot and Vecchi, 2015a). We also map distributional information to feature norms, but we do it based on a single textual instance (one-shot learning).

In the current paper we use the **Quantified McRae (QMR)** dataset (Herbelot and Vecchi, 2015b), which extends the McRae et al. (2005) feature norms by ratings on the proportion of category members that have a property, and the **Animal** dataset (Herbelot, 2013), which is smaller but has the same shape. For example, *most* alligators are dangerous. The quantifiers are given probabilistic interpretations, so if *most* alligators are dangerous, the probability for a random alligator to be dangerous would be 0.95. This makes this dataset a good fit for our probabilistic distributional model. We discuss QMR and the Animal data further in Section 4.

Bayesian models in lexical semantics. We use Bayesian models for the sake of interpretability and because the existing definitional property datasets are small. The Bayesian models in lexical semantics that are most related to our approach are Dinu and Lapata (2010), who represent word meanings as distributions over latent topics that approximate senses, and Andrews et al. (2009) and Roller and Schulte im Walde (2013), who use multi-modal extensions of Latent Dirichlet Allocation (LDA) models (Blei et al., 2003) to represent co-occurrences of textual context and definitional features. Ó Séaghdha (2010) and Ritter et al. (2010) use Bayesian approaches to model selectional preferences.

3 Models

In this section we develop a series of models to test our hypothesis that acquiring general knowledge is helpful to word learning, in particular knowledge about similarities between context items (H1) and co-occurrences between properties (H2). The count-based model will implement neither hypoth-

esis, while the bimodal topic model will implement both. To test the hypotheses separately, we employ two clustering approaches via Bernoulli Mixtures, which we use as extensions to the count-based model and bimodal topic model.

3.1 The Count-based Model

Independent Bernoulli condition. Let Q be a set of definitional properties, C a set of concepts that the learner knows about, and V a vocabulary of context items. For most of our models, context items $w \in V$ will be predicate-role pairs such as *eat-dobj*. The task is determine properties that apply to an unknown concept $u \notin C$. Any concept $c \in C$ is associated with a vector \mathbf{c}_{Ind} (where “Ind” stands for “independent Bernoulli probabilities”) of $|Q|$ probabilities, where the i -th entry of \mathbf{c}_{Ind} is the probability that an instance of concept c would have property q_i . These probabilities are independent Bernoulli probabilities. For instance, $\mathbf{alligator}_{\text{Ind}}$ would have an entry of 0.95 for *dangerous*. An *instance* $\underline{c} \in \{0, 1\}^{|Q|}$ of a concept $c \in C$ is a vector of zeros and ones drawn from \mathbf{c}_{Ind} , where an entry of 1 at position i means that this instance has the property q_i .

The model proceeds in two steps. First it learns property probabilities for context items $w \in V$. The model observes instances \underline{c} occurring textually with context item w , and learns property probabilities for w , where the probability that w has for a property q indicates the probability that w would appear as a context item with an instance that has property q . In the second step the model uses the acquired context item representations to learn property probabilities for an unknown concept u . When u appears with w , the context item w “imagines” an instance (samples it from its property probabilities), and uses this instance to update the property probabilities of u . Instead of making point estimates, the model represents its uncertainty about the probability of a property through a Beta distribution, a distribution over Bernoulli probabilities. As a Beta distribution is characterized by two parameters α and β , we associate each context item $w \in V$ with vectors $\mathbf{w}^\alpha \in \mathbb{R}^{|Q|}$ and $\mathbf{w}^\beta \in \mathbb{R}^{|Q|}$, where the i -th α and β values are the parameters of the Beta distribution for property q_i . When an instance \underline{c} is observed with context item w , we do a Bayesian update on w simply as

$$\begin{aligned} \mathbf{w}^\alpha &= \mathbf{w}^\alpha + \underline{c} \\ \mathbf{w}^\beta &= \mathbf{w}^\beta + (1 - \underline{c}) \end{aligned} \quad (1)$$

because the Beta distribution is the conjugate prior of the Bernoulli. To draw an instance from w , we draw it from the predictive posterior probabilities of its Beta distributions, $\mathbf{w}_{\text{Ind}} = \mathbf{w}^\alpha / (\mathbf{w}^\alpha + \mathbf{w}^\beta)$.

Likewise, we associate an unknown concept u with vectors \mathbf{u}^α and \mathbf{u}^β . When the model observes u in the context of w , it draws an instance from \mathbf{w}_{Ind} , and performs a Bayesian update as in (1) on the vectors associated with u . After training, the property probabilities for u are again the posterior predictive probabilities $\mathbf{u}_{\text{Ind}} = \mathbf{u}^\alpha / (\mathbf{u}^\alpha + \mathbf{u}^\beta)$. The model can be used for multi-shot learning and one-shot learning in the same way.

Multinomial condition. We also test a multinomial variant of the count-based model, for greater comparability with the LDA model below. Here, the concept representation \mathbf{c}_{Mult} is a multinomial distribution over the properties in Q . (That is, all the properties compete in this model.) An instance of concept c is now a single property, drawn from c ’s multinomial. The representation of a context item w , and also the representation of the unknown concept u , is a Dirichlet distribution with $|Q|$ parameters. Bayesian update of the representation of w based on an occurrence with c , and likewise Bayesian update of the representation of u based on an occurrence with w , is straightforward again, as the Dirichlet distribution is the conjugate prior of the multinomial.

The two count-based models do not implement either of our two hypotheses. They compute separate selectional constraints for each context item, and do not attend to co-occurrences between properties. In the experiments below, the count-based models will be listed as **Count Independent** and **Count Multinomial**.

3.2 The Bimodal Topic Model

We use an extension of LDA (Blei et al., 2003) to implement our hypotheses on the usefulness of overarching structure, both commonalities in selectional constraints across predicates, and co-occurrence of properties across concepts. In particular, we build on Andrews et al. (2009) in using a *bimodal topic model*, in which a single topic simultaneously generates both a context item and a property. We further build on Dinu and Lapata (2010) in having a “pseudo-document” for each concept c to represent its observed occurrences. In our case, this pseudo-document contains pairs of a context item $w \in V$ and a property $q \in Q$,

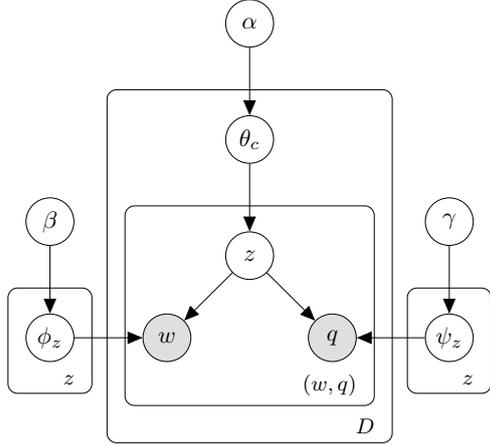

Figure 1: Plate diagram for the Bimodal Topic Model (bi-TM)

meaning that w has been observed to occur with an instance of c that had q .

The generative story is as follows. For each known concept c , draw a multinomial θ_c over topics. For each topic z , draw a multinomial ϕ_z over context items $w \in V$, and a multinomial ψ_z over properties $q \in Q$. To generate an entry for c 's pseudo-document, draw a topic $z \sim \text{Mult}(\theta_c)$. Then, from z , simultaneously draw a context item from ϕ_z and a property from ψ_z . Figure 1 shows the plate diagram for this model.

To infer properties for an unknown concept u , we create a pseudo-document for u containing just the observed context items, no properties, as those are not observed. From this pseudo-document d_u we infer the topic distribution θ_u . Then the probability of a property q given d_u is

$$P(q|d_u) = \sum_z P(z|\theta_u)P(q|\psi_z) \quad (2)$$

For the one-shot condition, where we only observe a single context item w with u , this simplifies to

$$P(q|w) = \sum_z P(z|w)P(q|\psi_z) \quad (3)$$

We refer to this model as **bi-TM** below. The topics of this model implement our hypothesis H1 by grouping context items that tend to occur with the same concepts and the same properties. The topics also implement our hypothesis H2 by grouping properties that tend to occur with the same concepts and the same context items. By using multinomials ψ_z it makes the simplifying assumption that all properties compete, like the Count Multinomial model above.

3.3 Bernoulli Mixtures

With the Count models, we investigate word learning without any overarching structures. With the bi-TMs, we investigate word learning with both types of overarching structures at once. In order to evaluate each of the two hypotheses separately, we use clustering with Bernoulli Mixture models of either the context items or the properties.

A Bernoulli Mixture model (Juan and Vidal, 2004) assumes that a population of m -dimensional binary vectors \mathbf{x} has been generated by a set of mixture components K , each of which is a vector of m Bernoulli probabilities:

$$p(\mathbf{x}) = \sum_{k=1}^{|K|} p(k)p(\mathbf{x}|k) \quad (4)$$

A Bernoulli Mixture can represent co-occurrence patterns between the m random variables it models without assuming competition between them.

To test the effect of modeling *cross-predicate selectional constraints*, we estimate a Bernoulli Mixture model from n instances $\underline{\mathbf{w}}$ for each $w \in V$, sampled from \mathbf{w}_{Ind} (which is learned as in the Count Independent model). Given a Bernoulli Mixture model of $|K|$ components, we then assign each context item w to its closest mixture component as follows. Say the instances of w used to estimate the Bernoulli Mixture were $\{\underline{\mathbf{w}}_1, \dots, \underline{\mathbf{w}}_n\}$, then we assign w to the component

$$k_w = \text{argmax}_k \sum_{j=1}^n p(k|\underline{\mathbf{w}}_j) \quad (5)$$

We then re-train the representations of context items in the Count Multinomial condition, treating each occurrence of c with context w as an occurrence of c with k_w . This yields a Count Multinomial model called **Count BernMix H1**.

To test the effect of modeling *property co-occurrences*, we estimate a $|K|$ -component Bernoulli Mixture model from n instances of each known concept $c \in C$, sampled from \mathbf{c}_{Ind} . We then represent each concept c by a vector \mathbf{c}_{Mult} , a multinomial with $|K|$ parameters, as follows. Say the instances of c used to estimate the Bernoulli Mixture were $\{\underline{\mathbf{c}}_1, \dots, \underline{\mathbf{c}}_n\}$, then the k -th entry in \mathbf{c}_{Mult} is the average probability, over all $\underline{\mathbf{c}}_i$, of being generated by component k :

$$\mathbf{c}_k = \frac{1}{n} \sum_{j=1}^n p(k|\underline{\mathbf{c}}_j) \quad (6)$$

This can be used as a Count Multinomial model where the entries in c_{Mult} stand for Bernoulli Mixture components rather than individual properties. We refer to it as **Count BernMix H2**.²

Finally, we extend the bi-TM with the H2 Bernoulli Mixture in the same way as a Count Multinomial model, and list this extension as **bi-TM BernMix H2**. While the bi-TM already implements both H1 and H2, its assumption of competition between all properties is simplistic, and bi-TM BernMix H2 tests whether lifting this assumption will yield a better model. We do not extend the bi-TM with the H1 Bernoulli Mixture, as the assumption of competition between context items that the bi-TM makes is appropriate.

4 Data and Experimental Setup

Definitional properties. As we use probabilistic models, we need probabilities of properties applying to concept instances. So the QMR dataset (Herbelot and Vecchi, 2015b) is ideally suited. QMR has 532 concrete noun concepts, each associated with a set of quantified properties. The quantifiers have been given probabilistic interpretations, mapping $\text{all} \rightarrow 1$, $\text{most} \rightarrow 0.95$, $\text{some} \rightarrow 0.35$, $\text{few} \rightarrow 0.05$, $\text{none} \rightarrow 0$.³ Each concept/property pair was judged by 3 raters. We choose the majority rating when it exists, and otherwise the minimum proposed rating. To address sparseness, especially for the one-shot learning setting, we omit properties that are named for fewer than 5 concepts. This leaves us with 503 concepts and 220 properties. We intentionally choose this small dataset: One of our main objectives is to explore the possibility of learning effectively from very limited training data. In addition, while the feature norm dataset is small, our distributional dataset (the BNC, see below) is not. The latter essentially serves as a pivot for us to propagate the knowledge from the feature norm data to the wider semantic space.

It is a problem of both the original McRae et al. (2005) data and QMR that if a property is not named by participants, it is not listed, even if it applies. For example, the property *four-legged*

²We use the H2 Bernoulli Mixture as a soft clustering because it is straightforward to do this through concept representations. For the H1 mixture, we did not see an obvious soft clustering, so we use it as a hard clustering.

³The dataset also contains *KIND* properties that do not have probabilistic interpretations. Following Herbelot and Vecchi (2015a) we omit these properties.

is missing for *alligator* in QMR. So we additionally use the **Animal** dataset of Herbelot (2013), where every property has a rating for every concept. The dataset comprises 72 animal concepts with quantification information for 54 properties.

Distributional data. We use the British National Corpus (BNC) (The BNC Consortium, 2007), with dependency parses from Spacy.⁴ As context items, we use pairs $\langle \text{pred}, \text{dep} \rangle$ of predicates *pred* that are content words (nouns, verbs, adjectives, adverbs) but not stopwords, where a concept from the respective dataset (QMR, Animal) is a dependency child of *pred* via *dep*. In total we obtain a vocabulary of 500 QMR concepts and 72 Animal concepts that appear in the BNC, and 29,124 context items. We refer to this syntactic context as **Syn**. For comparison, we also use a baseline model with a bag-of-words (**BOW**) context window of 2 or 5 words, with stopwords removed.

Models. We test our probabilistic models as defined in the previous section. While our focus is on one-shot learning, we also evaluate a multi-shot setting where we learn from the whole BNC, as a sanity check on our models. (We do not test our models in an incremental learning setting that adds one occurrence at a time. While this is possible in principle, the computational cost is prohibitive for the bi-TM.) We compare to the Partial Least Squares (**PLS**) model of Herbelot and Vecchi (2015a)⁵ to see whether our models perform at state of the art levels. We also compare to a baseline that always predicts the probability of a property to be its relative frequency in the set C of known concepts (**Baseline**).

We can directly use the property probabilities in QMR and the Animal data as concept representations c_{Ind} for the Count Independent model. For the Count Multinomial model, we never explicitly compute c_{Mult} . To sample from it, we first sample an instance $\underline{c} \in \{0, 1\}^{|\mathcal{Q}|}$ from the independent Bernoulli vector of c , c_{Ind} . From the properties that apply to \underline{c} , we sample one (with equal probabilities) as the observed property. All priors for the count-based models (Beta priors or Dirichlet priors, respectively) are set to 1.

For the bi-TM, a pseudo-document for a known

⁴<https://spacy.io>

⁵Herbelot and Vecchi (2015a) is the only directly relevant previous work on the subject. Further, to the best of our knowledge, for one-shot property learning from text (only), our work has been the first attempt.

Models		QMR		Animal Syn
		BOW5	Syn	
Baseline		0.12	0.16	0.63
PLS		0.24	0.35	0.71
Count	Mult.	0.13	0.25	0.64
	Ind.	0.11	0.23	0.64
	BernMix H1	0.11	0.17	0.65
	BernMix H2	0.10	0.18	0.63
bi-TM	plain	0.23	0.36	0.80
	BernMix H2	0.20	0.34	0.81

Table 1: MAP scores, multi-shot learning on the QMR and Animal datasets

concept c is generated as follows: Given an occurrence of known concept c with context item w in the BNC, we sample a property q from c (in the same way as for the Count Multinomial model), and add $\langle w, q \rangle$ to the pseudo-document for c . For training the bi-TM, we use collapsed Gibbs sampling (Steyvers and Griffiths, 2007) with 500 iterations for burn-in. The Dirichlet priors are uniformly set to 0.1 following Roller and Schulte im Walde (2013). We use 50 topics throughout.

For all our models, we report the average performance from 5 runs. For the PLS benchmark, we use 50 components with otherwise default settings, following Herbelot and Vecchi (2015a).

Evaluation. We test all models using 5-fold cross validation and report average performance across the 5 folds. We evaluate performance using *Mean Average Precision* (MAP), which tests to what extent a model ranks definitional properties in the same order as the gold data. Assume a system that predicts a ranking of n datapoints, where 1 is the highest-ranked, and assume that each datapoint i has a gold rating of $I(i) \in \{0, 1\}$. This system obtains an Average Precision (AP) of

$$AP = \frac{1}{\sum_{i=1}^n I(i)} \sum_{i=1}^n \text{Prec}_i \cdot I(i)$$

where Prec_i is precision at a cutoff of i . Mean Average Precision is the mean over multiple AP values. In our case, $n = |Q|$, and we compare a model-predicted ranking of property probabilities with a binary gold rating of whether the property applies to any instances of the given concept. For the one-shot evaluation, we make a separate prediction for each occurrence of an unknown concept u in the BNC, and report MAP by averaging over the AP values for all occurrences of u .

5 Results and Discussion

Multi-shot learning. While our focus in this paper is on one-shot learning, we first test all models in a multi-shot setting. The aim is to see how well they perform when given ample amounts of training data, and to be able to compare their performance to an existing multi-shot model (as we will not have any related work to compare to for the one-shot setting.) The results are shown in Table 1, where *Syn* shows results that use syntactic context (encoding selectional constraints) and *BOW5* is a bag-of-words context with a window size of 5. We only compare our models to the baseline and benchmark for now, and do an in-depth comparison of our models when we get to the one-shot task, which is our main focus.

Across all models, the syntactic context outperforms the bag-of-words context. We also tested a bag-of-words context with window size 2 and found it to have a performance halfway between *Syn* and *BOW5* throughout. This confirms our assumption that it is reasonable to focus on syntactic context, and for the rest of this paper, we test models with syntactic context only.

Focusing on *Syn* conditions now, we see that almost all models outperform the property frequency baseline, though the MAP scores for the baseline do not fall far behind those of the weakest count-based models.⁶ The best of our models perform on par with the PLS benchmark of Herbelot and Vecchi (2015a) on QMR, and on the Animal dataset they outperform the benchmark. Comparing the two datasets, we see that all models show better performance on the cleaner (and smaller) *Animal* dataset than on QMR. This is probably because QMR suffers from many false negatives (properties that apply but were not mentioned), while *Animal* does not. The Count Independent model shows similar performance here and throughout all later experiments to the Count Multinomial (even though it matches the construction of the QMR and Animal datasets better), so to avoid clutter we do not report on it further below.

One-shot learning. Table 2 shows the perfor-

⁶This is because MAP gives equal credit for all properties correctly predicted as non-zero. When we evaluate with Generalized Average Precision (GAP) (Kishida, 2005), which takes gold weights into account, the baseline model is roughly 10 points below other models. This indicates our models learn approximate property distributions. We omit GAP scores because they correlate strongly with MAP for non-baseline models.

Models			all	oracle top20	AvgCos top20
QMR	Count	Mult.	0.16	0.37	0.28
		BernMix H1	0.14	0.33	0.21
		BernMix H2	0.15	0.31	0.22

		BernMix H2	0.65	0.89	0.66

Table 2: MAP scores, one-shot learning on the QMR and Animal datasets

mance of our models on the one-shot learning task. We cannot evaluate the benchmark PLS as it is not suitable for one-shot learning. The baseline is the same as in Table 1. The numbers shown are Average Precision (AP) values for learning from a single occurrence. Column *all* averages over all occurrences of a target in the BNC (using only context items that appeared at least 5 times in the BNC), and column *oracle top-20* averages over the 20 context items that have the highest AP for the given target. As can be seen, AP varies widely across sentences: When we average over all occurrences of a target in the BNC, performance is close to baseline level.⁷ But the most *informative* instances yield excellent information about an unknown concept, and lead to MAP values that are much higher than those achieved in multi-shot learning (Table 1). We explore this more below.

Comparing our models, we see that the bi-TM does much better throughout than any of the count-based models. Since the bi-TM model implements both cross-predicate selectional constraints (H1) and property co-occurrence (H2), we find both of our hypotheses confirmed by these results. The Bernoulli mixtures improved performance on the Animal dataset, with no clear pattern of which one improved performance more. On QMR, adding a Bernoulli mixture model harms performance across both the count-based and bi-TM models. We suspect that this is because of the false negative entries in QMR; an inspection of Bernoulli mixture H2 components supports this intuition, as the QMR ones were found to be of poorer quality than those for the Animal data.

Comparing Tables 1 and 2 we see that they show

⁷Context items with few occurrences in the corpus perform considerably worse than baseline, as their property distributions are dominated by the small number of concepts with which they appear.

Count Mult.	clothing, made_of_metal, different_colours, an_animal, is_long
bi-TM	clothing, made_of_material, has_sleeves, different_colours, worn_by_women
bi-TM one-shot	clothing, is_long, made_of_material, different_colours, has_sleeves

Table 3: QMR: top 5 properties of *gown*. Top 2 entries: multi-shot. Last entry: one-shot, context *undo-dobj*

Top	<i>undo-dobj</i> (0.70), <i>nylon-nmod</i> (0.66), <i>pink-amod</i> (0.65), <i>retie-dobj</i> (0.64), <i>silk-amod</i> (0.64)
Bottom	<i>sport-nsubj</i> (0.01), <i>contemplate-dobj</i> (0.01), <i>comic-amod</i> (0.01), <i>wait-nsubj</i> (0.01), <i>fibrous-amod</i> (0.01)

Table 4: QMR one-shot: AP for top and bottom 5 context items of *gown*

the same patterns of performance: Models that do better on the multi-shot task also do better on the one-shot task. This is encouraging in that it suggests that it should be possible to build incremental models that do well both in a low-data and an abundant-data setting.

Table 3 looks in more detail at what it is that the models are learning by showing the five highest-probability properties they are predicting for the concept *gown*. The top two entries are multi-shot models, the third shows the one-shot result from the context item with the highest AP. The bi-TM results are very good in both the multi-shot and the one-shot setting, giving high probability to some quite specific properties like *has_sleeves*. The count-based model shows a clear frequency bias in erroneously giving high probabilities to the two overall most frequent properties, *made_of_metal* and *an_animal*. This is due to the additive nature of the Count model: In updating unknown concepts from context items, frequent properties are more likely to be sampled, and their effect accumulates as the model does not take into account interactions among context items. The bi-TM, which models these interactions, is much more robust to the effect of property frequency.

Informativity. In Table 2 we saw that one-shot performance averaged over all context items in the whole corpus was quite bad, but that good, *informative* context items can yield high-quality property information. Table 4 illustrates this point fur-

	Model		Freq.	Entropy	AvgCos
QMR	Count	Mult.	0.09	-0.12	0.18
	Count	BernMix H1	0.07	-0.10	0.17
	Count	BernMix H2	0.10	-0.09	0.17
	bi-TM	plain	0.15	-0.09	0.41*
	bi-TM	BernMix H2	0.16	-0.10	0.39*
Ani.	bi-TM	plain	0.25	-0.40	0.49*
	bi-TM	BernMix H2	0.23*	-0.37*	0.52*

Table 5: Correlation of informativity with AP, Spearman’s ρ . * and • indicate significance at $p < 0.05$ and $p < 0.1$

ther. For the concept *gown*, it shows the five context items that yielded the highest AP values, at the top *undo-obj*, with an AP as high as 0.7.

This raises the question of whether we can predict the informativity of a context item.⁸ We test three measures of informativity. The first is simply the **frequency** of the context item, with the rationale that more frequent context items should have more stable representations. Our second measure is based on **entropy**. For each context item w , we compute a distribution over properties as in the count-independent model, and measure the entropy of this distribution. If the distribution has few properties account for a majority of the probability mass, then w will have a low entropy, and would be expected to be more informative. Our third measure is based on the same intuition, that items with more “concentrated” selectional constraints should be more informative. If a context item w has been observed to occur with known concepts c_1, \dots, c_n , then this measure is the average cosine (**AvgCos**) of the property distributions (viewed as vectors) of any pair of $c_i, c_j \in \{c_1, \dots, c_n\}$.

We evaluate the three informativity measures using Spearman’s rho to determine the correlation of the informativity of a context item with the AP it produces for each unknown concept. We expect frequency and AvgCos to be positively correlated with AP, and entropy to be negatively correlated with AP. The result is shown in Table 5. Again, all measures work better on the Animal data than on QMR, where they at best approach significance. The correlation is much better on the bi-TM models than on the count-based models, which is probably due to their higher-quality predictions. Overall, AvgCos emerges as the most robust indicator

⁸Lazaridou et al. (2016), who use a bag-of-words context in one-shot experiments, propose an informativity measure based on the number of context that constitute properties. We cannot do that with our syntactic context.

Type	MAP
Function	0.45
Taxonomic	0.62
Visual	0.34
Encyclopaedic	0.35
Perc	0.40

Table 6: QMR, bi-TM, one-shot: MAP by property type over (oracle) top 20 context items

for informativity.⁹ We now test AvgCos, as our best informativity measure, on its ability to select good context items. The last column of Table 2 shows MAP results for the top 20 context items based on their AvgCos values. The results are much below the oracle MAP (unsurprisingly, given the correlations in Table 5), but for QMR they are at the level of the multi-shot results of Table 1, showing that it is possible to some extent to automatically choose informative examples for one-shot learning.

Properties by type. McRae et al. (2005) classify properties based on the brain region taxonomy of Cree and McRae (2003). This enables us to test what types of properties are learned most easily in our fast-mapping setup by computing average AP separately by property type. To combat sparseness, we group property types into five groups, *function* (the function or use of an entity), *taxonomic*, *visual*, *encyclopaedic*, and *other perceptual* (e.g., sound). Intuitively, we would expect our contexts to best reflect *taxonomic* and *function* properties: Predicates that apply to noun target concepts often express functions of those targets, and manually specified selectional constraints are often characterized in terms of taxonomic classes. Table 6 confirms this intuition. Taxonomic properties achieve the highest MAP by a large margin, followed by functional properties. Visual properties score the lowest.

6 Conclusion

We have developed several models for one-shot learning word meanings from single textual contexts. Our models were designed learn word properties using distributional contexts (H1) or about co-occurrences of properties (H2). We find evidence that both kinds of general knowledge are

⁹We also tested a binned variant of the frequency measure, on the intuition that medium-frequency context items should be more informative than either highly frequent or rare ones. However, this measure did not show better performance than the non-binned frequency measure.

helpful, especially when combined (in the bi-TM), or when used on clean property data (in the Animal dataset). We further saw that some contexts are highly informative, and preliminary experiments in informativity measures found that average pairwise similarity of seen role fillers (AvgCos) achieves some success in predicting which contexts are most useful.

In the future, we hope to test with other types of general knowledge, including a taxonomy of known concepts (Xu and Tenenbaum, 2007); wider-coverage property data (Baroni and Lenci, 2010, Type-DM); and alternative modalities (Lazaridou et al., 2016, image features as “properties”). We expect our model will scale to these larger problems easily.

We would also like to explore better informativity measures and improvements for AvgCos. Knowledge about informative examples can be useful in human-in-the-loop settings, for example a user aiming to illustrate classes in an ontology with a few typical corpus examples. We also note that the bi-TM cannot be used in for truly incremental learning, as the cost of global re-computation after each seen example is prohibitive. We would like to explore probabilistic models that support incremental word learning, which would be interesting to integrate with an overall probabilistic model of semantics (Goodman and Lassiter, 2014).

A Computational Study on Word Meanings and Their Distributed Representations via Polymodal Embedding

Abstract

A distributed representation has become a popular approach to capturing a word meaning. Besides its success and practical value, however, questions arise about the relationships between a true word meaning and its distributed representation. In this paper, we examine such a relationship via polymodal embedding approach inspired by the theory that humans tend to use diverse sources in developing a word meaning. The result suggests that the existing embeddings lack in capturing certain aspects of word meanings which can be significantly improved by the polymodal approach. Also, we show distinct characteristics of different types of words (e.g. concreteness) via computational studies. Finally, we show our proposed embedding method outperforms the baselines in the word similarity measure tasks and the hypernym prediction tasks.

1 Introduction

Word representations based on the distributional hypothesis of Harris (1954) have become a dominant approach including word2vec (Mikolov et al., 2013) and GloVe (Pennington et al., 2014), which show remarkable performances in a wide spectrum of natural language processing. However, a question arises about a relationship between a true word meaning and its distributed representation. While the context-driven word representations seem to be able to capture word-to-word relations, for example, *men* is to *women* as *king* is to *queen*, it still remains unclear what aspects of

word meaning they capture and miss. For example, a word, *coffee*, can be understood from multiple perspectives. It may be associated with a ceramic cup filled with dark brown liquid from the perceptual perspective or an emotion such as happiness or tranquility. It may provoke other related concepts like *bagel* or *awakening*. We raise the question of how well the current distributed representation captures such aspects of word meanings.

In order to help answering this question, we propose a polymodal word representation based on the theory that humans tend to use diverse sources in developing a word meaning. In particular, we construct six modules for polymodality including linear context, syntactic context, visual perception, cognition, emotion, and sentiments based on the human cognitive model proposed by Maruish and Moses (2013). They are combined to build a single word representation.

We conduct a series of experiments to examine the relationships between word meanings and their distributed representations and compare the results with other representations such as word2vec, GloVe, and meta-embedding (Yin and Schütze, 2015). We attempt to understand how well the model capture the diverse aspects of word meanings via two experiments: the property norms analysis and the sentiment polarity analysis. The result suggests that the existing embedding methods lack in capturing visual properties and sentiment polarities and show that they can be much improved by adopting polymodal approaches.

Finally, we examine distinct characteristics of different types of words via computational studies, focusing along the dimension of concept concreteness and similarity. We find that the importance of a certain module (e.g. visual perception or lexical relations) varies depending on the word properties. Our study provides some computational evidence for the heterogeneous nature of word meanings,

* Currently at Search Solutions Inc., Seongnam, 13561, Korea

which has been extensively studied in the field of psycholinguistics. We briefly introduce it in the following subsection.

2 Related Work

2.1 Theoretical works

Word meanings are thought to have diverse aspects. Steels (2008) address that languages are inherently built upon our cognitive system to fulfill the purpose of communication between mutually unobservable internal representations. So many psycholinguistic theories have attempted to understand the diverse nature of word meanings by human minds. Barsalou (1999) claims that many human modalities such as conceptual/perceptual systems cooperate with each other in a complex way and influence word meanings, while Pulvermüller (1999) argues that concepts are grounded in complex simulations of physical and introspective events, activating the frontal region of the brain that coordinates the multimodal information. Studies on semantic priming (Plaut and Booth, 2000) also supports them that words can be similar to each other in various ways to foster the priming effect. The experiments in this paper are designed to provide some computational evidence on such studies on the multifaceted nature of word meanings.

2.2 Multimodal approaches

From a computational point of view, there exist a number of bimodal approaches that extend the semantic representation to include perceptual information or understandings of the world around us. Bruni et al. (2014) and Kiros et al. (2014a) propose a way to augment text-based word embeddings using public image datasets while Roller and Im Walde (2013) integrate visual features into LDA models. A recent study on Image caption generation (Xu et al., 2015) suggests an interesting way to align word embeddings and image features. Moreover, Kiros et al. (2014b) jointly trains the image abstraction network and sentence abstraction network altogether, making the visual features naturally combined into word embeddings. Similar attempts have been made not only for visual perception but also auditory (Kiela and Clark, 2015) and olfactory (Kiela et al., 2015) perception. On the other hand, Henriksson (2015) demonstrates that semantic space ensemble models created by exploiting various corpora are

able to outperform any single constituent model. Yin and Schütze (2015) propose meta-Embedding that ensembles multiple semantic spaces trained by different methods with different tasks such as word2vec, GloVe, HLBL (Luong et al., 2013) and C&W (Collobert and Weston, 2008). Above works succeed to improve word embedding quality by extending the semantic representation, but it still remains unclear how those improvements are related to the word meanings.

3 Polymodal word embedding

To embrace the multifaceted nature of word meanings, we propose a polymodal word embedding. More specifically, we take into account perception, sentiment, emotion, and cognition (lexical relation) derived from diverse sources, in addition to linear context and syntactic context obtained from the corpus. Note that the term *polymodal* is used to distinguish it from *bimodal* (Kiela, 2017). In bimodal approach, a single cognitive modality is used whereas more than one modalities are used in polymodal.

3.1 Modules

We describe each of the modules in detail.

Linear context refers to linear embeddings (Mikolov et al., 2013) comprising 300-dimensional vectors trained over 100 billion words from the Google News dataset using skip-gram and negative sampling.

Syntactic context takes a similar skip-gram approach as in linear context but defines the context window differently using a dependency parsing result (Levy and Goldberg, 2014). While the linear skip-gram defines the contexts of a target word w as $w_{-k}, w_{-k+1}, \dots, w_{k-1}, w_k$ where k is a size of the window, syntactic context defines them as $(m_1, lbl_1), (m_2, lbl_2), \dots, (m_k, lbl_k), (m_{-1}, lbl_{-1})$ where m is the modifiers of word w and lbl is the type of dependency relation.

Both linear and syntactic contexts are similar in the sense that they capture word characteristics from the corpus. However, the different definitions of the contexts make the model focus on the different aspects of word meanings. Levy and Goldberg (2014) report that linear context tends to capture topical similarity whereas syntactic context captures functional similarity. For example, the word *Florida* is close to *Miami* in linear context but close to *California* in syntactic context.

We harness both types of contexts to take into account functional and syntactic similarities.

Cognition (Lexical relation) encompasses all the relations between words, which are captured in the form of a lexicon or ontology in a cognitive system. In this paper, we mainly focus on synonym, hypernym and hyponym relations in WordNet (Miller, 1995) which contains 149k words and 935k relations between them. We train lexical-relation-specific word embedding using retro-fitting (Faruqui et al., 2015).

Specifically, let $V = \{w_1, \dots, w_n\}$ be a vocabulary and Ω be an ontology that encodes semantic relations between words in V . Ω can be represented as a set of edges of undirected graph where $(w_i, w_j) \in \Omega$ if w_i and w_j holds semantic relationship of interest. The matrix \hat{Q} is the collection of the vector representation of $\hat{q}_i \in \mathbb{R}^d$ for each word $w_i \in V$ where d is the length of pre-trained word vectors. In this experiment, we use GloVe as such vectors. The objective of learning is to train the matrix $Q = (q_1, \dots, q_n)$ so as to make q_i close to its counterpart \hat{q}_i and also to its adjacent vertices in Ω . Thus the objective function to be minimized can be written as

$$\Psi(Q) = \sum_{i=1}^n \left[\alpha_i \|q_i - \hat{q}_i\|^2 + \sum_{(i,j) \in \Omega} \beta_{ij} \|q_i - q_j\|^2 \right]$$

where α_i and β_{ij} are hyperparameters. This procedure of training transforms the manifold of semantic space to make words in relations located more closer in Euclidean distance.

Perception is a vital component for human cognition and has a significant influence on word meanings. In this paper, we only consider visual perception. We jointly train the embeddings of images and sentences together into the multi-modal vector space to build vision-specific word embeddings (Kiros et al., 2014b).

In particular, let T be the training dataset where one image I_i is associated with a corresponding caption sentence S_i , i.e., $(I_i, S_i) \in T$. An embedding of image I_i , $x_i \in \mathbb{R}^d$, can be obtained through convolutional neural networks, in this case, 19-layer OxfordNet (Simonyan and Zisserman, 2014), where d is the size of the dimension of multimodal space. Similarly, an embedding of sentence S_i , $x_s \in \mathbb{R}^d$, can be composed through one of the sentence modeling networks, in this case, LSTM (Hochreiter and Schmidhuber, 1997). These two image and sentence modeling

networks are jointly trained together to minimize the pairwise ranking loss function

$$L = \sum_{x_i} \sum_{x_{\hat{s}}} \max(0, \alpha - x_i \cdot x_s + x_i \cdot x_{\hat{s}}) + \sum_{x_s} \sum_{x_{\hat{i}}} \max(0, \alpha - x_s \cdot x_i + x_s \cdot x_{\hat{i}})$$

to place correct samples closer while separating negative samples farther in the joint space. α is a hyperparameter and $x_{\hat{s}}$ and $x_{\hat{i}}$ are incorrect image and sentence pair obtained through negative sampling. We use MS COCO dataset (Lin et al., 2014) to train the network which contains 300k images and 5 captions per image. Final perception embeddings of dimension 1024 are sampled from the joint space regarding one word as a sentence.

Sentiment, either positive or negative, is determined for words that have sentiment orientations depending on their inherent meanings, usages, backgrounds etc. To capture the sentiment polarity of words (positive and negative), we use SentiWordNet3.0 (Baccianella et al., 2010), a lexical resource that automatically annotates the degree of positivity, negativity, and neutrality of English words. It is a one-dimensional value and if a word has multiple senses, we take the difference between the maximum positivity and the minimum negativity.

Emotion are considered by using NRC Emotion Lexicon (Mohammad and Turney, 2013) to reflect the emotional characteristics of words. It contains 15k words that are annotated with 10 emotion categories: anger, anticipation, disgust, fear, joy, sadness, surprise, trust, negative and positive. We built 10-dimensional one-hot emotion vectors based on this dataset.

Note that some embedding sets may not cover every word in our set of test vocabulary. In that case, out-of-vocabulary (OOV) words are initialized to zero for the missing modules. All embeddings are L2-normalized.

3.2 Ensemble methods

While the most rudimentary way for the amalgamation of several vectors is a concatenation with weights, other ensemble methods are expected to produce the vectors with improved quality (Henriksson, 2015). Faruqui and Dyer (2015) suggest that singular value decomposition (SVD) can be a promising way to merge the information by approximating the original matrix. Motivated by

their work, we examine two matrix factorization techniques, SVD and non-negative matrix factorization (NMF). In addition, we explore an unsupervised ensemble method via autoencoder (AE) networks. The details of these methods are illustrated below. Hyperparameters such as dimension d are selected to obtain the highest Spearman’s correlation score in the RG-65 dataset (Rubenstein and Goodenough, 1965), which is used as a development set to minimize the interference on the test set. Note that before applying SVD, NMF, and AE, embeddings from different modules are concatenated with weights.

Concatenation (CONC) is used as the first step for ensembling multiple vectors of different dimensions. That is, let S be a set of n semantic spaces and s_i be a single vector space in S . $e_{id} \in s_i$ is a representation of word w_d in the semantic space $s_i \in S$. Then the resulting concatenated embedding e_d of word w_d is

$$e_d = \alpha_1 e_{d1} \oplus \dots \oplus \alpha_i e_{di} \oplus \dots \oplus \alpha_n e_{dn}$$

where \oplus is the concatenation operator and $\sum_i \alpha_i = 1$. RG-65 is used as a development set to tune the weights α_i of particular embedding e_{di} .

Singular Value Decomposition (SVD) is a generalization of eigenvalue decomposition to any $m \times n$ matrix where it is reported to be effective in signal processing (Sahidullah and Kinnunen, 2016). Let V be the set of m words and k is the dimension of word embedding e_i for word $w_i \in V$. The dictionary matrix M is a $m \times k$ matrix where each row vector m_i of M is an embedding vector of e_i of word w_i . Then this matrix M is decomposed into $M = U\Sigma V^T$ where U and V are $m \times m$ and $n \times n$ real unitary matrices respectively, and Σ is a $m \times n$ non-negative real rectangular diagonal matrix. u_{id} is the first d dimension of i -th row vector u_i of U and we use it as a representation of word w_i . d is 230 for SVD. The size of vocabulary m is 20150.

Non-negative matrix factorization (NMF) has been reported to be effective method in various research areas including bioinformatics (Taslaman and Nilsson, 2012), signal denoising (Schmidt et al., 2007), and topic modeling (Arora et al., 2013). Two non-negative matrix W and H are optimized to approximate the dictionary matrix $M^T \approx WH$ by minimizing the frobenius norm $\|M^T - WH\|_F$ where $W, H \geq 0$. NMF has an inherent property of clustering the column vectors

of the target matrix. To make M^T non-negative, we normalize the values of each embedding into the $[0,1]$. Let s_{id} be the first d dimension of i -th column vector s_i of W . Then we use s_{id} as a representation of word w_i . d is 200 for NMF.

Autoencoder (AE) is a neural network used for unsupervised learning of efficient coding for data compression or dimensionality reduction (Hinton and Sejnowski, 1986). Previous work suggests that an autoencoder may be able to learn relationships between the modules and result in higher-level embeddings (Silberer and Lapata, 2014). Our autoencoder consists of simple feedforward network. We trained two matrices W_{enc} of size $k \times d$ and W_{dec} of size $d \times k$ to learn efficient coding of word representation where k is the dimension of original word embedding and d is the dimension of compressed representation. Parameters are optimized to minimize cosine proximity loss:

$$L = \sum_{x \in T} 1 - \frac{\tilde{x} \cdot x}{\|\tilde{x}\| \cdot \|x\|}$$

where x is a k -dimensional word embedding, T is a training data set of size 20150 words, $\tilde{x} = f(W_{dec}f(W_{enc}x + b_{enc}) + b_{dec})$ and f is a ReLU non-linear activation function. We set $d = 900$.

4 Experiments

We introduce the experiments taken to examine how well the representations embed word meanings incorporating distinct properties. First, we apply our proposed embedding method to a word similarity measure task and a hypernym prediction task to measure its overall quality. Then we conducted a series of experiments for analyzing the characteristics of word meanings.

4.1 Word Similarity Measure and Hypernym Prediction

To assess the overall quality of proposed embedding method, we examined its performance via the word similarity task on SimLex-999 (Hill et al., 2016), WordSim-353 (Agirre et al., 2009), and MEN (Bruni et al., 2014) datasets. The similarity of each word pair is computed through cosine proximity, and we use Spearman’s rank correlation as an evaluation metric. We also measure the performance of the different ensemble methods described in subsection 3.2. The result is compared with three baselines: Word2Vec, GloVe, and

Meta-embedding(1toN) (Yin and Schütze, 2015). The result is shown on table 1.

Baseline	SL	WS	MEN
Word2Vec	.442	.698	.782
GLoVe	.453	.754	.816
MetaEmb	.464	.745	.816
Polymodal (CONC)	.533	.622	.778
Polymodal (SVD)	.580	.775	.838
Polymodal (AE)	.507	.599	.751
Polymodal (NMF)	.414	.509	.589
Avg. Human	.780	.791	.840

Table 1: Spearman’s correlation score on SimLex-999 (SL), WordSim-353 (WS), and MEN datasets. “Avg. Human” score is an inter-agreement between human annotators.

Our proposed method clearly outperforms the baselines in all the datasets, with near-human performance in WordSim-353 and MEN. Among the ensemble methods, SVD gave the best result showing its strong capability of combining information from different modules for this task.

We also conducted a hypernym prediction experiment using HyperLex dataset (Vulić et al., 2016) to analyze the quality of proposed embedding from a different perspective. Given a pair of two words, the task is to predict the degree of the first word being a type of the second word, for example “To what degree is *chemistry* a type of *science*?”. We build a 2-layer feedforward network of dimensions 1000 and 500 respectively with a ReLU activation function to predict the hypernyms. Then the network is trained to predict the degree of hypernymity of the scale from 0.0 to 10.0 to minimize categorical cross-entropy loss using AdaGrad optimizer on the training set. The final evaluation metrics are obtained by calculating Spearman’s correlation between the predicted degrees and the test set.

As in Table 2, the proposed method shows the highest correlation to the test set among all the cases including the baselines. Among the ensemble method, SVD again shows the highest performance. For the hypernym prediction, NMF gives a slightly better result than the simple weighted concatenation.

4.2 Property Norms Analysis

While the corpus-driven word representations such as Word2vec and GLoVe have been shown to

	Test correlation (ρ)
Word2Vec	.319
GloVe	.391
MetaEmb	.400
Polymodal (CONC)	.445
Polymodal (SVD)	.463
Polymodal (NMF)	.454
Polymodal (AE)	.434

Table 2: Spearman’s correlation score of HyperLex test dataset and predictions. The proposed method shows the highest correlation with the test dataset.

embed some word-to-word relations such as *men* is to *women* as *king* is to *queen*, but it is still uncertain that they are also able to capture the properties like *has_four_legs* or *is_delicious*. To see how well the models capture such properties of words, we perform the property norms analysis. We utilize the CSLB concept property norms dataset (Devereux et al., 2014) which annotates the normalized feature labels to the set of concepts. This dataset provides the normalized features of five categories: visual perceptual, other perceptual, taxonomic, encyclopedic, and functional. C is the set of all concepts and F is the set of all normalized features in CSLB dataset where $|C| = 638$ and $|F| = 5929$. For $f \in F$ and $c \in C$, $c \in C_f$ if and only if c has the feature f where $C_f \subset C$. The valid feature set F_v is a subset of F such that $f \in F_v$ only if there exist more than three concepts that have f , or equivalently, $|C_f| > 3$. Then the $|F_v| = 1053$.

To examine how well each representation captures the normalized feature $f_i \in F_v$, we calculate the cosine similarity between $R(c)$ for $c \in C_{f_i}$ and $R(\overline{C_{f_i}})$ where $R(\cdot)$ is a mapping from concept to its distributed representation and $\overline{C_{f_i}}$ is a centroid of all concepts in C_{f_i} or

$$\overline{C_{f_i}} = \frac{1}{|C_{f_i}|} \sum_{c \in C_{f_i}} R(c)$$

In other words, $\overline{C_{f_i}}$ is a centroid of concepts that share the feature f_i . We define the *feature density* as the cosine similarity between the concept and the centroid. That is,

$$feature\ density(c, f) = R(c) \cdot \overline{C_f}$$

We calculate the feature density of all target concept-feature pairs assuming vectors that share

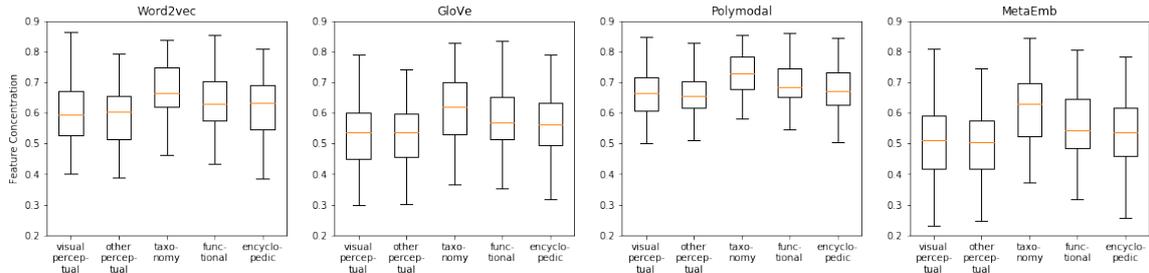

Figure 1: The feature density of different types of embedding on CSLB Concept Property Norms dataset.

	Word2Vec	GloVe	MetaEmb	Proposed
All features	.308	.262	.283	.343
Visual Perceptual	.204	.162	.188	.241
Other Perceptual	.122	.143	.148	.148
Taxonomic	.271	.236	.244	.263
Encyclopedic	.138	.129	.145	.136
Functional	.314	.288	.280	.310

Table 3: Spearman’s correlation between the CSLB normalized feature representation and the target distributed representation.

the same features will also be distributionally similar (Erk, 2016).

In Figure 1 that summarizes the result, the proposed embedding method shows higher averages and lower deviations of feature densities across all the categories. It shows that our proposed embedding method is more capable of capturing normalized features than the baselines.

To further cement the observations, we calculate Spearman’s correlation of word similarity measures between the normalized feature representation and the target distributed representation. The normalized feature representation of a concept is constructed as an one-hot vector which assigns 1 if the concept has the feature and 0 otherwise, and then L2-normalized to have length 1. Then we calculate the correlations of similarity measures by the feature categories. The results are shown in Table 3. While the proposed embedding method shows the highest correlation to the case of using all normalized features, it also shows a noticeable improvement in the visual perceptual category.

4.3 Positive vs Negative

One of the critical weakness of context-based word representation is that it cannot differentiate the sentiment polarity correctly. So we examine the ratio of neighbors that have same/opposite/neutral sentiment polarities with a

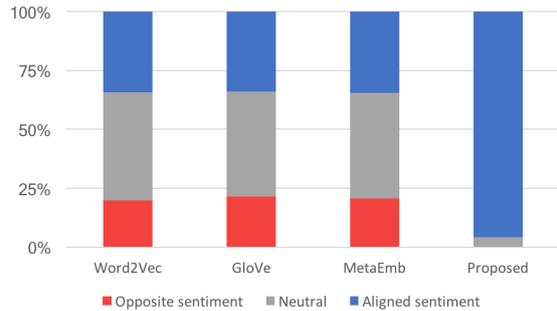

Figure 2: The ratio of 10 nearest neighbors that have same/opposite/neutral sentiment polarities of 15010 words.

target word among 15010 words and see how this problem can be mitigated. Figure 2 illustrates the result. The three context-based approaches show roughly 20% of incorrect sentiment differentiation. This can be benefited greatly from the sentiment module of the proposed approach as this issue is almost perfectly resolved by simply attaching sentiment values to the embedding. The result might be straightforward but this can improve the quality of embedding greatly.

4.4 Concrete vs Abstract

We hypothesize that the role of a certain module would be different depending on word characteristics such as the degree of concreteness. To validate this idea, we divided the Simlex-999 dataset into

two groups for different degrees of concept concreteness. This corresponds to 500 pairs of concrete words vs. 499 pairs of abstract words. Then we examine the relative importance of the different modules to each group via an ablation test. The result is reported in Table 4.

Modules	All	Concrete	Abstract
L (linear)	.442	.462	.449
T (syntactic)	.446	.439	.459
C (cognition)	.464	.451	.456
P (perception)	.157	.355	<u>.010</u>
S (sentiment)	.221	<u>-.100</u>	.293
E (emotion)	.376	.350	.385
All-but-L	.527∇	.464∇	.538∇
All-but-T	.524∇	.478∇	.501∇
All-but-C	.514∇	.466∇	.492∇
All-but-P	.531∇	.476∇	.570▲
All-but-S	.503∇	.491▲	.484∇
All-but-E	.526∇	.488▲	.540∇
All	.533	.483	.545

Table 4: Ablation tests for different word groups in Simlex-999. The metric is Spearman’s correlation. Embeddings here are ensembled via weighted concatenation.

Interesting properties are revealed through the ablation test. By comparing the results between the different word groups, we can observe that the importance of a certain word aspect varies depending on the word characteristics. While concrete words profit from perception embeddings, the sentiment and emotion aspects are somewhat disturbing. We can observe an opposite result for abstract words. This result is quite intuitive since we can easily imagine the perceptual image from a concrete concept but not from an abstract one like *love*.

For a deeper analysis, we further investigate the role of each module in different word groups. For instance, since concrete concepts are perception-revealing, they would benefit from a strong emphasis on the perception embedding. On the other hand, emotion-revealing word groups such as abstract concepts would be opposite. Noting that the different types of words may have different sensitivity toward the modules, we adjusted the relative weights for a particular aspect of interest to be from 0.1 to 3.5 while maintaining others to 1.0. Then we observed the changes of the performance in word similarity task. The result is shown in Fig-

ure 3.

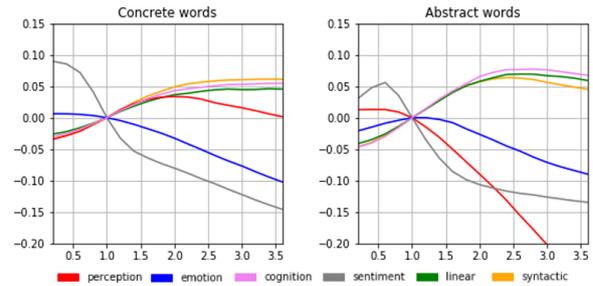

Figure 3: The result of sensitivity analysis. The weight of aspect-of-interest is adjusted while others are fixed to 1. These graphs reveal the distinct profiles of different word groups. Gradual patterns of emotion and perception are opposite for the concrete and abstract word groups.

The result of sensitivity analysis supports the idea that different word groups are influenced by each module with varying degrees. The x-axis refers to the relative weight of a particular aspect while setting the others to 1.0. The y-axis indicates the changes of Spearman’s correlation score ρ on Simlex-999. The results in Figure 3 illustrate the different preferences among different word groups, which show the distinct nature between the two groups. In particular, the gradual patterns revealed by increasing relative weights of perception and emotion are contrary to concrete and abstract words. Increasing the weight of perception is beneficial for concrete word groups but detrimental to abstract word groups. However an exactly reverse pattern can be observed for the emotion. Increasing the weight of emotion is advantageous for abstract words but adverse for concrete words.

4.5 Similarity vs Relatedness

The “similarity” between two words is more strict term than the “relatedness”. While the relatedness measures how much the two words are related to each other in some senses, the similarity measures how much the two words can be regarded as “similar” than just simply related. For example, consider the three word pairs: (bread, butter), (bread, toast), and (bread, stale). All of them can be regarded as “related” but only the (bread, toast) pairs can be regarded as “similar” because the other two words (butter and stale) are related but not similar to the “bread”.

The two data sets SimLex-999 and WordSim-

353 capture this difference of similarity and relatedness. While the scores of WordSim-353 focus on the relatedness, those of the Simlex-999 deliberately try to distinguish between them. For example, a word pair (cloth, closet) is scored 8.00 in WordSim-353 dataset whereas 1.96 in the SimLex-999 dataset. To capture the difference between relatedness and similarity and see what modules contributes most to capture the similarity or the relatedness, we conduct a sensitivity analysis on WordSim-353 and SimLex-999 dataset.

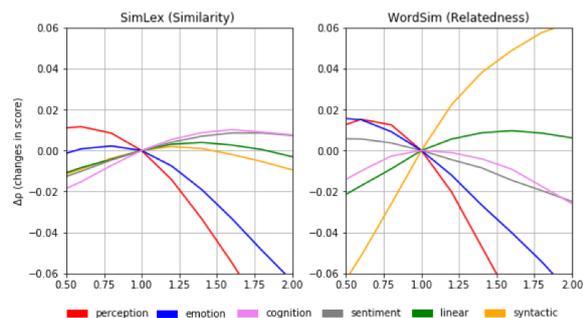

Figure 4: The result of sensitivity analysis on word similarity and word relatedness. While context information is important to the relatedness, sentiment polarity and lexical relations are important to the similarity.

Figure 4 shows the result of sensitivity analysis. In the SimLex-999 dataset which focuses on the word similarity, the cognition (lexical relation) and the sentiment modules turned out to be important. On the other hand, in the WordSim-353 dataset which focuses on the word relatedness, both linear context and syntactic context are turned out to be critical. This difference can be interpreted that the word properties extracted from the contexts are of the word relatedness, and in order to differentiate the similarity from the relatedness, additional properties such as lexical relations and sentiment polarities need to be introduced.

5 Conclusion

In this paper, we raise a question if the current distributed word representations sufficiently capture different aspects of word meanings. To address the question, we proposed a novel method for composing word embeddings, inspired by a human cognitive model. We compared our proposed embedding to the current state-of-the-art distributed word embedding methods such as Word2Vec, GloVe, and Meta-embedding from the perspective

of capturing diverse aspects of word meanings.

Our proposed embedding performs better in the word similarity and hypernym prediction tasks than the baselines. We further conducted a series of experiments to study how well the word meanings are reflected by the representations and analyze the relationships between the modules and the word properties. From the property norms analysis, our findings show that the proposed method can capture the visual properties of words better than the baselines. Also, harnessing sentiment values helps the embedding greatly to resolve the sentiment polarity issue which is a limitation of current context-driven approaches. Based on the experimental results, we can conclude that some aspects of word meanings are not captured enough from the corpus and we can further improve the word embedding by referring to additional data related to a human mind model.

Finally, using our proposed method we show the different characteristics of concrete and abstract word groups and the difference between the concept relatedness and the concept similarity. We observe that emotional information is more important than the perceptual information for the abstract words whereas the opposite result is observed for the concrete words. Also, we see that the context-driven embeddings mostly capture the word relatedness and therefore lexical relation and sentiment polarities would be beneficial when considering the word similarity.

In conclusion, we concentrate on analyzing the relationships between the diverse aspects of word meanings and their distributed representations and propose a way to improve them by harnessing additional information based on the human cognitive model. Since our proposed method largely relies on the labeled extra data, this work has a limitation in terms of the scalability. For future research, we need to explore unsupervised ways of introducing perceptual properties and lexical relationships of words and annotating their sentiment and emotional properties. It will make our method more scalable.

Abstract

Word embeddings are commonly compared either with human-annotated word similarities or through improvements in natural language processing tasks. We propose a novel principle which compares the information from word embeddings with reality. We implement this principle by comparing the information in the word embeddings with geographical positions of cities. Our evaluation linearly transforms the semantic space to optimally fit the real positions of cities and measures the deviation between the position given by word embeddings and the real position. A set of well-known word embeddings with state-of-the-art results were evaluated. We also introduce a visualization that helps with error analysis.

1 Introduction

In recent years the improvements in quality of word embeddings led to significant improvements in many natural language processing (NLP) tasks, e.g. sentiment analysis (Maas et al., 2011), named entity recognition (Lample et al., 2016), or machine translation (Zou et al., 2013). New models for word embeddings and improvements to the old ones are introduced rapidly (Bojanowski et al., 2017; Salle et al., 2016; Yin and Schütze, 2016). As the number of various word embeddings increases, it becomes very time consuming to choose word embeddings for a particular task (Nayak et al., 2016).

To mitigate the problem, it is necessary to provide appropriate evaluation together with the word embeddings. The evaluation should cover multiple properties of word embeddings in order to allow the user to choose the model directly based on

the results (Nayak et al., 2016). Many evaluation approaches have already been proposed and they can be roughly divided to intrinsic and extrinsic (Schnabel et al., 2015).

The intrinsic evaluation measures the quality of the model directly by comparison with human-annotated data that capture semantic information. The advantage of this approach is that it is fast, simple, and easy to reproduce and analyze (Schnabel et al., 2015; Nayak et al., 2016). The main issue is that the evaluation score often does not correlate with improvements in NLP tasks (Chiu et al., 2016).

The extrinsic evaluation is indirect and measures the improvements through other tasks – currently mainly through NLP tasks. The advantage of this approach is that for each task we know which model to choose. The disadvantage is the computational complexity (Nayak et al., 2016). For each new word embeddings we need to train models for several approaches to several tasks and find the optimal hyperparameters of the models. Moreover, the same data and implementations should be used by all researchers for the evaluation.

We propose a new evaluation paradigm that is in between the intrinsic and extrinsic evaluation (actually, half the people believe its intrinsic and the other half believe its extrinsic). We measure neither the semantic word similarity as in intrinsic evaluation nor improvements in a particular task that uses word embeddings. We compare the information encoded in word embeddings directly with real-world data. We implement the paradigm with geographical data. We take GPS coordinates of cities and measure to what degree is the information encoded in the word embeddings.

The paper is organized as follows. In Section 2 we describe commonly used evaluation approaches for word embeddings and discuss their

strengths and weaknesses. Our evaluation metric is introduced in Section 3. In Section 4 we provide various experiments with our evaluation metric, including evaluation of state-of-the-art word embeddings. Finally, we conclude in Section 5.

2 Related Work

There are two common tasks which fall under intrinsic evaluation: word similarity and word analogy tasks.

In the word similarity task, the evaluation data consist of pairs of words and their similarity annotated by humans. The word embeddings are compared with the evaluation data usually by Spearman rank correlation. The word similarity task has a long tradition in the semantics research (Rubenstein and Goodenough, 1965). Currently there are multiple corpora created to test different properties of the word embeddings (Finkelstein et al., 2001; Agirre et al., 2009; Luong et al., 2013; Hill et al., 2015).

The word analogy task evaluates the ability of the word embeddings to capture relations between words consistently. The evaluation data consists of questions (with answers) in the form: if word a is related to word b the same way as word c is related to word d , what word is d given a , b , and c ? The word embeddings are compared based on their accuracy. The Google Word Analogy corpus is usually used for evaluation (Mikolov et al., 2013a). The word analogy task is closest to our evaluation because some of the questions are also based on real-world data, e.g. countries and their capital cities. Unlike our evaluation, they handle city names as common words, use the global semantic space, and compare them using cosine similarity.

The extrinsic evaluation uses other NLP tasks for comparison of word embeddings. Many tasks are used for extrinsic evaluation, e.g. sentiment analysis (Schnabel et al., 2015), named entity recognition (Konkol et al., 2015), or parsing (Bansal et al., 2014). Word embeddings are compared based on the improvements measured with standard evaluation metrics for the given task.

Both intrinsic and extrinsic evaluations have their advantages and disadvantages. The word similarity task was analysed and criticized by multiple authors (Faruqui et al., 2016; Chiu et al., 2016; Batchkarov et al., 2016; Gladkova and Drozd, 2016). The advantages of word similar-

ity evaluation are that it is very fast and can be easily interpreted from the linguistic point of view (or generally by human). The corpora often suffer from a subset of the following disadvantages: low correlation with extrinsic evaluation (applications), polysemy is not supported, subjectivity of single value similarity, overfitting (no training, heldout, test sets), significance tests are not common for word similarity, and the data are often small.

The word analogy task has the same disadvantages as the word similarity task; moreover the evaluation is quite slow, because it is necessary to sort all words based on their similarity with the question. Linzen (2016) provides a detailed analysis of the word analogy task and shows that results in this evaluation are to a large extent based on proximity in the semantic space rather than consistent offsets between the word pairs.

The main advantage of the extrinsic evaluation is that it directly measures application improvements. The main disadvantage is computational complexity. There exist many tasks that could be used for evaluation, but it is intractable to use all of them (Nayak et al., 2016). Moreover, there exist many approaches to all the tasks and some embeddings might be good for one approach and bad for the others. Choosing a single approach as a general benchmark could lead to incorrect conclusions. If we still want to choose a single model, then which one? On one hand, the state-of-the-art approaches of the tasks evolve in time – state-of-the-art method may well become a baseline in a few years. On the other hand, using baseline approaches loses the ability to measure application improvements. Word embeddings may have a high score with the baseline approach, but may contain the same information that is already present in the state-of-the-art approach. Other embeddings may have low score with the baseline approach, but the information may be usable in the state-of-the-art approach.

Many disadvantages of intrinsic evaluation are also related to particular tasks in extrinsic evaluation, e.g. named entity recognition or sentiment analysis usually do not use significance tests, are subjective, or use small data sets.

Nayak et al. (2016) propose a system for standard automatic extrinsic evaluation. They selected a representative subset of tasks for the evaluation and chose a single approach for each task (based

on standard neural network architectures) in order to achieve reasonable evaluation times (4-5 hours). Even though this approach has the disadvantages presented in the previous two paragraphs, it is definitely a step forward to a standardized evaluation.

3 Proposed Evaluation

The evaluation data set consists of a list of n names of cities and their GPS coordinates stored in matrix $\mathbf{G} \in \mathbb{R}^{n \times 2}$. We assume that Earth is perfectly spherical and its radius is 6,371. Given the assumption, the GPS coordinates in matrix \mathbf{G} can be transformed to Euclidean coordinates in matrix $\mathbf{Y} \in \mathbb{R}^{n \times 3}$ and back. The word embeddings of cities are in matrix $\mathbf{X} \in \mathbb{R}^{n \times d}$ with a d -dimensional vector for each city name. We normalize rows of \mathbf{X} and \mathbf{Y} , because it is helpful for stability of the optimization and we need only the cosine similarity between the rows.

The first step of our evaluation is to find a subspace of the original d -dimensional word embeddings space that contains the information about city locations. The word embeddings transformed to the subspace are represented by matrix $\mathbf{W} \in \mathbb{R}^{n \times 3}$. The matrices \mathbf{W} and \mathbf{Y} have to share the same dimensions because we want to compare the distances between their rows (cities). We are looking for a linear transformation $\mathbf{W} = \mathbf{X}\mathbf{T}$ parametrized by transformation matrix $\mathbf{T} \in \mathbb{R}^{d \times 3}$. We use the least squares cost function, the optimal transformation matrix \mathbf{T}^* is defined as a transformation matrix that minimizes squared distances between real and approximate city positions $\|\mathbf{W} - \mathbf{Y}\|_2$. This optimization problem is highly prone to overfitting as $n \approx d$; moreover the row rank of \mathbf{X} is likely lower than n , because the embeddings for cities are highly correlated and thus they are likely linearly dependent. Thus we employ L_2 regularization. The final optimization problem is given by Equation (1), where α is the regularization weight.

$$\mathbf{T}^* = \arg \min_{\mathbf{T}} (\|\mathbf{X}\mathbf{T} - \mathbf{Y}\|_2 + \alpha \|\mathbf{T}\|_2) \quad (1)$$

Finally, we can compare \mathbf{W} and \mathbf{Y} . The primary metric for the evaluation is mean geographic distance, i.e. the distance between two points on a globe measured on the surface. We firstly need to normalize rows of \mathbf{W} because the vectors can be above or below the surface. The geographic distance can be measured using Equation (2), where

g is the geographic distance, \mathbf{w}_i and \mathbf{y}_i denote the i -th row of \mathbf{W} and \mathbf{Y} respectively, and r is the radius of Earth.

$$g = r \cdot \arccos(\mathbf{w}_i \cdot \mathbf{y}_i) \quad (2)$$

While the mean geographic distance is a good metric for a global view, it does not take the local structure into account, i.e. a random model moves the cities in all directions and breaks the local structure (nearest neighbors), but other model (with the same mean geographic distance) can move the cities in one direction and preserve local structure. We measure the ability of the embeddings to capture local structure by Precision at K (Prec@ K). This metric creates two sets of K nearest neighbors for each city, one for the evaluation data \mathbf{Y} and one for the transformed word embeddings \mathbf{W} . The precision between these two sets is averaged over all cities.

We also provide more statistics that help with understanding of the primary score. Median geographic distance gives a better idea about common distances, because it is not affected by extreme values. Sometimes, we found it easier to think about the errors in angles rather than distances, mainly because angles are independent of the size of the globe.

4 Experiments

In this section we firstly describe the data used for the proposed evaluation. Then we briefly introduce the word embeddings used to demonstrate the proposed evaluation. Finally, we follow with experiments that show some properties of the evaluation.

4.1 Data

We downloaded the list of 640 known cities from <https://www.timeanddate.com/worldclock/full.html> and further adjusted it. We removed cities that consist of multiple words from the list, because the evaluated models were trained only on single word expressions. It has lead to a reduction of the set to 540 cities. Then we created a dictionary of the top 10,000 words from Wikipedia and filtered out cities not present in the models, which resulted into a set of 483 cities. Finally we removed cities with ambiguous names and inconsistent use of diacritics, leaving us with 440 cities.

Model	Data	Dimension	Mean distance	Median distance	Mean angle	Prec@10	Prec@20
Random placement	—	—	10007	10007	90°	0.03	0.06
Random embeddings	—	300	10040	10422	90.3°	0.031	0.065

Table 1: Results of the selected set of word embeddings.

The data needed to be split into the training and test set. The training set is used to find optimal transformation matrix \mathbf{T}^* and optimal regularization weight α . The test set is used for the evaluation.

We manually selected the train set from the cities to evenly cover geographical area by the cities with the highest Wikipedia term frequency. The final train set contains 124 cities and the final test set contains 316 cities.

4.2 Word Embeddings

We chose a set of well-known word embeddings to show their differences using the proposed evaluation. In the following paragraphs we briefly introduce the chosen word embeddings.

SkipGram is a neural network based model (Mikolov et al., 2013b). Levy and Goldberg (2014) provide trained SkipGram models with two sizes of the context window (2, 5) and their own model that uses dependency-based context, denoted by SkipGram - BoW2, SkipGram - BoW5, and SkipGram - Dep, respectively.

GloVe is a log-bilinear model that tries to find word embeddings that are good at predicting global word co-occurrence statistics (Pennington et al., 2014). We use embeddings provided by authors of the model trained on various corpus sizes (6, 42, and 840 billions words) and with various vector dimensions (50, 100, 200, 300).

FastText is an extension to SkipGram, where the word is represented as character n -grams (Bojanowski et al., 2017). We use embeddings provided by authors of the model trained on Wikipedia.

LexVec is based on factorization of positive point-wise mutual information matrix using proven strategies from GloVe, SkipGram, and methods based on singular value decomposition (Salle et al., 2016). We use two models provided by the authors of the model trained on Wikipedia and News Crawl (LexVec - w + nc), and Common Crawl (LexVec - cc).

MetaEmbeddings is an ensemble method that combines several embeddings (Yin and Schütze, 2016). We use the embeddings provided by the authors of the model.

WoRel is an extension of SkipGram, where a phrase (instead of a word) is used to guess the context words (Konkol, 2017). We use the model provided by the authors trained on Wikipedia and Gigaword corpus.

LSA is a count based method that creates a word-document co-occurrence matrix and reduces its dimension by singular value decomposition (SVD) (Landauer et al., 1998). We trained the models on Wikipedia.

PPMI-SVD creates word co-occurrence matrix where the co-occurrence is measured by positive

pointwise mutual information. The dimension of the matrix is then reduced by SVD. We used the hyperwords package (Levy et al., 2015) and trained it on Wikipedia and Gigaword corpus.

4.3 Evaluation

In our first experiment we evaluate the selected set of embeddings with the proposed evaluation metric. The results are shown in Table 1.

We provide results for two baselines. The first baseline (random placement) places cities randomly on the globe. The results for this baseline are computed analytically. The second baseline generates random embeddings, each value is selected randomly from uniform distribution between -1 and 1 . The random embeddings are then evaluated in the same way as normal embeddings. The results show average results for five random embeddings. The comparison of the baselines show that the evaluation works as expected: random embeddings produce randomly placed cities.

The results show that all the evaluated word embeddings are significantly better than the baselines. This proves that the embeddings do not capture only the similarity between words but also nontrivial knowledge about the world.

Most geographic information was clearly captured by LSA, followed by FastText. A group of models, namely WoRel, SkipGram – BoW5, PPMI-SVD, and LexVec, achieved similar results and are only slightly worse than FastText. Surprisingly, GloVe (trained with similar amount of data) performed significantly worse. MetaEmbeddings achieved the worst results, probably because the ensemble was optimized for other purposes.

There is a high correlation between the performance in the mean geographic distance and Prec@10 measures. Models that are good at capturing global structure tend to be good at capturing local structure.

The type of the training data is probably more important than the size of the data. This can be seen on the LexVec models, where the model trained on Wikipedia and news articles outperforms the other model trained on significantly more data. Still, an extreme amount of data leads to good results as seen on the results of GloVe trained on various corpus sizes.

Recently, most of the NLP tasks use word embeddings based on local (window-based) context. Surprisingly, our evaluation shows that LSA, a

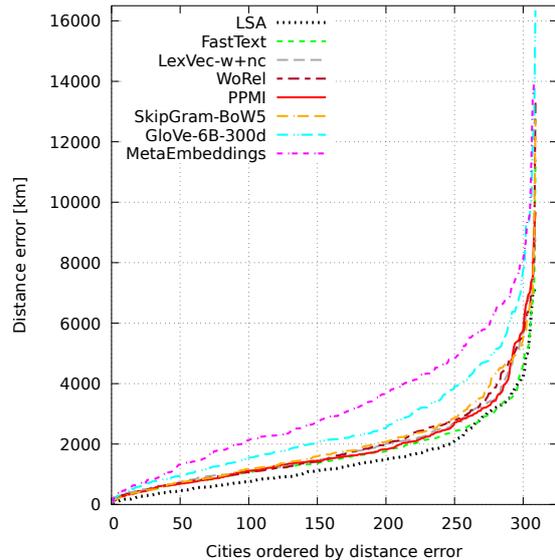

Figure 1: Distribution of distance errors.

method based on global (document-wide) context, outperforms all the other models in the proposed evaluation. The comparison of count based (PPMI-SVD) and predictive models (e.g. SkipGram, FastText) shows no significant differences between these two approaches.

Our evaluation shows that the mainstream models such as SkipGram and GloVe that perform similarly in intrinsic word similarity and extrinsic task based evaluations may have very different results in other types of evaluation.

4.4 Error Analysis

Figure 1 shows the distribution of geographic distance errors for individual cities. The distance error is reasonable (≤ 2500 km) for approximately 90% of the cities for most of the word embeddings. Unfortunately, the rest of the cities has significantly larger error. In this section, we try to identify the source of the extreme errors.

Firstly, we suspected that the reason is sparseness and the extreme errors are caused by under-represented words. In Figure 2 we show a relation between the number of occurrences of the city name in Wikipedia (training data for most of the methods) and the mean distance error. The word occurrences are equidistantly grouped into ten bins. We concluded that there is no clear relation between the number of occurrences of a city name and the distance error.

We also suspected ambiguity with common words. To check this hypothesis, we counted how

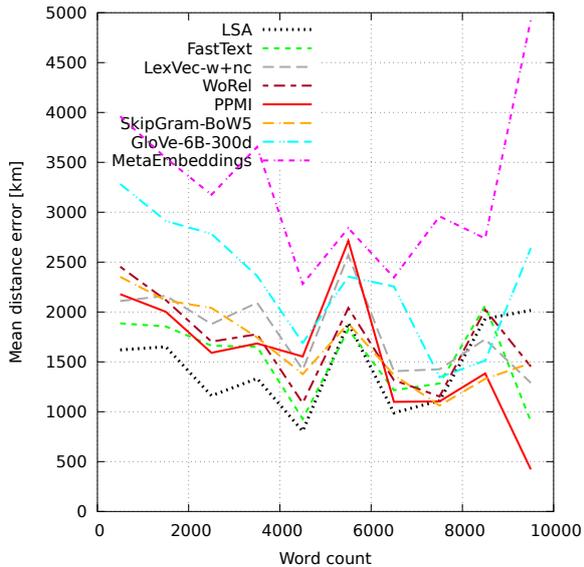

Figure 2: Relation between the number of occurrences of the city name and the distance error for LSA.

many times the city name appears as lowercase and how many times with a capital letter. We found out that most of the words does not appear at all in lowercase version. A small portion of words has significant number of occurrences of the lowercase version (e.g. Phoenix), but they do not correlate with the distance error.

Lastly, we manually checked all the cities with extreme distance errors. We found out that the main problem is ambiguity with other named entities that are more famous than the city, e.g. the city Kobe is overshadowed by Kobe Bryant, Bismarck by Otto von Bismarck, Montgomery by the common first name. A special case of this problem is multiple cities with the same name. This is not a problem if there is large difference between the fame of the cities (e.g. London), but it is a problem for cities that are similar in size and fame (e.g. Midland, Kingstown, Bridgetown).

4.5 Embeddings Dimension

The dimension of the word embeddings obviously affects their results (Table 1). In this experiment we explore the effect of higher dimensions on the results. This should provide a hint to the authors of the semantic spaces how to choose the appropriate dimension.

In Figure 3, we show the results of LSA with dimension ranging from 100 to 1000. The performance degrades quickly as we decrease the dimen-

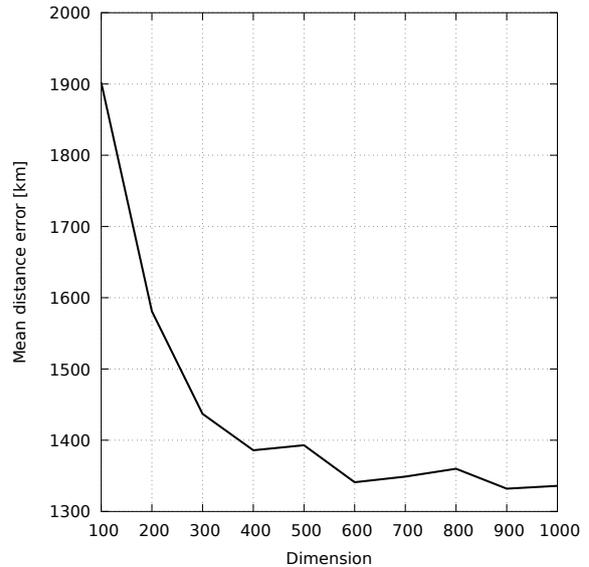

Figure 3: The relation between dimension of the vector space and the mean distance error for LSA.

sion under 300. The results slightly improve as we increase the dimension from 300 to 600. There are no significant improvements as the dimension is increased over 600.

4.6 Regularization

The proposed evaluation uses regularization and requires the regularization weight α . Setting optimal regularization weight is difficult for some algorithms. We conducted an experiment to prove that the regularization weight does not play an important role in the evaluation, i.e. the scores of the embeddings are not heavily affected by our inability to find optimal regularization weights.

We performed randomized 10-fold cross-validation to find optimal regularization weight multiple times. The variance of the found regularization weights and also the impact of this variance were very small for a particular word embeddings method. Moreover, the optimal regularization weight is very similar for all the word embeddings. Figure 4 shows the mean geographic distance as a function of the regularization weight and suggests that the function can be easily optimized.

4.7 Noise Sensitivity

Given a set of models, the evaluation metric should be able to rank them reliably based on their quality. Batchkarov et al. (2016) propose a test of the reliability. They incrementally add noise to

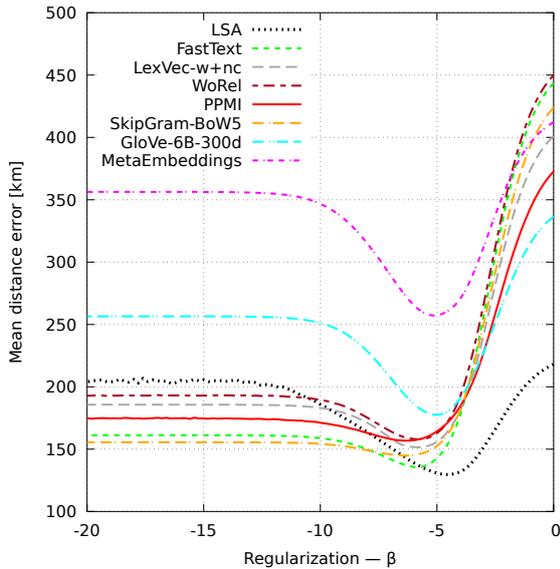

Figure 4: Influence of the regularization weight $\alpha = e^\beta$ on the mean geographic distance. The values are computed using 10 fold cross-validation on the training data.

word embeddings and assume that word embeddings with more noise have lower quality. The metric should be able to capture the differences of the quality and smoothly and monotonically go from good results to results of random embeddings.

In Figure 5 we show the behavior of the proposed metric. We use the best embeddings (LSA) as a starting point. Then we add noise uniformly sampled from interval $[0, p]$ to each value in the embeddings. The parameter p is incrementally increased with step 0.01 from 0 to 1. For each value of p we repeat the evaluation 1000 times. The proposed metric works as expected. Firstly, the mean distance error almost linearly increases. As the embeddings become more random the increases slow down until they converge to the results of random embeddings.

4.8 Visualization

As a side effect, our evaluation approach also produces a natural visualization presented in Figure 6. The visualization can be used for comparison of methods, error analysis, or demonstration of semantics and unsupervised learning. The transformation also allows us to visualize common words on the map, not only city names.

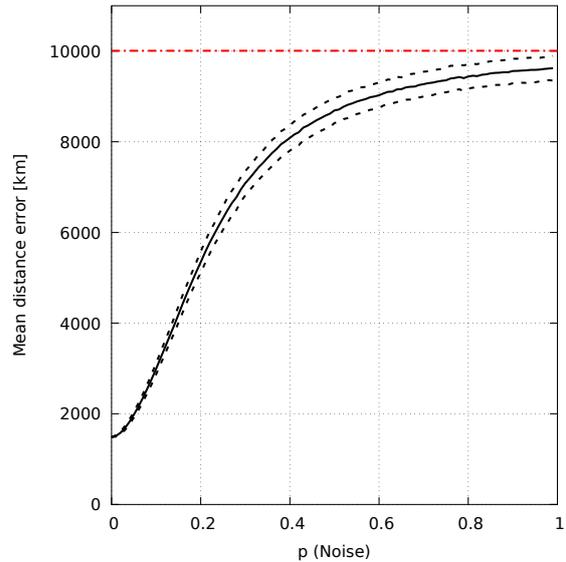

Figure 5: The effect of noise added to LSA embeddings. The figure shows mean value and standard deviation of 1000 runs. The red line on the top represents random city placement.

5 Conclusion

We have proposed a new evaluation method for word embeddings. It measures how much information about geographic location of cities is contained in word embeddings. This type of evaluation differs from previously presented evaluations and forms a new word embeddings evaluation paradigm. The new paradigm does not evaluate the embeddings from the natural language processing view, but rather from the artificial intelligence view, where the algorithm tries to capture some information about the world.

We have analyzed both the evaluation metric and commonly used embeddings. We have shown that the metric is stable and can reliably distinguish between good and poor models.

LSA achieved the best results with mean geographic distance error of 1437 kilometers. Surprisingly, it outperformed mainstream models such as SkipGram. GloVe, with state-of-the-art results from other evaluations, performed rather poorly in the proposed evaluation.

In the future, we would like to implement the proposed paradigm with other similar evaluations, where we try to find out if the model is able to capture a specific real-world information.

The dataset and the evaluation software can be

Abstract

To enhance the expression ability of distributional word representation learning model, many researchers tend to induce word senses through clustering, and learn multiple embedding vectors for each word, namely multi-prototype word embedding model. However, most related work ignores the relatedness among word senses which actually plays an important role. In this paper, we propose a novel approach to capture word sense relatedness in multi-prototype word embedding model. Particularly, we differentiate the original sense and extended senses of a word by introducing their global occurrence information and model their relatedness through the local textual context information. Based on the idea of fuzzy clustering, we introduce a random process to integrate these two types of senses and design two non-parametric methods for word sense induction. To make our model more scalable and efficient, we use an online joint learning framework extended from the Skip-gram model. The experimental results demonstrate that our model outperforms both conventional single-prototype embedding models and other multi-prototype embedding models, and achieves more stable performance when trained on smaller data.

1 Introduction

Word embedding, representing words in a low dimensional vector space, plays an increasing important role in various IR and NLP related tasks, such as language modeling (Bengio et al., 2006;

Mnih and Hinton, 2009), named entity recognition and disambiguation (Turian et al., 2010; Collobert et al., 2011), and syntactic parsing (Socher et al., 2011, 2013). This trend has been accelerated by the CBOW and the Skip-gram models of (Mikolov et al., 2013b,a) due to its efficiency and remarkable semantic compositionality of embedding vectors (e.g. $vec(king)-vec(queen)=vec(man)-vec(woman)$). However, the assumption that each word is represented by only one single vector is problematic when dealing with the polysemous words.

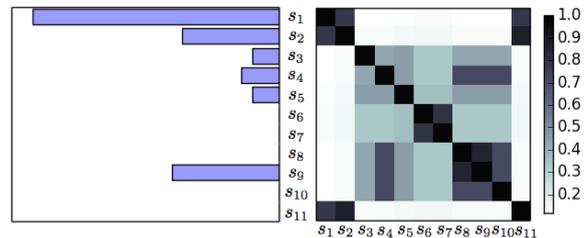

Figure 1: Relatedness among senses of the word “book”.

To enhance the expression ability of the embedding model, recent research has a rising enthusiasm for representing words at sense level. That is, an individual word is represented as multiple vectors, where each vector corresponds to one of its meanings. Pervious work mostly focus on using clustering to induce word senses (each cluster refers to one of the senses) and then learn the word sense representations respectively (Reisinger and Mooney, 2010; Huang et al., 2012; Tian et al., 2014; Neelakantan et al., 2014; Li and Jurafsky, 2015). However, the above approaches ignore the relatedness among the word senses. Hence the following limitations arise in the usage of hard clustering. First of all, many clustering errors will be caused by using hard clustering based method because the senses of the polysemous word actu-

*Corresponding author.

ally have no distinct semantic boundary (Liu et al., 2015). Secondly, due to dividing the occurrences of a word into separate clusters, the embedding model will suffer from more data sparsity issue as compared to the Skip-gram model. Thirdly, the embedding quality is considerably sensitive to the clustering results due to the isolation of different sense clusters.

To address this problem, we learn the embedding vectors of the word senses with some common features if the senses are related. Instead of clearly cutting the sense cluster boundaries, one occurrence of the word will be assigned into multiple sense clusters with different probabilities, which agrees with a classic task of word sense annotation, Graded Word Sense Assignment (Erk and McCarthy, 2009; Jurgens and Klapaftis, 2013).

Actually, the senses of a polysemous word are related not only by the contiguity of meaning within a semantic field¹, but also by the extended relationship between the original meaning and the extended meaning (Von Engelhardt and Zimmermann, 1988). We investigate the relatedness of the synsets (word senses) in WordNet (Miller, 1995) through the Wu & Palmer measure² (Wu and Palmer, 1994), and present an interesting example of the word “book” in Figure 1. The right side is the similarity matrix of its 11 nominal synsets, where s_i denotes the i th synset. Each tile represents a similarity value between two synsets whose color deepens as the value increases. The left side is their frequencies in WordNet. On one hand, we can see apparent correlations among these senses in different levels. Note that (s_1, s_2, s_{11}) are strongly related, and so are (s_6, s_7) and (s_8, s_9, s_{10}) . This is because of their extended relationship. Take (s_1, s_2, s_{11}) for example, s_1 refers to the sense of “the written work printed on pages bound together”, s_2 refers to “physical objects consisting of a number of pages bound together” and s_{11} refers to “a number of sheets (or stamps, etc.) bound together”. Obviously, s_1 is the original meaning, s_2 and s_{11} are the extended meanings. Moreover, the relatedness suggests that the senses share some common textual features in the contexts. On the other hand, the frequency of the original meaning s_1 is much

¹According to <https://en.wikipedia.org/wiki/Polysemy>.

²The Wu & Palmer measure is an edge based approach that is tied to the structure of WordNet. Also, one can try different relatedness approaches and will find similar results.

higher than that of the extended meanings s_2 and s_{11} , which suggests that the word sense distribution in corpus should be taken into account when modeling word sense relatedness.

In this paper, we propose a novel method, namely FCSE (Fuzzy Clustering-based multi-Sense Embedding model), that models the relatedness among word senses by using the fuzzy clustering based method for word sense induction, and then learns sense embeddings via a variant of Skip-gram model. The basic idea behind fuzzy clustering is that the senses may be related and share common features through the overlaps of the sense clusters. Based on our observations of the original meaning and the extended meaning, we further design two non-parametric methods, FCSE-1 and FCSE-2, to model the local textual context information of senses as well as their global occurrence distribution by incorporating the Generalized Polya Urn (GPU) model. For efficiency and scalability, our proposed model also adopts an online joint learning procedure.

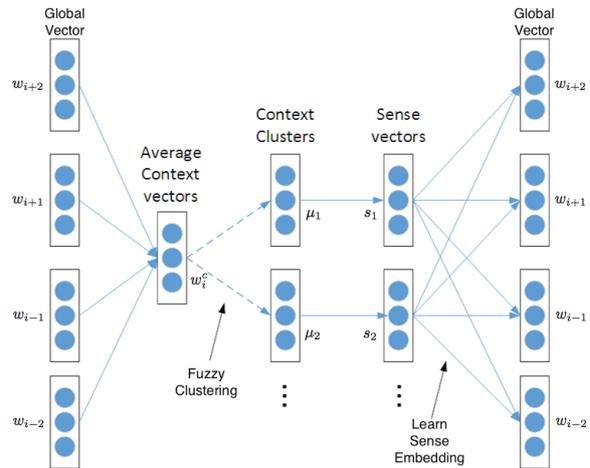

Figure 2: Framework of FCSE

2 The Framework of FCSE

FCSE adopts an online procedure that induces the word sense and learns the sense embeddings jointly. Given a word sequence $D = \{w_1, w_2, \dots, w_M\}$, we obtain the input of our model, the word and its context words, by sliding a window with the length of $2k + 1$. The output is also the context words. During the learning process, two types of vectors are maintained for each word, the global vector w_i and its sense vectors³

³All the vectors are randomly initialized.

$w_i^{s_i}$. Note that the number of senses $|S_i|$ is varying because the cluster method is non-parametric.

As shown in Figure 2, there are mainly two steps: the clustering step and the embedding learning step. The former step incrementally clusters all the occurrences of one word according to its context vectors by computing the average sum of the global vectors of the context words: $w_i^c = \frac{1}{2k} \sum_{-k \leq j \leq k} w_{i+j}$. Each cluster refers to one word sense, thus each occurrence will be annotated with at least one sense.

In the second step, we update the sense embeddings via a variant of the Skip-gram model (Mikolov et al., 2013b). The main difference between our model and Skip-gram is that we aim to predict the context words given the exact sense of the target word instead of the word itself. Moreover, because several senses are assigned to the current word with probabilities, we leverage all the related senses to predict the context words. The intuition is that the related senses tend to have common context words as mentioned in Section 1. Thus, all the assigned sense vectors will be updated with weights simultaneously as follows:

$$\mathcal{L}(D) = \frac{1}{M} \sum_{i=1}^M \sum_{-k \leq j \leq k} \sum_{s_i}^{|S_i|} \lambda_{s_i} \log p(w_{i+j} | w_i^{s_i}) \quad (1)$$

where the probability of $p(w_{i+j} | w_i^{s_i})$ is defined using softmax function, and s_i denotes the sense index of word w_i . S_i is the set of existing senses, λ_{s_i} is the update weight of sense s_i . We set the weights proportional to the probabilities of the current word being annotated with sense s_i , which is equivalent to the results of fuzzy clustering, the likelihood of the context w_i^c assigned into the sense cluster s_i :

$$\lambda_{s_i} \propto \begin{cases} p(s_i | w_i^c) & s_i \text{ is sampled} \\ 0 & \text{otherwise} \end{cases} \quad (2)$$

Finally, we use negative sampling technique⁴ for efficient learning.

3 Word Sense Induction

Section 2 describes the framework of our model including how to obtain the input features of clustering and to use the cluster results for the sense

⁴More detailed information can be found in (Mikolov et al., 2013b).

embedding learning. In this section, we present two fuzzy clustering based methods for clustering-based word sense induction, FCSE-1 and FCSE-2. Both of them are non-parametric and conduct on-line procedures.

Based on our observations in Section 1, the occurrence of word senses is usually distinguishing between the original meaning and the extended meaning, while the original meaning and its extended meanings are semantically related with some common textual contexts. Considering both of the two aspects, in FCSE-1, we induce the word sense according to the cluster probability proportional to the distance of its centroid to the current word’s contexts; and FCSE-2 utilizes a random process, the Generalized Polya Urn (GPU) model, to further incorporate the senses’ global occurrence distribution.

3.1 FCSE-1

Adopting an online procedure, FCSE-1 clusters the contexts of one word incrementally. When first meet one word, we create a cluster with the centroid of its context vector. Then, for each occurrence of the word, several existing clusters are sampled following a probability distribution; or a new cluster is created only if all the probabilities of the context belonging to the clusters equal to zero. Finally, all the sampled clusters will be updated by adding the current context vector into them.

Remember that each word w_i is associated with a global vector, varying number of clusters, and the corresponding sense vectors. FCSE-1 measures the semantic distance of the context vector to its cluster centers, and aims to sample the nearest ones (maybe multiple related senses). Given the context vector w_i^c , the probability of the word belonging to the existing l th sense is:

$$p(s_i = l | w_i^c) = \begin{cases} \frac{1}{Z} Sim(\mu_i^l, w_i^c) \\ 0 & \text{if } Sim(\mu_i^l, w_i^c) < \epsilon_{under} \end{cases} \quad (3)$$

where μ_i^l denotes the centroid of the l th sense cluster, Z is the normalization term and $Sim(\cdot, \cdot)$ can be any similarity measurement. In the experiments we use cosine similarity as the semantic distance measurement. ϵ_{under} is a pre-defined threshold that indicates how easily we create a new sense cluster. Similarly, we use another threshold ϵ_{upper} for deciding the number of sampled clusters. Sup-

pose that the probabilities $\{p_{n_i}|n_i \in S_i\}$ is ranked in descending order, then we pick up the clusters with top n_i probabilities until $p_{n_i} - p_{n_i+1} > \epsilon_{upper}$. Note that the hyper-parameters meet $0 \leq \epsilon_{under}, \epsilon_{upper} \leq 1$.

3.2 FCSE-2

Since FCSE-1 uses two hyper-parameters to respectively control a new cluster initialization and the number of clusters sampled, which is difficult to set manually. So, instead of the fixed thresholds, we make a further randomization by introducing a random process, GPU, in FCSE-2. Besides, more inherit properties of the word senses can be taken into account, including not only the local information of the semantic distance from the context to the cluster centers, but also the frequency, which is related to how likely the current sense is an original meaning or an extended meanings.

In this section, we will firstly give a brief summarization of the GPU model, and then introduce how to incorporate it into our model.

3.2.1 Generalized Polya Urn model

Polya urn model is a type of random process that draws balls from an urn and replaces it along with extra balls. Suppose that there are some balls of colors in the urn at the beginning. For each draw, the ball of the i th color is selected followed by the distribution:

$$p(\text{color} = i) = \frac{m_i}{m}$$

where m is the total number of balls, and m_i is the number of balls of the i th color. A standard urn model returns the ball back along with an extra ball of the same color, which can be seen as a reinforcement and sometimes expressed as the richer gets richer. More detailed information can be found in the survey paper (Pemantle et al., 2007). Polya urn model can be used for non-parametric clustering, where each data point refers to a ball in the urn, and its cluster label is denoted by the ball’s color.

Since the fixed replacement lacks of flexibility, the GPU model conducts the reinforcement process following another distribution over the colors. That is, when a ball of color i is drawn, another A_{ij} balls of color j will be put back. Then, for each draw, we replace the ball with different number of balls of various colors according to the distribution matrix A . As repeating this process, the

drawing probability will be altered if the number of extra balls are nonzero.

3.2.2 Incorporating GPU into Embedding model

The induction process of the word senses can be regarded as a GPU model. The original meaning is sampled firstly, and then the extended meanings are sampled through the reinforcement. That is, we sample an extended meaning according to a conditional probability given the original meaning. The basic idea is that knowing the original meaning is necessary for understanding the target word annotated with an extended meaning in a document. For example, the extended meaning of the word “milk” when used in the terms “glacier milk” won’t be well understood unless we know the original meaning of “milk”.

Correspondingly, in the GPU model, a urn denotes a word, the ball and the color refers to the occurrence and the sense, respectively. Note that each ball has an index that distinguishes different occurrences. Thus, the balls of the same color correspond to a sense cluster.

We sample the related senses in two stages. In the first stage, for the occurrence of the word w_i , we sample a sense $s_{io} = l$ considering the global distribution of the word senses as well as the semantic distance from the context features to the cluster center. In the second stage, several senses are sampled conditioned on the previous result: $p(s_{ie} = l' | s_{io} = l)$.

In this way, we find the original meaning and the extended meanings separately following different distributions. Considering the observation that the original meaning occurs more frequently (as described in Section 1), we define the probability distribution of the original meaning as follows:

$$p(s_{io} = l | w_i^c) \propto \begin{cases} \frac{m_{il}}{\gamma + m_i} \cdot \text{Sim}(\mu_i^l, w_i^c) & l \in S_i \\ \frac{\gamma}{\gamma + m_i} & l \text{ is new} \end{cases} \quad (4)$$

where m_i is the total number of occurrences of the target word w_i , m_{il} is the number of the l th cluster and we have $\sum_l^{S_i} m_{il} = m_i$. Note that γ is a hyper-parameter that indicates how likely a new cluster will be created, and its impact decreases as the size of training data m_i increases.

The probability of sampling an extended meaning is proportional to the semantic distance of the corresponding cluster center to the context fea-

tures as well as the cluster center sampled in the first stage, which is defined as follows:

$$p(s_{ie} = l' | s_{io} = l, w_i^c) \propto \epsilon_e \cdot \text{Sim}(w_i^{s_{ie}}, \frac{w_i^{s_{io}} + w_i^c}{2}) \quad (5)$$

where ϵ_e varies from 0 to 1 and controls the strength of the reinforcement. We will talk about it in the next subsection.

Sampling separately, the relatedness of the original meaning and the extended meanings are modeled and each occurrence of the word has been annotated with one original sense and several extended senses (or there is no additional extended meanings). Note that the likelihood of the occurrence of the word annotated with an extended meaning is $p(s_{ie} = l' | s_{io} = l, w_i^c)p(s_{io} = l | w_i^c)$. Clearly, the probabilities of sampling the extended meanings are always lower than that of the original meaning.

3.3 Relationship with State-of-the-art Methods

FCSE-1 The hyper-parameters meet $0 \leq \epsilon_{under}, \epsilon_{upper} \leq 1$. ϵ_{upper} is used to control the number of clusters assigned to the current word, and FCSE-1 will degrade to hard assignment if we set $\epsilon_{upper} = 0$, which is similar with the NP-MSSG model in (Neelakantan et al., 2014). We can use ϵ_{under} to control the sense number of each word, and an extreme case of $\epsilon_{under} = 0$ denotes that we create only a sense cluster for each word, then the model is equivalent to the Skip-gram.

FCSE-2 The number of the extended meanings $|S_{ie}|$ varies from 0 to $|S_i^{-l}|$, where S_i^{-l} denotes the set excluding the original meaning s_i^l . The hyper-parameter $0 \leq \epsilon_e \leq 1$ is used to control the strength of the GPU reinforcement as well as the number of the extended meanings. Particularly, if we set $\epsilon_e = 0$, the second sample for the extended meanings has been turned off, and then FCSE-2 degrades to the SG+ model in (Li and Jurafsky, 2015), which is another state-of-the-art method for multi-prototype word embedding model based on hard clustering. By setting $\gamma = 0$ in Equation 4, which is used to control the probability of creating a new sense, FCSE-2 won't create new senses. Learning a single sense for each word makes the step of sense sampling becomes meaningless. Thus, FCSE-2 uses the only embedding of the current word to predict its context

words, which is equivalent to the Skip-gram.

4 Empirical Evaluation

In this section, we demonstrate the effectiveness of our model from two aspects, qualitative and quantitative analysis. For qualitative analysis, we presents nearest 10 neighbors for each word sense to give an intuitive impression. For quantitative analysis, we conduct a series of experiments on the NLP task of word similarity using two benchmark datasets, and explore the influence of the size of training corpus.

4.1 Data Preparation

We train our model on Wikipedia, the April 2010 dump also used by (Huang et al., 2012; Liu et al., 2015; Neelakantan et al., 2014). Before training, we have conducted a series of preprocessing steps. At first, the articles have been splitted into sentences, following by stemming and lemmatization using the python package of NLTK⁵. Then, we rank the vocabulary according to their frequencies, and only learn the embeddings of the top 200,000 words. The other words out of the vocabulary are replaced by a pre-defined mark "UNK". Note that FCSE is slower than word2vec⁶, but the efficiency is far away from being an obstacle on training.

Below we describe three baseline methods and parameter settings, followed by qualitative analysis of nearest neighbors of each word sense. Then, quantitative performance will be presented via experiments on two benchmark word similarity tasks.

4.2 Baseline Methods

Word Embedding model can be roughly divided into two types: single vector embedding model and multi-prototype embedding model. To validate the performance, we compare our model with three models of both the two types: Skip-gram, NP-MSSG and SG+. The reason why we select them as the baseline methods is because: (i) they are the state-of-the-art methods of word embedding model; (ii) NP-MSSG and SG+ adopts the similar learning framework to our model.

- **Skip-gram*** aims to leverage the current word to predict the context words and learn

Table 1: Nearest 10 neighbors of each sense of the words “apple” and “berry”, computed by cosine similarity, for different models.

the embeddings within a two-layer neural network.

- **NP-MSSG*** measures the distance of the current word to each sense, picks up the nearest one and learning its embedding via a standard Skip-gram model.
- **SG+*** improves the NP-MSSG model by introducing a random process that induces the word sense with probabilities.

The symbol * denotes that we, instead of using their released codes, carefully reimplement these models for the sake of making the comparisons as fairly as possible. Thus, all the models share the same program switched by the correspondingly parameters (as described in Section 3.3). Note that there may be some minor differences such as optimizing tricks between our program and that of their released.

4.3 Parameter Setting

As discussed in Section 3.3, our model can degrade to the baseline methods by switching different parameters: the threshold ϵ_{upper} , ϵ_e and the max number of word senses N_{MAX} . All the meth-

ods are implemented on the same java program⁷, and use, at the greatest extent, the same settings including the training corpus, shared parameters and the program code, etc.

Switching parameters For FCSE-1 and NP-MSSG, ϵ_{upper} is set 0.05 and 0, respectively. Similarly, We set $\epsilon_e = 1$ for FCSE-2, and $\epsilon_e = 0$ for SG+. When setting $N_{MAX} = 1$, all the multi-prototype word embedding models degrade to single vector embedding model, that is, the Skip-gram model.

Shared parameters Following the original papers of NP-MSSG and SG+, the threshold ϵ_{under} in FCSE-1 is also set with -0.5, and $\gamma = 0.01$ is used in both FCSE-2 and SG+. The initial learning rate $\alpha = 0.015$ is used for parameter estimation. We pick up 5 words as the context window, and 400 dimensional vectors to learn sense embeddings of the top 200,000 frequent words. Note that all the parameters including the embedding vectors are initialized randomly.

⁷We will publish the code if accepted, which is based on the published project of SG+ in <https://github.com/jiweil/multi-sense-embedding>.

4.4 Qualitative Analysis

Before conducting the experiments on word similarity task, we first give qualitative analysis of our model as well as two baseline models⁸ by representing the word sense with its nearest neighbors, which are computed through cosine similarity of the embeddings between each of the word senses and the senses of the other words.

Table 1 presents the nearest 10 neighbors of each sense of two words ranked through the similarity. Skip-gram shows a mixed result of different senses, while the other two models produce a reasonable number of word sense, and their neighbors are indeed semantically correlated. For the word “*Apple*”, there are two meanings of the fruit and technology company. NP-MSSG and FCSE-1 can differentiate the two senses, but FCSE-1 clearly achieves a more coherent ranking results. For the word “*Berry*”, FCSE-1 outperforms NP-MSSG for it successfully identifies another sense of person’s name except the dominant sense of fruit. This is because “*Berry*” is used as a person’s name much less frequently than a fruit. Thus, it may cause the data sparsity issue, while our model is capable of addressing this problem by improving the usage of training corpus, which will be further discussed in Section 4.5.3.

4.5 Word Similarity

In this subsection, we evaluate our embeddings on two classic tasks of measuring word similarity: word similarity and contextual word similarity. To better test the ability of our model to address the problem of data sparsity, we train it using only 30% of the training corpus (sampled randomly). Also, we give comparisons with the performance using all the training data.

WordSim353 (Finkelstein et al., 2001) is a benchmark dataset for word similarity. It contains 353 word pairs and their similarity scores assessed by 16 subjects. SCWS, released by (Huang et al., 2012), is a benchmark dataset for contextual word similarity, which computes the semantic relatedness between two words conditioned on the specific context. It consists 2,003 pairs of words and their sentential contexts. WordSim353 focuses on the ambiguity among similar words, and SCWS is for the ambiguity of word senses in different con-

⁸To be fair, we only show the comparisons among FCSE-1, NP-MSSG and Skip-gram, since the paper of SG+ (Li and Jurafsky, 2015) didn’t give the qualitative results.

texts.

4.5.1 Evaluation Metrics

To evaluate the performance of our model, we compute the similarity between each word pair through some measurement, and then use the spearman correlation between our results and the human judgments to evaluate the performance of the model.

Working on WordSim353, we compute the average similarity between the word pairs the same as (Reisinger and Mooney, 2010; Neelakantan et al., 2014). And working on SCWS, we use two similarity measurements, avgSimC and maxSimC, proposed by (Neelakantan et al., 2014; Liu et al., 2015). avgSimC focuses on evaluating the average similarity between all the senses of the two words, and maxSimC evaluates the similarity between the senses with max probability for the current word.

4.5.2 Results and Analysis

Table 2 and 3 shows the overall performance of our proposed model as well as the baseline methods on WordSim353 and SCWS datasets. We only obtain lower performance numbers for SG+, which suggests that they may be more susceptible to noise and worse generalization ability. However, this is a fair comparison because all the methods share the same parameter settings and the code. The following is indicated in the results:

Model	$\rho \times 100$
NP-MSSG*	67.3
SG+*	66.9
Skip-gram*	66.7
FCSE-1	68.8
FCSE-2	69.5

Table 2: Results on the wordsim353 dataset. The table presents spearman correlation ρ between each model’s similarity rank results and the human judgement.

- Both of FCSE-1 and FCSE-2 outperform all of the baseline methods, because it models the relatedness among word senses through the common features, which inherits the advantages of multi-prototype model and ensures adequate training data as compared to single vector model.

Model	<i>avg</i>	<i>max</i>
NP-MSSG*	64.0	65.2
SG+*	64.4	65.6
Skip-gram*	64.1	65.5
FCSE-1	67.1	67.1
FCSE-2	66.3	67.5

Table 3: Results on the SCWS dataset. “avg” and “max” respectively denotes the similarity measurements of avgSimC and maxSimC.

- The skip-gram model achieves rather comparative performance due to its good generalization ability, especially in a smaller training set as compared to hard-cluster based multi-prototype word embedding models.
- FCSE-2 achieves the best performance due to the separately sample for the original meaning and the extended meanings, which follows different distributions incorporating both the global and local information.

We also investigate the ability of our method that helps address the data sparsity issue by training on different size of data.

4.5.3 Training on Different Size Data

Generally speaking, the embedding model performs better when trained on a larger corpus. The multi-prototype embedding model suffers more data sparsity issue than single prototype embedding due to its further partition on the set of words’ contexts by clustering, and then performs even worse using a smaller training corpus. In this subsection, we study the capability of FCSE to help address this problem by testing the performance when training on different size corpus.

Figure 3 shows the comparison between the performance of all the models trained on 30% data and on 100% data. As the training data decreases, all the models perform worse especially the hard clustering based method. Compared to full corpus, we can see more apparent gap between NP-MSSG and FCSE-1 (from 2.6% to 3.1%), SG+ and FCSE-2 (from 0.1% to 1.9%). That is, the gap between FCSE and other methods gets closer when there are adequate training corpus, which is in accordance with the intuition. The data sparsity issue gradually vanishes along with the growth of training data. Besides, the performance of the single-prototype word embedding model increases

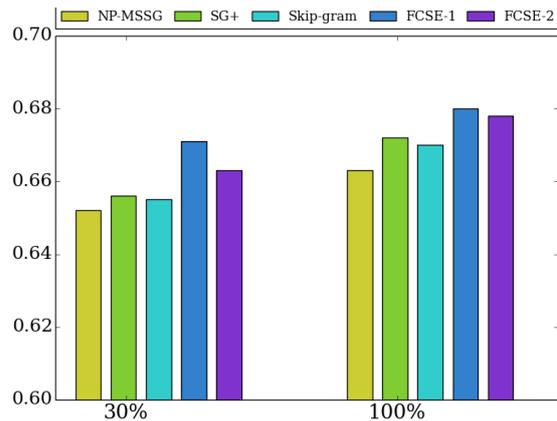

Figure 3: The performance of each model when training on different size of data

only 1.6%. Our proposed model, both FCSE-1 and FCSE-2, achieves more stable performance (0.2% and 0.6% changes).

5 Related Work

Multi-prototype word embedding has been extensively studied in the literature (Chen et al., 2014; Cao et al., 2017; Liu et al., 2015; Reisinger and Mooney, 2010; Huang et al., 2012; Tian et al., 2014; Neelakantan et al., 2014; Li and Jurafsky, 2015). They can be roughly divided into three groups. The first group is clustering based methods. As described in Section 1, (Reisinger and Mooney, 2010; Huang et al., 2012; Tian et al., 2014; Neelakantan et al., 2014; Li and Jurafsky, 2015) use clustering to induce word sense and then learn sense embeddings via Skip-gram model. The second group is to introduce topics to represent different word senses, such as (Liu et al., 2015) considers that a word under different topics leads to different meanings, so it embeds both word and topic simultaneously and combines them as the word sense. However, it is difficult to determine the number of topics. The third group incorporates external knowledge (i.e. knowledge bases) to induce word/phrase senses. (Chen et al., 2014) jointly represents and disambiguates the word sense on the basis of the synsets in WordNet. (Cao et al., 2017) regards entities in KBs as word/phrase senses, and first learn word/phrase and sense embeddings separately, then align them via Wikipedia anchors. However, it fails to deal with the words that are not included in knowledge bases.

6 Conclusion

In this paper, we propose a novel method that models the word sense relatedness in multi-prototype word embedding model. It considers the difference and relatedness between the original meanings and the extended meanings. Our proposed method adopts an online framework to induce the word sense and learn sense embeddings jointly, which makes our model more scalable and efficient. Two non-parametric methods for fuzzy clustering produce flexible number of word senses. Particularly, FCSE-2 introduces the Generalized Polya Urn process to integrate both the global occurrence information and local textual context information. The qualitative and quantitative results demonstrate the stable and higher performance of our model.

In the future, we are interested in incorporating external knowledge, such as WordNet, to supervise the clustering results, and in extending our model to learn more precise sentence and document embeddings.

Unsupervised Segmentation of Phoneme Sequences based on Pitman-Yor Semi-Markov Model using Phoneme Length Context

Abstract

Unsupervised segmentation of phoneme sequences is an essential process to obtain unknown words during spoken dialogues. In this segmentation, an input phoneme sequence without delimiters is converted into segmented sub-sequences corresponding to words. The Pitman-Yor semi-Markov model (PYSMM) is promising for this problem, but its performance degrades when it is applied to phoneme-level word segmentation. This is because of insufficient cues for the segmentation, e.g., homophones are improperly treated as single entries and their different contexts are also confused. We propose a phoneme-length context model for PYSMM to give a helpful cue at the phoneme-level and to predict succeeding segments more accurately. Our experiments showed that the peak performance with our context model outperformed those without such a context model by 0.045 at most in terms of F-measures of estimated segmentation.

1 Introduction

1.1 Motivation

The final goal of our current project is to achieve the development of robots or systems that acquire knowledge during spoken interactions between them and human beings in the open world. Unknown or new words appear frequently in our daily lives, and because their meanings may be different for the systems deployed in different areas, automatic lexicon acquisition is a useful function for maintenance-free spoken dialogue systems.

Goal: Unsupervised lexicon acquisition through spoken dialogue

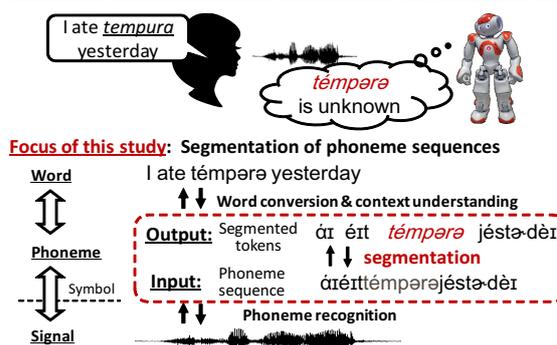

Figure 1: Our target problem

In this paper, we focus on the phoneme-level representation of utterance – not in the signal-level – to relax the problem, which results in an issue with phoneme sequence segmentation. The *segmentation* converts an input phoneme sequence into segmented sub-sequences corresponding to individual words. The focus of our study is illustrated in Figure 1. When the robot listens to a human utterance that includes an unknown word like “tempura,” the robot will estimate the unknown segment “tempura” by the iterative search based on trial-and-error of many hypotheses among different layers. Here, the phoneme sequence of an unknown word is necessary as an intermediate representation between signals and lexicon because we cannot directly obtain the spelling of an unknown word just from sound information. Note that our assumption of a phoneme sequence given is partly supported by the high accuracy of state-of-the-art speech and phoneme recognition (Dahl et al., 2012; Hinton et al., 2012; Seide et al., 2011a,b).

Approaches based on Bayesian nonparametrics are promising methods to achieve lexical acquisition from unsegmented characters or phonemes. These methods estimate the *segmentation labels* of

Word (character)	Phoneme	Phoneme length	Word	l	see	him	[EOS]	
l	úr	2	Phoneme	úr	si:	him	[EOS]

sea	si:	2						

Figure 2: Example of phoneme-length and its context

phonemes corresponding to words with an unsupervised manner. The label represents the boundary of each *word*. Mochihashi *et al.* proposed the nested Pitman-Yor language model (NPYLM) (Mochihashi *et al.*, 2009), or Pitman-Yor semi-Markov model (PYSMM) in other words. The model achieved high computational efficiency and high segmentation accuracy compared with a previous method based on the hierarchical Dirichlet process using simple Gibbs sampling (Goldwater *et al.*, 2006). Uchiumi *et al.* also proposed a method that estimates the segmentation labels and part-of-speech tagging of words at the same time based on Pitman-Yor hidden semi-Markov models (PYHSMM) for character-level segmentation (Murphy, 2002; Uchiumi *et al.*, 2015). PYHSMM has not been applied to the segmentation of phoneme sequences.

The difficulty with phoneme sequence segmentation is insufficient cues to distinguish or predict the context and segmentation labels. For example, the homophones are improperly treated as single entry and their different contexts are also confused in phoneme-level segmentation. This is a similar situation with the homographs in character-level segmentation, but it occurs much more frequently in phoneme-level segmentation, resulting in more serious problem. Although NPYLM and PYHSMM have been applied to character-level segmentation, they do not utilize cues useful for phoneme-level segmentation. We need to determine such useful cues to achieve accurate segmentation of phoneme sequences. Note that the performance comparison of NPYLM and PYHSMM methods in phoneme-level segmentation have not been conducted. We believe that comparing these methods on the basis of phoneme sequences is also useful for further improvement of the model.

We propose a *phoneme-length* context model for segmentation, which was not used in the NPYLM and PYHSMM. Note that the *length* is not the *duration* of a phoneme (the phoneme ‘a’ continues for three frames in the time axis, for

example), which is used in signal-level segmentation (Lee and Glass, 2012). Figure 2 illustrates phoneme length and its contexts in the case of bi-grams. The phoneme sequence of ‘see’ and ‘sea’ is same and both lengths are two as shown in the left side of Fig. 2. The context of phoneme length is the sequence of these lengths. For example, if ‘him’ succeeds to ‘see’, the bi-gram of phoneme length is the pair of 3 and 2 where 3 is the length of phonemes ‘him’ and 2 is the length of phonemes ‘si:’. We denote the pair as (3, 2) as shown in the right side of Fig. 2. Since the length of each segmented phoneme also depends on the previously segmented phonemes, this context represents one aspect of parts of speech. For example, the phoneme-length context captures the tendency that the length of the adposition is usually short and the length of the succeeding segment will be relatively long. We expect the phoneme-length context to be another cue for segmentation because the phoneme-length context is more abstract than word-level context. This phoneme-length model is expected to capture a rhythmic aspect of language.

We model the phoneme-length context as a prior probability distribution of sequential segmentation labels. This is because the probability distribution is expected to control how long each segmented phoneme becomes. Since the joint prior probability distribution of sequential segmentation labels were decomposed into factorized probabilities like N -gram, the phoneme-length model follows the Markov process and has a transition probability. The transition probability is also modeled and smoothed by using the Pitman-Yor N -gram model as other language models did. Our method, using NPYLM and PYHSMM, is evaluated by using a conversational corpus in English and Japanese in terms of the F-measures of the estimated segmentation labels. Because the corpus contains fillers and hesitations, the property of utterance used for evaluation matches our research purpose.

1.2 Related Work

There are several approaches based on Bayesian nonparametrics to achieve lexical acquisition from raw audio signals (Neubig *et al.*, 2010; Lee and Glass, 2012; Kamper *et al.*, 2016; Taniguchi *et al.*, 2016), unsegmented phonemes, or words (Mochihashi *et al.*, 2009;

Segmented phoneme seq.	á	r	é	t	t	é	m	p	ə	r	ə	j	é	s	t	ə	d	è	r	

Figure 3: Word segmentation

Goldwater et al., 2009; Elsnér et al., 2013; Uchiumi et al., 2015). The lexical acquisition technique is necessary in other areas, such as dialogue system that acquires knowledge through dialogue (Ono et al., 2016).

The advantages of Bayesian approach compared with other approaches (Kuo et al., 2007; Räsänen et al., 2015) are that a) the number of words in the system’s vocabulary can be increased automatically in accordance with the amount of data and b) the semi-supervised learning of segmentation labels is easy to apply to utilize our knowledge of language. A typical estimation procedure is a Gibbs-sampling-based iteration of 1) the estimation of borders (segmentation labels) given a temporal N -gram language model (Goodman, 2001) and 2) the estimation of an N -gram language model given the temporal segmentation labels.

2 Unsupervised Segmentation and Baselines

We explain the overview and segmentation algorithm of NPYLM and PYHSMM as baseline methods. PYHSMM is an extended model of NPYLM to estimate the part-of-speech tagging of segmented words at the same time.

2.1 Overview

The unsupervised segmentation problem is defined finding the latent segmentation labels $\mathbf{z} = [z_1, \dots, z_{L_c}]^T$ that correspond to each phoneme in the phoneme sequence $\mathbf{c} = [c_1, \dots, c_{L_c}]^T$ with length L_c . If the binary label $z_i = 1$, the phoneme sequence is separated after the phoneme c_i . Figure 3 illustrates the role of \mathbf{z} . Other latent parameters $\mathbf{m} = [m_1, \dots, m_{L_m}]$ with length L_m are also introduced to represent part of speech labels for each segmented phoneme sequences if necessary. The number of classes of part of speech label, M , is defined in advance of this study. The latent parameters are estimated by maximizing the follow-

ing probabilities:

$$\arg \max_{\mathbf{z}} p(\mathbf{z}|\mathbf{c}) \propto p(\mathbf{c}|\mathbf{z}) \quad \text{or} \quad (1)$$

$$\arg \max_{\mathbf{z}, \mathbf{m}} p(\mathbf{z}, \mathbf{m}|\mathbf{c}) \propto p(\mathbf{c}|\mathbf{z}, \mathbf{m})p(\mathbf{m}), \quad (2)$$

where NPYLM uses Eq. (1) and PYHSMM uses Eq. (2). The definition of each likelihood, such as $p(\mathbf{c}|\mathbf{z})$ and $p(\mathbf{c}|\mathbf{z}, \mathbf{m})$, is important. Because the border of phonemes \mathbf{z} is given in these models, the likelihood can be factorized like N -gram probability. For example, the likelihood can be factorized as $p(c_{i+1}, \dots, c_N | c_1, \dots, c_i, \mathbf{z})p(c_1, \dots, c_i | \mathbf{z})$, where the phoneme segments are considered to be two *word* segments $w_1 = c_1 \dots c_i$ and $w_2 = c_{i+1} \dots c_{L_c}$. This N -gram modeling is also adopted to decompose the part-of-speech label \mathbf{m} , and this controls the grammar and the number of words.

The nested hierarchical Pitman-Yor language model (NPYLM) is used to represent the factorized N -gram probability (Mochihashi et al., 2009). Here, we represent the context of N -gram as \vec{h} and the depth of the hierarchical context tree of \vec{h} as $|\vec{h}|$. Given the seating arrangement of customers that are represented by hidden variables \vec{s} in the hierarchical Chinese restaurant process (CRP), the conditional probability of a word segment w with the context \vec{h} is defined as follows:

$$p(w|\vec{s}, \vec{h}) = \frac{c_{\vec{h}w} - d_{|\vec{h}|}t_{\vec{h}w}}{c_{\vec{h}*} + \theta_{|\vec{h}|}} + \frac{\theta_{\vec{h}} + d_{|\vec{h}|}t_{\vec{h}*}}{c_{\vec{h}*} + \theta_{|\vec{h}|}} p(w|\vec{s}, \vec{h}'), \quad (3)$$

where $c_{\vec{h}w}$ is the count of word w at context \vec{h} , and $c_{\vec{h}*} = \sum_w c_{\vec{h}w}$ is its sum. \vec{h}' is the reduced context of \vec{h} , in which the relationship $|\vec{h}'| = |\vec{h}| - 1$ exists. $t_{\vec{h}w}$ is the number of tables at context \vec{h} , and $t_{\vec{h}*}$ is its sum. $\theta_{|\vec{h}|}$ and $d_{|\vec{h}|}$ are the common parameters of \vec{h} with the same depth $|\vec{h}|$. Here, the uni-gram segment probability $p(w = c_i \dots c_j)$ is smoothed by the phoneme-level N -gram probability $p(c_i, \dots, c_j) = p(c_j | c_i, \dots, c_{j-1})p(c_i, \dots, c_{j-1})$. Please see the work of Teh (2006) for the sampling algorithm of seating arrangement.

The segmentation labels \mathbf{z} and other parameters such as the N -gram language model are updated iteratively. If the segmentation labels are given, we can calculate the statistics of the N -gram model. If the N -gram model is given, we can estimate the probability of the segmentation labels. Because the update of the N -gram model is well known, we explain the update of the estimation of the segmentation labels in the latter parts of this section.

end while

2.2 Inference for NPYLM

Mochihashi *et al.* (2009) proposed introducing the forward-backward inference to estimate the segmentation labels efficiently. This method uses a semi-Markov model, and it considers the problem as a sequential estimation of the hidden labels. The procedure consists of two steps: forward filtering and backward sampling.

The forward filtering calculates the forward probability that is used for the Bayesian learning of the hidden Markov model (HMM) (Scott, 2002). The following equation denotes $\alpha[t][k]$ as the probability of generating the partial phonemes c_1, \dots, c_t of c using the last k phonemes in the case of bi-grams.

$$\alpha[t][k] = \sum_{j=1}^{t-k} p(c_{t-k+1}^t | c_{t-k-j+1}^{t-k}) \alpha[t-k][j], \quad (4)$$

where $\alpha[0][0] = 1$ and $c_n, \dots, c_m = c_n^m$.

Backward sampling is achieved by drawing a phoneme segment w from the end of a sentence by using forward probability $\alpha[t][k]$. Because the end of sentence is represented by the special symbol \mathbb{E} , we can start sampling a word with the probability proportional to $p(\mathbb{E} | c_{N-k}^N)$. The algorithm is summarized in Alg. 1.

Note that we do not use the correction of phoneme-level N -gram probability based on the phoneme length using the Poisson distribution in the NPYLM. This is because the length property is embedded into our model naturally.

2.3 Inference for PYHSMM

The PYHSMM, which is an extended model of NPYLM, estimates the parts of speech of each segmented phoneme. We expect that the performance of PYHSMM is better than that of NPYLM. The forward probability, $\alpha[t][k][m]$, is newly introduced in the case of bi-grams, and the following equation denotes it as the probability of generating the partial phonemes c_1, \dots, c_t with

part-of-speech m from the last k phonemes.

$$\alpha[t][k][m] = \sum_{j=1}^{t-k} \sum_{r=0}^M p(c_{t-k+1}^t | c_{t-k-j+1}^{t-k}, m) p(m|r) \alpha[t-k][j][r] \quad (5)$$

where $p(m|r)$ is the transition probability of the latent parts of speech and assumed the hierarchical Pitman-Yor language model.

The algorithm of the backward sampling is similar to that of NPYLM. The parts of speech are sampled as well as the segmentation label. Because the end of the sentence and its parts of speech are represented using the special symbol \mathbb{E} , we can start sampling a word with the probability proportional to $p(\mathbb{E} | c_{N-k}^N, \mathbb{E}) p(\mathbb{E} | m)$ like NPYLM. Note that *the computational cost of PYHSMM is larger than that of NPYLM* due to the search part-of-speech labels.

3 Analysis and Our Approach

We focus on the distribution of phoneme length to distinguish the confused contexts. If we have two different words with the same pronunciation, we can sometimes distinguish the phoneme representations of them on the basis of the length of the preceding or succeeding phoneme segments. The phoneme-length context will capture the tendency that the length of the adposition is usually short and the length of the succeeding segment will be relatively long.

Figure 4 illustrates the real phoneme-length distribution in the English and Japanese spoken-dialogue transcriptions used in our evaluation (Sec. 5.2). Given that the function $len(w)$ returns the phoneme length of word w , the matrices represent the bi-gram length probability $p(len(w_n) | len(w_{n-1}))$, and the horizontal axis is $len(w_{n-1})$ and the vertical axis is $len(w_n)$. w_n represents the n -th word in each sentences. The line graphs represent the uni-gram length probability $p(len(w_n))$. These probabilities were calculated on the basis of maximum likelihood estimation. *Verb* and *Noun* represent the phoneme-length probability of verbs and nouns in Japanese data, respectively. The definitions of bi-gram and uni-gram probability for *Verb* and *Noun* are $p(len(w_n) | len(w_{n-1}), pos(w_n))$ and $p(len(w_n) | pos(w_n))$, where $pos(w)$ is a function that returns a part-of-speech tag of the word w .

We determined that the phoneme-length probability depends on 1) language, 2) context, and

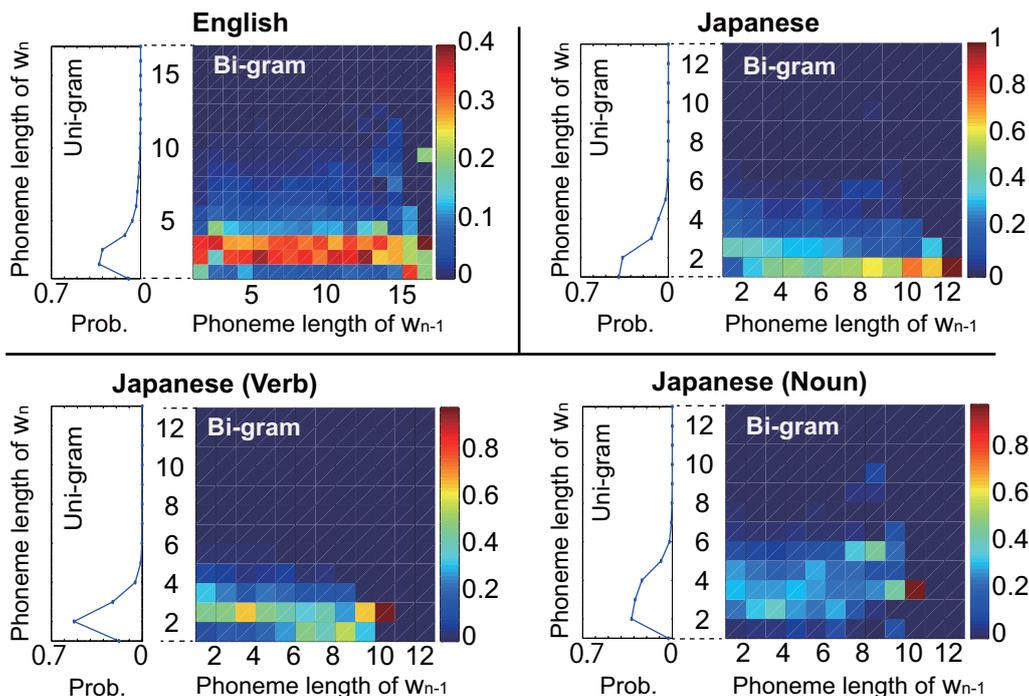

Figure 4: Real phoneme-length distribution

3) parts of speech. The bi-gram phoneme-length probabilities in English are relatively similar to each other but different from those in Japanese. Some bi-gram probabilities have several peaks, and they vary in accordance with parts of speech. If we utilize this information, we will achieve an accurate segmentation.

The straightforward approach to exploit phoneme-length information is to utilize the prior distribution of the segmentation labels \mathbf{z} that is not used in either NPYLM and PYSHMM. Because the prior probability is considered to be the source that determines the length of each phoneme segment, embedding this prior into a model is expected to improve the segmentation performance. Therefore, we need to construct a model that considers the prior of the segmentation labels and should also reveal the performance of these models for phoneme-level word segmentation.

4 Phoneme-Length Context Model for Pitman-Yor Semi-Markov Models

We extend the NPYLM and PYHSM to exploit the phoneme-length patterns of each phoneme segment. First, we explain our problem statement for unsupervised segmentation of phoneme sequences. Next, we derive the context model of the phoneme length and show the forward-backward algorithms for our extended NPYLM

and PYHSM.

4.1 Problem Statement and Model

We exploit the probability of phoneme length in estimating latent segmentation labels \mathbf{z} and latent part-of-speech labels \mathbf{m} . The parameters are estimated by maximizing the following probabilities:

$$\arg \max_{\mathbf{z}} p(\mathbf{z}|\mathbf{c}) \propto p(\mathbf{c}|\mathbf{z})p(\mathbf{z}) \quad \text{or} \quad (6)$$

$$\arg \max_{\mathbf{z}, \mathbf{m}} p(\mathbf{z}, \mathbf{m}|\mathbf{c}) \propto p(\mathbf{c}|\mathbf{z}, \mathbf{m})p(\mathbf{z}|\mathbf{m})p(\mathbf{m}). \quad (7)$$

The former objective function is for NPYLM, and the latter is for PYHSM. The probabilities of segmentation labels $p(\mathbf{z})$ in Eq. (6) and $p(\mathbf{z}|\mathbf{m})$ in Eq. (7) are used in our objective functions. $p(\mathbf{z})$ is a prior probability distribution of segmentation labels \mathbf{z} in Eq. (6).

We decompose each joint probability into N -gram probabilities. For an easy explanation of this decomposition, here we use the length of part-of-speech labels L_m and the correct segmentation labels as if these are given, which are actually searched for during training. The non-zero indices of segmentation labels \mathbf{z} are represented by $\mathbf{g} = [g_1, \dots, g_W]$, where W is the number of “true” phoneme segments. W equals L_m in the case of part-of-speech estimation. We also define $g'_i = g_i + 1$. The factorized models in the case

of bi-grams for NPYLM and PYHSMM are represented as follows:

$$p(\mathbf{c}|\mathbf{z}) = \prod_i p(c_{g'_{i-1}}^{g_i} | c_{g'_{i-2}}^{g_{i-1}}, z_{g'_{i-1}}^{g_i}, z_{g'_{i-2}}^{g_{i-1}}), \quad (8)$$

$$p(\mathbf{z}) = \prod_i p(z_{g'_{i-1}}^{g_i} | z_{g'_{i-2}}^{g_{i-1}}), \quad (9)$$

$$p(\mathbf{c}|\mathbf{z}, \mathbf{m}) = \prod_i p(c_{g'_{i-1}}^{g_i} | c_{g'_{i-2}}^{g_{i-1}}, z_{g'_{i-1}}^{g_i}, z_{g'_{i-2}}^{g_{i-1}}, m_i), \quad (10)$$

$$p(\mathbf{z}|\mathbf{m}) = \prod_i p(z_{g'_{i-1}}^{g_i} | z_{g'_{i-2}}^{g_{i-1}}, m_i), \quad (11)$$

$$p(\mathbf{m}) = \prod_i p(m_i | m_{i-1}), \quad (12)$$

where $p(m_i | m_{i-1})$ is a transition probability of latent part-of-speech labels, $z_{g'_{i-1}}^{g_i} = z_{g_{i-1}+1}, \dots, z_{g_i}$ and $p(z_{g'_{i-1}}^{g_i} | z_{g'_{i-2}}^{g_{i-1}})$ and $p(z_{g'_{i-1}}^{g_i} | z_{g'_{i-2}}^{g_{i-1}}, m_i)$ are transition probabilities of the segmentation labels. The transition probability of segmentation labels is derived naturally. The latent variables for the seating arrangement of N -gram probability in Eq. (3) are omitted in these equations.

We design the transition probability of segmentation labels, such as $p(z_{g'_{i-1}}^{g_i} | z_{g'_{i-2}}^{g_{i-1}})$, to depend on the length of each phoneme segment. Because the length of each segment can be represented using the non-zero indices \mathbf{g} , the bi-gram transition probability is rewritten as

$$p(z_{g'_{i-1}}^{g_i} | z_{g'_{i-2}}^{g_{i-1}}) = p(g_i - g_{i-1} | g_{i-1} - g_{i-2}) \quad (13)$$

where m_{g_i} is omitted in the case of PYHSMM, and each integer, such as $g_i - g_{i-1}$, is considered as a symbol or label. This transition probability is the phoneme-length bi-gram probability as mentioned in Sec. 3, and it is also modeled by the hierarchical Pitman-Yor language model (HPYLM) not by a Poisson distribution (Mochihashi et al., 2009) because HPYLM is a count-based representation, which is appropriate for multimodal distribution. Such probability for duration modeling is also seen in (Kuo et al., 2007).

4.2 Inference

We derived the forward-backward algorithms to estimate the segmentation labels and part-of-speech labels. The inference for NPYLM is introduced first; then, the inference of PYHSMM is explained. Note that the segmentation label \mathbf{z} and part-of-speech labels \mathbf{m} are estimated simultaneously.

The forward probability $\alpha[t][k]$ of NPYLM with phoneme-length context is modified as follows.

$$\alpha[t][k] = \sum_{j=1}^{t-k} p(c_{t-k+1}^t | c_{t-k-j+1}^{t-k}, k, j) p(k|j) \alpha[t-k][j] \quad (14)$$

where $p(k|j)$ is a transition probability of the length of each phoneme segment. The forward probability is modified by the bi-gram probability of lengths. We can use $p(c_{t-k+1}^t | c_{t-k-j+1}^{t-k}, k)$ instead of $p(c_{t-k+1}^t | c_{t-k-j+1}^{t-k}, k, j)$ because information of length j is included in the phoneme sequence representation, $c_{t-k-j+1}^{t-k}$.

As with NPYLM, the context of phoneme lengths can be embedded into PYHSMM. The forward probability is also represented as

$$\alpha[t][k][m] = \sum_{j=1}^{t-k} \sum_{r=0}^M p(c_{t-k+1}^t | c_{t-k-j+1}^{t-k}, k, j, m) p(k|j, m) p(m|r) \alpha[t-k][j][r] \quad (15)$$

where m represents a part of speech. The forward probability is also biased by a transition probability of the length of each phoneme segment $p(k|j, m)$. We can also use $p(c_{t-k+1}^t | c_{t-k-j+1}^{t-k}, k, m)$. Because the number of parameters is large in this case of latent parts of speech, the convergence speed will degrade compared with NPYLM. Backward sampling of both cases is achieved in the same way as in NPYLM. The details are omitted due to space limitation.

4.3 Substitution

We substitute the conditional probability into simpler one by ignoring the dependency on length k in this work as follows:

$$p(c_{t-k+1}^t | c_{t-k-j+1}^{t-k}, k) := p(c_{t-k+1}^t | c_{t-k-j+1}^{t-k}). \quad (16)$$

The probability should be ideally normalized only on the tokens that have length k , and this substitution makes a double count of the length information of token c_{t-k+1}^t . On the other hand, the difference between NPYLM and our proposed model in the inference is clear. The transition probability $p(k|j)$ is added in our model, and its implementation becomes simple. Our strict model will be evaluated in the future work.

We also use $p(c_{t-k+1}^t | c_{t-k-j+1}^{t-k}, m)$ instead of $p(c_{t-k+1}^t | c_{t-k-j+1}^{t-k}, k, m)$.

Note that there are several options on the back-off structure of the conditional probability $p(c_{t-k+1}^t | c_{t-k-j+1}^{t-k}, k)$. For example, the word uni-gram $p(c_{t-k+1}^t | k)$ might be smoothed by un-conditioned word uni-gram or by the k -conditioned character N -gram. If the amount of data is limited, the parameter estimation of the conditional character N -gram may fail. We adopt the existing model, NPYLM, as the structure in this work. The optimal structure should also be investigated in the future work.

5 Experiments

5.1 Evaluation Procedure

We evaluated each model by comparing the estimated segmented labels with the correct segmented original phoneme text (transcription of speech corpus). Utterances in the corpus were divided manually, and each utterance was treated as one sentence. The unsegmented phoneme text is generated by replacing the word-segmented transcription text into phoneme text with a dictionary and by removing whitespaces.

The criteria for the evaluations were the F-measures of the estimated lexicon set and segmentation label set. These F-measures are the harmonic mean of recall and precision; therefore, we could consider the recall and precision at the same time. The lexicon set after unsupervised segmentation was compared with that of the original segmented phoneme text. The estimated set of segmentation labels was also compared with that of the original phoneme text.

We used a development set to monitor the maximum performance of segmentation methods. The 1% data set was randomly selected from each test set, and its F-measure of segmentation labels was used to determine the epochs for calculating F-measures. Since we can obtain some correctly-transcribed text in a real situation, this evaluation process is reasonable. First, we ran each method over a sufficient number of epochs. Next, we calculated the F-measure of each development set’s segmentation label and identified the 20-epoch section where the averaged F-measure was the highest. We calculated the F-measures of test sets that averaged over 20 epochs corresponding to the identified 20-epoch section. Note that each method is based on sampling and the max-

Table 1: Parameters of experiment

	English	Japanese
Target text	SwitchBoard	CSJ
# of sentences	5,239	17,493
# of segments	88,127	132,900
# of phonemes	276,329	264,544
Vocab. size (word)	6,203	8,325
Vocab. size (phoneme)	5,422	6,589
Phoneme set	43	79

imum likelihood estimation sometimes does not match the segmentation on the basis of linguistic definitions.

5.2 Data

We used two types of speech transcription in English and Japanese for evaluation. This is because the distribution of phoneme length also differs in languages as mentioned in Sec. 3.

We used the Switchboard-1 Telephone Speech Corpus (Godfrey et al., 1992) for the English set, which includes the transcription of conversational dialogue speech¹. We selected 5,239 sentences from the session “ID 20,” which included 88,127 word segments with 6,203 unique words. These words were converted into phonemes, totaling 276,329 phoneme characters. The vocabulary size in terms of phoneme representation was 5,422, and this was a unique number of phoneme sequences of words. For example, because the pronunciation of the words “see” and “sea” is the same “si:”, the phoneme sequence “si:” is considered to be a unique vocabulary item. The phoneme set used in the English corpus included 43 phonemes in total including end-of-sentence symbols. The properties of the corpus are summarized in Table 1.

We used the Corpus of Spontaneous Japanese (CSJ) for the Japanese set, which is a collection of spoken dialogue recordings and their transcriptions (Maekawa, 2003). We used 17,493 sentences, including 132,900 word segments with 8,325 of them being unique words. The phoneme set for Japanese includes the combination of consonants and vowels and almost completely corresponds to “*katakana*” in Japanese to remove redundancy. The words were also transformed into phonemes (“*katakana*”), resulting in 264,544 of them. The vocabulary size in terms of phoneme representation was 6,589, and this was the unique number of phoneme sequences of words. The phoneme set used in the Japanese corpus included

¹<http://www.isip.msstate.edu/projects/switchboard/releases/>

79 phonemes in total including end-of-sentence symbols. The properties of the corpus are also summarized in Table 1.

5.3 Parameter Settings

The parameters of NPYLM were the same for all models. The hyper parameters of the word language model were initialized as $\theta_{|h|} = 2.0$, $d_{|h|} = 0.5$, and the other parameters of prior probability distribution were all set to 1.0, such as the parameters of the beta distribution in NPYLM.

The hyper parameters of the phoneme (character) language, part-of-speech model and length model were the same as those in the language model. We set the maximum length of the phoneme sequence L_c to 10 due to the computational complexity. The number of classes of part of speech label, M , was set to 4 due to the small corpus size and computational cost. The initial labels of parts of speech were initialized randomly within the number of classes.

5.4 Results

The maximum F-measures of the lexicon and segmentation are listed in Tables 2 and 3 for the English and Japanese test sets. The notations *Lex.* and *Seg.* represent the F-measures of the lexicon and segmentation, respectively. *NPYLM-D* denotes the proposed NPYLM with our phoneme-length context model in Table 2, and *PYHSMM-D* denotes the proposed PYHSMM with our context model in Table 3.

The F-measures of the proposed NPYLM-D outperformed the NPYLM for both the English and Japanese test sets as shown in Table 2. The improvements in the Japanese corpus, 0.067 (*Lex.*) and 0.045 (*Seg.*), were larger than those in the English corpus, 0.003 (*Lex.*) and 0.01 (*Seg.*). This is because the bi-gram probability of phoneme length varies more in Japanese than in English, and the NPYLM-D could capture such tendencies. The NPYLM does not use any information other than the context of a segmented phoneme sequence. Therefore, the length model is useful to model the phoneme-level features. The lower performance of NPYLM-D after convergence might be caused by the conditional probability substitution and its double-count of length information.

The F-measures of the proposed PYHSMM-D were worse than those of PYHSMM for both the English and Japanese test sets as shown in Table 3. The performances of these methods were

Table 2: F-measures of segmentation by NPYLM and NPYLM-D

		NPYLM (baseline)	NPYLM-D (proposed)
English	Lex.	0.602	0.605
	Seg.	0.897	0.907
Japanese	Lex.	0.344	0.411
	Seg.	0.748	0.793

Table 3: F-measures of segmentation by PYHSMM and PYHSMM-D

		PYHSMM (baseline)	PYHSMM-D (proposed)
English	Lex.	0.528	0.471
	Seg.	0.825	0.788
Japanese	Lex.	0.202	0.158
	Seg.	0.499	0.437

worse than those of NPYLM and NPYLM-D. The reasons for this are due to 1) the smaller amount of data to treat latent context variable \mathbf{m} and 2) the overlap of *contextual information* between the phoneme length and the latent variable \mathbf{m} . Since the latent variable \mathbf{m} represents the class of context, a sufficient amount of data will be required for achieving stable performance compared with NPYLM. Moreover, the context information represented by the latent variable \mathbf{m} possibly includes our phoneme length context. Thus, it might be difficult for the PYHSMM-D to separate these two contexts in the case of completely unsupervised training. These problems may be solved in the *semi-supervised* case where we exploit pre-labeled data with already segmented words and their tagged parts of speech.

The F-measures of segmentation during training for the English and Japanese test sets are shown in Figures 5 and 6, respectively. The horizontal axis represents the epoch of Gibbs sampling, and the vertical axis represents the F-measures for the segmentation label set. The Gibbs sampling was stopped after at least ten days. Note that the F-measure of segmentation does not necessarily correlate with the likelihood and all methods were based on stochastic segmentation.

The F-measures of NPYLM and PYHSMM for the English and Japanese corpora improved in proportion to the number of epochs, and those of PYHSMM and PYHSMM-D did not converge as shown in Figures 5 and 6. Because the number of hidden parameters of PYHSMM and PYHSMM-D was large, their convergence speeds were slow.

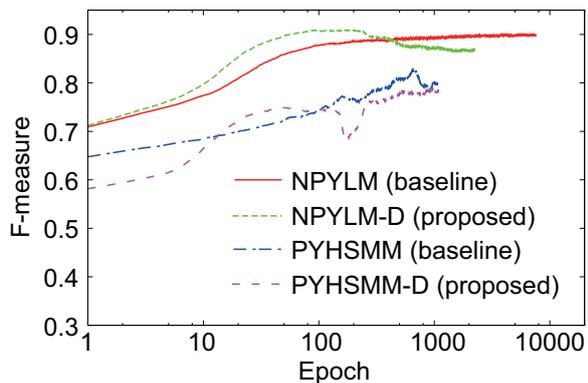

Figure 5: F-measures of segmentation for English test set

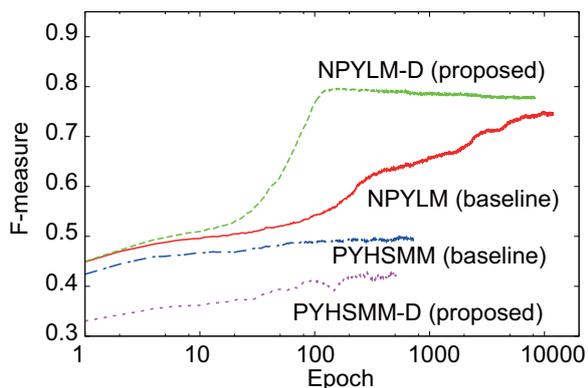

Figure 6: F-measures of segmentation for Japanese test set

The proposed NPYLM-D had peak F-measures at 100–200 epochs, and they went down and converged as the number of epochs increased. This was mainly because the phoneme-length context model accelerated the segmentation in the early epochs, and the small number of observations and un-supervised condition caused over-fitting. Therefore, the performance of the NPYLM-D is expected to be improved by using a larger corpus or by optimizing hyper parameters to match the actual prior probability of phoneme length.

The semi-supervised training would be effective for segmentation in practical use because it matches the actual use case. Evaluating the performance under such a condition is planned for future work. We expect the PYHSMM-D to work well more after 1000 epochs, but it requires a large computational cost. Its results could also be improved with a larger corpus and semi-supervised condition.

6 Conclusions

Unsupervised segmentation of phoneme sequences is an essential process to obtain unknown words during spoken dialogues with users. The PYSMM is a promising model to achieve unsupervised segmentation, but its performance degrades when it is applied to phoneme-level word segmentation. We proposed a phoneme-length context model for PYSMM to give a helpful cue at the phoneme-level and to predict succeeding phoneme segmentation more accurately. Our experiments showed that the peak performances with our context model outperformed those without such a context model by 0.045 at most in terms of F-measures of estimated segmentation labels.

There are the several future works on 1) optimization of parameters, 2) evaluation of semi-supervised training and other languages, and 3) improvement of our model and inference method. To further improve our method, we must investigate the hyper parameters setting for the estimation of segmentation labels to operate efficiently. The semi-supervised training will also improve the performance of our method. We will evaluate our method not only for English and Japanese but also other languages, such as African languages because the rhythmic information might be vivid. The performance of our strict model and the optimal back-off structure should be investigated to reveal the limitation of our model. The modification of inference algorithm will be required due to the computational efficiency when we use longer context information more than tri-gram. Since the rhythm information of latent segmentation might not be captured well by bi-grams, the challenge of using longer context is one of the important issues for our purpose.

Abstract

Convolutional Neural Networks (CNNs) have recently achieved remarkably strong performance on the practically important task of sentence classification (Kim, 2014; Kalchbrenner et al., 2014; Johnson and Zhang, 2014; Zhang et al., 2016). However, these models require practitioners to specify an exact model architecture and set accompanying hyperparameters, including the filter region size, regularization parameters, and so on. It is currently unknown how sensitive model performance is to changes in these configurations for the task of sentence classification. We thus conduct a sensitivity analysis of one-layer CNNs to explore the effect of architecture components on model performance; our aim is to distinguish between important and comparatively inconsequential design decisions for sentence classification. We focus on one-layer CNNs (to the exclusion of more complex models) due to their comparative simplicity and strong empirical performance, which makes it a modern standard baseline method akin to Support Vector Machine (SVMs) and logistic regression. We derive practical advice from our extensive empirical results for those interested in getting the most out of CNNs for sentence classification in real world settings.

1 Introduction

Convolutional Neural Networks (CNNs) have recently been shown to achieve impressive results on the practically important task of sentence categorization (Kim, 2014; Kalchbrenner et al., 2014; Wang et al., 2015; Goldberg, 2015; Iyyer et al.,

2015; Zhang et al., 2016, 2017). CNNs can capitalize on distributed representations of words by first converting the tokens comprising each sentence into a vector, forming a matrix to be used as input (e.g., see Fig. 1). The models need not be complex to realize strong results: Kim (2014), for example, proposed a simple one-layer CNN that achieved state-of-the-art (or comparable) results across several datasets. The very strong results achieved with this comparatively simple CNN architecture suggest that it may serve as a drop-in replacement for well-established baseline models, such as SVM (Joachims, 1998) or logistic regression. While more complex deep learning models for text classification will undoubtedly continue to be developed, those deploying such technologies in practice will likely be attracted to simpler variants, which afford fast training and prediction times.

Unfortunately, a downside to CNN-based models – even simple ones – is that they require practitioners to specify the exact model architecture to be used and to set the accompanying hyperparameters. In practice, tuning all of these hyperparameters is simply not feasible, especially because parameter estimation is computationally intensive. Emerging research has begun to explore hyperparameter optimization methods, including random search (Bengio, 2012), and Bayesian optimization (Yogatama and Smith, 2015; Bergstra et al., 2013). However, these sophisticated search methods still require knowing which hyperparameters are worth exploring to begin with (and reasonable ranges for each).

In this work our aim is to identify empirically the settings that practitioners should expend effort tuning, and those that are either inconsequential with respect to performance or that seem to have a ‘best’ setting independent of the specific dataset, and provide a reasonable range for each hyperpa-

parameter. We take inspiration from previous empirical analyses of neural models due to Coates et al. (2011) and Breuel (2015), which investigated factors in unsupervised feature learning and hyperparameter settings for Stochastic Gradient Descent (SGD), respectively. Here we report the results of a large number of experiments exploring different configurations of CNNs run over nine sentence classification datasets. Most previous work in this area reports only mean accuracies calculated via cross-validation. But there is substantial variance in the performance of CNNs, even on the *same folds* and with model configuration held constant. Therefore, in our experiments we perform replications of cross-validation and report accuracy/Area Under Curve (AUC) score means and ranges over these.

2 Background and Preliminaries

Deep and neural learning methods are now well established in machine learning (LeCun et al., 2015; Bengio, 2009). They have been especially successful for image and speech processing tasks. More recently, such methods have begun to overtake traditional sparse, linear models for NLP (Goldberg, 2015; Bengio et al., 2003; Mikolov et al., 2013; Collobert and Weston, 2008; Collobert et al., 2011; Kalchbrenner et al., 2014; Socher et al., 2013).

Recently, word embeddings have been exploited for sentence classification using CNN architectures. Kalchbrenner (2014) proposed a CNN architecture with multiple convolution layers, positing latent, dense and low-dimensional word vectors (initialized to random values) as inputs. Kim (2014) defined a one-layer CNN architecture that performed comparably. This model uses pre-trained word vectors as inputs, which may be treated as *static* or *non-static*. In the former approach, word vectors are treated as fixed inputs, while in the latter they are ‘tuned’ for a specific task. Elsewhere, Johnson and Zhang (2014) proposed a similar model, but swapped in high dimensional ‘one-hot’ vector representations of words as CNN inputs. Their focus was on classification of longer texts, rather than sentences (but of course the model can be used for sentence classification).

The relative simplicity of Kim’s architecture – which is largely the same as that proposed by Johnson and Zhang (2014), modulo the word vec-

tors – coupled with observed strong empirical performance makes this a strong contender to supplant existing text classification baselines such as SVM and logistic regression. But in practice one is faced with making several model architecture decisions and setting various hyperparameters. At present, very little empirical data is available to guide such decisions; addressing this gap is our aim here.

2.1 CNN Architecture

We begin with a tokenized sentence which we then convert to a *sentence matrix*, the rows of which are word vector representations of each token. These might be, e.g., outputs from trained word2vec (Mikolov et al., 2013) or GloVe (Pennington et al., 2014) models. We denote the dimensionality of the word vectors by d . If the length of a given sentence is s , then the dimensionality of the sentence matrix is $s \times d$. Suppose that there is a filter matrix w with region size h ; w will contain $h \cdot d$ parameters to be estimated. We denote the sentence matrix by $\mathbf{A} \in \mathbb{R}^{s \times d}$, and use $\mathbf{A}[i : j]$ to represent the sub-matrix of \mathbf{A} from row i to row j . The output sequence $\mathbf{o} \in \mathbb{R}^{s-h+1}$ of the convolution operator is obtained by repeatedly applying the filter on sub-matrices of \mathbf{A} :

$$o_i = \mathbf{w} \cdot \mathbf{A}[i : i + h - 1], \quad (1)$$

where $i = 1 \dots s - h + 1$, and \cdot is the dot product between the sub-matrix and the filter (a sum over element-wise multiplications). We add a bias term $b \in \mathbb{R}$ and an activation function f to each o_i , inducing the *feature map* $\mathbf{c} \in \mathbb{R}^{s-h+1}$ for this filter:

$$c_i = f(o_i + b). \quad (2)$$

One may use multiple filters for the same region size to learn complementary features from the same regions. One may also specify multiple kinds of filters with different region sizes (i.e., ‘heights’). The dimensionality of the feature map generated by each filter will vary as a function of the sentence length and the filter region size. A pooling function is thus applied to each feature map to induce a fixed-length vector. A common strategy is *1-max pooling* (Boureau et al., 2010b), which extracts a scalar from each feature map. Together, the outputs generated from each filter map can be concatenated into a fixed-length, ‘top-level’ feature vector, which is then fed through a softmax function to generate the final classification. At this softmax layer, one may apply ‘dropout’ (Hinton

et al., 2012) as a means of regularization. This entails randomly setting values in the weight vector to 0. One may also impose an l_2 norm constraint, i.e., linearly scale the l_2 norm of the vector to a pre-specified threshold when it exceeds this. Fig. 1 provides a schematic illustrating the model architecture just described. The training objective to be minimized is the categorical cross-entropy loss. The parameters to be estimated include the weight vector(s) of the filter(s), the bias term in the activation function, and the weight vector of the softmax function. In the ‘non-static’ approach, one also tunes the word vectors. Optimization is performed using SGD and back-propagation (Rumelhart et al., 1988).

3 Datasets

We use nine sentence classification datasets in all; seven of which were also used by Kim (2014). Briefly, these are summarized as follows. (1) **MR**: sentence polarity dataset from (Pang and Lee, 2005). (2) **SST-1**: Stanford Sentiment Treebank (Socher et al., 2013). To make input representations consistent across tasks, we only train and test on sentences, in contrast to the use in (Kim, 2014), wherein models were trained on both phrases and sentences. (3) **SST-2**: Derived from SST-1, but pared to only two classes. We again only train and test models on sentences, excluding phrases. (4) **Subj**: Subjectivity dataset (Pang and Lee, 2005). (5) **TREC**: Question classification dataset (Li and Roth, 2002). (6) **CR**: Customer review dataset (Hu and Liu, 2004). (7) **MPQA**: Opinion polarity dataset (Wiebe et al., 2005). Additionally, we use (8) **Opi**: Opinosis Dataset, which comprises sentences extracted from user reviews on a given topic, e.g. “sound quality of ipod nano”. There are 51 such topics and each topic contains approximately 100 sentences (Ganesan et al., 2010). (9) **Irony** (Wallace et al., 2014): this contains 16,006 sentences from *reddit* labeled as ironic (or not). The dataset is imbalanced (relatively few sentences are ironic). Thus before training, we under-sampled negative instances to make classes sizes equal.¹ For this dataset we report the Area Under Curve (AUC), rather than accuracy, because it is imbalanced.

¹Empirically, under-sampling outperformed over-sampling in mitigating imbalance, see also Wallace (2011).

4 Baseline Models

4.1 Baseline Configuration

We give a baseline CNN configuration described in Table 1. We argue that it is critical to assess the variance due strictly to the parameter estimation procedure. Most prior work, unfortunately, has not reported such variance, despite a highly stochastic learning procedure. This variance is attributable to estimation via SGD, random dropout, and random weight parameter initialization.

Description	Values
input word vectors	Google word2vec
filter region size	(3,4,5)
feature maps	100
activation function	ReLU
pooling	1-max pooling
dropout rate	0.5
l_2 norm constraint	3

Table 1: Baseline configuration. ‘feature maps’ refers to the number of feature maps for each filter region size. ‘ReLU’ refers to *rectified linear unit* (Maas et al., 2013), a commonly used activation function in CNNs.

Then we consider the effect of different architecture decisions and hyperparameter settings. To this end, we hold all other settings constant (as per Table 1) and vary only the component of interest. For every configuration that we consider, we replicate the experiment 10 times, where each replication constitutes a run of 10-fold CV. We report average CV means and associated ranges achieved over the replicated CV runs.

4.2 Effect of input word vectors

A nice property of sentence classification models that start with distributed representations of words as inputs is the flexibility such architectures afford to swap in different pre-trained word vectors during model initialization. Therefore, we first explore the sensitivity of CNNs for sentence classification with respect to the input representations used. Specifically, we replaced word2vec with GloVe representations. Google word2vec uses a local context window model trained on 100 billion words from Google News (Mikolov et al., 2013), while GloVe is a model based on global word-word co-occurrence statistics (Pennington et al., 2014). We used a GloVe model trained on a cor-

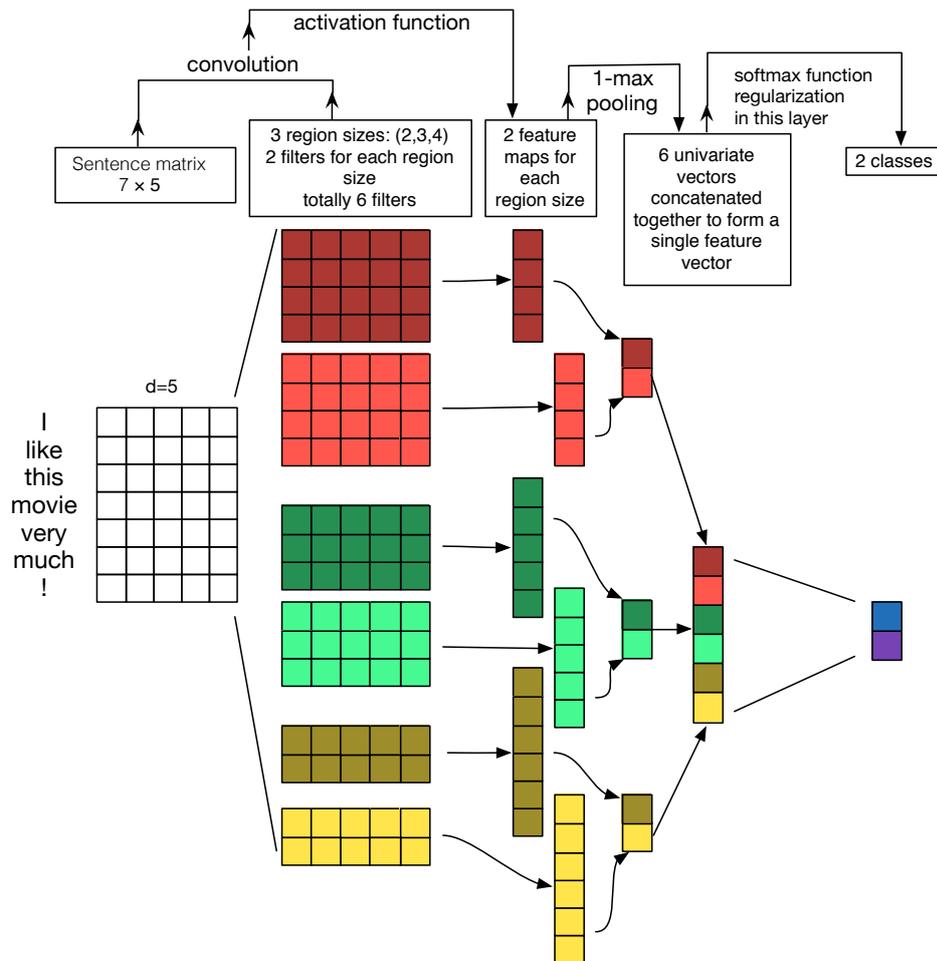

Figure 1: Illustration of a CNN architecture for sentence classification. We depict three filter region sizes: 2, 3 and 4, each of which has 2 filters. Filters perform convolutions on the sentence matrix and generate (variable-length) feature maps; 1-max pooling is performed over each map, i.e., the largest number from each feature map is recorded. Thus a univariate feature vector is generated from all six maps, and these 6 features are concatenated to form a feature vector for the penultimate layer. The final softmax layer then receives this feature vector as input and uses it to classify the sentence; here we assume binary classification and hence depict two possible output states.

pus of 840 billion tokens of web data. For both word2vec and GloVe we induce 300-dimensional word vectors. We report results achieved using GloVe representations in Table 2. Here we only report non-static GloVe results (which uniformly outperformed the static variant).

We also experimented with concatenating word2vec and GloVe representations, thus creating 600-dimensional word vectors to be used as input to the CNN. Pre-trained vectors may not always be available for specific words (either in word2vec or GloVe, or both); in such cases, we randomly initialized the corresponding sub-vectors. Results are reported in the final column of Table 2. The relative performance

achieved using GloVe versus word2vec depends on the dataset, and, unfortunately, simply concatenating these representations does not necessarily seem helpful. For how to better utilize multiple sets of embeddings, we refer to (Zhang et al., 2016).

We also experimented with using long, sparse one-hot vectors as input word representations, in the spirit of Johnson and Zhang (2014). In this strategy, each word is encoded as a one-hot vector, with dimensionality equal to the vocabulary size. Though this representation combined with one-layer CNN achieves good results on document classification, it is still unknown whether this is useful for sentence classification. We keep the other settings the same as in the basic con-

Dataset	Non-static word2vec-CNN	Non-static GloVe-CNN	Non-static GloVe+word2vec CNN
MR	81.24 (80.69, 81.56)	81.03 (80.68,81.48)	81.02 (80.75,81.32)
SST-1	47.08 (46.42,48.01)	45.65 (45.09,45.94)	45.98 (45.49,46.65)
SST-2	85.49 (85.03, 85.90)	85.22 (85.04,85.48)	85.45 (85.03,85.82)
Subj	93.20 (92.97, 93.45)	93.64 (93.51,93.77)	93.66 (93.39,93.87)
TREC	91.54 (91.15, 91.92)	90.38 (90.19,90.59)	91.37 (91.13,91.62)
CR	83.92 (82.95, 84.56)	84.33 (84.00,84.67)	84.65 (84.21,84.96)
MPQA	89.32 (88.84, 89.73)	89.57 (89.31,89.78)	89.55 (89.22,89.88)
Opi	64.93 (64.23,65.58)	65.68 (65.29,66.19)	65.65 (65.15,65.98)
Irony	67.07 (65.60,69.00)	67.20 (66.45,67.96)	67.11 (66.66,68.50)

Table 2: Performance using non-static word2vec-CNN, non-static GloVe-CNN, and non-static GloVe+word2vec CNN, respectively. Each cell reports the mean (min, max) of summary performance measures calculated over multiple runs of 10-fold cross-validation. We will use this format for all tables involving replications

figuration, and the one-hot vector is fixed during training. Compared to using embeddings as input to the CNN, we found the one-hot approach to perform poorly for sentence classification tasks. We believe that one-hot CNN may not be suitable for sentence classification, likely due to sparsity: the sentences are perhaps too brief to provide enough information for this high-dimensional encoding. Alternative one-hot architectures (Johnson and Zhang, 2015) might be more appropriate for this scenario.

4.3 Effect of filter region size

Region size	MR
1	77.85 (77.47,77.97)
3	80.48 (80.26,80.65)
5	81.13 (80.96,81.32)
7	81.65 (81.45,81.85)
10	81.43 (81.28,81.75)
15	81.26 (81.01,81.43)
20	81.06 (80.87,81.30)
25	80.91 (80.73,81.10)
30	80.91 (80.72,81.05)

Table 3: Effect of single filter region size. Due to space constraints, we report results for only one dataset here, but these are generally illustrative.

We first explore the effect of filter region size when using only one region size, and we set the number of feature maps for this region size to 100 (as in the baseline configuration). We consider region sizes of 1, 3, 5, 7, 10, 15, 20, 25 and 30, and record the means and ranges over 10 replications of 10-fold CV for each. We report results in Table 3 and Fig. 2. Because we are only interested in the trend of the accuracy as we alter the region size (rather than the absolute performance on each

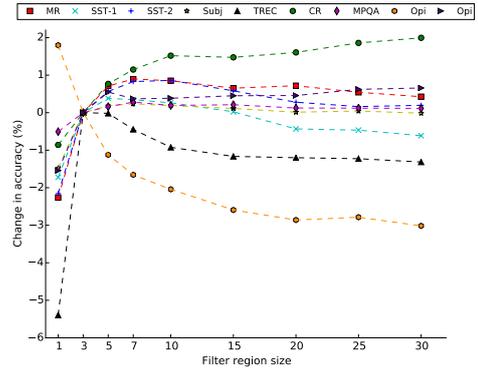

Figure 2: Effect of the region size (using only one).

task), we show only the percent change in accuracy (AUC for Irony) from an arbitrary baseline point (here, a region size of 3).

From the results, one can see that each dataset has its own optimal filter region size. Practically, this suggests performing a coarse grid search over a range of region sizes; the figure here suggests that a reasonable range for sentence classification might be from 1 to 10. However, for datasets comprising longer sentences, such as CR (maximum sentence length is 105, whereas it ranges from 36-56 on the other sentiment datasets used here), the optimal region size may be larger. We also explored the effect of combining different filter region sizes, while keeping the number of feature maps for each region size fixed at 100. We found that combining several filters with region sizes close to the optimal single region size can improve performance, but adding region sizes far from the optimal range may hurt performance. For example, when using a single filter size, one can observe that the optimal single region size for the MR dataset is 7. We therefore combined several

different filter region sizes close to this optimal range, and compared this to approaches that use region sizes outside of this range. From Table 5, one can see that using (5,6,7), and (7,8,9) and (6,7,8,9) – sets near the best single region size – produce the best results. The difference is especially pronounced when comparing to the baseline setting of (3,4,5). Note that even only using a single good filter region size (here, 7) results in better performance than combining different sizes (3,4,5). The best performing strategy is to simply use many feature maps (here, 400) all with region size equal to 7, i.e., the single best region size. However, we note that in some cases (e.g., for the TREC dataset), using multiple different, but near-optimal, region sizes performs best. We report its results in table 4.

Multiple region size	Accuracy (%)
(3)	91.21 (90.88,91.52)
(5)	91.20 (90.96,91.43)
(2,3,4)	91.48 (90.96,91.70)
(3,4,5)	91.56 (91.24,91.81)
(4,5,6)	91.48 (91.17,91.68)
(7,8,9)	90.79 (90.57,91.26)
(14,15,16)	90.23 (89.81,90.51)
(2,3,4,5)	91.57 (91.25,91.94)
(3,3,3)	91.42 (91.11,91.65)
(3,3,3,3)	91.32 (90.53,91.55)

Table 4: Effect of filter region size with several region sizes using non-static word2vec-CNN on TREC dataset

In light of these observations, we believe it advisable to first perform a coarse line-search over a single filter region size to find the ‘best’ size for the dataset under consideration, and then explore

Multiple region size	Accuracy (%)
(7)	81.65 (81.45,81.85)
(3,4,5)	81.24 (80.69, 81.56)
(4,5,6)	81.28 (81.07,81.56)
(10,11,12)	81.52 (81.27,81.87)
(11,12,13)	81.53 (81.35,81.76)
(3,4,5,6)	81.43 (81.10,81.61)
(6,7,8,9)	81.62 (81.38,81.72)
(7,7,7)	81.63 (81.33,82.08)
(7,7,7,7)	81.73 (81.33,81.94)

Table 5: Effect of filter region size with several region sizes on the MR dataset.

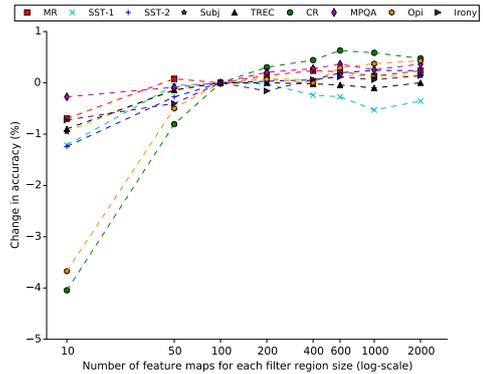

Figure 3: Effect of the number of feature maps.

the combination of several region sizes nearby this single best size, including combining both different region sizes and copies of the optimal sizes.

4.4 Effect of number of feature maps for each filter region size

We again hold other configurations constant, and thus have three filter region sizes: 3, 4 and 5. We change only the number of feature maps for each of these relative to the baseline of 100; we consider values $\in \{10, 50, 100, 200, 400, 600, 1000, 2000\}$. We report results in Fig. 3.

The ‘best’ number of feature maps for each filter region size depends on the dataset. However, it would seem that increasing the number of maps beyond 600 yields at best very marginal returns, and often hurts performance (likely due to overfitting). Another salient practical point is that it takes a longer time to train the model when the number of feature maps is increased.

In practice, the evidence here suggests perhaps searching over a range of 100 to 600. Note that this range is only provided as a possible standard trick when one is faced with a new similar sentence classification problem; it is of course possible that in some cases more than 600 feature maps will be beneficial, but the evidence here suggests expending the effort to explore this is probably not worth it. In practice, one should consider whether the best observed value falls near the border of the range searched over; if so, it is probably worth exploring beyond that border, as suggested in (Ben-gio, 2012).

4.5 Effect of activation function

We consider seven different activation functions in the convolution layer, including: ReLU (as per the baseline configuration), hyperbolic tangent (tanh),

Sigmoid function (Maas et al., 2013), SoftPlus function (Dugas et al., 2001), Cube function (Chen and Manning, 2014), and tanh cube function (Pei et al., 2015). We use ‘Iden’ to denote the identity function, which means not using any activation function.

We show the numerical results of tanh, Softplus, Iden and ReLU in table 6. For 8 out of 9 datasets, the best activation function is one of Iden, ReLU and tanh. The SoftPlus function outperform these on only one dataset (MPQA). Sigmoid, Cube, and tanh cube all consistently performed worse than alternative activation functions. The performance of the tanh function may be due to its zero centering property (compared to Sigmoid). ReLU has the merits of a non-saturating form compared to Sigmoid, and it has been observed to accelerate the convergence of SGD (Krizhevsky et al., 2012). One interesting result is that not applying any activation function (Iden) sometimes helps. This indicates that on some datasets, a linear transformation is enough to capture the correlation between the word embedding and the output label. However, if there are multiple hidden layers, Iden may be less suitable than non-linear activation functions. Practically, with respect to the choice of the activation function in one-layer CNNs, our results suggest experimenting with ReLU and tanh, and perhaps also Iden.

4.6 Effect of pooling strategy

We next investigated the effect of the pooling strategy and the pooling region size. We fixed the filter region sizes and the number of feature maps as in the baseline configuration, thus changing only the pooling strategy or pooling region size.

In the baseline configuration, we performed 1-max pooling globally over feature maps, inducing a feature vector of length 1 for each filter. However, pooling may also be performed over small equal sized local regions rather than over the entire feature map (Boureau et al., 2011). Each small local region on the feature map will generate a single number from pooling, and these numbers can be concatenated to form a feature vector for one feature map. The following step is the same as 1-max pooling: we concatenate all the feature vectors together to form a single feature vector for the classification layer. We experimented with local region sizes of 3, 10, 20, and 30, and found that 1-max pooling outperformed all local max pooling

configurations. This result held across all datasets.

We also considered a k -max pooling strategy similar to (Kalchbrenner et al., 2014), in which the maximum k values are extracted from the entire feature map, and the relative order of these values is preserved. We explored the $k \in \{5, 10, 15, 20\}$, and again found 1-max pooling fared best, consistently outperforming k -max pooling.

Next, we considered taking an average, rather than the max, over regions (Boureau et al., 2010a). We experimented with local average pooling region sizes $\{3, 10, 20, 30\}$. We found that average pooling uniformly performed (much) worse than max pooling, at least on the CR and TREC datasets.

Our analysis of pooling strategies shows that 1-max pooling consistently performs better than alternative strategies for the task of sentence classification. This may be because the location of predictive contexts does not matter, and certain n -grams in the sentence can be more predictive on their own than the entire sentence considered jointly.

4.7 Effect of regularization

Two common regularization strategies for CNNs are dropout and l_2 norm constraints; we explore the effect of these here. ‘Dropout’ is applied to the input to the penultimate layer. We experimented with varying the dropout rate from 0.0 to 0.9, fixing the l_2 norm constraint to 3, as per the baseline configuration. The results for non-static CNN are shown in in Fig. 4, with 0.5 designated as the baseline. We also report the accuracy achieved when we remove both dropout and the l_2 norm constraint (i.e., when no regularization is performed), denoted by ‘None’.

Separately, we considered the effect of the l_2 norm imposed on the weight vectors that parametrize the softmax function. Recall that the l_2 norm of a weight vector is linearly scaled to a constraint c when it exceeds this threshold, so a smaller c implies stronger regularization. (Like dropout, this strategy is applied only to the penultimate layer.) We show the relative effect of varying c on non-static CNN in Figure 5, where we have fixed the dropout rate to 0.5; 3 is the baseline here (again, arbitrarily).

From Figures 4 and 5, one can see that non-zero dropout rates can help (though very little) at some points from 0.1 to 0.5, depending on datasets. But

Dataset	tanh	Softplus	Iden	ReLU
MR	81.28 (81.07, 81.52)	80.58 (80.17, 81.12)	81.30 (81.09, 81.52)	81.16 (80.81, 83.38)
SST-1	47.02 (46.31, 47.73)	46.95 (46.43, 47.45)	46.73 (46.24, 47.18)	47.13 (46.39, 47.56)
SST-2	85.43 (85.10, 85.85)	84.61 (84.19, 84.94)	85.26 (85.11, 85.45)	85.31 (85.93, 85.66)
Subj	93.15 (92.93, 93.34)	92.43 (92.21, 92.61)	93.11 (92.92, 93.22)	93.13 (92.93, 93.23)
TREC	91.18 (90.91, 91.47)	91.05 (90.82, 91.29)	91.11 (90.82, 91.34)	91.54 (91.17, 91.84)
CR	84.28 (83.90, 85.11)	83.67 (83.16, 84.26)	84.55 (84.21, 84.69)	83.83 (83.18, 84.21)
MPQA	89.48 (89.16, 89.84)	89.62 (89.45, 89.77)	89.57 (89.31, 89.88)	89.35 (88.88, 89.58)
Opi	65.69 (65.16, 66.40)	64.77 (64.25, 65.28)	65.32 (64.78, 66.09)	65.02 (64.53, 65.45)
Irony	67.62 (67.18, 68.27)	66.20 (65.38, 67.20)	66.77 (65.90, 67.47)	66.46 (65.99, 67.17)

Table 6: Performance of different activation functions

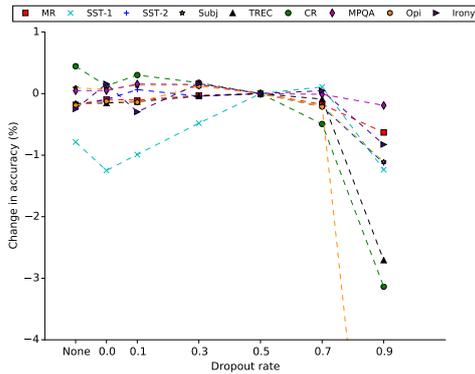

Figure 4: Effect of dropout rate. The accuracy when the dropout rate is 0.9 on the Opi dataset is about 10% worse than baseline, and thus is not visible on the figure at this point.

imposing an l_2 norm constraint generally does not improve performance much (except on Opi), and even adversely effects performance on at least one dataset (CR).

We then also explored dropout rate effect when increasing the number of feature maps. We increase the number of feature maps for each filter size from 100 to 500, and set max l_2 norm constraint as 3. The effect of dropout rate is shown in Fig. 6. We see that the effect of dropout rate is almost the same as when the number of feature maps is 100, and it does not help much. But we observe that for the dataset SST-1, dropout rate actually helps when it is 0.7. Referring to Fig. 3, we can see that when the number of feature maps is larger than 100, it hurts the performance possibly due to overfitting, so it is reasonable that in this case dropout would mitigate this effect.

We also experimented with applying dropout only to the convolution layer, but still setting the max norm constraint on the classification layer to 3, keeping all other settings exactly the same. This means we randomly set elements of the sentence matrix to 0 during training with probability p , and

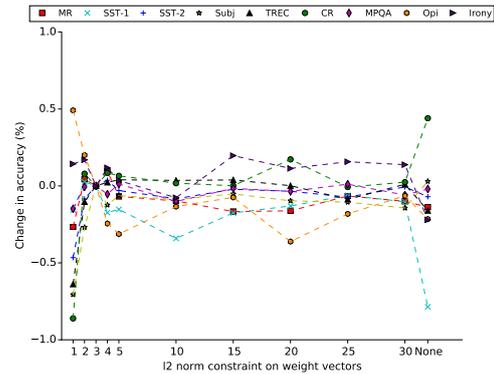

Figure 5: Effect of the l_2 norm constraint on weight vectors.

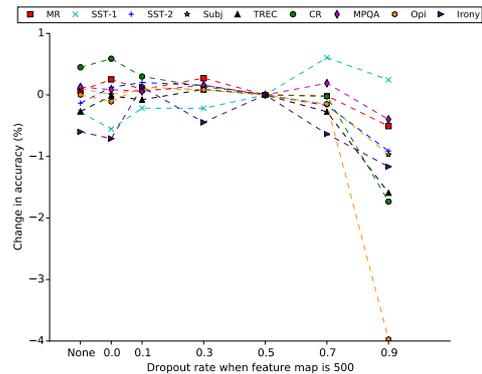

Figure 6: Effect of dropout rate when using 500 feature maps.

then multiplied p with the sentence matrix at test time. The effect of dropout rate on the convolution layer is shown in Fig. 7. Again we see that dropout on the convolution layer helps little, and large dropout rate dramatically hurts performance.

To summarize, contrary to some of the existing literature (Srivastava et al., 2014), we found that dropout had little beneficial effect on CNN performance. We attribute this observation to the fact that one-layer CNN has a smaller number parameters than multi-layer deep learning models. Another possible explanation is that using word em-

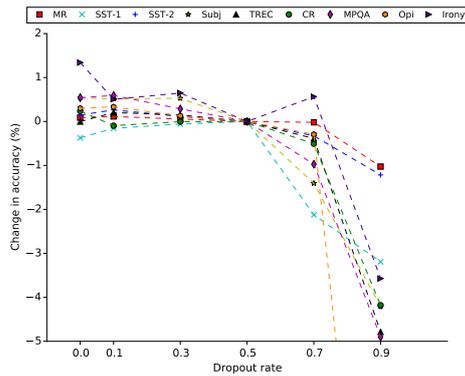

Figure 7: Effect of dropout rate on the convolution layer (The accuracy when the dropout rate is 0.9 on the Opi dataset is not visible on the figure at this point, as in Fig. 4)

beddings helps to prevent overfitting (compared to bag of words based encodings). However, we are not advocating completely foregoing regularization. Practically, we suggest setting the dropout rate to a small value (0.0-0.5) and using a relatively large max norm constraint, while increasing the number of feature maps to see whether more features might help. When further increasing the number of feature maps seems to degrade performance, it is probably worth increasing the dropout rate.

5 Conclusions

We have conducted an extensive experimental analysis of CNNs for sentence classification. We conclude here by summarizing our main findings and deriving from these practical guidance for researchers and practitioners looking to use and deploy CNNs in real-world sentence classification scenarios.

From our experimental analysis we draw several conclusions that we hope will guide future work and be useful for researchers new to using CNNs for sentence classification.

- We find that, even when tuning them to the task at hand, the choice of input word vector representation (e.g., between word2vec and GloVe) has an impact on performance, however different representations perform better for different tasks. At least for sentence classification, both seem to perform better than using one-hot vectors directly. Consider starting with the basic configuration described in Table 1 and using non-static word2vec or GloVe.

- The filter region size can have a large effect on performance, and should be tuned. Line-search over the single filter region size to find the ‘best’ single region size. A reasonable range might be 1~10. However, for datasets with very long sentences like CR, it may be worth exploring larger filter region sizes. Once this ‘best’ region size is identified, it may be worth exploring combining multiple filters using regions sizes near this single best size, given that empirically multiple ‘good’ region sizes always outperformed using only the single best region size.
- 1-max pooling uniformly outperforms other pooling strategies.
- Consider different activation functions if possible: ReLU and tanh are the best overall candidates.
- Alter the number of feature maps for each filter region size from 100 to 600, and when this is being explored, use a small dropout rate (0.0-0.5) and a large max norm constraint. Pay attention whether the best value found is near the border of the range (Bengio, 2012). If the best value is near 600, it may be worth trying larger values.
- When assessing the performance of a model (or a particular configuration thereof), it is imperative to consider variance. Therefore, replications of the cross-fold validation procedure should be performed and variances and ranges should be considered.

Of course, the above suggestions are applicable only to datasets comprising sentences with similar properties to the those considered in this work. And there may be examples that run counter to our findings here. Nonetheless, we believe these suggestions are likely to provide a reasonable starting point for researchers or practitioners looking to apply a simple one-layer CNN to real world sentence classification tasks.

We recognize that manual and grid search over hyperparameters is sub-optimal, and note that our suggestions here may also inform hyperparameter ranges to explore in random search or Bayesian optimization frameworks.

Coordination Boundary Identification with Similarity and Replaceability

Hiroki Teranishi Hiroyuki Shindo Yuji Matsumoto

Nara Institute of Science and Technology

{teranishi.hiroki.sw5, shindo, matsu}@is.naist.jp

Abstract

We propose a neural network model for coordination boundary detection. Our method relies on two common properties — similarity and replaceability in conjuncts — in order to detect both similar and dissimilar pairs of conjuncts. The model improves the identification of clause-level coordination using bidirectional recurrent neural networks incorporating two properties as features. We show that our model outperforms existing state-of-the-art methods for the coordination annotated Penn Treebank and Genia corpus without any syntactic information from parsers.

1 Introduction

Coordination is a common structure and one of major ambiguities in human languages. Although coordination gives a large amount of syntactic or semantic information of coordinated phrases, disambiguating coordination still remains one of the difficult problems that state-of-the-art parsers cannot cope with.

Given a coordinator word, how can we find conjuncts? Coordinate structures are characterized by two properties: (1) similar structures often appear in conjuncts, and (2) one conjunct can be replaced with another conjunct without losing sentence consistency in syntax or semantics. However, many previous studies of coordination disambiguation rely only on the similarities between conjuncts, despite the fact that similarities are not always helpful (Shimbo and Hara, 2007; Hara et al., 2009; Hanamoto, 2012). For example, the sentence “[at least two commercial versions have been put on the U.S. market], and [an estimated 500 have been sold].” does not have sim-

ilar phrases around the coordinating conjunction “and.” Thus, existing methods sometimes fail to capture coordination. In addition to the case where there is a lack of similarities, many similarity-based methods use handcrafted features, heuristic rules, or external resources such as thesauri.

To overcome these problems, Ficler and Goldberg (2016) proposed a neural network model with the replaceability feature as well as the similarity feature. Their model produces candidate pairs of conjuncts using probabilities assigned by the Berkeley Parser. All candidate pairs are scored on the basis of the similarity, replaceability and parser-derived features, and then the best scored pair is picked. Their approach outperforms existing constituent parsers for the Penn Treebank and similarity-based coordination disambiguation methods such as those by Shimbo and Hara (2007) and Hara et al. (2009) for the Genia treebank. Although Ficler and Goldberg’s (2016) method improves performance significantly, it heavily depends on the syntactic parser. They use the outputs from the parser not only for candidates generation and the feature for scoring, but also for computation of the similarities. The problems of propagated errors from the parser and dependencies on external resources still remain in their work.

In this work, we propose a neural network model for coordination disambiguation that does not require any external syntactic parser. Our model exploits both the similarity and replaceability properties to avoid suffering from an absence of these properties (Section 2). We use bidirectional recurrent neural networks (RNNs) to obtain the contextual information of candidate conjuncts and then compute similarity and replaceability features without syntactic information (Section 3). We show that our model performs well for both types of coordination: NP coordination (whose conjuncts tend to be similar) and S coordination

(whose conjuncts make sense individually) and outperforms the methods by Fidler and Goldberg (2016) and Hara et al. (2009) in Section 4.

The contributions of our work include the following:

- (i) Our model can capture dissimilar conjuncts as well as similar ones using the similarity and replaceability features.
- (ii) Our model performs better than others without any thesauri, feature engineering, or syntactic parsers to extract conjunct features.

2 Coordinate Structure Analysis

2.1 Task Description

Coordination is a frequently occurring syntactic structure along with several phrases, known as conjuncts. The task of coordination disambiguation is identifying the boundaries of each conjunct with a single coordinator word as one coordinate structure instance. Given a coordinator word (e.g., “and,” “or,” or “but”), a system must return each conjunct span if the word actually plays the role of a coordinator; otherwise, NONE is output for the absence of coordination. The task sounds simple, yet is difficult because two complex phenomena appear in coordination.

1. A coordinator does not always connect two conjuncts. Sometimes, a coordinate structure consists of three or more consecutive conjuncts. For example¹,

“It was not an unpleasant evening, certainly, thanks to [the high level of performance], [the compositional talents of Mr. Douglas], and₂₅ [the obvious sincerity with which Mr. Stoltzman chooses his selection].”

2. Two or more coordinate structures can be found in the same sentence. In addition, one coordinate structure can be nested inside another. For example,

“Aside from [the Soviet economic plight] and₇ [talks on cutting (strategic) and₁₂ (chemical) arms], one other issue the Soviets are likely to want to raise is naval force reduction.”

¹We write coordinator words with their position in a sentence in the form of *word_{position}* to distinguish them.

Input Sentence:

But₁ it said Charles Johnston, ISI chairman and₉ president, agreed to sell his 60% stake in ISI to Memotec upon completion of the tender offer for a combination of cash, Memotec stock and₃₇ debentures.

Expected Output:

[Original Task]
 but₁: NONE
 and₉: (8, 8) chairman ; (10, 10) president
 and₃₇: (33, 33) cash ; (35, 36) Memotec stock ; (38, 38) debentures

[Our Subtask]:
 but₁: NONE
 and₉: (8, 10) chairman and president
 and₃₇: (33, 38) cash, Memotec stock and debentures

Figure 1: The coordination identification task and our subtask.

In this work, we solve this task by focusing on identifying the beginning and end of an entire coordinate structure. Figure 1 shows our task. We attempt to identify two conjuncts to the left and right sides of a conjunction. We call these conjuncts the *preconjunct* and *post-conjunct*, respectively². In addition, we assume that the end of the preconjunct and the beginning of the post-conjunct adjoin a coordinator word; thus it appears that we work on the subtask of coordinate structure span identification. After identifying a coordination span, we recover individual conjuncts within the span.

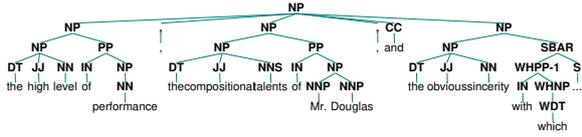

2.2 Conjunct Properties

Coordination has many unique traits other than its structure. We focus on the key properties between conjuncts that can be helpful to disambiguate a coordination boundary.

- (a) **Similarity:** Conjuncts in a coordination have a similar structure or meaning.
- (b) **Replaceability:** A conjunct can be replaced with another conjunct in the same coordination.

Conjuncts tend to have similar semantic or syntactic constituents. For example, the three conjuncts “*the high level of performance,*” “*the compositional talents of MR. Douglas,*” and “*the obvious sincerity with which Mr. Stoltzman chooses his selection*” have part-of-speech (POS) tag sequences starting with “*DT JJ NN(S) IN NN(P)*”

²If two or more conjuncts appear before a conjunction, we regard them as one conjunct.

(a) Similar structures between conjuncts

1. Aside from [the Soviet economic plight], one other ...
2. Aside from [talks on cutting (strategic) arms], one other ...
3. Aside from [talks on cutting (chemical) arms], one other ...

(b) Replaceability

Figure 2: Characteristic of conjuncts

...” in common. At a phrase level, they all are categorized as NP and have identical tree structures (Figure 2 (a)). Many previous works exploit this characteristic to detect conjuncts (Shimbo and Hara, 2007; Hara et al., 2009).

The replaceability of conjuncts is also often observed. A sentence is still consistent even if one conjunct is replaced with another. For example, the coordination “Aside from [the Soviet economic plight] and [talks on cutting (strategic) and (chemical) arms]” can be transformed into “Aside from [talks on cutting (chemical) and (strategic) arms] and [the Soviet economic plight]” by exchanging conjuncts. Using this property, we can expand a coordinate structure as one sentence by one conjunct (Figure 2 (b)). Replaceability has recently been used to capture conjuncts (Ficler and Goldberg, 2016).

The two properties described above are essential clues to identify conjunct spans; however, they are not always available. Coordination sometimes has different types of conjuncts or an ellipsis in conjuncts. For similarity, when conjuncts belong to the S type or are different types of syntactic categories, their semantic and syntactic structures can be apart from each other (e.g., “[We turned the trading system on]s, and [it did whatever it was programmed to do]s.” ; “Bill is [in trouble]pp and [trying to come up with an excuse]vp.”). For replaceability, when words are omitted in a latter conjunct, we cannot replace one conjunct with another unless we supplement omitted words (e.g., “[Honeywell’s contract totaled \$69.7 million], and [IBM’s \$68.8 million].”). To cope with the case where there is a lack of similarity or replaceability, our proposed method incorporates both features.

3 Proposed Method

Our proposed model calculates the scores of all possible preconjunct and post-conjunct pairs. Given a sentence $x = \{x_1, x_2, x_3, \dots, x_N\}$ and coordinator word x_k , the preconjunct and post-conjunct can be written as $s_1 = \{x_i, \dots, x_{k-1}\}$ ($1 \leq i \leq k-1$) and $s_2 = \{x_{k+1}, \dots, x_j\}$ ($k+1 \leq j \leq N$), respectively. As we mentioned in Section 2, we fix the end of the preconjunct at $k-1$ and the beginning of the post-conjunct at $k+1$. Thus, our model learns and predicts a set of spans (i, j) , which indicate the two positions of the beginning and end of a coordination. We identify preconjuncts and post-conjuncts by picking the highest scoring pairs as predicted conjunct spans.

Figure 3 shows an overview of our neural network architecture. This model consists of four components.

Input Layer: Map a sequence of one-hot words and POS tags onto their representations from embeddings.

RNN Layer: Produce a sequence of sentence-level representations based on contexts using a bidirectional RNN.

Feature Extractor: Generate the conjunct phrase representations and feature vectors of possible pairs of conjuncts.

Output Layer: Calculate the scores of pairs of conjuncts using MLP.

In the following subsections, we describe these components in detail.

3.1 Input Layer

The first step of our neural network model is to represent a sequence of words and POS tags in distributed vectors, known as embeddings (Bengio et al., 2003). Our model receives a sequence of one-hot encoded words and POS tags $\{x_n^{word}\}_{n=1}^N$, $\{x_n^{tag}\}_{n=1}^N$ and then looks them up in the matrices $E^{word} \in \mathbb{R}^{d_{word} \times |v_{word}|}$, $E^{tag} \in \mathbb{R}^{d_{tag} \times |v_{tag}|}$, resulting in a sequence of real-valued vectors $\mathbf{h}_n^{word} \in \mathbb{R}^d$, $\mathbf{h}_n^{tag} \in \mathbb{R}^d$, respectively. These real-valued vectors are concatenated as the input of the

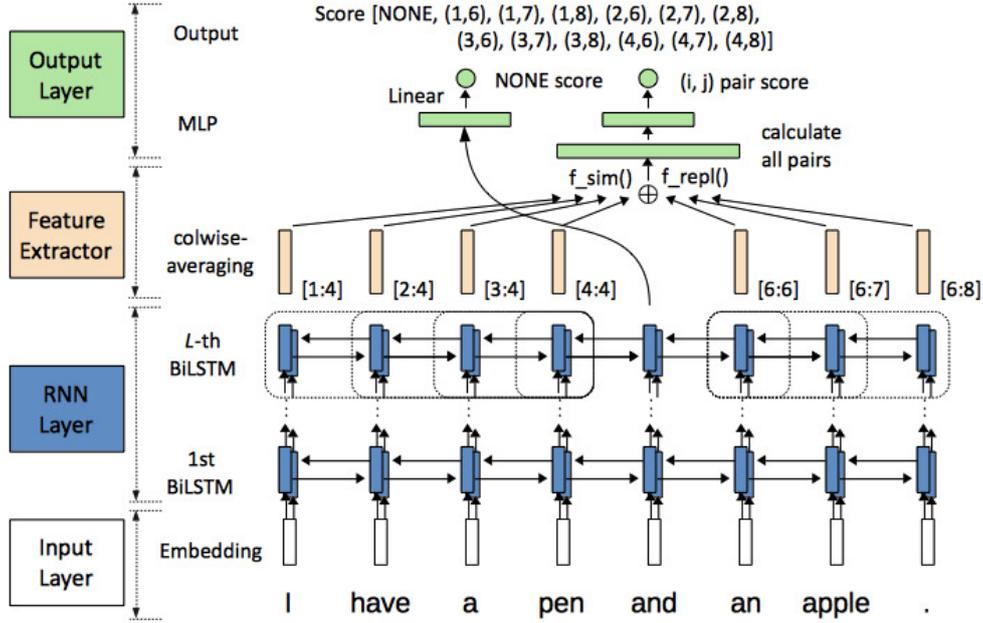

Figure 3: Overview of the architecture for coordination analysis.

next layer.

$$\begin{aligned}
 \mathbf{h}_t^{word} &= W^{word} x_t^{word} \\
 \mathbf{h}_t^{tag} &= W^{tag} x_t^{tag} \\
 \mathbf{h}_t^{(0)} &= [\mathbf{h}_t^{word}, \mathbf{h}_t^{tag}] \\
 \mathbf{h}^{(0)} &= \{\mathbf{h}_1^{(0)}, \dots, \mathbf{h}_N^{(0)}\}
 \end{aligned} \tag{1}$$

3.2 RNN Layer

A sequence of distributed vectors is transformed into hidden state vectors using stacked bidirectional RNNs. Bidirectional RNNs process a time series of inputs from the past to a future direction and from the future to a past direction. We can make use of left-to-right (forward) and right-to-left (backward) contexts using these networks. The output of the ℓ -th layer of stacked bidirectional RNNs at a time step t in the forward direction, which is denoted as $\mathbf{h}_{\ell,t}^f$, is computed as

$$\mathbf{h}_{\ell,t}^f = f(\mathbf{h}_{\ell,t-1}^f, \mathbf{h}_{\ell-1,t}) \tag{2}$$

where $\mathbf{h}_{\ell,t-1}^f$ is the hidden state vector of the same layer at the previous time step $t-1$ in the same direction and $\mathbf{h}_{\ell-1,t}$ is the hidden state vector of the previous bidirectional layer at the same time step t . The hidden vector of the ℓ -th layer of stacked bidirectional RNNs at a time step t in the backward direction is also computed in the same way. The stacked bidirectional RNNs that we use in this work output hidden state vectors by concatenating

the vectors $\{\mathbf{h}_{\ell,t}^f\}_{t=1}^T$ from the forward direction and $\{\mathbf{h}_{\ell,t}^b\}_{t=1}^T$ from the backward direction at each time step t in every layer.

In general, an RNN has a function $f(\cdot)$ expressed as

$$f(\mathbf{x}_t, \mathbf{h}_{t-1}) = g(W\mathbf{x}_t + U\mathbf{h}_{t-1})$$

where $g(\cdot)$ is an arbitrary nonlinear function such as the hyperbolic tangent $\tanh(\cdot)$ or rectified linear unit (ReLU). We use the long short term memory (LSTM) (Hochreiter and Schmidhuber, 1997) as the function $f(\cdot)$ to prevent backpropagated errors from vanishing or exploding, which arise in RNNs (Pascanu et al., 2013).

3.3 Feature Extractor

This component produces a feature vector based on a representation of a preconjunct and postconjunct and a series of vectors $\{\mathbf{h}_t\}_{t=1}^T$ from bidirectional RNNs. We compute the preconjunct representation \mathbf{v}_i^{pre} and postconjunct \mathbf{v}_j^{post} using the function $g(\cdot)$. In this work, we define element-wise averaging as the function $g(\cdot)$.

$$g(\mathbf{h}_{l:m}) = \text{average}(\mathbf{h}_l, \mathbf{h}_{l+1}, \dots, \mathbf{h}_{m-1}, \mathbf{h}_m) \tag{3}$$

Thus, \mathbf{v}_i^{pre} and \mathbf{v}_j^{post} are expressed as

$$\begin{aligned}
 \mathbf{v}_i^{pre} &= g(\mathbf{h}_{i:k-1}) \quad (1 \leq i \leq k-1) \\
 \mathbf{v}_j^{post} &= g(\mathbf{h}_{k+1:j}) \quad (k+1 \leq j \leq N)
 \end{aligned} \tag{4}$$

Then \mathbf{v}_i^{pre} and \mathbf{v}_j^{post} are fed into the following two feature extraction functions.

Similarity feature vector

In order to capture the similarity between the pre-conjunct and the post-conjunct, the feature vector is computed as follows:

$$f_{sim}(\mathbf{v}_i^{pre}, \mathbf{v}_j^{post}) = [|\mathbf{v}_i^{pre} - \mathbf{v}_j^{post}|; \mathbf{v}_i^{pre} \odot \mathbf{v}_j^{post}] \quad (5)$$

where $|\mathbf{v}_i^{pre} - \mathbf{v}_j^{post}|$ is the absolute value of element-wise subtraction, and $\mathbf{v}_i^{pre} \odot \mathbf{v}_j^{post}$ is element-wise multiplication. These subtraction and multiplication operations are intended to model the semantic distance and relatedness (Ji and Eisenstein, 2013; Tai et al., 2015; Hashimoto et al., 2016).

Replaceability feature vector

We define a feature vector based on the conjunct replaceability as follows.

$$f_{repl}(\mathbf{h}_{1:N}, i, j, k) = [|\mathbf{h}_{i-1} \odot \mathbf{h}_i - \mathbf{h}_{i-1} \odot \mathbf{h}_{k+1}|; |\mathbf{h}_j \odot \mathbf{h}_{j+1} - \mathbf{h}_{k-1} \odot \mathbf{h}_{j+1}|] \quad (6)$$

where \mathbf{h}_{i-1} is the context vector that is linked to the heads of conjuncts and \mathbf{h}_{j+1} is the context vector that is linked to the tails of conjuncts. The first subtraction $|\mathbf{h}_{i-1} \odot \mathbf{h}_i - \mathbf{h}_{i-1} \odot \mathbf{h}_{k+1}|$ is the difference between two context-conjunct connections at the beginning of coordination. The second subtraction $|\mathbf{h}_j \odot \mathbf{h}_{j+1} - \mathbf{h}_{k-1} \odot \mathbf{h}_{j+1}|$ is the difference between two context-conjunct connections at the end of coordination. These distance measures can be interpreted as difficulty in replacing conjuncts. Note that the function $f_{repl}(\mathbf{h}_{1:N}, i, j, k)$ returns a zero vector when $i = 0$ or $j = N$.

3.4 Output Layer

This layer computes the scores of pairs of conjuncts based on the similarity feature vectors and the replaceability feature vectors. The network is a multilayered perceptron (MLP) that consists of multiple layers of computational units interconnected in a feed-forward way. The score of a pre-conjunct $(i, k - 1)$ and post-conjunct $(k + 1, j)$ candidate pair is calculated as

$$\text{Score}(i, j) = \text{MLP}([f_{sim}(\mathbf{v}_i^{pre}, \mathbf{v}_j^{post}); f_{repl}(\mathbf{h}_{1:N}, i, j, k)]) \quad (7)$$

To cope with the absence of coordination against a coordinator, we also calculate the score for a candidate of NONE. The score NONE is simply computed as the product of a weight vector and the sentence-level representation of the coordinator from the RNN layer.

$$\text{Score}(\text{NONE}) = w \cdot \mathbf{h}_k + b \quad (8)$$

Using these scoring functions, we assign scores to all possible pairs of conjuncts. Thus, when the length of a sentence is N and a coordinator appears as the k -th word, we obtain $(k - 1) \times (N - k) + 1$ candidates and choose the pair with the best score as the predicted conjuncts with the softmax function.

$$\begin{aligned} \mathbf{s} &= [\text{Score}(\text{NONE}); \text{Score}(1, k + 1); \dots; \\ &\quad \text{Score}(1, N); \dots; \text{Score}(k - 1, N)] \\ \hat{p}_\theta(y|x) &= \text{softmax}(\mathbf{s}) \\ \hat{y} &= \arg \max_y (\hat{p}_\theta(y|x)) \end{aligned} \quad (9)$$

3.5 Learning

The loss function is the negative log-likelihood of the true pair of conjuncts $y^{(k)}$:

$$J(\theta) = - \sum_{d=1}^D \log \hat{p}_\theta(y^{(d)} | x^{(d)}) + \frac{\lambda}{2} \|\theta\|^2 \quad (10)$$

where D is the number of occurrences of coordinator words in a training dataset, θ is a set of model parameters, and the hyperparameter λ adjusts the regularization strength. The model parameters are optimized by minimizing the loss using the stochastic gradient descent (SGD).

4 Experiments

We evaluate our proposed model using the coordination annotated Penn Treebank (Ficler, 2016) and the Genia treebank beta (Kim et al., 2003). We present the number of occurrences of coordinator words and the number of sentences with coordination in Table 1³.

³We consider “and,” “or,” “but,” “nor,” and “and/or” in the PTB and “and,” “or,” and “but” in the Genia as coordinator words following Ficler and Goldberg (2016) and Hara et al. (2009).

	# Coordinators	# Sentences
Penn Treebank	27903 (24450)	21314 (19095)
Training	22670 (17893)	17282 (13932)
Development	953 (848)	742 (673)
Testing	1282 (1099)	985 (873)
Genia	3598 (3598)	2508 (2508)

Table 1: The number of coordinators in the datasets. (#count) indicates the number of actual presences of coordination.

4.1 Evaluation Using the Penn Treebank

4.1.1 Experimental Setup

We use the coordination annotated Penn Treebank and divide it into wsj 2-21 as the training set, wsj 22 as the development set, and wsj 23 as the testing set. We use pretrained 200-dimensional word embeddings from the New York Times section in English Gigaword (fifth edition) (Parker et al., 2011) using Word2Vec⁴ with its default parameter. For the POS tags, we use 10-way jackknifing using the Stanford POS Tagger (Toutanova et al., 2003) and initialize the 50-dimensional embeddings with the uniform distribution within $[-1, 1]$. We use three-layer bidirectional LSTMs as an RNN layer. The dimensionality of the LSTM hidden vectors in each direction is selected from $\{400, 600\}$. Our MLP consists of one hidden layer with ReLU activation, and an output layer. The number of the hidden layer units is selected from $\{1200, 2400\}$. The model parameters are optimized by the mini-batched SGD with a batch size of 20. The learning rate is automatically tuned by Adam (Kingma and Ba, 2014). When training, we apply dropout (Srivastava et al., 2014) to the embeddings, input vectors of each LSTM in bidirectional LSTMs (except the first layer), and the hidden layer of the MLP. Dropout ratio is selected from $\{0.33, 0.50\}$. We choose the regularization strength λ from $\{0.0001, 0.0005, 0.001\}$. We train our model for 50 iterations and choose the model that achieves the best F1 score⁵ on the development set and evaluate it with the testing set. We present the final hyperparameters choice in Table 2.

4.1.2 Evaluation Metrics

We evaluate our model on the basis of the ability to predict the beginning and end of each co-

⁴<https://code.google.com/archive/p/word2vec/>

⁵This F1 score is measured for the *whole* criterion, which is mentioned later.

Parameter	Value
Dimension of the LSTM hidden vector	600
MLP units in the hidden layer	2400
Dropout ratio (all)	0.50
Regularization term λ	0.0001

Table 2: The final hyperparameters in the experiment for the Penn Treebank.

ordination (*whole*) with the precision, recall, and F1 measures. In another setup, we focus on NP coordination⁶. To compare the performance with Ficler and Goldberg (2016), we also evaluate our model with two conjunct spans that are adjacent to the coordinator (*inner*), the first and last conjuncts (*outer*), and all complete conjuncts (*exact*). Furthermore, in order to investigate the effectiveness of our proposed features, we perform the experiment with a simple baseline model that uses two averaged vectors as features (Eq. 3) and feeds them into the MLP instead of the similarity and replaceability features (Eq. 7).

Note that our proposed model learns and predicts the coordinate structure boundaries and not each conjunct; thus, when evaluating the inner, outer, and exact metrics, we simply divide the pre-conjuncts into subconjuncts using the character “,” as the divider.

4.1.3 Results

We present the results in Table 3. For all metrics, the recall values are low compared with the precision values. Our model is likely to produce NONE for some coordinators by mistake. The proposed model suffers from a worse outer metric than the inner metric. Intuitively, this is because the pre-conjunct for the inner prediction is placed next to a coordinator and it is easier to identify its span, while outer conjuncts occur apart from the coordinators.

Table 4 summarizes the performance of different uses of features. The similarity and replaceability features work better than the baseline independently. However, the joint model performs the best by exploiting both features.

Table 5 presents a comparison with existing methods. For all coordination, our proposed method outperforms the state-of-the-art models with a test set F1 score of 72.81 (0.11 better than

⁶We consider that NP and NX are NP coordination as in Ficler and Goldberg (2016).

	All			NP		
	P	R	F	P	R	F
whole	75.92	72.87	74.36	77.90	75.05	76.45
outer	72.48	69.57	70.99	76.24	73.45	74.82

the previously reported result). For NP coordination, our model achieves competitive results, despite the rough extraction of conjuncts from pre-conjuncts, even for inner-conjunct prediction.

4.2 Evaluation Using Genia

4.2.1 Experimental Setup

We also evaluate our model with the Genia treebank beta to compare with the previous work of Hara et al. (2009) and Ficler and Goldberg (2016). The settings of this experiment are based on those presented in Section 4.1.1, except for the following hyperparameters: Word embeddings are initialized by the pretrained 200-dimensional representation that BioASQ (Tsatsaronis et al., 2012) provides. These embeddings are trained from biomedical abstracts by using Word2Vec. We use gold POS as in Hara et al. (2009), and the dimension of the POS embeddings is 50. For regularization, we set $\lambda = 0.0005$ and train our model for 20 iterations.

4.2.2 Evaluation Metrics

As in Hara et al. (2009), we measure the recall values of coordinate structure boundary prediction, disregarding individual conjunct spans⁷. Thus, we do not decode conjuncts because our model can be compared directly. Coordination phrases in the

⁷In the Genia corpus, all coordinator words are associated with conjuncts; thus, there is no absence of coordination, as described in Table 1.

	Dev			Test		
	P	R	F	P	R	F
	All Coordination					
Berkeley	70.14	70.72	70.42	68.52	69.33	68.92
Zpar	72.21	72.72	72.46	68.24	69.42	68.82
Ficler16	72.34	72.25	72.29	72.81	72.61	72.7
Ours	74.07	71.10	72.56	73.46	72.16	72.81
	NP Coordination					
Berkeley	67.53	70.93	69.18	69.51	72.61	71.02
Zpar	69.14	72.31	70.68	69.81	72.92	71.33
Ficler16	75.17	74.82	74.99	76.91	75.31	76.1
Ours	77.43	74.59	75.99	75.87	74.76	75.31

Table 5: Performance of inner-conjunct prediction on all coordination and on NP coordination for the PTB. The results for the three methods other than our method are reported in Ficler16 : (Ficler and Goldberg, 2016).

COOD	#	Ours	Ficler16	Hara09
Overall	3598	65.98	64.14	61.5
NP	2317	66.59	65.08	64.2
VP	465	63.87	71.82	54.2

ADVP	21	85.71	80.95	85.7
Others	3	33.33	33.33	66.7

Table 6: Recall with Genia treebank beta. The numbers in the columns “Ficler16” and “Hara09” are taken from their papers; Ficler16 : (Ficler and Goldberg, 2016) ; Hara09 : (Hara et al., 2009).

Genia treebank are explicitly annotated with a special label (COOD). Making use of this label, we also measure the performance for each type of coordination, as reported in previous work. We evaluate our model by five-fold cross-validation, as in Hara et al. (2009).

4.2.3 Results

We present the results in Table 6. For all coordination, our model outperforms the scores reported by Hara et al. (2009) and Ficler and Goldberg (2016). In the evaluation of each type, our method greatly improves the performance for VP, SBAR, and especially the S type of coordination compared with the similarity-based method of Hara et al. (2009). Regarding the S type, our results are considerably better than those of Ficler and Goldberg (2016). As presented in Table 4, our proposed replaceability feature significantly contributes to the detection of this type of coordination, where only the similarity feature does not work because of a collapse

of similarity between conjuncts. The results for NP coordination, which accounts for nearly 65% of all coordination, are fairly good for the Genia corpus; however, the model proposed by [Ficler and Goldberg \(2016\)](#) exhibits better performance than ours for the PTB for the inner metric.

5 Related Works

Approaches using the similarity property between conjuncts have been developed in previous works. Regarding the task of coordination identification in Japanese, [Kurohashi and Nagao \(1994\)](#) used a chart to compute the similarity between conjuncts and identify conjunct spans with a dynamic programming technique. [Shimbo and Hara \(2007\)](#) proposed a sequence alignment model with dynamic programming to capture locally similar structures in two conjuncts on the basis of the set of features including word surfaces, POS tags, and morphological characteristics. The similarity score in their work is computed by a weighted linear combination (perceptron) of manually designed features assigned to edges and nodes in graphs, while the score in the work of [Kurohashi and Nagao \(1994\)](#) is calculated from a score function that uses some rules based on the observation of coordination. Although the method of [Shimbo and Hara \(2007\)](#) could not handle nested coordinate structures, [Hara et al. \(2009\)](#) extended their work to cope with nested coordination as well as three or more than consecutive conjuncts. Their proposed method defined several production rules to build consistent coordination trees with discriminative functions based on the similarity score. [Hanamoto \(2012\)](#) used dual decomposition to combine an HPSG parser with the model of [Hara et al. \(2009\)](#).

The method of use of the replaceability property has recently been adopted by [Ficler and Goldberg \(2016\)](#). They incorporated the replaceability property between conjuncts into the feature representations, as well as the similarity property. They made use of these properties to assign scores to candidate pairs of conjuncts. Their method consists of three components: a binary classifier to detect the presence of coordination, the parser extended from the Berkeley Parser ([Petrov et al., 2006](#)) to generate candidate pairs, and a discriminative neural network to identify conjuncts. As similarity features, they compute the Euclidean distance between the two representations of con-

juncts, which are computed from syntactic trees generated by the parser, and this is more efficient with respect to the time complexity compared with the methods with graphs. The replaceability feature vectors are produced from bidirectional LSTMs by processing two sentences that are produced by leaving out one of two conjuncts. Their model then scores all candidate pairs of conjuncts from feature vectors including similarities, replaceabilities, and additional three values derived from the probabilities assigned by the parser. The best scored pair is selected as the most probable conjuncts. For the Genia corpus, their model outperformed the method of [Hara et al. \(2009\)](#) which only relied on the similarity property. Using neural networks, they overcame the problems of manually elaborated features and of access to external sources such as thesauri. However, their method heavily depends on their extension of the Berkeley Parser. Therefore, the problem of error propagation between components and the parser still remains.

[Kawahara and Kurohashi \(2008\)](#) tried to resolve coordination disambiguation without any similarities on the basis of the dependency relations and generative probabilities of phrases including conjuncts. [Yoshimoto et al. \(2015\)](#) extended the graph-based dependency parsing algorithm to handle coordinations.

6 Conclusions

We propose a neural network model to disambiguate coordinate structure boundaries. Our method relies on two properties: (i) conjuncts tend to have a similar structure in syntax or semantics and (ii) conjuncts can be replaced with each other, maintaining sentence consistency. On the basis of these observations, we compute two feature vectors from a sequence of vectors produced by bidirectional RNNs. Our model can capture the connections between conjuncts and other parts of sentences and sentence-level coordination. As a result, our model outperforms existing methods and achieves state-of-the-art performance. The biggest contribution of our work is resolving dependency on information from syntactic parsers.

We plan to improve our model to handle three or more conjuncts in future work. In addition, since our method treats nested coordinate structures individually, we expect to create constraints to build non-overlapping coordination spans.

Turning Distributional Thesauri into Word Vectors for Synonym Extraction and Expansion

Olivier Ferret

CEA, LIST, Vision and Content Engineering Laboratory,
Gif-sur-Yvette, F-91191 France.
olivier.ferret@cea.fr

Abstract

In this article, we propose to investigate a new problem consisting in turning a distributional thesaurus into dense word vectors. We propose more precisely a method for performing such task by associating graph embedding and distributed representation adaptation. We have applied and evaluated it for English nouns at a large scale about its ability to retrieve synonyms. In this context, we have also illustrated the interest of the developed method for three different tasks: the improvement of already existing word embeddings, the fusion of heterogeneous representations and the expansion of synsets.

1 Introduction

Early work about distributional semantics (Grefenstette, 1994; Lin, 1998; Curran and Moens, 2002) was strongly focused on the notion of distributional thesaurus. Recent work in this domain has been more concerned by the notions of semantic similarity and relatedness (Budanitsky and Hirst, 2006) and by the representation of distributional data. This trend has been strengthened even more recently with all work about distributed word representations and embeddings, whether they are built by neural networks (Mikolov et al., 2013) or not (Pennington et al., 2014).

From a more global perspective, distributional thesauri and distributional data, *i.e.* distributional contexts of words, can be considered as dual representations of the same semantic similarity information. Distributional data are an intensional form of this information that can take an extensional form as distributional thesauri by applying a similarity measure to them. Going from an intensional to an extensional representation corresponds to the

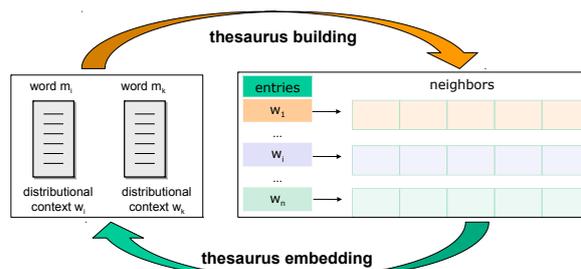

Figure 1: Duality of semantic information

rather classical process underlying the building of distributional thesauri. In the context of word embeddings, Perozzi et al. (2014a) extend this process to the building of lexical networks.

Going to the other way, from an extensional to an intensional representation, is, as far as we know, a new problem in the context of distributional semantics. The interest of this transformation is twofold. First, whatever the initial form of the semantic knowledge, it can be turned into the most suitable form for a particular use. For instance, thesauri are more suitable for tasks like query expansion while word embeddings are more adapted as features for statistical classifiers. Second, each form is also associated with specific methods of improvement. A lot of work has been done for improving distributional contexts by studying various parameters, which has led to an important improvement of distributional thesauri. Conversely, work such as (Claveau et al., 2014) has focused on methods for improving thesauri themselves. It would clearly be interesting to transpose the improvements obtained in such a way to distributional contexts, as illustrated by Figure 1.

Hence, we propose in this article to investigate the problem of turning a distributional thesaurus into word embeddings, that is to say embedding a thesaurus. We will show that such process can

be achieved without losing too much information and moreover, that its underlying principles can be used for improving already existing word embeddings. Finally, we will illustrate the interest of such process for building word embeddings integrating external knowledge more efficiently and extending this knowledge.

2 Embedding Distributional Thesauri

A distributional thesaurus is generally viewed as a set of entries with, for each entry, a list of semantic neighbors ranked in descending order of semantic similarity with this entry. Since the neighbors of an entry are also entries of the thesaurus, such thesaurus can be considered as a graph in which vertices are words and edges are the semantic neighborhood relations between them, weighted according to their semantic similarity. The resulting graph is undirected if the semantic similarity measure between words is symmetric, which is the most common case. Such representation was already adopted for improving distributional thesauri by reranking the neighbors of their entries (Claveau et al., 2014) for instance.

One specificity of distributional thesauri from that perspective is that although the weight between two words is representative of their semantic similarity, we know from work such as (Ferret, 2010; Claveau et al., 2014) that the relevance of the semantic neighbors based on this weight strongly decreases as the rank of the neighbors increases. Consequently, our strategy for embedding distributional thesauri is two-fold: first, we build an embedding by relying on methods for embedding graphs, either by exploiting directly their structure or from their representation as matrices; second, we adapt the embedding resulting from the first step according to the specificities of distributional thesauri. We detail these two steps in the next two sections.

2.1 Graph Embedding

The problem of embedding graphs in the perspective of dimension reduction is not new and was already tackled by much work (Yan et al., 2007), going from spectral methods (Belkin and Niyogi, 2001) to more recently neural methods (Perozzi et al., 2014b; Cao et al., 2016). As graphs can be represented by their adjacency matrix, this problem is also strongly linked to the matrix factorization problem. The basic strategy is to perform the

eigendecomposition of the matrix as for instance in the case of Latent Semantic Analysis (LSA) (Landauer and Dumais, 1997). However, such decomposition is computationally expensive and for large matrices, as in the context of Collaborative Filtering (Koren, 2008), less constrained matrix factorization techniques are used.

For turning a distributional thesaurus into word embeddings, we tested three different methods:

- the LINE algorithm (Tang et al., 2015), a recent method for embedding weighted graphs;
- the application of Singular Value Decomposition (SVD) to the adjacency matrix of the thesaurus;
- the matrix factorization approach proposed by Hu et al. (2008), also applied to the adjacency matrix of the thesaurus.

LINE defines a probabilistic model over the space $V \times V$, with V , the set of vertices of the considered graph. This probabilistic model is based on the representation of each vertex as a low-dimensional vector. This vector results from the minimization of an objective function based on the Kullback-Leibler divergence between the probabilistic model and the empirical distribution of the considered graph. This minimization is performed by the Stochastic Gradient Descent (SGD) method. Tang et al. (2015) propose more precisely two probabilistic models: one is based on the direct relation between two vertices while the second defines the proximity of two vertices according to the number of neighbors they share. We adopted the second model, which globally gives better results on several benchmarks.

In our second option, SVD factorizes T , the adjacency matrix of the thesaurus to embed, into the product $U \cdot \Sigma \cdot V^T$. U and V are orthonormal and Σ is a diagonal matrix of eigenvalues. We classically adopted the truncated version of SVD by keeping only the first d elements of Σ , which finally leads to $T_d = U_d \cdot \Sigma_d \cdot V_d^T$. Levy et al. (2015) investigated in the context of word co-occurrence matrices the best option for the low-dimensional representation of words as the usual setting was $U_d \cdot \Sigma_d$ while Caron (2001) suggested that $U_d \cdot \Sigma_d^P$ with $P < 1$ would be a better option. They found that $P = 0$ or $P = 0.5$ are clearly better than $P = 1$, with a slight superiority for $P = 0$. Similarly, we found $P = 0$ to be the best option.

Our last choice is based on a less constrained form of matrix factorization where T is decom-

posed into two matrices in such a way that $U \cdot V = \hat{T} \approx T$, with $T \in \mathbb{R}^{m \cdot n}$, $U \in \mathbb{R}^{m \cdot d}$, $V \in \mathbb{R}^{d \cdot n}$ and $d \ll m, n$. U and V are obtained by minimizing the following expression:

$$\sum_{i,j} (t_{ij} - u_i^\top v_j)^2 + \lambda (\|u_i\|^2 + \|v_j\|^2) \quad (1)$$

where the first term minimizes the reconstruction error of T by the product $U \cdot V$ while the second term is a regularization term, controlled by the parameter λ for avoiding overfitting. We used U as embedding of the initial thesaurus. (Hu et al., 2008) is a slight variation of this approach where t_{ij} is turned into a confidence score and the minimization of equation 1 is performed by the Alternating Least Squares method. One of the interests of this matrix factorization approach is its ability to deal with undefined values, which implements an implicit feedback in the context of recommender systems and can deal in our context with the fact that the input graph is generally sparse and does not include the furthest semantic neighbors of an entry.

2.2 From Graph to Thesaurus Embeddings

As mentioned previously, all the graph embedding methods of the previous section exploit the semantic similarity between words but for an entry, this similarity is not linearly correlated with the rank of its relevant neighbors in the thesaurus. In other words, the relevance of the semantic neighbors of an entry strongly decreases as their rank increases and the first neighbors are particularly important.

For taking into account this observation, we have adopted a strategy consisting in using the first neighbors of each entry of the initial thesaurus as constraints for adapting the embeddings built from this thesaurus by the graph embedding methods we consider. Such adaptation has already been tackled by some work in the context of the injection of external knowledge made of semantic relations into embeddings built mainly by neural methods such as the Skip-Gram model (Mikolov et al., 2013). Methods for performing such injection can roughly be divided into two categories: those operating during the building of the embeddings, generally by modifying the objective function supporting this building (Yih et al., 2012; Zhang et al., 2014), and those applied after the building of the embeddings (Yu and Dredze, 2014; Xu et al., 2014). We have more particularly used or adapted two methods from the second category

and transposed one method from the first category for implementing our endogenous strategy.

The first method we have considered is the *retrofitting* method from Faruqui et al. (2015). This method performs the adaptation of a set of word vectors q_i by minimizing the following objective function through a label propagation algorithm (Bengio et al., 2006):

$$\sum_{i=1}^n \left[\|q_i - \hat{q}_i\|^2 + \sum_{(i,j) \in E} \|q_i - q_j\|^2 \right] \quad (2)$$

where \hat{q}_i are the q_i vectors after their adaptation. The first term is a stability term ensuring that the adapted vectors do not diverge too much from the initial vectors while the second term represents an adaptation term, tending to bring closer the vectors associated with words that are part of a relation from an external knowledge source E . In our case, this knowledge corresponds to the relations between each entry of the initial thesaurus and its first neighbors.

The second method, *counter-fitting* (Mrkšić et al., 2016), is close to *retrofitting* and mainly differentiates from it by adding to the objective function a repelling term for pushing vectors corresponding to antonymous words away from each other. However, a distributional thesaurus does not contain identified antonymous words¹. Hence, we discarded this term and used the following objective function, minimized by SGD:

$$\sum_{i=1}^N \sum_{j \in N(i)} \tau(\text{dist}(\hat{q}_i, \hat{q}_j) - \text{dist}(q_i, q_j)) + \sum_{(i,j) \in E} \tau(\text{dist}(\hat{q}_i, \hat{q}_j)) \quad (3)$$

with $\text{dist}(x, y) = 1 - \cos(x, y)$ and $\tau(x) = \max(0, x)$. As in equation 2, the first term tends to preserve the initial vectors. In this case, this preservation does not focus on the vectors themselves but on the pairwise distances between a vector and its nearest neighbors ($N(i)$). The second term is quite similar to the second term of equation 2 with the use of a distance derived from the Cosine similarity instead of the Euclidean distance².

¹We tried to exploit semantic neighbors that are not very close to their entry as antonyms but results were globally better without them.

²Since the Cosine similarity is used as similarity measure between words through their vectors, this distance should be more adapted in this context than the Euclidean distance.

The last method we have used for improving the embeddings built from the initial thesaurus, called *rank-fitting* hereafter, is a transposition of the method proposed by Liu et al. (2015). The objective of this method is to integrate into embeddings order constraints coming from external knowledge with the following form: $\text{similarity}(w_i, w_j) > \text{similarity}(w_i, w_k)$, abbreviated $s_{ij} > s_{ik}$ in what follows. This kind of constraints particularly fits our context as the semantic neighbors of an entry in a distributional thesaurus are ranked and can be viewed as a set of such constraints. More precisely, i corresponds in this case to an entry and j and k to two of its neighbors such that $\text{rank}(j) > \text{rank}(k)$. However, the method of Liu et al. (2015) is linked to the Skip-Gram model and was defined as a modification of the objective function underlying this model. We have transposed this approach for its application to the adaptation of embeddings after their building, without a specific link to the Skip-Gram model.

The general idea is to adapt vectors to minimize $s_{ij} - s_{ik} \quad \forall (i, j, k) \in E$. The objective to minimize takes more specifically the following form:

$$\sum_{(i,j,k) \in E} f(s_{ik} - s_{ij}) \quad (4)$$

where $f(s_{ik} - s_{ij}) = \max(0, s_{ik} - s_{ij})$ corresponds to a kind of hinge loss function and the similarity between words i and j , s_{ij} , is given by the Cosine measure between their associated vectors. The minimization of this objective is performed as for *counter-fitting* by SGD.

Finally, we have also defined a mixed *counter-rank-fitting* method that associates constraints about the proximity of word vectors and their relative ranking. This association was done by mixing the objective functions of *counter-fitting* and *rank-fitting* through the addition of the second term of equation 3, *i.e.* its adaptation term, and equation 4. In this configuration, the first term of the *counter-fitting* function, that preserves the initial embeddings, was not found useful anymore in preliminary experiments.

3 Evaluation of Thesaurus Embedding

3.1 Experimental Framework

For testing and evaluating the proposed approach, we needed first to choose a reference corpus and to build a distributional thesaurus from it. We chose

the AQUAINT-2 corpus, already used for various evaluations, a middle-size corpus of around 380 million words made of news articles in English. The main preprocessing of the corpus was the application of lemmatization and the removal of function words. According to (Bullinaria and Levy, 2012), the lemmatization of words leads to only a small improvement in terms of results but it is also a way to obtain the same results with a smaller corpus.

The building of our reference distributional thesaurus, T_{cnt} , was achieved by relying on a classical count-based approach with a set of parameters that were found relevant by several systematic studies (Baroni et al., 2014; Kiela and Clark, 2014; Levy et al., 2015):

- distributional contexts: co-occurents restricted to nouns, verbs and adjectives having at least 10 occurrences in the corpus, collected in a 3 word window, *i.e.* ± 1 word around the target word;
- directional co-occurents, which were found having a good performance by Bullinaria and Levy (2012);
- weighting function of co-occurents in contexts = *Positive Pointwise Mutual Information* (PPMI) with the *context distribution smoothing* factor proposed by (Levy et al., 2015), equal to 0.75;
- similarity measure between contexts, for evaluating the semantic similarity of two words = *Cosine* measure;
- filtering of contexts: removal of co-occurents with only one occurrence.

The building of the thesaurus from the distributional data was performed as in (Lin, 1998) or (Curran and Moens, 2002) by extracting the closest semantic neighbors of each of its entries. More precisely, the similarity measure was computed between each entry and its possible neighbors. Both the entries of the thesaurus and their possible neighbors were nouns with at least 10 occurrences in the corpus. These neighbors were then ranked in the decreasing order of the values of this measure.

The evaluation of distributional objects such as thesauri or word embeddings is currently a subject of research as both intrinsic (Faruqui et al., 2016; Batchkarov et al., 2016) and extrinsic (Schnabel et al., 2015) evaluations exhibit insufficiencies that question their reliability. In our case, we per-

Method	#eval. words	#syn./word	R@100	R _{prec}	MAP	P@1	P@2	P@5
T _{cnt}			29.0	11.3	13.1	15.7	11.4	6.6
GloVe	10,544	2.9	21.3	6.7	8.0	9.8	7.4	4.5
SGNS			22.4	8.7	10.3	12.3	8.8	5.2

Table 1: Evaluation of the initial thesaurus and two reference models of embeddings (values x 100)

formed an intrinsic evaluation relying on the synonyms of WordNet 3.0 (Miller, 1990) as Gold Standard. This choice was first justified by our overall long-term perspective, illustrated in Section 5, which is the extraction of synonyms from documents and the expansion of already existing sets of synonyms. However, it is also likely to alleviate some evaluation problems as it narrows the scope of the evaluation, by restricting to a specific type of semantic relations, but performs it at a large scale, the combination of which making its results more reliable. For focusing on the evaluation of the extracted semantic neighbors, the WordNet 3.0’s synonyms were filtered to discard entries and synonyms that were not part of the AQUAINT-2 vocabulary. The number of evaluated words and the average number of synonyms in our Gold Standard for each entry are given by the second and the third columns of Table 1.

In terms of methodology, the kind of evaluation we have performed follows (Curran and Moens, 2002; Ferret, 2010) by adopting an Information Retrieval point of view in which each entry is considered as a query and its neighbors are viewed as retrieved synonyms. Hence, we adopted the classical evaluation measures in the field: the R-precision (R_{prec}) is the precision after the first R neighbors were retrieved, R being the number of Gold Standard synonyms; the Mean Average Precision (MAP) is the mean of the precision values each time a Gold Standard synonym is found; precision at different cut-offs is given for the 1, 2, 5 first neighbors. We also give the global recall for the first 100 neighbors.

Table 1 shows the evaluation according to these measures of our initial distributional thesaurus T_{cnt} along with the evaluation in the same framework of two reference models for building word embeddings from texts: GloVe from Pennington et al. (2014) and Skip-Gram with negative sampling (SGNS) from Mikolov et al. (2013)³. The

³Following (Levy et al., 2015), SGNS was preferred to the Continuous Bag-Of-Word (CBOW) model.

input of these two models was the lemmatized version of the AQUAINT-2 corpus as for T_{cnt} but with all its words. Each model was built with the best parameters found from previous work and tested on this corpus. For GloVe: vectors of 300 dimensions, window size = 10, addition of word and context vectors and 100 iterations; for SGNS: vectors of 400 dimensions, window size = 5, 10 negative examples and default value for down-sampling of highly frequent words.

Two main trends can be drawn from this evaluation. First, T_{cnt} significantly outperforms GloVe and SGNS for all measures⁴. This superiority of a count-based approach over two predict-based approaches can be seen as contradictory with the findings of Levy et al. (2015). Our analysis is that the use of directional co-occurrences, a rarely tested parameter, explains a large part of this superiority. The second conclusion is that SGNS significantly outperforms GloVe for all measures. Hence, we will report results hereafter only for SGNS as a reference word embedding model.

3.2 Graph Embedding Evaluation

We have evaluated the three methods presented in Section 2.1 for embedding our initial thesaurus T_{cnt} according to the evaluation framework presented in the previous section. For all methods, the main parameters were the number of neighbors taken into account and the number of dimensions of the final vectors. In all cases, the number of neighbors was equal to 5,000, LINE being not very affected by this parameter, and the size of the vectors was 600⁵. For LINE, 10 billion samplings of the similarity values were done and for the matrix factorization (MF) approach, we used $\lambda = 0.075$.

According to Table 2, SVD significantly appears as the best method even if LINE is a competitive alternative. SVD outperforms GloVe while

⁴The statistical significance of differences were judged according to a paired Wilcoxon test with p-value < 0.05. The same test was applied for results reported hereafter.

⁵The values of these parameters were optimized on another thesaurus, coming from (Ferret, 2010).

Method	R_{prec}	MAP	P@1	P@2	P@5
T_{cnt}	11.3	13.1	15.7	11.4	6.6
SGNS	8.7	10.3	12.3	8.8	5.2
SVD	7.8	9.5	11.3	8.1	5.0
LINE	6.8	8.3	9.7	7.1	4.4
MF	4.0	4.9	5.9	4.4	2.7

Table 2: Evaluation of the embedding of a thesaurus as a graph

LINE is equivalent to it, which is a first interesting result: this first embedding step of a distributional thesaurus is already able to produce better word representations than a state-of-the-art method, even if it does not reach the level of the best one (SGNS). However, Table 2 also shows that there is still room for improvement for reaching the level of the initial thesaurus T_{cnt} . Finally, the matrix factorization approach is obviously a bad option, at least under the tested form.

3.3 Thesaurus Embedding Evaluation

Table 3 shows the results of the evaluation of the word embedding adaptation methods of Section 2.2, which is also the evaluation of the global thesaurus embedding process. For all methods, the input embeddings were produced by applying SVD to the initial thesaurus T_{cnt} , which was shown as the best option by Table 2. For *retrofitting* (Retrofit) and *counter-fitting* (Counterfit), only the relations between each entry of the thesaurus and its first and second neighbors were considered. For *rank-fitting* (Rankfit), the neighborhood was extended to the first 50 neighbors. For the optimization processes, we used the default settings of the methods: 10 iterations for *retrofitting* and 20 iterations for *counter-fitting*. We also used 20 iterations for *rank-fitting* and *counter-rank-fitting* (Counter-rankfit). For all optimizations by SGD, the learning rate was 0.01.

Several observations can be done. First, all the tested methods significantly improve the initial embeddings. Second, the results of the different methods are quite close for all measures. *retrofitting* outperforms *counter-fitting* but not significantly for R_{prec} . *rank-fitting* is significantly the worst method and its association with *counter-fitting* is better than *retrofitting* for P@1 only, but not significantly. However, we can globally note that the association of SVD and the best adapta-

Method	R_{prec}	MAP	P@1	P@2	P@5
T_{cnt}	11.3	13.1	15.7	11.4	6.6
SGNS	8.7	10.3	12.3	8.8	5.2
SVD	7.8	9.5	11.3	8.1	5.0
Retrofit	10.9	12.9	15.2	11.4	6.8
Counterfit	10.6	12.8	14.0	11.9	7.3
Rankfit	9.0	10.5	12.6	9.0	5.3
Counter-rankfit	10.7	12.4	15.2	11.0	6.3

Table 3: Evaluation of the global thesaurus embedding process

tion methods obtains results close to the results of the initial T_{cnt} (the difference is even not significant for R_{prec} and P@5). As a consequence, we can conclude, in connection with our initial objective, that embedding a distributional thesaurus while preserving its information in terms of semantic similarity is possible.

4 Applications of Thesaurus Embedding

4.1 Improvement of Existing Embeddings

In the previous section, we have shown that the strongest relations of a distributional thesaurus can be used for improving word vectors built from the embedding of this thesaurus. Since this adaptation is performed after the building of the vectors, it can actually be applied to all kinds of embeddings elaborated from the corpus used for building the distributional thesaurus. As for the process of the previous section, this is a kind of bootstrapping approach in which the knowledge extracted from a corpus is used for improving the word representations elaborated from this corpus. Moreover, as GloVe and most word embedding models, SGNS relies on first-order co-occurrences between words. From that perspective, adapting SGNS embeddings with relations coming from a distributional thesaurus built from the same corpus as these embeddings is a way to incorporate second-order co-occurrence relations into them.

Method	R_{prec}	MAP	P@1	P@2	P@5
(S)GNS	8.7	10.3	12.3	8.8	5.2
Emb _{retrof} (T_{cnt})	10.9	12.9	15.2	11.4	6.8
S+Counter-rankfit	9.5	11.1	13.8	9.9	5.6
S+Retrofit	9.3	10.6	13.2	9.6	5.5

Table 4: Evaluation of the adaptation of SGNS embeddings with thesaurus relations

For this experiment, we applied both *retrofitting* and *counter-rank-fitting* with exactly the same pa-

rameters as in Section 3.3. The results of Table 4 clearly validate the benefit of the technique: both *retrofitting* and *counter-rank-fitting* significantly improve SGNS embeddings. As in Section 3.3, the results of *retrofitting* and *counter-rank-fitting* are rather close, with a global advantage for *counter-rank-fitting*. We can also note that the improved versions of SGNS embeddings are still far from the best results of our thesaurus embedding method (*SVD + Retrofit*).

4.2 Fusion of Heterogeneous Representations

Being able to turn a distributional thesaurus into word embeddings also makes it possible to fusion different types of distributional data. In the case of thesaurus, fusion processes were early proposed by Curran (2002) and more recently by Ferret (2015). In the case of word embeddings, the recent work of Yin and Schütze (2016) applied ensemble methods to several word embeddings. By exploiting the possibility to change from one type of representation to another, we propose a new kind of fusion, performed between a thesaurus and word embeddings and leading to improve both the input thesaurus and the embeddings.

The first step of this fusion process consists in turning the input word embeddings into a distributional thesaurus. Then, the resulting thesaurus is merged with the input thesaurus, which consists in merging two lists of ranked neighbors for each of their entries. We followed (Ferret, 2015) and applied for this fusion the CombSum strategy to the similarity values between entries and their neighbors, normalized with the Zero-one method (Wu et al., 2006). Finally, we applied the method of Section 2 for turning the thesaurus resulting from this fusion into word embeddings.

Method	R_{prec}	MAP	P@1	P@2	P@5
$(T)_{cnt}$	11.3	13.1	15.7	11.4	6.6
(S)GNS	8.7	10.3	12.3	8.8	5.2
Fusion T-S	12.5	14.8	17.2	12.8	7.5
$Emb_{retrof}(fusion\ T-S)$	11.8	13.8	16.7	12.4	7.0

Table 5: Evaluation of the fusion of a distributional thesaurus T and word embeddings S

The evaluation of this fusion process, performed in a shared context as the considered thesaurus and word embeddings are built from the same corpus, is given in Table 5. The *Fusion T-S* line corresponds to the evaluation of the thesaurus

resulting from the second step of the fusion process. The significant difference with the results of T_{cnt} and SGNS confirms the conclusions of Ferret (2015) about the interest of merging thesauri built differently. The $Emb_{retrof}(fusion\ T-S)$ line shows the evaluation of the word embeddings produced by the global fusion process. In a similar way to the findings of Section 3.3, the embeddings built from the *Fusion T-S* thesaurus are less effective than the thesaurus itself but the difference is small here too. Moreover, we can note that these embeddings have significantly higher results than SGNS, the input embeddings, but also higher results than the input thesaurus T_{cnt} , once again without any external knowledge.

5 Knowledge Injection and Synset Expansion

In this section, we will illustrate how the improvement of a distributional thesaurus, obtained in our case by the injection of external knowledge, can be transposed to word embeddings. Moreover, we will show that the thesaurus embedding process achieving this transposition obtains better results for taking into account external knowledge than methods, such as *retrofitting*, that are applied to embeddings built directly from texts (SGNS in our case). We will demonstrate this superiority more precisely in the context of synset expansion.

The overall principle is quite straightforward: first, the external knowledge is integrated into a distributional thesaurus built from the source corpus (T_{cnt} in our experiments). Then, the resulting thesaurus is embedded following the method of Section 2. This external knowledge is supposed to be made of semantic similarity relations. We have considered more particularly pairs of synonyms (E, K) such that E is an entry of T_{cnt} and K is a synonym of E randomly selected from the WordNet 3.0’s synsets E is part of. Each E is part of only one pair (E, K) .

5.1 Injecting External Knowledge into a Thesaurus

The integration of the semantic relations into a distributional thesaurus is done for each entry E by reranking the neighbor K of the (E, K) pair at the highest rank with the highest similarity. The line $T_{cnt}+K$ of Table 6 gives the evaluation of this integration for 10,544 pairs (E, K) of synonyms, which means one synonym by entry.

Method	Evaluation of memorization					Global evaluation				
	R_{prec}	MAP	P@1	P@2	P@5	R_{prec}	MAP	P@1	P@2	P@5
SGNS	6.5	9.7	6.5	4.6	2.6	8.7	10.3	12.3	8.8	5.2
SGNS+retrof(K)	82.4	90.3	82.4	47.8	19.9	80.1	82.0	98.1	72.3	36.9
T_{cnt}	8.5	12.4	8.5	5.9	3.2	11.3	13.1	15.7	11.4	6.6
svd(T_{cnt})	5.8	9.0	5.8	4.0	2.3	7.8	9.5	11.3	8.1	5.0
svd(T_{cnt})+retrof(K)	86.6	92.8	86.6	48.8	20.0	81.5	83.5	98.8	72.6	37.4
$T_{cnt}+K$	100	100	100	50.0	20.0	62.7	63.8	100	54.0	23.1
svd($T_{cnt}+K$)	12.0	18.0	12.0	8.3	4.7	13.8	17.1	19.0	13.7	8.1
svd($T_{cnt}+K$)+retrof(K)	88.3	93.9	88.3	49.2	20.0	82.6	84.5	99.5	73.2	38.2

Table 6: Evaluation of the injection of external knowledge into word embeddings for synset expansion

As our evaluation methodology is based on the synonyms of WordNet, we have split our evaluation in two parts. One part takes as Gold Standard the synonyms used for the knowledge injection (see the *Evaluation of memorization* columns in Table 6) and evaluates to what extent the injected knowledge has been memorized. The second part (see the *Global evaluation* columns in Table 6) considers all the synonyms used for the evaluations in the previous sections as Gold Standard for evaluating the ability of models not only to memorize the injected knowledge but also to retrieve new synonyms, *i.e.* synonyms that are not part of the injected knowledge. In the context of our evaluation, which is based on synonym retrieval, this kind of generalization can also be viewed as a form of synset expansion. This is another way to extract synonyms from texts compared to work such as (Leeuwenberg et al., 2016; Minkov and Cohen, 2014; van der Plas and Tiedemann, 2006).

In the case of $T_{cnt}+K$, we can note that the memorization is perfect, which is not a surprise since the injection of knowledge into the thesaurus corresponds to a kind of memorization. No specific generalization effect beyond the synonyms already present in the thesaurus is observed for the same reason.

5.2 From a Knowledge-Boosted Thesaurus to Word Embeddings

The result of the process described in the previous section is what we could call a knowledge-boosted distributional thesaurus. However, its form is not different from a classical distributional thesaurus and it can be embedded similarly by applying the method of Section 2. The only difference with this method concerns its second step: instead of leveraging the first n neighbors of each entry for improving the embeddings obtained by SVD, we ex-

ploited the set of relations used for “boosting” the initial thesaurus.

The evaluation of the new method we propose for building word embeddings integrating external knowledge is presented in Table 6. More precisely, three different methods are compared: a state-of-the-art method, *SGNS+retrof(K)*, consisting in applying *retrofitting* to SGNS embeddings. *retrofitting* was chosen as it is quick and gives good results. The second method, *svd(T_{cnt})+retrof(K)*, applies *retrofitting* to the embeddings built from T_{cnt} by SVD. The last method, *svd($T_{cnt}+K$)+retrof(K)*, corresponds to the full process we have presented, where the external knowledge is first injected into the initial thesaurus T_{cnt} before its embedding.

First, we can note that all the methods considered for producing word embeddings by taking into account external knowledge leads to a very strong improvement of results compared to their starting point. This is true both for the memorization and global evaluations. From the memorization viewpoint, all the injected synonyms can be found among the first five neighbors returned by the three methods as illustrated by their P@5 and even at the first rank in nearly nine times out of ten for the best method, which is clearly our thesaurus embedding process (except the pure memorization performed by $T_{cnt}+K$).

We can also observe that the method used for knowledge injection can reverse initial differences. For instance, the application of SVD to a thesaurus built from a corpus, *svd(T_{cnt})*, obtains lower results than the application of SGNS to the same corpus. After the injection of external knowledge, this ranking is reversed: the values of the evaluation measures are higher for *svd(T_{cnt})+retrof(K)* than for *SGNS+retrofit(K)*.

More importantly, Table 6 shows that the inte-

Entries	K	Synonyms in neighbors of $T_{cnt}+K$	Synonyms in neighbors of $svd(T_{cnt}+K)+retrof(K)$
richness	fullness	fullness [1] 1.0, affluence [1,665] 0.06, profusion [1,950] 0.06, fertility [2,000] 0.06, cornucopia [2,919] 0.06	fullness [1] 0.80, affluence [2] 0.71, cornucopia [3] 0.71, fertility [5] 0.66, profusion [6] 0.44
butchery	abattoir	abattoir [1] 1.0, slaughterhouse [2] 0.05, carnage [65] 0.03, slaughter [90] 0.03, massacre [132] 0.03, shambles [3,735] 0.02	abattoir [1] 0.64, massacre [2] 0.62, carnage [3] 0.61, slaughterhouse [4] 0.53, shambles [5] 0.45, slaughter [11] 0.21
idiom	dialect	dialect [1] 1.0, phrase [16] 0.09, accent [62] 0.09, parlance [2,971] 0.07	dialect [1] 0.80, phrase [2] 0.75, accent [3] 0.71, parlance [4] 0.71
spectator	witness	witness [1] 1.0, viewer [28] 0.14, watcher [519] 0.12	watcher [1] 0.59, witness [2] 0.56, viewer [3] 0.51, looker [10] 0.30

Table 7: Examples of the interest of thesaurus embedding for synset expansion. Each synonym is given with its [rank] among the neighbors of the entry and its similarity value with the entry

gration of external knowledge into the thesaurus before its embedding is clearly effective as illustrated by the significant differences between $SGNS+retrofit(K)$ and $svd(T_{cnt}+K)+retrof(K)$. Finally, from the synset expansion viewpoint, it is worth adding that the P@2 value of our best method means that the first synonym proposed by the expansion in addition to the injected synonyms is correct with a precision equal to 46.9, which represents 4,945 new synonyms and illustrates the generalization capabilities of the method.

Table 7 illustrates more qualitatively for some words the interest of the thesaurus embedding method we propose for the expansion of existing synsets. In accordance with the findings of Table 6, it first shows that the method has a good memorization capability of the injected knowledge (K) in the initial thesaurus since in the resulting embeddings ($svd(T_{cnt}+K)+retrof(K)$), the synonym provided for each entry appears as the first or the second neighbor.

Table 7 also illustrates the good capabilities of the method observed in Table 6 in terms of generalization as the rank of synonyms of an entry not provided as initial knowledge tend to decrease strongly. For instance, for the entry *idiom*, the rank of the synonym *parlance* is equal to 2,971 in the initial thesaurus with the injected knowledge ($T_{cnt}+K$) while it is only equal to 4 after the embedding of the thesaurus. Interestingly, this improvement in terms of rank comes from a change in the distributional representation of words that also impacts the evaluation of the semantic similarity between words. While the similarity between the word *richness* and its synonym *profusion* was initially very low (0.06), its value after the embedding process is very much higher (0.66)

and more representative of the relation between the two words.

6 Conclusion and Perspectives

In this article, we presented a method for building word embeddings from distributional thesauri with a limited loss of semantic similarity information. The resulting embeddings outperforms state-of-the-art embeddings built from the same corpus. We also showed that this method can improve already existing word representations and the injection of external knowledge into word embeddings.

A first extension to this work would be to better leverage the ranking of neighbors in a thesaurus and to integrate more tightly the two steps of our embedding method. We also would like to define a more elaborated method for injecting external knowledge into a distributional thesaurus, more precisely by exploiting the injected knowledge to rerank its semantic neighbors. Finally, we would be interested in testing further the capabilities of the embeddings with injected knowledge for extending resources such as WordNet.

Training Word Sense Embeddings With Lexicon-based Regularization

Luis Nieto-Piña and Richard Johansson

University of Gothenburg

{luis.nieto.pina, richard.johansson}@gu.se

Abstract

We propose to improve word sense embeddings by enriching an automatic corpus-based method with lexicographic data. Information from a lexicon is introduced into the learning algorithm's objective function through a regularizer. The incorporation of lexicographic data yields embeddings that are able to reflect expert-defined word senses, while retaining the robustness, high quality, and coverage of automatic corpus-based methods. These properties are observed in a manual inspection of the semantic clusters that different degrees of regularizer strength create in the vector space. Moreover, we evaluate the sense embeddings in two downstream applications: word sense disambiguation and semantic frame prediction, where they outperform simpler approaches. Our results show that a corpus-based model balanced with lexicographic data learns better representations and improve their performance in downstream tasks.

1 Introduction

Word embeddings, as a tool for representing the meaning of words based on the context in which they appear, have had a considerable impact on many of the traditional Natural Language Processing tasks in recent years. (Turian et al., 2010; Collobert et al., 2011; Socher et al., 2011; Glorot et al., 2011) This form of semantic representation has come to replace in many instances traditional count-based vectors (Baroni et al., 2014), as they yield high-quality semantic representations in a computationally efficient manner, which allows them to leverage information from large corpora.

Due to this success, some attention has been devoted to the question of whether their representational power can be refined to further advance the state of the art in those tasks that can benefit from semantic representations. One instance in which this could be realized concerns polysemous words, which has led to several attempts at representing word senses instead of simple word forms. Doing so would help avoid the situation in which several meanings of a word have to be conflated into just one embedding, typical of simple word embeddings.

Among the different approaches to learning word sense embeddings, a distinction can be made between those that make use of a semantic network (SN) and those that do not. Approaches in the latter group usually apply an unsupervised strategy for clustering instances of words based on the context formed by surrounding words. The resulting clusters are then used to represent the different meanings of a word. These representations characterize word usage in the training corpus rather than lexicographic senses, and run the risk of marginalizing under-represented word senses. Nonetheless, for well represented word senses, this strategy proves to be effective and adaptable to changes.

The alternative is to integrate an SN in the learning process. This kind of resource encodes a lexicon of word senses, connecting lexically and semantically related concepts, usually in the form of a graph. Methods that take this approach are able to work with lexicographic word senses as defined by experts, usually integrating them in different ways with corpus-learned embeddings. However, their completeness depends on the quality of the underlying SN.

In this paper, we present an approach that tries to achieve a balance between these two variants. We propose to make use of an SN for learn-

ing word sense embeddings by leveraging its signal through a regularizer function that is applied on top of a traditional objective function used to learn embeddings from corpora. In this manner, our model is able to merge these two opposed sources of data with the expectation that each one will balance the limitations of the other: flexible, high-quality embeddings learned from a corpus, with well defined separation between the expert-defined senses of any given polysemic word. The influence of each source of information can be regulated through a mix parameter.

As the corpus-based part of our model, we use a version of the Skip-gram (Mikolov et al., 2013) model that is modified so that it is able to learn two distinct vocabularies: word senses and word forms as introduced by Nieto-Piña and Johansson (2015). Regarding the SN data, we focus our attention on its underlying graph. We assume that neighboring nodes in such a graph correspond to semantically related concepts. Thus, given a word sense, a sequence of related word senses can be generated from its neighbors. A regularizer function can then be used to update their corresponding embeddings so that they become closer in the vector space. This has the benefit of creating clear separations between the different senses of polysemic words, precisely as they are described in the SN, even in the cases where this separation would not be clear from the data in a corpus.

We give an overview of related work in Section 2, and our model is described in detail in Section 3. The resulting word sense embeddings are evaluated in Section 4 on two separate automated tasks: word sense disambiguation (WSD) and lexical frame prediction (LFP). The experiments used for evaluation allow us to investigate the influence of the lexicographic data on the embeddings by comparing different model parameterizations. We conclude with a discussion of our results in Section 5.

2 Related Work

The recent success of word embeddings as effective semantic representations across the broad spectrum of NLP tasks has led to an increased interest in developing embedding methods further in order to acquire finer-grained representations able to handle polysemy and homonymy. This effort can be divided into two approaches: those that tackle the problem as an unsupervised task, aiming

to discover different usages of words in corpora, and those that make use of knowledge resources as a way of injecting linguistic knowledge into the models.

Among the earliest efforts in the former group is the work of Reisinger and Mooney (2010) and Huang et al. (2012), who propose to cluster occurrences of words based on their contexts to account for different meanings. With the advent of the Skip-gram model (Mikolov et al., 2013) as an efficient way of training prediction-based word embedding models, much of the research into obtaining word sense representations revolved around it. Neelakantan et al. (2014) and Nieto-Piña and Johansson (2015) make use of context-based word sense disambiguation (WSD) during corpus training to allow on-line learning of multiple senses of a word with modified versions of Skip-gram. Li and Jurafsky (2015) and Bartunov et al. (2016) apply stochastic processes to allow for representations of a variable number of senses per word to be learnt in unsupervised fashion from corpora.

The embeddings obtained using this approach tend to be word-usage oriented, rather than represent formally defined word senses. While this is descriptive of the texts in the corpus at hand, it can be problematic for generalization. For instance, word senses that are underrepresented or absent in the training corpus will not be assigned a functional embedding. On the other hand, due to the ability of these models to process large amounts of data, well-represented word senses will acquire meaningful representations.

The alternative approach to unsupervised methods is to include data from knowledge resources, usually graph-encoded semantic networks (SN) such as WordNet (Miller, 1995). Chen et al. (2014) and Iacobacci et al. (2015) propose to make use of knowledge resources to produce a sense-annotated corpus, on which known techniques can then be applied to generate word sense embeddings. A usual way of circumventing the lack of sense-annotated corpora is to apply post-processing techniques onto pre-trained word embeddings as a way of leveraging lexical information to produce word sense embeddings. The following models share this method: Johansson and Nieto-Piña (2015) formulate an optimization problem to derive multiple word sense representations from word embeddings, while Pilehvar and Collier (2016) and one of the models proposed by Jauhar

et al. (2015) use graph learning techniques to do so.

A characteristic of this approach is that these models can generate embeddings for a complete inventory of word senses. However, the dependence on manually crafted resources can potentially lead to incompleteness, in case of unlisted word senses, or to inflexibility in the face of changes in meaning, failing to account for new meanings of a word.

The model that we present in this article tries to preserve desirable characteristics from both approaches. On one side, the model learns word sense embeddings from a corpus using a predictive learning algorithm that is efficient, streamlined, and flexible with respect to being able to discriminate between different usages of a word from running text. This learning algorithm is based on the idea of adding an extra latent variable to the Skip-gram objective function to account for different senses of a word, that has been explored in previous work by Jauhar et al. (2015) and Nieto-Piña and Johansson (2015). On the other side, the learning process is guided by a regularizer function that introduces information from an SN, in an attempt to achieve a clear, complete, and fair division between the different senses of a word. Furthermore, from a technical point of view, the effect of the regularizer function is applied in parallel to the embedding learning process. This eliminates the need for a two-step training process or pre-trained word embeddings, and makes it possible to regulate the influence that each source of data (corpus and SN) has on the learning process.

3 Model Description

3.1 Learning Word Sense Embeddings

The Skip-gram word embedding model (Mikolov et al., 2013) works on the premise of training the vector for a word w to be able to predict those context words c_i with which it appears often together in a large training corpus, according to the following objective function:

$$\sum_{i=1}^n \log p(c_i|w)$$

where $p(c_i|w)$ can be approximated using the softmax function, The model, thus, works by maintaining two separate vocabularies which represent word forms in their roles as *target* and *context*

words. The resulting word embeddings (usually those vectors trained for the target word vocabulary) are able to store meaningful semantic information about the words they represent.

The original Skip-gram model is, however, limited to word forms in both its vocabularies. Nieto-Piña and Johansson (2015) introduced a modification of this model in which the target vocabulary holds a variable number of vectors for each word form, intended to represent its different senses. The training objective of such a model now has the following shape:

$$\log p(s|w) + \sum_{i=1}^n \log p(c_i|s) \quad (1)$$

Thus the word sense embeddings are trained to maximize the log-probability of context words c_i given a word's sense s plus the log-probability of that sense given the word w . For our purposes, this prior is a constant, $p(s|w) = \frac{1}{n}$, as we do not have information on the probability of each sense of a given word.

This formulation requires a sense s of word w to be selected for each instance in which the objective function above is applied. This word sense disambiguation is applied on-line at training time and based on the target word's context: The sense s chosen to disambiguate an instance of w is the one whose embedding maximizes the dot product with the sum of the context words' embeddings.

$$\arg \max_s \frac{e^s \sum_i c_i}{\sum_s e^s \sum_i c_i} \quad (2)$$

This unsupervised model learns different usages of a word with minimal overhead computation on top of the original, word-based Skip-gram. The number of senses per word can be obtained from a lexicon or set to a fixed number.

3.2 Embedding a Lexicon

In order to adapt the graph-structured nature of the data in an SN to be used in continuous representations, we propose to introduce it through a regularizer that can act upon the same embeddings trained by the unsupervised model described above.

Any given node s in a graph will have a set of neighbors n_i directly connected to it. In the graph underlying an SN, we assume n_i to be lexically or semantically similar to s . In this setting, a collection of sequences composed of word senses s

and n_i can be collected by visiting all nodes in the SN’s graph and collecting its immediate neighbors. Note that extracting such a collection of sequences from a semantic graph follows quite naturally, but in fact it could be generated from any other resource that relates concepts, such as a thesaurus, even if it is not encoded in a graph, as long as the relations it contains are relevant to the model being trained.

We propose to use a collection of sequences of related word senses to update their corresponding word sense vectors by pulling any two vectors closer together in their geometric space whenever they are encountered in a sequence. This action can be easily modeled by minimizing the following expression:

$$\sum_{i=1}^k \|s - n_i\|^2 \quad (3)$$

for each sequence of word senses $(s, n_1, n_2, \dots, n_k)$. By minimizing the distance in the vector space between vectors representing interconnected concepts according to the SN’s organization, the vector model is effectively representing that organization in a way that geometrical distance correlates with lexical or semantical relatedness, a central concept in the word embedding literature.

3.3 Combined Model

The two preceding sections describe the two parts of a combined model that is able to learn simultaneously from a corpus and an SN. This is achieved by training embeddings from a corpus with the objective described in Equation 1, and complementing this procedure with lexicographic data by means of using Equation 3 as a regularizer. The extent of the regularizer’s influence on the model is adapted by a mix parameter $\rho \in [0, 1]$: the higher the value of ρ , the more influence the SN data has on the model, and vice versa.

Thus, the objective function of our model is as follows:

$$\log p(s|w) + (1-\rho) \sum_{i=1}^n \log p(c_i|s) - \rho \sum_{j=1}^m \|s - n_j\|^2$$

In practice, this objective is realized by alternating updates through each of the model’s parts, the number of which is regulated by ρ . Updates on the corpus-based part are executed with Skip-gram

with negative sampling (Mikolov et al., 2013), adapted to work with a vocabulary of word senses as explained in §3.1.

On top of the formulation of the lexicon-based part of the model given in the previous section we propose two variations on this model in order to explore the extent to which the SN data can be used to influence the combined model explained in the following section. The initial formulation of the model will be referenced as V0 in this paper.

In the first variation (henceforth V1) we propose to only apply Equation 3 on word senses pertaining to polysemous words. If by using the SN we intend to learn clear separations between different senses of a word, it attends to reason to limit its application to those cases, while monosemous words can be sufficiently well trained by the usual corpus-based approach, and act as semantic anchors in the broader vector space.

The second variation (henceforth V2) deals with the specific architecture of the corpus-based training algorithm. As mentioned in the previous section, this model trains a target and a context vocabulary. We propose to use the regularizer to act not only on word sense vectors, but also on context (word form) vectors. By doing this we expect the context vocabulary to be ready for instances of different senses of a word, training context vectors to be potentially more effective in the disambiguation scheme introduced in Equation 2. This variation introduces an extra term into Equation 3,

$$\sum_{i=0}^n \|w(s) - w(n_i)\|^2$$

where $w(x)$ is a mapping from a given sense x to its corresponding word form.

4 Experiments

4.1 Experimental Setting

We trained the three variants of our model using different parameterizations of $\rho \in (0, 1)$. Each of these instances learned target and context embeddings of 50 dimensions, using a window of size 5 on the corpus-based part of the training algorithm, for a total number of 5 iterations over a number of updates equal to the size of the training corpus.

Below we describe the lexicon and corpus used to train the sense embeddings.

4.1.1 SALDO: a Semantic Network of Swedish Word Senses

SALDO (Borin et al., 2013) is the largest graph-structured semantic lexicon available for Swedish. The version used here contains roughly 125,000 concepts (word senses) organized into a single semantic network.

The sense nodes in the SALDO network are connected by edges that are defined in terms of semantic *descriptors*. A descriptor of a sense is another sense used to define its meaning. The most important descriptor is called the *primary* descriptor (PD), and since every sense in SALDO (except an abstract root sense) has a single unique PD, the PD subgraph of SALDO forms a tree. In most cases, the PD of a sense s is a hypernym or a synonym of s , but other types of semantic relations are also possible.

To exemplify, Figure 1 shows a fragment of the PD tree. In the example, there are some cases where the PD edges correspond to hypernymy, such as *hard rock* being a type of *rock music*, which in turn is a type of *music*, but there are also other types of relations, such as *music* being defined in terms of *to sound*.

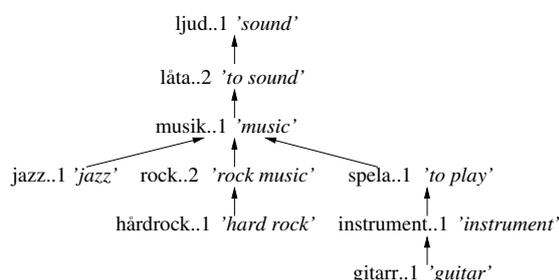

Figure 1: A fragment of the network in SALDO.

4.1.2 Training Corpus

For training the embedding models, we created a mixed-genre corpus of approximately 1 billion words downloaded from Språkbanken, the Swedish language bank.¹ The texts were tokenized, part-of-speech-tagged and lemmatized. Compounds were segmented automatically and when a compound-word lemma was not listed as an entry in the SALDO lexicon, we used the compound parts instead. For instance, *hårdrock* ‘hard rock’ would occur as a single token in the corpus, while *rockstjärna* ‘rock star’ would be split into two separate tokens.

¹<http://spraakbanken.gu.se>

4.2 Qualitative Inspection of Word Senses

By inspecting lists of nearest neighbors to a given embedding, some insight can be gained into how a model represents the meaning of the concept it represents. It is especially interesting in the case of polysemous words, where the neighbors of each of its senses can help judging how well it manages to separate their different meanings.

In Table 1 we list nearest neighbors for each of the two senses of the Swedish word *rock*: ‘coat’ and ‘rock music’. The neighboring concepts in the table are extracted from two separate vector models trained with different parameterizations for the mix parameter ρ : The first, $\rho = 0.01$, has little influence from the lexicon and thus is similar to a corpus-only approach; the second, $\rho = 0.5$, allows for more information from the lexicon to influence the embeddings. In our corpus, the music sense is overrepresented; this can be seen in the table, where both senses trained with $\rho = 0.01$ have most of their nearest neighbors semantically related to music. The model that is more influenced by the lexicon with $\rho = 0.5$ is, however, able to learn two distinct senses. Note how the music sense is not negatively affected by this change: many of its nearest neighbors are the same in both models, and all of them keep the music-related topic in common.

It is also interesting to filter these lists of nearest neighbors to limit them to unlisted words; i.e., words that are not present in the lexicon and appear only in the corpus. This provides an observation of how well those embeddings that are trained by both parts of the model are integrated with those others whose training is based only on the corpus. Table 2 contains such lists of unlisted items for the two senses of *rock* on two models with different parameterization. It presents a similar behavior to the previous experiment: In a model with low influence from the lexicon, the representations of both senses tend towards that of the overrepresented one; when more influence from the lexicon is allowed, a clear separation of the two senses into their expected meanings is observed.

4.3 Word Sense Disambiguation

We trained and evaluated several parameterizations of our model on a Swedish language word sense disambiguation (WSD) task. The aim of this task is to select a sense of an instance of a polyse-

Table 2: Nearest unlisted neighbors for the two senses of *rock* ‘coat’ and ‘rock music’ for different ρ .

mous word in context. For this purpose, we use a disambiguation mechanism similar to the one introduced in §3.1. Given an ambiguous word in context, a score is calculated for each of its possible senses by applying the expression in Equation 2; however, to correct for skewed sense distributions, we replaced the uniform prior with a power-law prior $P(s_k|w) \propto k^{-2}$, where k is the numerical identifier of the sense. The highest scoring sense is then selected to disambiguate that instance of the word.

As baselines for this experiment, we used random sense and first sense² selection. Additionally, we show the results achieved by a disambiguation system, UKB, based on Personalized PageRank (Agirre and Soroa, 2009), and which was trained on the PD tree from SALDO. The implementation of this model makes no assumptions on the underlying graph and thus it is easily adaptable to work with any kind of SN. Our models were all parameterized with $\rho = 0.9$ based on the results obtained on the SweFN dataset. All evaluated systems including the baselines are unsupervised: none of them has used a sense-annotated corpus during training.

4.3.1 Sense-annotated Datasets

We evaluated the WSD systems on eleven different datasets, which to our knowledge are all sense-annotated datasets that exist for Swedish. The datasets consist of instances, where each instance

²No frequency information is available for SALDO’s sense inventory and the senses are not ordered by frequency. The senses are ordered by lexicographers so that the lower-numbered senses are more “central” or “primitive”, which often but not always correlates with the sense frequency.

is a sentence where a single target word has been selected for disambiguation.

Two datasets consist of *lexicographical examples* (Lex-Ex): the *SALDO examples* (SALDO-ex) and *Swedish FrameNet examples* (SweFN-ex). The latter of these is annotated in terms of semantic frames, but there is a deterministic mapping from frames to SALDO senses.

Two additional datasets are taken from the Senseval-2 Swedish lexical sample task (Kokkinakis et al., 2001). It uses a different sense inventory, which we mapped manually to SALDO senses. The lexical sample originally consisted of instances for 40 lemmas, out of which we removed 7 lemmas because they were unambiguous in SALDO. Since we are using an unsupervised experimental setup, we report results not only on the designated test set but also on the training set.

The other datasets come from the *Koala* annotation project (Johansson et al., 2016). The latest version consists of seven different corpora, each sampled from text in a separate domain: blogs, novels, Wikipedia, European Parliament proceedings, political news, newsletters from a government agency, and government press releases. Unlike the two lexicographical example sets and the Senseval-2 lexical sample, in which the instances have been selected by lexicographers to be prototypical and to have a good coverage of the sense variation, the instances in the *Koala* corpora are annotated ‘as is’ in running text.

The sentences in all datasets were tokenized, compound-split, and lemmatized, and for each target word we automatically determined the set of possible senses, given its context and inflec-

Test set	Subset	Size	RND	S1	UKB	V0	V1	V2

tion. We only considered senses of content words: nouns, verbs, adjectives, and adverbs. Multi-word targets were not included, and we removed all instances where only one sense was available.³

4.3.2 Disambiguation Results

Table 3 shows disambiguation accuracies for our models on the datasets described above, along with the scores achieved by our baselines and the UKB model. The results of each variant of our model were obtained with a parameterization of $\rho = 0.9$, which was chosen as the best scoring value on the Swe-FN subset used as validation set. The model which only applies the regularizer to polysemous words (V1) dominates most highest scores, overtaken in some instances by V0 and in one by the first sense baseline. Note how the general magnitudes of the scores within each type of dataset underline their different characteristics explained above.

Additionally, for the sake of making a more detailed analysis of the influence of the parameter ρ that dominates the extent of the lexicon’s influence on the model, Figure 2 shows the average performance of our models on each dataset for a wide range of values for ρ . There is a clear pattern across all models and datasets by which a greater input from the SN translates into a better performance in WSD. These figures also confirm the superior performance of the variant V1 of our model seen in Table 3.

³In addition, to facilitate a comparison to the UKB system as a baseline, we removed a small number of instances that could not be lemmatized unambiguously.

4.4 Frame Prediction

In our second evaluation, we investigated how well the sense vector models learned by the different training algorithms correspond to semantic classes defined by the Swedish FrameNet (Friberg Heppin and Toporowska Gronostaj, 2012). In a frame-semantic model of lexical meaning (Fillmore and Baker, 2009), the meaning of words is defined by associating them with broad semantic classes called *frames*; for instance, the word *falafel* would belong to the frame FOOD. Important classes of frames include those corresponding to objects and people, mainly populated by nouns, such as FOOD or PEOPLE_BY_AGE; verb-dominated frames corresponding to events, such as IMPACT, STATEMENT, or INGESTION; and frames dominated by adjectives, often referring to relations, qualities, and states, e.g. ORIGIN or EMOTION_DIRECTED.

In case a word has more than one sense, it may belong to more than one frame. In the Swedish FrameNet, unlike its English counterpart, these senses are explicitly defined using SALDO (see §4.1.1): for instance, for the highly polysemous noun *slag*, its first sense (‘type’) belongs to the frame TYPE, the second (‘hit’) to IMPACT, the third (‘battle’) to HOSTILE_ENCOUNTER, etc.

In the evaluation, we trained classifiers to determine whether a SALDO sense, represented as a sense vector, belongs to a given frame or not. To train the classifiers, we selected the 546 frames from the Swedish FrameNet for which at least 5 entries were available. In total we had 28,842 verb, noun, adjective, and adverb entries, which we split into training (67% of the entries in each

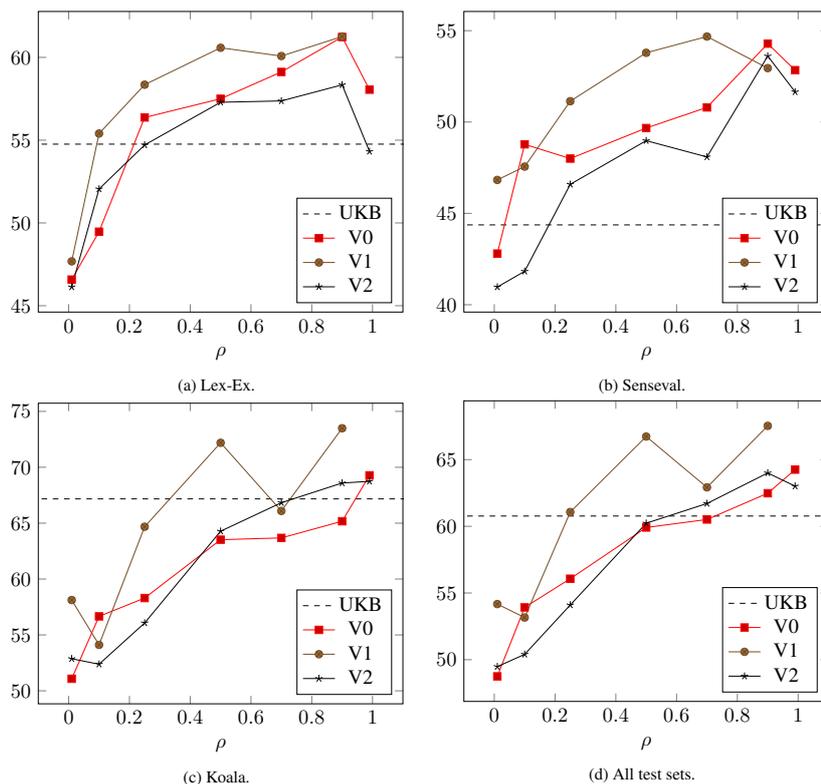

Figure 2: Average WSD accuracies on all instances of each dataset for different values of ρ on the three variants of our model.

frame) and test sets (33%). For each frame, we used LIBLINEAR (Fan et al., 2008) to train a linear support vector machine, using the vectors of the senses associated with that frame as positive training instances, and all other senses listed in FrameNet as negative instances.

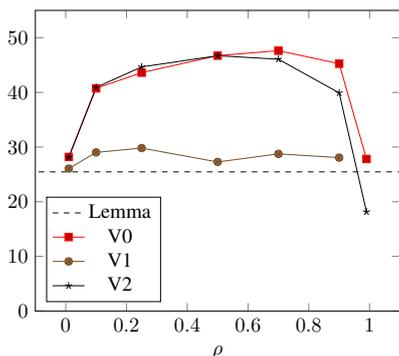

Figure 3: MAP scores for the frame prediction classifiers for the different types of models.

4.4.1 Evaluation Results

At test time, for each frame we applied the SVM scoring function of its classifier to each sense in the test set. The ranking induced by this score was evaluated using the Average Precision (AP) metric commonly used to evaluate rankers; the goal of

this ranking step is to score the senses belonging to the frame higher than those that do not. We computed the Mean Averaged Precision (MAP) score by macro-averaging the AP scores over the set of frames.

Figure 3 shows the MAP scores of frame predictors based on different sense vector models. We compared the three training algorithms described in Section 3 for different values of the regularization strength parameter ρ . As a baseline, we included a model that does not distinguish between different senses: it represents a SALDO sense with the word vector of its lemma.

As the figure shows, almost all sense-aware vector models outperformed the model that just used lemma vectors. The result shows tendencies that are different from what we saw in the WSD experiments. The best MAP scores were achieved with mid-range values of ρ , so it seems that this task requires embeddings that strike a balance between representing the lexicon structure faithfully and representing the cooccurrence patterns in the corpus. An model with very light influence of the lexicon was hardly better than just using lemma embeddings, and unlike what we saw for the WSD task we see a strong dropoff when increasing ρ .

In addition, the tendencies here differ from the WSD results in that the training algorithm that only applies the lexicon-based regularizer to polysemous words (V1) gives lower scores than the other two approaches. We believe that this is because it is crucial in this task that sense vectors are clustered into coherent groups, which makes it more useful to move sense vectors closer to their neighbors even when they are monosemous; this as opposed to the WSD task, where it is more useful to leave the monosemous sense vectors in place as “anchors” for the senses of polysemous words. The context-regularized training algorithm (V2) gives no improvement over the original approach (V0), which is expected since context vectors are not used in this task.

Frame	Lemma	V0	V1
ANIMALS	0.73	0.86	0.76
FOOD	0.72	0.84	0.77
REMOVING	0.20	0.50	0.22
MAKE_NOISE	0.40	0.62	0.46
ORIGIN	0.90	0.90	0.89
COLOR	0.73	0.88	0.80
FREQUENCY	0.40	0.43	0.35
TIME_VECTOR	0.40	0.52	0.27

Table 4: Frame prediction AP scores for selected frames dominated by nouns, verbs, adjectives, and adverbs respectively.

To get a more detailed picture of the strengths and weaknesses of the models in this task, we selected eight frames: two frames dominated by nouns, two for verbs, two for adjectives, two for adverbs. Table 4 shows the AP scores for these frames of the lemma-vector baseline, the initial approach (V0), and the version that only regularizes senses of polysemous words (V1). All lexicon-aware models used a ρ value of 0.7. Almost across the board, the V0 method gives very strong improvements. The exception is the frame ORIGIN, which contains adjectives of ethnicity and nationality (*Mexican, African*, etc); this set of adjectives is already quite coherently clustered by a simple word vector model and is not substantially improved by any lexicon-based approach.

5 Conclusion

In this article we have introduced a family of word sense embedding models that are able to leverage information from two concurrent sources of information: a semantic network and a corpus. Our hypothesis was that by combining them, the

robustness and coverage of embeddings trained on a large corpus could achieve a more balanced and linguistically informed representation of the senses of polysemic words. This point has been proved in the evaluation of our models on Swedish language tasks.

A manual inspection of the word sense representation through their nearest neighbors exemplified it in §4.2. Indeed, an increased influence from the SN causes a clearer distinction between different senses of a word, even in the case where one of them is underrepresented in the corpus.

A WSD experiment was carried out on a variety of sense-annotated datasets. Our model consistently outperformed random and first sense baselines, as well as a comparable graph-based WSD system trained on a Swedish SN, which underlines the fact that the strength of our model resides in a combination of lexicon- and corpus-learning.

This is further confirmed in the evaluation of our model on a frame prediction task: A well balanced combination of lexicon and corpus data produces word sense embeddings that outperform common word embeddings when used to predict their semantic frame membership. Furthermore, this superiority is uniform across common frames dominated by different parts of speech.

An analysis of different values of our model’s mix parameter ρ showed the value of using lexicographic information in conjunction with corpus data. Especially on WSD, larger values of ρ (i.e., more influence from the SN) generally lead to improved results.

In conclusion, we have shown that automatic word sense representation benefits greatly from using a semantic network in addition to the usual corpus-learning. The combination of these sources of information yields robust, high-quality, and balanced embeddings that excel in downstream tasks where accurate representation of word meaning is crucial. Given these findings, we intend to continue exploring more refined ways in which data from a semantic network can be leveraged to increase sense-awareness in embedding models.

Abstract

Current research in text simplification has been hampered by two central problems: (i) the small amount of high-quality parallel simplification data available, and (ii) the lack of explicit annotations of simplification operations, such as deletions or substitutions, on existing data. While the recently introduced Newsela corpus has alleviated the first problem, simplifications still need to be learned directly from parallel text using black-box, end-to-end approaches rather than from explicit annotations. These complex-simple parallel sentence pairs often differ to such a high degree that generalization becomes difficult. End-to-end models also make it hard to interpret what is actually learned from data. We propose a method that decomposes the task of TS into its sub-problems. We devise a way to automatically identify operations in a parallel corpus and introduce a sequence-labeling approach based on these annotations. Finally, we provide insights on the types of transformations that different approaches can model.

1 Introduction

Text Simplification (TS) is the task of reducing the complexity of a text without changing its meaning. Simplification can be applied at various linguistic levels, from lexical substitution to more global operations such as sentence splitting, paraphrasing or the deletion or reordering of entire clauses.

Existing corpora for TS generally come in one of two variants. The first focuses on very specific sub-problems, such as sentence compression

(Bingel and Søgaard, 2016) or the identification of difficult words (Paetzold and Specia, 2016a), and typically encodes relevant simplification operations as discrete labels on tokens. The other variant includes more general, higher-level types of simplifications that often entail the rephrasing or re-structuring of sentences, with content added or removed. These “natural” simplifications are often created for end-users rather than for research purposes. Examples of the latter simplification resources include the Newsela (Xu et al., 2015) and Simple English Wikipedia corpora (Zhu et al., 2010; Coster and Kauchak, 2011b). These resources generally encode interdependencies between different types of simplification better than single-purpose resources and may thus seem favorable for learning simplifications. However, the freedom given to editors and lack of explicit labels on the modifications performed makes generalization much more difficult, especially when existing resources are relatively small in comparison to corpora for other text-to-text problems like machine translation (MT). Nevertheless, these corpora have been extensively used to learn phrase-based statistical and neural models for end-to-end TS systems that bear resemblance to MT models (Specia, 2010; Zhu et al., 2010; Coster and Kauchak, 2011b; Wubben et al., 2012; Narayan and Gardent, 2014; Xu et al., 2016; Zhang and Lapata, 2017; Zhang et al., 2017; Nisioi et al., 2017).

Adaptability and interpretability MT-style models are essentially black boxes that offer little or no control over the way in which a given input is modified. Additionally, in most cases the types of modifications that are actually learned are limited to paraphrasing of short sequences of words. We believe a middle ground is missing in terms of resources and approaches for TS, where models are learned from a more informed labeled

FA and JB contributed equally to this paper.

dataset of natural simplifications, and can then be applied in a controlled way, e.g., in adaptive simplification scenarios that prioritize different ways of simplifying (e.g. compression or sentence splitting) depending on a particular user’s needs.

The only previous work on TS via explicitly predicting simplification operations is that by [Bingel and Søgaard \(2016\)](#), who create training data from comparable text to label entire syntactic units and train a sequence labeling model to predict deletions and phrase substitutions in a complex sentence. Our approach is different in that it captures a larger variety of operations in a more global fashion, by using sentence-wide word alignments rather than surface heuristics. Furthermore, we use a more reliable (professionally created) corpus and our approach is more flexible as we do not rely on syntactic parse trees at test time.

Contributions This paper introduces the following main contributions: (1) We provide an in-depth analysis on the potential and limitations of the dominant approach to TS: end-to-end MT-style models; (2) We devise a method to automatically identify specific simplification operations in aligned sentences from complex-to-simple simplification corpora. This results in a corpus that can be used to study how human experts perform simplification tasks, as well as to train simplification models to address specific problems; and (3) We propose a sequence labeling model built from such a corpus to predict which simplification operations should be performed as a first step for a complete simplification pipeline. This approach is highly modular: once operations are identified, different methods can be applied to cover each simplification operation. We show that this operation-based TS approach is able to produce simpler texts than end-to-end models. The code for extracting the simplification operations is available at <https://github.com/ghpaetzold/massalign>, while our sequence labeling model is released at https://github.com/jbingel/ijcnlp2017_simplification.

2 Related Work

In what follows we give a brief description of previous work on statistical and neural models for TS. We first compare methods using versions of Simple English Wikipedia data ([Zhu et al., 2010](#); [Coster and Kauchak, 2011b](#)), before considering

recent work that relies on the professionally edited Newsela corpus ([Xu et al., 2015](#)).

Simple English Wikipedia [Zhu et al. \(2010\)](#) propose a syntax-based translation model for TS that learns operations over the parse trees of the complex sentences. They outperform several baselines in terms of Flesch index. [Coster and Kauchak \(2011b\)](#) train a phrase-based machine translation (PBMT) system and obtain significant improvements in terms of BLEU ([Papineni et al., 2002](#)) over a baseline. [Coster and Kauchak \(2011a\)](#) extend a PBMT model to include phrase deletion and outperform [Coster and Kauchak \(2011b\)](#). [Wubben et al. \(2012\)](#) also train a PBMT system for TS with a dissimilarity-based re-ranking heuristic, outperforming [Zhu et al. \(2010\)](#) in terms of BLEU. [Narayan and Gardent \(2014\)](#) built TS systems by combining discourse representation structures with a PBMT model, which outperforms previous approaches. [Xu et al. \(2016\)](#) modify a syntax-based MT system in order to use a new metric – SARI – for optimization and to include special rules for paraphrasing. Although their system does not outperform previous work in terms of BLEU, it achieves the best results according to SARI and human evaluation. [Zhang et al. \(2017\)](#) train a lexically constrained sequence-to-sequence neural network model for TS, based on the encoder-decoder architecture for MT. The system outperforms baseline systems (including a PBMT system) in terms of BLEU. Finally, [Nisioi et al. \(2017\)](#) propose a model for TS that is able to perform lexical replacements and content reduction. They use a neural encoder-decoder approach where they combine pre-trained (general domain and in-domain) word embeddings for the source and target sentences. They also perform beam search, finding the best beam size using either BLEU or SARI. Their best model outperforms previous PBMT-based approaches in terms of BLEU.

Newsela corpus To the best of our knowledge, [Zhang and Lapata \(2017\)](#) is the only work that explores MT-based approaches on the Newsela corpus. They train an attention-based encoder-decoder model ([Bahdanau et al., 2014](#)) and use reinforcement learning with a reward policy combining SARI, BLEU and cosine similarity (to measure meaning preservation). Their approach shows improvements over a PBMT system in terms of

BLEU and SARI, but no insights are given with respect to the transformations that are actually learned or how distant from the original sentences the simplifications are. They also experiment with the Simple Wikipedia corpus, yet do not outperform Narayan and Gardent (2014) on this data.

The neural end-to-end model we implement as a baseline in this paper is equivalent to that in Zhang et al. (2017) without the lexical constraints, while the statistical model is equivalent to the one in Coster and Kauchak (2011b).

3 Simplification via End-to-End Models

In addition to requiring large amounts of training data, MT-based approaches to TS are limited because of their black-box way of addressing the problem. As we are going to show in this section, standard end-to-end systems without special adaptation to TS do not succeed in learning alternative formulations of the original text. With a few exceptions (by the neural model), they tend to repeat the original text. We conjecture that this is because, for most original-side material, TS corpora do not consistently enough offer alternative simplified formulations: in the majority of instances, most words are kept as in the original.

To study the potential and limitations of end-to-end translation models for TS, we build models using state-of-the-art MT-based approaches and the Newsela corpus, arguably the most reliable (professionally created) and realistic (aimed at a target audience rather than research) resource to date.

The Newsela Corpus.¹ Newsela is a multi-comparable corpus where each document comes in up to six levels of simplicity, from 0 (original) to 5 (simplest). In our experiments, we only use sentence pairs stemming from adjacent levels of simplicity within the same document.²

Translation approaches require data aligned at the sentence level. Given the original Newsela

¹The Newsela Article Corpus was downloaded from <https://newsela.com/data>, version 2016-01-29.

²The motivations for only using adjacent levels are (i) that we assume that these are not “naturally” created (i.e. an expert would not start from an original text and directly generate a level 5 text, but rather go from 0 to 1, 1 to 2, ..., 4 to 5), and (ii) that the high degree of linguistic and stylistic differences between non-adjacent levels makes learning even more complex. For example, the average edit distance for sentences in the 0-1 group is 0.19, while for sentences in the 0-5 group, it is 0.65. As far as the first reason is concerned, note that we could not find any publicly available simplification guidelines for the Newsela corpus.

corpus, which only aligns different versions of the same document, we first align sentences using the algorithms described in (Paetzold and Specia, 2016b). Their algorithms search for the best alignment path between the paragraphs and sentences of parallel documents based on TF-IDF cosine similarity and an incremental vicinity search range. They address limitations of previous strategies (Barzilay and Elhadad, 2003; Coster and Kauchak, 2011b; Smith et al., 2010; Xu et al., 2015; Bott and Saggion, 2011) by disregarding the need for (semi-) supervised training, allowing long-distance alignment skips, and capturing N-to-N alignments. The alignments produced are categorized as:

- **Identical:** The alignment is one-to-one and the sentences are exactly the same (96,909 pairs across all adjacent levels).
- **1-to-1:** The alignment is one-to-one and the original-simplified sentences are different (130,790 pairs across all adjacent levels).
- **Split:** The alignment is 1-to-N (42,545 pairs across all adjacent levels).
- **Join:** The alignment is N-to-1 (7,962 pairs across all adjacent levels).

Translation Models. We built two types of models using state-of-the-art MT-based approaches: a phrase-based statistical MT model using Moses (Koehn et al., 2007),³ and a neural MT model using Nematus (Sennrich et al., 2017).⁴ The Neural Text Simplification tool (NTS) made available by Nisioi et al. (2017) was also used for comparison.⁵

For our translation-based experiments, we consider two combinations of sentence alignments, using (i) only one-to-one alignments (**1-to-1**) (130,970 sentence pairs), and (ii) all alignments (**all**), i.e., the entire sentence-aligned corpus with identical, 1-to-1, split and join alignments (278,206 sentence pairs). The first type of data (1-to-1) is the focus of this paper (see §4). The latter variant is included in the experiments for comparison, in particular to address the question whether more (but not necessarily better) data can aid data-intensive translation-based approaches. For all

³We follow instructions from <http://www.statmt.org/moses/?n=Moses.Baseline>

⁴We use a vocabulary size of 30,000 and the same parameters as in Sennrich et al. (2016).

⁵We use the same configurations as Nisioi et al. (2017).

System	Hyp vs. Ref		Hyp vs. Orig			
	BLEU↑	TER↓	BLEU	TER	%Same↓	SARI↑
Moses (all)	69.64	30.20	98.77	0.41	93.03	27.45
Nematus (all)	36.46	52.66	45.40	42.30	21.60	22.91
NTS (all)	68.35	31.37	90.52	7.19	72.91	27.36
Moses (1-to-1)	57.79	40.19	98.30	0.86	89.50	24.58
Nematus (1-to-1)	46.90	52.84	76.29	20.10	30.45	29.89
NTS (1-to-1)	53.79	45.24	77.63	16.70	42.76	30.44
Silver operations (1-to-1)	67.33	22.66	61.63	26.01	10.83	61.71
Predicted operations (1-to-1)	41.37	48.72	59.71	25.24	14.06	31.29

Table 1: Performance of translation-based and operation-based TS models (using silver or predicted operation labels, with only DELETION and REPLACE applied). Metrics are BLEU and TER between simplified version (Hyp) and reference (Ref) or original version (Orig), the percentage of sentences copied from the input (%Same), and SARI for the simplifications.

experiments, the respectively used data was first randomly split into training (80%), development (10%) and test (10%) sets and normalized for entities (incl. names, locations, numbers).

Simplification Quality. The first and second sections of Table 1 show the results of translation-based systems according to several metrics: similarity metrics commonly used in MT, comprising BLEU (Papineni et al., 2002) and TER (Snover et al., 2006, minimum edit distance), as well a specific text simplification metric, SARI (Xu et al., 2016). SARI measures how good the words added, deleted and kept by a simplification system are, after comparing the produced output to the original sentence and the simplification reference(s). It is similar to BLEU but rewards copying words from the original sentence. According to experiments performed by Xu et al. (2016), SARI is the metric that best correlates with human judgments of simplicity.

For both “all” and “1-to-1” variants, the BLEU and TER scores between hypotheses and references are worse for Nematus, showing that a baseline neural model tends to be more aggressive and potentially generate noisier modifications than Moses equivalents. To measure how strongly the various approaches modify the input sentences, these scores are also reported between the generated simplifications and the original inputs. Again, these metrics are worse for Nematus-based models, showing that they indeed perform more modifications on the sentences. Moses in turn is very conservative, keeping 90-93% of the test sentences

exactly in their original version. SARI shows low scores for all systems. NTS is also conservative in the “all” variant (attested by the high BLEU score between hypotheses and original sentences). For “1-to-1”, NTS produces more simplifications, diverging more from the original sentences.

Sentence-level Operations. Interestingly, even though Moses and Nematus are trained on the same data, they differ substantially with respect to what they can learn. This is demonstrated by an automatic inspection we conducted on the simplifications produced by both systems trained over all types of sentence alignments, i.e. including sentence splits and joins.

Table 2 reports the count and proportion of instances in the test set representing types of sentence-level transformation between the original and simplified sentence. It can be noted that Moses is much more conservative than Nematus and simply tends to copy the original as the output (“Identical” cases). However, as the majority (57%) of aligned sentences in the professional Newsela simplifications are edited, we do not consider copying a valid “simplification” in most cases. Note also that Moses displays an excessively high BLEU score between the *original* and hypothesis sentences (98.77), while the similarity between the original and reference sentences is much lower (71.57).

Manually inspecting some of the simplifications made, we find that when it comes to sentence splits, both MT-based simplifiers seem to be able to perform this type of transformation in an accu-

Operation	Moses		Nematus	
	Count	%	Count	%
Identical	25,882	93.03	10,906	39.20
1-to-1	1,920	6.90	15,428	55.45
Split	14	0.05	354	1.27
Join	4	0.01	1,132	4.07

Table 2: Count and proportion of instances affected by each type of simplification transformation performed by Moses and Nematus.

rate way. However, the proportion of such cases is very low (0.05% and 1.27% for Moses and Nematus, respectively) compared to the proportion in the gold data (13.5%) of the sentence pairs contain at least one split.

Moses only joins sentences in four cases, but these are all spurious instances where a period is incorrectly removed. Nematus is more successful at learning this type of operation. In most cases, it discards entire clauses that contain less relevant content. For example, it simplifies the sentence “*Lincoln often cried in public and recited sad poetry, according to Joshua Wolf Shenk, who wrote a book called Lincoln’s Melancholy*” to “*Lincoln often cried in public and recited sad poetry*”. We also find a few examples where the content that is not discarded is rewritten to some extent, mostly for grammaticality. The Nematus simplification of “*Frank was what the instructors called a ‘rock star’; he emerged as a leader who worked hard to keep the group together*” onto “*Frank was a leader who worked hard to keep the group together*” is a good example of that.

When it comes to 1-to-1 transformations, which can include a number of different operations (see §4), most transformations made by Nematus consist of segment deletions, some of which are paired with localized segment rewritings. As for Moses, most 1-to-1 outputs are identical to the original except for a few spurious typographic and punctuation changes. Because of that, Nematus simplifications are in average four tokens shorter than both complex originals and Moses simplifications.

A strong limitation of both models is their inability to address lexical complexity, performing very few lexical replacements. Most of the sentences that are lexically simplified have only one word replaced by another that does not preserve its original meaning. Take, for example, the word *clears* in the sentence “*It clears the way for troops on the ground with its huge bullets*”, which was

replaced by *gathers* by Nematus, and the word *agribusiness*, which was replaced by *offering* by Moses in sentence “*Older brother Nate has taken college courses on livestock raising and agribusiness*”. Some of these issues become more evident in the human evaluation we performed comparing both end-to-end systems to our proposed approach (§5.2).

4 Simplification via Sequence Labeling

Our approach to TS differs from translation-based models by explicitly predicting a set of operations to be applied at different positions in a complex sentence. Concretely, we tackle simplification as a sequence labeling problem, predicting operations at the token level and applying them downstream. As there are no high-quality and large-scale resources from which such operation sequences could be learned, we first generate training data as explained below.⁶

4.1 Generating Training Data

Given 1-to-1 sentence pairs, our method for data generation identifies deletions, additions, substitutions, rewrites (replacing or adding non-content words), and reorderings performed between sentences pairs.

Automatic operation annotation. The annotation process uses the following set of operation labels: DELETE (D), REPLACE (R), and MOVE (M) in the original (source) sentence; ADD (A) in the simplified sentence; and REWRITE (RW) in both.⁷

We first generate word alignments between the original and simplified sentences using the aligner by Sultan et al. (2014). Based on these alignments, we perform a word-level annotation for labels DELETE and REPLACE. Our heuristics are that if two words are aligned and are not an exact match, then the corresponding label is REPLACE. If a word in the original sentence is not aligned, it

⁶For the experiments with the proposed TS approach, only 1-to-1 alignments are suitable. It is indeed not realistic to expect that complex operations that involve significant structural changes (e.g., splitting or joining sentences) could be modeled using sequence labeling approaches. For such complex operations, we believe explicitly representing the sentences’ syntactic structures and learning abstract syntactic transformation rules (e.g. as in Woodsend and Lapata (2011) or Feblowitz and Kauchak (2013)) would be more advisable. However, we note that, as previously shown, translation-based end-to-end approaches also fail to learn such complex operations.

⁷Target-side annotations serve for analysis; they are ignored in our experiments as they are unavailable at test time.

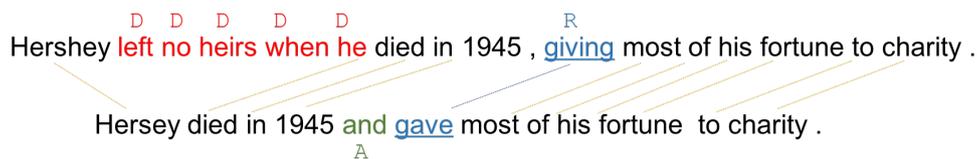

Figure 1: Example of automatic labeling based on word alignments between an original (top) and a simplified (bottom) sentence in the Newsela corpus. Unaligned words on the original side receive label ‘D’ (DELETE), while words that are aligned to a different form receive ‘R’ (REPLACE). Aligned words without an explicit label receive a ‘C’ label (COPY). Sentences are from the Newsela Article Corpus.

Figure 2: Example of automatic annotation for label MOVE (‘M’). Sentences are from the Newsela Article Corpus.

must be a DELETE, and if a word in the simplified sentence is not aligned, it is an ADD. In any other case, the word receives label C (COPY) or O (not part of a simplification operation) in the original or simplified sentence, respectively. For details, see Algorithm 1 in the supplementary material. Figure 1 presents an example for our automatic labeling approach. We consider REWRITE labels as special cases of REPLACE where the words involved are isolated (not in a group of same operation labels) and belong to a list of non-content words.

Finally, we label reorderings (MOVE) by determining if the relative index of a word (considering preceding or following deletions and additions) in the original sentence changes in the simplified one (Algorithm 2). See Figure 2 for an example. Words or phrases that are kept, replaced or rewritten, may be subject to reorderings, such that a token may have more than one label (e.g. REPLACE and MOVE). For that, we extend the set of operations by the compound operations REPLACE+MOVE (RM) and REWRITE+MOVE (RWM).

Evaluation of automatic labels. To test our algorithms, we compare their output to manual annotations for 100 sentences from level pair 0-1 of the Newsela corpus. The manual annotations were performed by four proficient English speakers. For 30 of those sentences, we calculated the pairwise inter-annotator agreement between annotators, yielding an average kappa value

of 0.57. We obtain an accuracy of 0.92 for all labels, and a micro-averaged F₁ score of 0.70 for all positive labels (i.e. excluding ‘C’ and ‘O’). Table 3 presents details on the performance of our annotation algorithms over the identified operations. Of the positive labels, the algorithms annotate most accurately additions and deletions. According to the confusion matrix in Table 4, the relatively low ability of capturing replacements is due to labeling them as deletions. This is mainly caused by word miss-alignments and by parser errors that our heuristics cannot recover from. The same logic applies for labels REPLACE+MOVE and REWRITE+MOVE. We are also able to capture most MOVEMENTS (high recall), but our reordering heuristic still requires improvement.

Label	Prec.	Rec.	F ₁	Support
A	0.66	0.92	0.77	261
D	0.76	0.90	0.82	371

O	0.99	0.95	0.97	2112
avg / total	0.92	0.92	0.92	4846

Table 3: Per-label performance of automatic annotation of operations.

We refer to these automatically generated labels as **silver labels**. As we describe in the next sections, the corpus annotated with these labels will be used to train our sequence labeling approach, eliminating the need for costly human-annotated data (i.e. gold labels). As a second way of evaluating the quality of our automatic labeling, we use these silver labels in a semi-oracle trial where we apply the actual simplification operations as given in the annotated corpus. In other words, we simply take the automatic labels as true and use the

	Automatically Annotated								O
	A	D	M	R	RM	RW	RWM	C	
A	240	0	0	0	0	2	0	0	19

O	105	0	0	0	0	9	0	0	1998

Table 4: Confusion matrix of true (rows) and automatically annotated (columns) operations on the manually annotated data.

alignments between original and simplified words to apply the actual operations. This is what we refer to as **silver operations** in Table 1. Using the automatic labeling would lead to much more accurate and less conservative simplifications than all translation-based approaches: it achieves the highest SARI and BLEU scores, and the lowest rate of copied input sentences among all systems tested using the 1-to-1 alignments. Therefore, the challenges now are (i) to predict such labels (§5.1), and (ii) to devise high-performing TS modules to apply simplification operations for each type of label (§4.2).

4.2 Application of Operations

For our experiments (§5), we consider two of the operations that our algorithms can identify with high precision: DELETE and REPLACE.⁸ Applying deletions is straightforward and amounts to simply omitting the respective token when generating the hypothesis sentence. For the REPLACE operation, we use the supervised Lexical Simplification approach of Paetzold and Specia (2017). Their simplifier generates candidate substitutions for target words using parallel complex-to-simple corpora and retrofitted context-aware word embedding models, selects the ones that fit the context of the target word through the unsupervised boundary ranking approach, then ranks candidates using a supervised neural ranking model trained

⁸We focus on this subset of operations since we currently lack good models to apply to the remaining operations. ADD, for example, would presume access to an external resource such as a knowledge base that would serve as a basis for inferring added content (which is oftentimes background information, for example an explanation that a certain person has a certain function). The results we obtain can thus be viewed as a lower bound on the simplification quality that can be expected from a model that integrates other operations.

over manually annotated simplifications. It also performs a final confidence check step: the target is only replaced by the highest ranking candidate if the trigram probability of two words preceding the target is higher for the candidate.

5 Experiments

Based on the automatic annotation procedure outlined above, we generate sequence annotations of 1-to-1 simplification operations in the Newsela corpus. On this data, we explore the questions (i) whether we can predict simplification operations to be performed on unseen data, and (ii) to what degree the prediction of these operations allows us to generate good simplifications.

5.1 Prediction of Simplification Operations

To predict simplification operations for each input word, we train a bidirectional recurrent neural network, with an initial embedding layer of size 300 and two hidden LSTM (Long-Short Term Memory) layers of size 100. The training is done using Keras (Chollet, 2015), with a batch size of 64, categorical cross-entropy loss and a dropout rate of 0.2 after the hidden layers. We optimize the model with Adagrad (Duchi et al., 2011). We monitor the tagging accuracy on held-out development data and employ early stopping when the development loss increases. We repeat this process ten times with random initializations and select the best model based on development set accuracy.

Table 5 shows that the LSTM model does not predict the silver labels very well. In particular, the model is relatively conservative with respect to the prediction of simplification operations, and tends to overpredict the majority class (i.e., to copy a token).⁹ DELETE is the operation that our model predicts best. Table 6 shows the relative confusion of predicted operations versus the silver labels, and confirms that the main error type of our system is to keep a token rather than performing some simplification operation on it. We also see a tendency for other operations to be predicted as deletions.

The results in the lower part of Table 1 (“Predicted operations (1-to-1)”), however, show that even though the operation predictions are far from the silver labels, our system is able to generate simple output by only applying the DELETE and

⁹By weighting the loss function by the ground truth class support at each timestep, we were able to alleviate the effect of a predominant majority class to some degree.

Label	Prec.	Rec.	F ₁	Support

Table 6: Confusion matrix of true (rows) and predicted (columns) operations on the test data.

REPLACE operations. In particular, our method achieves a better SARI score than all the baseline systems on the 1-to-1 alignments. As we consider the extrinsic evaluation of the final TS results to be more indicative of the quality of our model than its intrinsic evaluation in the sequence labeling task, we view this as a positive result.

5.2 Human Evaluation

We finally conduct a human evaluation of 100 simplifications produced by five simplifiers:

- The experts’ **Reference** simplification.
- The **Moses** simplifier (1-to-1).
- The **Nematus** simplifier (1-to-1).
- The **NTS** simplifier (1-to-1).
- Our **Sequence Labeling (SL)** simplifier.

Human evaluators (four NLP experts) are given the original sentence and the simplification in each of the above versions, and are asked to judge each of them with respect to their grammaticality (G), meaning preservation (M) and simplicity (S), using a Likert scale between 1 (worst) and 5 (best) for each aspect. We define “simplicity” as the extent to which the sentence was simpler than the original and thus easier to understand. A control

set of 20 sentences is evaluated by all annotators in order to compute inter-annotator agreement.

	G	M	S
Reference	5.00±0.0	4.45±0.9	2.70±1.3
SL	4.16±1.0	3.91±1.1	1.66±0.9
Nematus	4.49±0.9	3.99±1.2	1.46±0.9
Moses	4.98±0.2	4.99±0.1	1.14±0.4
NTS	4.75±0.6	4.08±1.26	1.53±1.0
Fleiss’ Kappa	0.372	0.457	0.342

Table 7: Average scores and standard deviation for grammaticality (G), meaning preservation (M) and simplicity (S) for the systems evaluated. The last row shows the inter-annotator agreement scores in terms of Fleiss’ Kappa.

Table 7 illustrates the average scores and standard deviations obtained by each system according to each criterion. As expected, the Moses simplifier obtains the highest grammaticality and meaning preservation scores, but the lowest simplicity scores, given that it tends to merely reproduce the input. Although Nematus and NTS manage to obtain slightly higher simplification scores, they still average very close to the lower end of the simplicity scale. Our SL approach, in turn, shows significantly higher simplicity scores than the other systems (according to a *t*-test with $p < 0.05$). Its less conservative edits, however, may in some cases come at the cost of lower scores for grammaticality and meaning preservation. The last row in Table 7 shows the values of inter-annotator agreement in terms of Fleiss’ Kappa for each evaluation aspect. Table 8 exemplifies some of the sentences for which our system was rated better and worse than the baselines. It is important to mention that, although the first two reference simplifications in Table 8 feature only minor punctuation changes, only 2,538 references (0.8%) in the dataset are of this type.

6 Conclusions and Further Work

We presented a novel approach to sentence simplification that uses automatically labeled training data from a large simplification corpus. Based on this annotated corpus, we devise a sequence labeling approach to text simplification that predicts simplification operations for individual words in the original sentence. Specific modules are then triggered to deal with each predicted operation.

Table 8: Example including original (O) and reference (R) sentences from the Newsela Article Corpus, and outputs generated by Moses (M), Nematus (N), NTS (T) and our sequence labeling approach (L).

The experiments reported here cover only deletions and lexical substitutions as operations.

Our approach has several theoretical advantages over end-to-end translation models, including easier interpretability of the types of simplification learned, as well as the possibility for late decoding for adaptive simplification. In practical terms, we showed that our system outperforms translation-based approaches on a number of metrics and overcomes the problems of excessive repetition of the original content.

According to human evaluation, our system achieves higher simplicity scores than the baseline systems, although this comes at the cost of

slightly lower meaning preservation and grammaticality. We hypothesize that some of the problematic cases stem from not realizing the addition operation. In general, our approach will likely profit from good models for the remaining operations, especially those that can also operate on spans of several tokens, making research on such models a natural direction for further work.

Domain-Adaptable Hybrid Generation of RDF Entity Descriptions

Or Biran*

Kathleen McKeown

Columbia University
kathy@cs.columbia.edu

Abstract

RDF ontologies provide structured data on entities in many domains and continue to grow in size and diversity. While they can be useful as a starting point for generating descriptions of entities, they often miss important information about an entity that cannot be captured as simple relations. In addition, generic approaches to generation from RDF cannot capture the unique style and content of specific domains. We describe a framework for hybrid generation of entity descriptions, which combines generation from RDF data with text extracted from a corpus, and extracts unique aspects of the domain from the corpus to create domain-specific generation systems. We show that each component of our approach significantly increases the satisfaction of readers with the text across multiple applications and domains.

1 Introduction

RDF ontologies are a wonderful source for generation: they feature standardized structure, are constantly expanding and span many interesting domains. However, generation from RDF introduces two major difficulties. First, RDF contains relationships between entities but often lacks other important information about an entity (e.g., historical background and context) which is hard to capture with simple relations. Second, RDF data spans many domains, and presents the difficulty of handling specific domains in generation.

Generally speaking, there are three approaches: domain-specific approaches (with hand-written or other rules relevant to each domain), which are not scalable; generic approaches (generating in

exactly the same way for all domains) which result in unnatural text and miss important content; and domain adaptation, which attempts to automatically transfer an approach from one domain to another.

Our approach aims to leverage the advantages of all three. We present a generic framework of generation *meta-systems* for RDF applications, which uses domain adaptation to create domain-specific systems. Biography and Company Description are examples of applications (an application is the description of RDF entities of a particular type), while Politician and Model are examples of domains within the Biography application.

The reason our framework is able to adapt to new domains automatically is that it relies on hybrid concept-to-text (C2T) and text-to-text (T2T) generation: part of the generated text consists of messages that are created from structured data according to a generic recipe, while another part comes from messages extracted from a domain corpus. In addition, we use existing methods to extract paraphrases and discourse models from the domain corpus, which further refines how text is generated differently for each domain.

2 Related Work

Generation from RDF data is not a new topic. [Duboue and McKeown \(2003\)](#) described a content selection approach for generation from RDF data. [Sun and Mellish \(2006\)](#) present a domain-independent approach for sentence generation from RDF triples. [Duma and Klein \(2013\)](#) propose an architecture for learning end-to-end generation systems from aligned RDF data and sampled generated text. End-to-end concept-to-text systems were proposed by [Galanis et al. \(2009\)](#), [Androutsopoulos et al. \(2013\)](#) and [Cimiano et al. \(2013\)](#), among others. For a survey of the

* Work done while at Columbia University

history of generation from semantic web data and its difficulties, see (Bouayad-Agha et al., 2014).

Generation *meta-systems* which can be automatically adapted to a new domain have been explored in recent years. Angeli et al. (2010) learn to make decisions about content selection and (separately) template selection from an aligned corpus of database records and text describing them. Kondadadi et al. (2013) describe a framework that learns domain-specific templates, content selection, ordering and template selection from an aligned corpus. Both approaches rely on supervised learning from an aligned corpus of data and sample texts generated from the data, which is a rare resource that does not exist for most domains.

Other recent work has focused on domain adaptation for existing generation systems (as opposed to creating adaptable meta-systems). There has been work on adapting generated text for different user groups (Janarthanam and Lemon, 2010; Gkatzia et al., 2014); adapting summarization systems to new genres (Lloret and Boldrini, 2015); adapting dialog generation systems to new applications (Rieser and Lemon, 2011) and domains (Walker et al., 2007); and parameterizing existing hand-crafted systems to increase the range of domains they can handle (Lukin et al., 2015).

In comparison, hybrid C2T-T2T generation is fairly unexplored territory. One recent example is Saldanha et al. (2016), which evaluated two approaches to generating company descriptions - one with Wikipedia structured data, the other utilizing web search results - and determined that the best results were achieved by combining the two. However, the hybrid system in this case was only a concatenation of two independent approaches.

3 Framework Overview

Our approach is a *framework* for creating generation *meta-systems* for specific applications of RDF entity description, such as *biography* and *company description* generation. Each meta-system, in turn, can be automatically adapted to a new *domain* within the application (e.g., the *politician* domain within the *biography* application) with only a simple text corpus, resulting in a *concrete generation system* that is specifically adapted to the domain. The generation system uses hybrid generation, building core messages from RDF data (C2T) and adding domain-specific secondary messages from the text corpus (T2T).

3.1 Semantic Data Structures

Our main data structure is the *Semantic Typed Template (STT)*. An STT is a tuple $\langle V, R, L \rangle$ consisting of a set of vertices labeled with entity types $V = \{v_1, \dots, v_n\}$, a set of edges labeled with relations among the vertices $R = \{r_1, \dots, r_m\}$ and a set of lexical templates $L = \{l_1, \dots, l_k\}$. The lexical templates L are all assumed to be lexicalizations of the semantics of the STT and paraphrases of each other, and must be phrases or sentences (that is, multiple-sentence lexicalizations are not allowed). The STT represents both the meaning and possible realizations of a sentence-level unit of semantics, without directly modeling the meaning in any way other than through the graph embodied in V and R . Instead, the meaning is grounded in the lexical template set.

A *message* is an instance of an STT τ with a concrete set of entities E . The set of types $V(\tau)$ constrains the number and types of entities that are allowed to participate in E , and the set of relations $R(\tau)$ constrains them further (the entities must have the proper relations among them).

3.2 Application Definition

RDF is a framework for organizing data using *triples*. Each triple contains a subject, a predicate and an object. In this paper, we use DBpedia (Auer et al., 2007) as our source of RDF data.

Each RDF application defines a single entity type η : each instance of the application is an entity belonging to this type (that is, there exists a triple such that the subject is the instance entity, the predicate is *typeOf* and the object is η). In *Biography*, $\eta = \text{Person}$, while in *Company Description* $\eta = \text{Company}$. In addition, each application defines a domain-differentiating predicate π : in *Biography*, $\pi = \text{Occupation}$, while in *Company Description* $\pi = \text{Industry}$. π must be chosen so that for each instance of the application, there exists an RDF triple where the subject is the instance entity and the predicate is π .

4 Domain Preparation

Our framework defines each application as a generation *meta-system*: a generic system from which concrete, domain-adapted systems can be created using a text corpus. This section describes the process of domain adaptation.

In this paper, we use Wikipedia as our source for domain corpora (each corpus is the set of Wikipe-

dia articles for all entities of the domain). While it is convenient to select the corpus in this way, there is nothing in the framework that requires the domain corpus to come from Wikipedia.

4.1 Extracting Domain STTs and Messages

Given a new domain corpus, we first extract *definitional sentences*: sentences in the corpus which contain an entity which is an instance of the domain. For example, in the Company Description application, in the Computer Hardware domain, definitional sentences for the entity *Apple* may include “Apple is an American multinational technology company” and “In 1984, Apple launched the Macintosh, the first computer to be sold without a programming language at all”.

To templatize the sentence and find its paraphrases, we use the approach of (Biran et al., 2016). Each definitional sentence is parsed, and NNPs that match an entity in DBpedia become typed slots, resulting in a template and a set of entities that match the slot types. The slot types are determined in two stages - sense disambiguation and hierarchical positioning - both achieved by leveraging the DBpedia ontology in combination with vector representations. We then use the templated paraphrase detection method described in (Biran et al., 2016) to compare the template with existing STTs that match the entities’ types and relations (all of which are known from the RDF ontology). The paraphrasing approach uses sentence-level vector representations to calculate the similarity of the template to all of the existing lexicalizations of an STT. If the template is determined to be a paraphrase for an existing STT, it is added as a new lexicalization; otherwise it is treated as a new STT. This new STT (or the old STT with a new lexicalization) can be used for any entity sets that have the appropriate types and relations.

In addition, we create a domain message from the STT and the entities found in the definitional sentence (effectively making the definitional sentence itself a possible lexicalization of this message, along with any alternative lexicalizations if the STT contains any). This gives us the set of potential secondary messages which we will use in the generation pipeline.

Figure 1 shows an example of this process. Two definitional sentences for the entity are found and templatized, and the first is matched to an existing STT (STT_1) as a paraphrase. The first two lexical-

izations of this STT are the default ones, created for all RDF triples as explained in Section 5.1; the third is the template of the definitional sentence. The STT can be used with any matching entity set, but in particular, it is matched to the entity set of the definitional sentence to create domain message 1. The second template cannot be matched to an existing STT, so a new one is created, along with domain message 2.

<p><u>Entity</u>: Candice Bergen (a model)</p> <p><u>Definitional sentences (found in Wikipedia)</u>:</p> <ul style="list-style-type: none"> - “Candice Bergen was born and raised in Beverly Hills, California” - “Bergen began her career as a fashion model and appeared on the front cover of Vogue magazine” <p><u>Templates</u>:</p> <ul style="list-style-type: none"> - [Person] was born and raised in [City] - [Model] began her career as a fashion model and appeared on the front cover of [Fashion Magazine] <p><u>STT_1 (matched through paraphrasing)</u>:</p> <p>$V = \{\text{Person, City}\}$ $R = \{v_2 \text{ birthPlace } v_1\}$ $L = \{$ “The birth place of $[v_1]$ is $[v_2]$”, “$[v_1]$’s birth place is $[v_2]$”, “$[v_1]$ was born and raised in $[v_2]$”, $\dots\}$</p> <p><u>Domain message 1</u>:</p> <p>$STT = STT_1$ $E = \{\text{Candice Bergen, Beverly Hills}\}$</p> <p><u>$STT_2$ (new, no RDF relation)</u>:</p> <p>$V = \{\text{Model, Fashion Magazine}\}$ $R = \{\emptyset\}$ $L = \{“[v_1]$ began her career as a fashion model and appeared on the front cover of $[v_2]”\}$</p> <p><u>Domain message 2</u>:</p> <p>$STT = STT_2$ $E = \{\text{Candice Bergen, Vogue Magazine}\}$</p>

Figure 1: An example of the domain STT and message extraction process.

4.2 Extracting the Discourse Planning Model

A discourse planning model is extracted from the domain corpus as described in (Biran and McKeown, 2015). The model provides prior and transition probabilities for the four top-level Penn Discourse TreeBank (PDTB) (Prasad et al., 2008) discourse relations: *expansion*, *comparison*, *contingency* and *temporal*. These probabilities reflect the discourse style that characterizes the domain, and will be used in Section 5 to determine the ordering of, and relations between, generated messages.

4.3 Extracting the Language Model

The language model used in the realization component of the pipeline is not a typical n-gram model. We are not trying to generate words within a sentence. Instead, we have a set of templates for each message to generate (which corresponds to a sentence or phrase in the final text) and we want to choose one that best fits the context. For this purpose, we define and extract three cross-sentence language models.

The first language model is a cross-sentence model for pairs of words that appear in adjacent sentences. The probability that a word w appears in a sentence if word v appears in the previous sentence, independently of everything else, is

$$P(w|v) = \frac{\text{Count}(v, w)}{\text{Count}(v)}$$

For the probability of a particular template \mathcal{T} given a selected previous sentence \mathcal{S} , we take the average over all word pairs:

$$P_{LM_1}(\mathcal{T}|\mathcal{S}) = \frac{\sum_{(w,v) \in \{\mathcal{T} \times \mathcal{S}\}} P(w|v)}{|\{\mathcal{T} \times \mathcal{S}\}|}$$

The second language model is a POS bigram pair model. It treats POS bigrams as individual words in the first model; in other words, $P_{LM_2}(\mathcal{T}|\mathcal{S})$ is defined in the same way as $P_{LM_1}(\mathcal{T}|\mathcal{S})$, except that w and v stand for POS bigrams (instead of words) in the candidate template and the selected previous sentence, respectively.

The third is a sentence length model. Here we compute the expected length of a sentence \mathcal{T} given the length of the previous sentence \mathcal{S} as

$$E[\#\mathcal{T}|\#\mathcal{S}] = \frac{\sum_{\{\sigma_i: \#\sigma_{i-1} = \#\mathcal{S}\}} \#\sigma_i}{|\{\sigma_i : \#\sigma_{i-1} = \#\mathcal{S}\}|}$$

where $\#\mathcal{S}$ is the length of sentence \mathcal{S} in words. We then smooth this expectation estimate using

the estimates of nearby lengths:

$$\tilde{E}[\#\mathcal{T}|\#\mathcal{S}] = \frac{\sum_{i=\#\mathcal{S}-3}^{\#\mathcal{S}+3} E[\#\mathcal{T}|i]}{7}$$

Based on this smoothed expectation, we define the probability of a template \mathcal{T} given a selected previous sentence \mathcal{S} :

$$P_{LM_3}(\mathcal{T}|\mathcal{S}) \triangleq \frac{1}{(\#\mathcal{T} - \tilde{E}[\#\mathcal{T}|\#\mathcal{S}])^2}$$

This definition is not intended to have a true probabilistic interpretation, but it preserves an order of likelihood since it increases monotonically as the length of \mathcal{T} approaches the expected values.

These models are used in Section 5 to rank possible templates for a message being generated.

5 Generation

Once a domain has been prepared, we can generate text for any instance in that domain. The generation pipeline contains four components: *core message selection*, *domain message selection*, *discourse planning* and *realization*.

5.1 Core Message Selection

For each instance, we produce one core message from each RDF triple that has the instance’s entity as the subject. To create a message from a triple, we first match it to an STT based on the predicate. Each predicate becomes an STT with two entity types (the type of the subject, which is the instance entity, and the type of the object) in V ; a single relation between the two types (the predicate) in R ; and two simple initial templates in L :

- The (PREDICATE) of $[v_1]$ is $[v_2]$
- $[v_1]$ ’s (PREDICATE) is $[v_2]$

where (PREDICATE) is replaced with the relevant predicate. Additional templates are then found using paraphrasal template mining as described in the previous section. We also create plural versions for cases where v_2 is a list of entities.

For example, in the biography domain, we create an STT for the *birthDate* predicate with $V = \{\text{person}, \text{date}\}$; $R = \{v_1 \text{ birthDate } v_2\}$; and an initial template set $L = \{\text{“The birth date of } [v_1] \text{ is } [v_2]\text{”}, \text{“} [v_1] \text{’s birth date is } [v_2]\text{”}\}$. In the preparation stage described in Section 4, L may be expanded with paraphrasal templates found in the corpus,

for example “[v_1] was born in [v_2]” (see Figure 1 for an example).

We then create a message that contains the relevant STT and the entities in the triple. In case there are multiple triples with the same subject and predicate but different objects, we create a single message with a plural version of the STT and define the second entity as the list of all objects. We shall refer to the set of core messages as C .

In this paper we separate the content selection problem into two parts. The first (this component) is application-dependent and domain-agnostic, and handles the skeleton or core structure of the generated text; the next component handles additional domain-specific content.

5.2 Domain Message Selection

The set of core messages gives us the core entities which participate in the core messages.

We also have the set of domain messages for the domain which are prepared (extracted from the domain corpus) ahead of time as described in Section 4. The set P of *potential domain messages* for generation is the subset of domain messages which contain the instance entity. In this stage of the pipeline, we select a subset of these potential domain messages to include in the generated text.

To select domain messages, we utilize the energy minimization framework described by [Barzilay and Lapata \(2005\)](#). They describe a formulation that allows efficient optimization of what they call *independent scores* of content units and *link scores* among them through the energy minimization framework. The function to minimize is:

$$\sum_{p \in S} ind_N(p) + \sum_{p \in N} ind_S(p) + \sum_{\substack{p_i \in S \\ p_j \in N}} link(p_i, p_j)$$

where S is the subset of P selected for generation, N is the subset not selected ($P - S = N$), $ind_S(p)$ is p 's intrinsic tendency to be selected, $ind_N(p)$ is p 's intrinsic tendency to not be selected and $link(p_i, p_j)$ is the dependency score for the link between p_i and p_j . A globally optimal partition of P to S and N can be found in polynomial time by constructing a particular kind of graph and finding a minimal cut partition ([Greig et al., 1989](#)).

The base preference of a message p is defined

$$Bp(p) = \begin{cases} |R(\tau(p))| & \text{if } M(p) = E(p) \\ -|E(p) \setminus M(p)| \frac{\#L(\tau(p))}{10} & \text{otherwise} \end{cases}$$

where $M(p)$ is the subset of $E(p)$ - the entities of message p - which contains only entities that participate in at least one relation in $R(\tau(p))$, and $\#L(\tau(p))$ is the average length in words of the templates of the STT $\tau(p)$. This definition results in a positive score for a message where all entities participate in a relation, whose weight is the number of relations it covers; conversely, messages which have entities that do not participate in a relation (*unaccounted entities*), have a negative score which increases in magnitude with the number of unaccounted entities and with the length of the templates realizing them. The intuition is that a long message containing many entities that match no triples is unlikely to be relevant.

Then, we define the individual preference scores $ind(p)$ as an average of the similarity of p to each of the core messages using the Jaccard coefficient as a similarity score:

$$ind(p) = \frac{\sum_{m \in C} J(p, m)}{|C|}$$

Finally, we define $ind_S(p)$ and $ind_N(p)$ as

$$ind_S(p) = \begin{cases} Bp(p) \times ind(p) & \text{if } Bp(p) \geq 0 \\ 0 & \text{otherwise} \end{cases}$$

$$ind_N(p) = \begin{cases} \frac{Bp(p)}{ind(p)} & \text{if } Bp(p) < 0 \\ 0 & \text{otherwise} \end{cases}$$

The link scores $link(p_i, p_j)$ are defined using a type similarity score. In contrast to the individual preference scores, where we maximize the entity overlap with core messages (to avoid including messages with no connection to the core of the text), we should not encourage the domain messages to all share the exact same set of entities. Instead, we focus on a softer semantic similarity: shared entity types. This score enhances the coherence of the generated text (for example, by encouraging a focus on the executives of a company in a particular instance, and on its products in another) but allows a flexible range of messages to be selected. The link score definition is

$$link(p_i, p_j) = \frac{\sum_{(e_i, e_j) \in \{E(p_i) \times E(p_j)\}} typsim(e_i, e_j)}{|\{E(p_i) \times E(p_j)\}|}$$

where

$$typsim(e_i, e_j) = \begin{cases} 1 & \text{if } type(e_i) = type(e_j) \\ 0 & \text{otherwise} \end{cases}$$

Denoting the subset of P selected by this process as $selected(P)$, at the end of this process, we have $M = C \cup selected(P)$ - the full set of messages to be generated.

5.3 Discourse Planning

The discourse planning component transforms the unordered set of messages M into an ordered sequence of paragraphs $\mathcal{P} = (p_1, \dots, p_k)$ where each paragraph p_i is an ordered discourse sequence $p_i = (m_1, r_1, m_2, r_2, \dots, r_{n-1}, m_n)$, where the alternating m_i and r_i are messages and discourse relations, respectively.

First, we calculate the semantic similarity of each pair of messages in M as follows:

$$sim(m_i, m_j) = \cos(\mathcal{V}_{\psi_{m_i}}, \mathcal{V}_{\psi_{m_j}})link(m_i, m_j)$$

where ψ_{m_i} is the pseudo-sentence of message m_i , constructed by concatenating all of its templates; $\mathcal{V}_{\psi_{m_i}}$ is the vector representing ψ_{m_i} , defined as the geometric mean of the vectors of all words participating in ψ_{m_i} (the word vectors are traditional context vectors extracted from Gigaword with a window of 5 words); and $link(m_i, m_j)$ is defined as above. Essentially, this is a combination of the entity type-based semantic similarity and the distributional similarity of the lexicalizations.

We use single-linkage agglomerative clustering (with a stopping criteria of $sim(m_i, m_j) \leq 0.05$) to group the messages into semantic groups of messages that are similar in topic. Then, within each semantic group, we find potential discourse relations for each pair of messages:

1. If the STTs of m_i and m_j are the same but they have no entities in common then there is a potential *comparison* relation between them
2. If $J(m_i, m_j) \geq 0.5$ then there is a potential *expansion* relation between them
3. Manually annotated relations for 20 specific pairs of RDF predicates, e.g. *birthPlace* and *residence* may have a temporal or a comparison relation between them
4. All message pairs can have a *norel* relation

Next, we use the discourse model extracted from the domain corpus to generate a discourse sequence. In order to make sure entity coherence is taken into account when choosing the ordering in addition to discourse coherence, we augment

the probabilities coming from the discourse model $P_{\mathcal{D}}(r_i|R_{i-1})$, where R_{i-1} is the sequence of relations chosen so far, with the entity coherence score $J(m_i, m_{i-1})$, so that the probability of a relation between two messages is given by

$$P(r_i|R_{i-1}, m_i, m_{i-1}) = P_{\mathcal{D}}(r_i|R_{i-1})J(m_i, m_{i-1})$$

The discourse sequence is created stochastically using these probabilities as described in (Biran and McKeown, 2015). Then, we break the discourse sequence into paragraphs that do not contain *norel* relations. Concatenating all of the paragraphs built from the discourse sequences of all semantic groups, we have an unordered set of paragraphs \mathcal{P} , where each p_i is an ordered discourse sequence of messages and relations.

To order the paragraphs, we use the following importance score:

$$imp(p_i) = \frac{\sum_{m \in p_i} |\{e | e \in E(m)\}| Bp(m)}{|p_i|}$$

which is the average number of entities in a message of p_i , weighted by the base preference score $Bp(m)$. The paragraphs are then sorted in decreasing order using this score, so that the paragraphs containing the most important messages tend to appear earlier in the text.

5.4 Realization

At this stage, we have the ordered set of paragraphs \mathcal{P} to be realized. To generate a paragraph, we select a template for each message and then select a discourse connective, or choose not to use one, for each discourse relation.

Selecting a template is done using the three language models prepared ahead of time, as described in Section 4. We build a ranker from each model, and choose the template from $\{l \in L(\tau(m))\}$ that maximizes the the sum of ranks given the previously realized sentence (in the paragraph) s :

$$\hat{l} = \operatorname{argmax}_{l \in L(\tau(m))} \sum_{i=1}^3 \operatorname{rank}(P_{LM_i}(l|s))$$

Once the template is chosen, we fill the slots with the entities $E(m)$ to make it a sentence.

At this point we have the final lexical form of the message, and the last task is to link it with the previous sentence. We have a small set of discourse connective templates for each one of the 4

class-level PDTB relations (for example, “ m_i . However, m_j ” is one of the templates for the *comparison* relation), and we know the relation between the message and the previous message. We randomly select a connective, with a 50% chance of having no connective and a uniform distribution among the connectives for the relation, but avoid using connectives for sentence pairs that are together larger than 40 words.

At the end of this step, all paragraphs are generated with lexicalized sentences and connectives.

6 Evaluation

To evaluate our RDF applications we conducted a crowd-sourced human experiment using texts generated from four domains in two applications: Biographies of *Politicians* and *Models*, and Company Descriptions of *Automobile Manufacturers* and *Video Game Developers*. We picked 100 instances from each domain of each application, for a total of 400 (we picked the instances that had the most RDF triples in each domain). Then, we generated 4 versions for each instance:

1. A full-system version
2. A version that excludes paraphrase detection (so core messages only had the two manually-created templates, and domain messages only had a single template each)
3. A version that excludes the discourse model (so discourse planning was done using only entity coherence scores)
4. A baseline version that has no domain adaptation at all and is fully C2T instead of hybrid (i.e., only core messages were generated, without any extracted domain messages)

Using these 4 versions, we devised 3 questions for each instance. In each question, the annotator saw two texts about the same entity - the full system version, and one of the other three versions - and was asked which is better (with an option of saying they are equal), along several criteria. The questions were presented in random order and the systems were anonymized. We showed each question to three annotators and used the majority vote, throwing out results where there was total disagreement between the annotators, which happened 12% of the time for the baseline version and 17 – 21% of the time for the other variants.

The questions included four criteria: the *content* of the text (information relevance); the *ordering* of the sentences and paragraphs; the *style* of the text (how human-like it is); and the *overall* satisfiability of the text as a description of the person/company in question.

We show the results of the experiment in Table 1. The results in this table are for both applications and all four domains. Each comparison (e.g., “No Hybrid VS Full System” shows the breakdown of preference by annotators when they were shown texts generated by the two variants: how many (in percentage) preferred the baseline system (e.g. No Hybrid), how many preferred the full system, and how many thought they were equal. We also show the *winning difference* between the two systems, i.e. those who thought that the full system was better than the baseline minus those who thought the opposite, and we measure statistical significance on these differences. Statistically significant results are marked with a dagger.

6.1 Discussion

The most striking result of Table 1 is that the full system is overwhelmingly favored by annotators over the non-hybrid baseline, with a 32% – 46% lead in all categories. This result, more than anything, shows the value of our framework and the hybrid approach. The full system was particularly better than this baseline in *content*, which is generally expected since it by definition contains less content than the full system (it only generates the core messages); note, however, that this result suggests that the extracted and selected messages are *relevant* and enhance the reader’s satisfaction with the text. The baseline (which, in addition to not using extracted domain messages, also does not use the extracted paraphrasal templates and discourse model) also loses heavily to the full system in *ordering* and *style*, as well as overall. In all criteria, the percentage of annotators who thought the texts were equally good was low (11% – 20%), suggesting that the difference was very visible.

While the effect of removing a single component is not as dramatic as removing both in addition to the domain messages, it is clearly visible in the preferences of Table 1. Both reduced versions (*No Paraphrases* and *No Discourse Model*) lose to the full system in every criteria, often in double digits. The more meaningful component

	Preference	Content	Ordering	Style	Overall
No Hybrid VS Full System	No Hybrid	20%	27%	24%	22%
	Equal	14%	11%	20%	14%
	Full System	66%	62%	56%	64%
	Full - baseline win diff.	46% †	35% †	32% †	42% †
No Paraphrases VS Full System	No Paraphrases	29%	33%	29%	30%
	Equal	31%	26%	28%	27%
	Full System	40%	41%	43%	43%
	Full - baseline win diff.	11% †	8% †	14% †	13% †
No Discourse Model VS Full System	No Discourse Model	33%	34%	32%	34%
	Equal	30%	22%	26%	23%
	Full System	37%	44%	42%	43%
	Full - baseline win diff.	4%	10% †	10%	9% †

Table 1: Preferences, with different criteria, given by the human annotators when presented with two versions - the full system VS each of the baseline versions. Statistically significant winning differences are marked with a dagger.

appears to be the paraphrases: the *No Paraphrases* version loses to the full system more heavily than *No Discourse* in *content*, *style* and *overall*. This result is not surprising since paraphrases have a dramatic effect on the text itself (they change the templates that are used to convey information, enhance the diversity of the text and may merge messages that are duplicates), and it suggests that the paraphrases we find are generally more satisfying than the default. It is also not surprising that the *No Discourse Model* variant loses most on ordering. While the difference is not as dramatic here, it is statistically significant and shows that our extracted domain-specific discourse model produces a more satisfying ordering of the text.

6.2 Examples

Figure 2 shows the output of the biography for politician *Marine Le Pen* of the full system and the non-hybrid baseline. To show the contributions of different components, we mark sentences generated from extracted domain messages in **bold**, and sentences generated from core messages using an extracted paraphrase in *italics*. Sentences in unmarked typeface are those that were generated from core messages using a default template.

The two variants make clear the main advantage of the full system: it simply has more content. The full output contains six sentences (messages) more than the baseline, which are clearly relevant to the biography. The entire last paragraph, concerned with Le Pen’s policies and positions - an important part of a politician’s biography - is missing

from the baseline. These messages were extracted from the corpus and show the power of the hybrid approach. In addition to the final paragraph, two extracted messages are included which are concerned with Le Pen’s controversial history, and together with the RDF-derived message about her offices, they comprise a paragraph generally about her political background. This is typical of the way that extracted messages contribute to the organization of the text in addition to the content: in the baseline version, the offices message is lumped together with messages about her background in general (alma mater, birth date, religion, partner etc). It demonstrates how the full system consistently outperforms the baseline in the *ordering* and *style* criteria, in addition to *content* and *overall*.

Figure 3 shows the output of the company description for video game developer *Taito Corporation* of the full system and the no-paraphrases variant. In this case the two outputs contain exactly the same information and have almost the same organization of the text. The way in which the text is realized, however, is very different in the last paragraph. The full system realizes four of the six messages in that paragraph using extracted templates, and merges two messages into a single template in one case (“Taito Corporation was founded in 1953 by Michael Kogan”, instead of the two sentences in the no-paraphrases baseline). The single-sentence messages also look better, e.g. “Taito Corporation has around 662 employees” instead of the awkward-sounding “Taito

<p>Full system output:</p> <p>Marine Le Pen's birth places are Neuilly-sur-Seine and France. Corporation's number of employees is 662".

7 Conclusion

We introduced a framework for creating hybrid concept-to-text and text-to-text generation systems that produce descriptions of RDF entities, and can be automatically adapted to a new domain with only a simple text corpus. We showed through a human evaluation that both the hybrid approach and domain adaptation result in significantly more satisfying descriptions, and that individual methods of domain adaptation help with the criteria we expect them to (i.e., finding paraphrases helps with content and style while an extracted discourse model helps with ordering). The code for this framework is available at www.cs.columbia.edu/~orb/hygen/.

Abstract

With the advent of the Internet, the amount of Semantic Web documents that describe real-world entities and their inter-links as a set of statements have grown considerably. These descriptions are usually lengthy, which makes the utilization of the underlying entities a difficult task. Entity summarization, which aims to create summaries for real world entities, has gained increasing attention in recent years. In this paper, we propose a probabilistic topic model, ES-LDA, that combines prior knowledge with statistical learning techniques within a single framework to create more reliable and representative summaries for entities. We demonstrate the effectiveness of our approach by conducting extensive experiments and show that our model outperforms the state-of-the-art techniques and enhances the quality of the entity summaries.

1 Introduction

With the emergence of Linked Open Data (LOD)¹ as a way of publishing and interacting with the information, many datasets such as DBpedia (Bizer et al., 2009) and YAGO (Hoffart et al., 2013) have been created and are publicly available on the Web. For example, DBpedia as part of LOD is a knowledge base extracted from Wikipedia that consists of Wikipedia resources (entities) described as RDF statements (i.e., RDF triples). The Resource Description Framework (RDF) is the Semantic Web standard data model used for representing information on the Web. An RDF triple is represented in the form of

$\langle \text{subject}, \text{predicate}, \text{object} \rangle$. The latest English version of DBpedia contains over 4.5 million entities collectively described by over 1.6 billion triples. This means that each entity description has an average of 355 RDF triples. Human users and computer applications need to consider these lengthy descriptions while performing various semantic tasks. Thus, *entity summarization*, a task of producing more concise, but still sufficient entity description, has garnered a significant amount of attention.

Recently, with the huge growth of information, summarization techniques are becoming some of the main approaches to making the information more readily available. In fact, summarization techniques aim to facilitate the identification of structure and meaning in data. Researchers in different communities have taken a strong interest in this task and, accordingly, have proposed various methods for a wide variety of summarization techniques in multiple areas. Document summarization (Nenkova and McKeown, 2012), database summarization (Bu et al., 2005), and graph summarization (Navlakha et al., 2008) are just a few examples that have been studied by different communities. RDF data summarization and in particular entity summarization, has attracted considerable attentions in recent years as it can benefit many other tasks in the natural language processing area, including entity recognition (Zhao and Kit, 2008), entity disambiguation (Dai et al., 2011), and many others. Several approaches have been developed to summarize RDF data with respect to entities, including RELIN (Cheng et al., 2011), FACES (Gunaratna et al., 2015), and LinkSUM (Thalhammer et al., 2016). RDF summarization differs from document summarization in the sense that RDF triples are structured and do not have many frequently used words to help the summarization task, which makes RDF

summarization more challenging.

Topic modeling has become a popular method for uncovering the hidden themes from text corpora. Topic models usually consider each document as a mixture of topics, where a topic is a probability distribution over words. When the topic proportions of documents are estimated, they can be used as the themes (high-level semantics) of the documents. Topic models have been widely used for various text mining tasks, such as machine translation (Su et al., 2015), word embedding (Batmanghelich et al., 2016; Das et al., 2015), automatic topic labeling (Wan and Wang, 2016; Allahyari and Kochut, 2015; Allahyari et al., 2017b), and others (Allahyari et al., 2017a).

In this paper, we propose a novel topic model, called ES-LDA, that integrates prior knowledge with the topic modeling within a single framework for RDF entity summarization. In our approach, each entity, which is considered as a document, is a multinomial distribution over the predicates (properties), where each predicate is a probability distribution over the subjects and objects of the triples in the RDF data. We rank the triples based on their probability distributions and choose the top- k triples that best describe the underlying entity as its summary. We evaluated our approach against state-of-the-art techniques and our experiments indicate that our approach outperforms other methods in terms of the quality of summarization.

The rest of the paper is organized as follows: Section 2 presents an overview of related work. Section 3 introduces the baseline for this paper. In Section 4, we define the main problem and propose our model in detail and afterwards, in Section 5, we explain the configurations of our model and describe the experiments. Finally, in Sections 6 and Section 7, we discuss the results and conclude the paper, respectively.

2 Related Work

Summarization methods can be divided into two main categories, which are called extractive and non-extractive (abstractive) summarization. In extractive approaches, which are usually applicable in text and ontology summarization (Jones, 2007) (Zhang et al., 2007), a set of features is extracted directly from the input data. On the other hand, in non-extractive methods, which generally are employed in graph (Navlakha et al., 2008)

and database (Bu et al., 2005) summarization, new sentences from the input data are generated (Hahn and Mani, 2000) to form a summary. In this research, we focus on extractive summarization. The concept of entity summarization in the form of RDF graph data has attracted more attention in recent years. Cheng et al. (Cheng et al., 2011) proposed entity summarization method, called RELIN, based on the PageRank algorithm to extract representative triples, called representative features for RDF graph entities. Because of the centrality based ranking issue, RELIN highlights the most similar and central triples, while in summarization, the diversity of summarized triples is the key point.

SUMMARUM (Thalhammer and Rettinger, 2014) is a system for a better navigation within Linked Data through the ranking of triples. This system also uses the PageRank algorithm to rank triples according to the popularity of resources with the help of Wikipedia pages. Two aforementioned approaches could not meet the diversity requirement in the summarization process. FACES (Gunnaratna et al., 2015), on the other hand, tries to keep a balance between the centrality and diversity of the selected triples for each entity. It utilizes a clustering algorithm, called Cobweb (Fisher, 1987), to cluster related triples before ranking them to keep the diversity in the summarization. The recent version of SUMMARUM, which is called LinkSUM (Thalhammer et al., 2016), focused more on the objects instead of the diversity of properties for entities and showed a better result on the same dataset, in comparison with FACES. Beside the aforementioned techniques dedicated to entity summarization, there are various ranking models and tools, including TripleRank (Franz et al., 2009) and TRank (Tonon et al., 2013) that rank triples and concepts, respectively, incorporating ranking algorithms. However, Cheng et al. (2011) indicated that these methods are not appropriate for the entity summarization problem, which needs ranking of feature sets based on their importance to identify the underlying entity.

3 Preliminaries

An RDF data graph is a collection of nodes and edges that connect the nodes together. Nodes are usually recognized by unique IDs which are called *Uniform Resource Identifiers (URIs)* or exact values (i.e. numbers, dates, etc) namely *Lit-*

erals. An RDF graph is represented in a form of a collection of triples, each including a *Subject*, *Predicate*, and *Object*. In an RDF graph, an entity is defined as a subject with all predicates and corresponding objects to those predicates, collectively forming the entity’s description. As Table 1 shows, the *J.C.Penny* entity is represented by its predicates (properties) and the corresponding objects in the triple format. For example, the triple $\langle J.C.Penny, industry, Retail \rangle$ introduces *J.C.Penny*’s industry as *Retail* (due to space limitations we have dropped the first part of the URIs).

Definition 1 (Entity summary): Given an entity e and a positive integer k , a summary of the entity e , denoted $Sum(e, k)$, is the top- k subset of all predicates and corresponding objects that are most relevant to that entity. As Table 1 shows the top-5 summary for *J.C.Penny* entity, which is represented through *foundedBy*, *industry*, *keyPerson*, *location*, and *type*.

3.1 Latent Dirichlet Allocation (LDA)

The Latent Dirichlet Allocation (LDA) is a generative probabilistic model for extracting thematic information (topics) from a collection of documents. LDA assumes that each document is made up of various topics, where each topic is a probability distribution over words.

Let $\mathcal{D} = \{d_1, d_2, \dots, d_{|\mathcal{D}|}\}$ be a corpus of documents and $\mathcal{V} = \{w_1, w_2, \dots, w_{|\mathcal{V}|}\}$ a vocabulary (words) of the corpus. A topic $z_j, 1 \leq j \leq K$ is represented as a multinomial probability distribution over the $|\mathcal{V}|$ words, $p(w_i|z_j), \sum_i^{|\mathcal{V}|} p(w_i|z_j) = 1$. LDA generates the words in a two-stage process: words are gener-

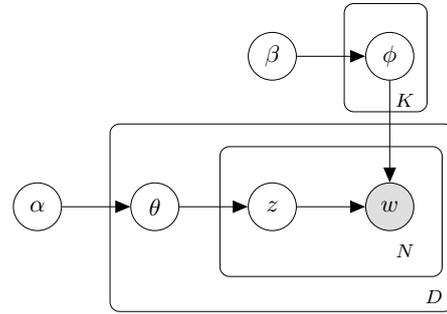

Figure 1: LDA Graphical Representation

ated from topics and topics are generated by documents. More formally, the distribution of words, given the document, is calculated as follows:

$$p(w_i|d) = \sum_{j=1}^K p(w_i|z_j)p(z_j|d) \quad (1)$$

The graphical model of LDA is shown in Figure 1 and the generative process for the corpus \mathcal{D} is:

1. For each topic $k \in \{1, 2, \dots, K\}$, sample a word distribution $\phi_k \sim \text{Dir}(\beta)$
2. For each document $d \in \{1, 2, \dots, \mathcal{D}\}$,
 - (a) Sample a topic distribution $\theta_d \sim \text{Dir}(\alpha)$
 - (b) For each word w_n , where $n \in \{1, 2, \dots, N\}$, in document d ,
 - i. Sample a topic $z_i \sim \text{Mult}(\theta_d)$
 - ii. Sample a word $w_n \sim \text{Mult}(\phi_{z_i})$

In the LDA model, the word-topic distribution $p(w|z)$ and topic-document distribution $p(z|d)$ are learned entirely in an unsupervised manner, without any prior knowledge about what words are re-

lated to the topics and what topics are related to individual documents.

4 Problem Statement

In this section, we first describe the problem and then define how to utilize topic models for RDF graphs. Then, we formally introduce our ES-LDA model and explain how to integrate prior knowledge from RDF data graph within a topic model for entity summarization.

4.1 Problem Definition

Generating summaries for voluminous Semantic Web data, and in particular RDF data, for quick identification of entities has gained considerable attention as a challenging problem in the Semantic Web community. In the literature, *Entity Summarization* is defined as selecting a small but representative subset of the original triples associated with an entity. In this context, given an RDF data set comprising a collection of entities, where each entity is described by a set of its properties (i.e., all triples with the entity as the subject), our goal is to choose *top-k* representative triples for each entity. In other words, since all triples associated with an entity (as its description) share the same subject, our objective is to select *top-k* predicates and their corresponding objects among these triples that best summarize the entity’s description.

4.2 Topic Models for RDF Graphs

Topic models were originally introduced for text documents, however, they have been applied to other types of data, such as images (Blei and Jordan, 2003), and recently (Sleeman et al., 2015) used topic modeling for RDF graphs. The first step in applying topic models is to define documents and word-like elements as the basic building blocks of documents. Since an RDF graph is usually represented as a set of triples, where each triple t consists of a subject s , predicate p , and an object o , in the form of $\langle s, p, o \rangle$, we can consider a collection of such triples as a “document”.

Definition 2 (document): A document d is defined as a set of triples, $d = \{t_1, t_2, \dots, t_n\}$, that describe a single entity e . In other words, all triples of a document d have the same subject.

“Words” of a document can be extracted from different parts of its triples. We define a “word” w as the subject or object of a triple t in document d . Therefore, each document is represented by a “bag

of words” including all the subjects and objects of its triples. In this paper, all subjects in the triples of a document are the same, because each document corresponds to a single entity, hence, in practice each document is a “bag of objects”²

Topic models usually utilize some data preprocessing, such as punctuation removal, down-casting, and abbreviation expansion, etc., to enhance the final performance. We also performed preprocessing on the RDF data and filtered out the schema and dataset dependent predicates, such as *sameAs*, *wikiPageExternalLink*, *subject*, *wikiPageWikiLink*, in addition to *literals*. Since we work with RDF graphs that differ from typical text documents in the sense that RDF data are represented as triples, we need to address several challenges mentioned in (Sleeman et al., 2015) to be able to run topic models on RDF data. These challenges include sparseness, use of unnatural language, and the lack of context. RDF data can be affected by **Sparseness**. We consider documents as sets of triples associated with a single entity. Such a set can be very large, leading to a large bag of words with a semantic theme, or small (sparse), resulting in a poor bag of words with less contextual information. It is also possible that a document with a high number of triples ends up having a small bag of words after pre-processing; for example based on Table 1, *J.C.Penny* entity comes with *United_States*, *James_Cash_Penney*, *Retail*, *Ron_Johnson*, *Plano*, *Texas*, *United_States*, *S&P_500* and *Public_company* as a bag of words for *J.C.Penny* entity, which shows sparseness in this document. **Unnatural Language** can be problematic for RDF data. A typical text document contains sentences where each sentence has a natural structure. These extra components of a sentence usually provide a further “**context**” for understanding words that are ambiguous or have multiple meanings, such as polysemous or homonymous ones. The aforementioned example for the *J.C.Penny* entity also confirms the unnatural language problem. The “**lack of context**” can further impact RDF data because they are potentially sparse, described by unnatural language, and often using words that have multiple meanings, difficult to differentiate (*J.C.Penny* bag of words example). Additionally, triples are more prone to pre-processing, because it is not uncom-

²“bag of words” and “bag of objects” are interchangeably used.

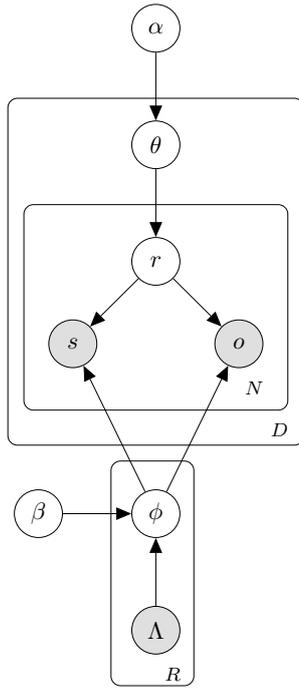

Figure 2: Entity Summarization Model

mon for triples to contain unexpected characters. RDF data resemble short texts in terms of the aforementioned challenges. Sparseness in a short text causes the model to be less discriminative to recognize how words are related and the limited context makes it hard for the model to identify the meanings of the words in such short text documents (Yan et al., 2013). In order to alleviate these issues, researchers usually take two approaches. They either augment the short text or design custom versions of the LDA model that address their specific problems. In this paper, we have used both approaches. We describe how to supplement the RDF data in the following section and describe the details of our model in section 4.4.

4.3 Supplementing RDF Data

As topic modeling is based on statistics of the co-occurrence of terms (Sleeman et al., 2015), when we are dealing with short texts with a very limited number of repetitions, which is the case with RDF data, we need to find a way to supplement the data to elevate the performance of the topic modeling approach. We augment the documents using two different methods. In the first method, we increase the frequency of the words in each document. But the question is “How many times each word of a document should be repeated?”.

Algorithm 1: ES-LDA Model

```

1 foreach predicate  $r \in \{1, 2, \dots, R\}$  do
2   | Draw an object distribution  $\phi_r \sim$ 
3   |  $\text{Dir}(\beta_r \times \Lambda_r)$ 
4 end
5 foreach document  $d \in \{1, 2, \dots, D\}$  do
6   | Draw a predicate distribution  $\theta_d \sim$ 
7   |  $\text{Dir}(\alpha_d)$ 
8   | foreach subject  $s$  and object  $o$  of
9   | document  $d$  do
10  | | Draw a predicate  $r \sim \text{Mult}(\theta_d)$ 
11  | | Draw a subject  $s$  from predicate
12  | |  $r, s \sim \text{Mult}(\phi_r)$ 
13  | | Draw an object  $o$  from predicate
14  | |  $r, o \sim \text{Mult}(\phi_r)$ 
15  | end
16 end

```

Entities in DBpedia have been organized into a category network, therefore, every entity has a number of categories associated with it. The relationship between an entity and a category is defined by the “<http://purl.org/dc/terms/subject>” predicate. Since each word of a document is an object of a triple, and accordingly, an entity in DBpedia, it is related to several categories. We assume that objects (words) of a document that have more categories are likely more important. Thus, We expand each document by increasing the frequency of each object by the number of its categories. In the second method, instead of repeating each object a certain number of times, we enlarge each document by adding categories of the objects as extra words, directly to the document. There are multiple advantages of supplementing each document by adding object categories: (i) the sparseness in the document, related to each entity, is lowered as we are adding a number of related words to it; (ii) we reduce the ambiguity in the document, because adding extra categories alleviates the lack of context and helps distinguish the appropriate meanings of the words with multiple connotations; and lastly (iii), adding object categories makes the documents semantically more relevant to their topical themes. We evaluated our model using both methods and the results demonstrate that the first method gives significantly better summaries than the second method.

4.4 Proposed Model

ES-LDA is a probabilistic generative model for modeling entities in RDF graphs. The key idea behind our model is twofold: (1) we exploit statistical topic models as the underlying quantitative framework for entity summarization; and (2) ES-LDA incorporates the prior knowledge from the RDF knowledge base directly into the topic model. The plate notation is shown in Figure 2.

In our model, each document is a multinomial distribution over the predicates. If we consider predicates as topics, at the document level, our model is the same as standard LDA. However, we set the number of topics in ES-LDA to be the number of unique predicates in the corpus. Unlike the standard LDA, where each topic is a multinomial distribution over the vocabulary from the Dirichlet prior β , in our model each predicate is a multinomial distribution over all the subjects and objects of the RDF graph. In our approach, a document consists of a set of triples describing a single entity, i.e. all these triples share the same subject. Thus, we constrain the documents to only have the objects of related triples and also restrict the predicates to be defined only over the objects. In addition, for each predicate r , we further smooth its distribution by Λ_r . Λ is a matrix that has encoded the background knowledge about predicate-object values from DBpedia. Section 4.5 explains how Λ is constructed. The generative process of ES-LDA is shown in Algorithm 1.

Following this process, the joint probability of generating a corpus $D = \{d_1, d_2, \dots, d_{|D|}\}$, the predicate assignments \mathbf{r} given the hyperparameters α, β and the prior matrix Λ is:

$$\begin{aligned} & P(\mathbf{o}, \mathbf{s}, \mathbf{r} | \alpha, \beta, \Lambda) \\ &= \int_{\phi} P(\phi | \beta; \Lambda) \prod_d \sum_{r_d} P(\mathbf{o}_d | r_d, \phi) P(\mathbf{s}_d | r_d, \phi) \\ &\times \int_{\theta} P(\theta | \alpha) P(\mathbf{r}_d | \theta, \phi) d\theta d\phi \end{aligned} \quad (2)$$

4.5 Constructing Predicate-Object Prior Matrix Λ

In the ES-LDA model, each predicate has a probability distribution over the objects of the RDF graph. Entity summarization is the task of choosing the top- k predicate-object pairs that best describe an entity. Presumably, if an object is associated with more categories in DBpedia, it is likely more important. We create the the Λ matrix to encode the prior weight of the predicate-object pairs

and utilize it to smooth the predicate-object distributions ϕ by incorporating this domain knowledge into the topic model. We build the Λ matrix of size $R \times O$, where R is the number of predicates and O is the number of objects in the RDF graph. Let f be an indicator function where $f(i, j) = 1$ if there is a triple in RDF graph with predicate i and object j , and 1 otherwise, for $1 \leq i \leq R$ and $1 \leq j \leq O$. Additionally, let c be the number of categories assigned to object j . Then, we define Λ_{ij} as follows:

$$\Lambda_{ij} = \begin{cases} c & \text{if } f(i, j) = 1 \\ 1 & \text{otherwise.} \end{cases} \quad (3)$$

For example, the “*Barack_Obama*” entity has multiple predicate-object pairs in DBpedia, including “*profession-author*”, “*profession-lawyer*” and “*profession-professor*” pairs. According to DBpedia, $c_{author} = 2$, $c_{lawyer} = 4$ and $c_{professor} = 2$. It is reasonable to expect a higher probability for the “*profession-lawyer*” pair as it seems to be slightly more important than the other two pairs for “*Barack_Obama*”. As a result, $\Lambda_{profession-lawyer} = 4$, which promotes “*profession-lawyer*” in Eq. 5.

4.6 Inference using Gibbs Sampling

Since the posterior inference of the LDA is intractable, we need to find an algorithm for estimating the posterior inference. A variety of algorithms have been used to estimate the parameters of topic models, such as variational EM (Blei et al., 2003) and Gibbs sampling (Griffiths and Steyvers, 2004). In this paper we use the collapsed Gibbs sampling procedure for our ES-LDA topic model. Collapsed Gibbs sampling (Griffiths and Steyvers, 2004) is a Markov Chain Monte Carlo (MCMC) (Robert and Casella, 2004) algorithm, which constructs a Markov chain over the latent variables in the model and converges to the posterior distribution, after a number of iterations. In our case, we aim to construct a Markov chain that converges to the posterior distribution over \mathbf{r} conditioned on observed subjects \mathbf{s} , objects \mathbf{o} , hyperparameters α, β , and the prior matrix Λ .

In our modified version of the learning algorithm to infer $p(o_i | r_j)$ and $p(r_j | d)$, we (1) constrain the objects that are not paired with a predicate to have 0 probability, i.e. $p(o_i | r_j) = 0$, if $(r_i, o_j) \notin$ RDF graph, and (2) $P(s | r_j) = 1$, since all the triples of a document have the same subject s . We derive the posterior inference from Eq. 2 as

follows:

$$P(\mathbf{r}|\mathbf{o}, \mathbf{s}, \alpha, \beta, \Lambda) = \frac{P(\mathbf{r}, \mathbf{o}, \mathbf{s}|\alpha, \beta, \Lambda)}{P(\mathbf{o}|\alpha, \beta, \Lambda)} \quad (4)$$

$$\propto P(\mathbf{r}, \mathbf{o}|\alpha, \beta, \Lambda) \propto P(\mathbf{r})P(\mathbf{o}|\mathbf{r})P(\mathbf{s}|\mathbf{r})$$

$$P(r_i = r|o_i = o, \mathbf{r}_{-i}, \mathbf{o}_{-i}, \alpha, \beta, \Lambda) \propto$$

$$\frac{n_{r,-i}^{(d)} + \alpha_r}{\sum_{r'} (n_{r',-i}^{(d)} + \alpha_{r'})} \times \frac{n_{o,-i}^{(r)} + \Lambda_{ro}\beta_o}{\sum_{o'} (n_{o',-i}^{(r)} + \Lambda_{ro}\beta_o)} \quad (5)$$

where $n_o^{(r)}$ is the number of times object o is assigned to predicate r . $n_r^{(d)}$ denotes the number of times predicate r is associated with document d . The subscript $-i$ indicates that the contribution of the current object o_i being sampled is removed from the counts. After Gibbs sampling, we can use the sampled predicate to estimate the probability of a predicate, given a document, θ_{dr} and the probability of an object, given a predicate, ϕ_{ro} :

$$\theta_{dr} = \frac{n_r^{(d)} + \alpha_r}{\sum_{r'} (n_{r'}^{(d)} + \alpha_{r'})} \quad (6)$$

$$\phi_{ro} = \frac{n_o^{(r)} + \Lambda_{ro}\beta_o}{\sum_{o'} (n_{o'}^{(r)} + \Lambda_{ro}\beta_o)} \quad (7)$$

5 Experiments

We evaluated our ES-LDA model against the state-of-the-art LinkSUM (Thalhammer et al., 2016) and FACES (Gunaratna et al., 2015) systems. Our goal was to show that the ES-LDA model produces results that are closer to human judgment, in comparison with the other approaches. We used the same dataset³ that was used in the experiments conducted with FACES, as well as LinkSUM models. The dataset contained 50 entities randomly selected from DBpedia (English version 3.9) in domains including *politician, actors, scientist, song, film, country, city, river, company, game, etc.* 15 people in the field of Semantic Web were selected as reviewers and each entity was evaluated by at least 7 reviewers to produce the top-5 and top-10 summaries. The average number of properties for each entity was 44.

Based on the two types of RDF supplement methods we discussed in 4.3, we applied two different configurations for the proposed model. In

³<http://wiki.knoesis.org/index.php/FACES>

the first experiment, ES-LDA @config-1, we configured the system to supplement each entity (document) by repeating each object based on the *number of categories* that the object has in the DBpedia knowledge base. For example, for the triple $\langle J.C.Penney, industry, Retail \rangle$ we repeated *Retail* object, 5 times in that document, as *Retail* has five different categories in DBpedia (i.e. "Retailers, Retailing, French words and phrases, Merchandising, Marketing")

In the second experiment, ES-LDA @config-2, we configured the system to supplement each entity (document) by adding the corresponding category(ies) of each object into the document. In this case, each entity is defined as a bag of words including objects and categories of each object. For example, for the aforementioned triple, in addition to the *Retail* we included "Retailers, Retailing, French words and phrases, Merchandising, Marketing" as the corresponding categories to the *Retail* object.

For the other parameters, we assumed a symmetric Dirichlet prior and set $\beta = 0.01$ and $\alpha = 50/R$, where R is the total number of unique predicates. We ran the Gibbs sampling algorithm for 1000 iterations and computed the posterior inference after the last sampling iteration. We selected the top-5 and top-10 most probable properties for each entity and calculate the quality of the summary for each entity through equation 8.

$$Quality(Sum(e)) = \frac{1}{n} \sum_{i=1}^n |Sum(e) \cap Sum_i^I(e)| \quad (8)$$

In our experiments, we used the quality of the summary proposed in (Cheng et al., 2011), in which n ideal summaries $Sum_i^I(e)$ generated by expert users for $i = 1, \dots, n$ and the summaries generated by the system $Sum(e)$ were compared. The average of the overlap between an ideal summary and a summary generated by the system is denoted as the quality of the summary, which is $0 \leq Quality(Sum(e)) \leq k$ in the top- k settings.

5.1 Experiment Results

The summary in our model is defined as sets of representative triples that can summarize each entity (sets of triples with the same subject) in a way close to a human-created summary. We decided to use the last part of a *URI* to compare the generated summaries with the expert summaries and produce

Table 2: Overall quality results of different models. Best result are bold.

<i>Model</i>	Top-5	Top-10
ES-LDA @ config-1	1.20	3.50
ES-LDA @ config-2	1.10	3.26
LinkSUM@ config-1	1.20	3.15
LinkSUM@ config-2	1.20	3.20
FACES	0.93	2.92

the Summary Quality for each entity and average them. As (Thalhammer et al., 2016) reproduced the FACES overall Summary Quality based on this criteria and also applied it to their model, we decided to use their result as it was completely aligned with our summary definition.

In Table 2, we compare the quality of the results from LinkSUM, FACES, and ES-LDA with two distinct configurations (supplementing by object reputation and object categories). As Table 2 shows, the quality of our model outperforms the FACES approach, in both cases. The ES-LDA @ config-2 demonstrates a comparable result with the two configurations of LinkSUM, while ES-LDA @ config-1 outperforms LinkSUM. For some of the entities, the predicates that ES-LDA selected as top-5 most probable did not exist in the FACES dataset. It forced us to calculate the quality of summary for some of the entities with just 4 predicates instead of 5. We believe to be the only reason why top-5 Quality of Summary was lower than or equal to LinkSUM. Although, we had the same issue for the top-10 results, overall, ES-LDA shows a better performance in two configurations.

6 Discussion

We evaluated our approach against the state-of-the-art summarization techniques, including LinkSUM and FACES. LinkSUM primarily focuses on the most relevant facts for each entity, while FACES tries to keep a balance between diversity and relevancy in entity summarization. There is usually a trade-off between diversity and relevancy of the selected predicates. Our ES-LDA model maintains both diversity and relevancy, while representing each entity through *top-k* predicates. As shown in Table 2, our model outperforms the state-of-the-art approaches.

Table 3 illustrates a sample of entities from the dataset along with their top-10 predicates, for all approaches. As Table 3 shows, the LinkSUM model is focusing more on the *objects*, while predicate repetition is permitted. For example, $\langle Marie_Curie, birthPlace, Warsaw \rangle$, $\langle Marie_Curie, birthPlace, Russian_Empire \rangle$, and $\langle Marie_Curie, birthPlace, Congress_Polandare \rangle$ are representing *Marie_Curie*'s birth place. Although, they differ in terms of objects, it is arguable that referring to the same predicate with multiple objects that are more likely relevant reduces the chance of other important triples that could potentially appear in the summary. It should be noted that in the current ES-LDA configuration, we have not considered predicate repetition, thus, all the predicates of the triples appearing in the resultant summary are unique. FACES on the other hand, considers predicate diversity and tries to keep a balance between the diversity and relevancy but the overall quality of the FACES model is lower than LinkSUM and ES-LDA. In the FACES model, there are selected predicates which seems to be less informative in the sense to be top-10 representative for a particular entity. For example, $\langle Marie_Curie, thumbnail, 200px-Marie_Curie_c1920.png \rangle$, which is referring to a *png* file, could be replaced with more descriptive one. Additionally, our proposed technique features several unique characteristics: (1) the ES-LDA is a *knowledge-based probabilistic* model that combines prior knowledge with statistical learning technique into a unified framework for entity summarization; (2) for each entity, it ranks all predicates based on their importance by computing marginal probabilities for the predicates. Table 4 illustrates the top-5 predicates for a sample of two entities; and finally (3), each predicate can be represented as a probability distribution over objects in the ES-LDA model, which allows us to describe the relations (predicates) of the RDF graph based on its nodes as shown in Table 5.

7 Conclusions

We have proposed a knowledge-based probabilistic topic model, called ES-LDA, based on the RDF entity representation for entity summarization. In our experiments, we have applied two different configurations: one based on object repetitions and the other based on adding object's categories, to alleviate common RDF data problems including

sparseness, unnatural language, and lack of context. We conducted extensive experiments, which show the quality of the top-10 triples in both configurations outperforms the state-of-the-art techniques, LinkSUM and FACES, while for the top-5 quality we surpassed FACES and equaled the LinkSUM results.

There are many interesting future research directions of this work. It would be interesting to investigate how this model and a much richer set of topic models that combine prior knowledge with statistical learning techniques could be used for various tasks in the Semantic Web domain, such as ontology summarization, ontology tagging, and finding similar ontologies.

Abstract

In recent years, there has been a surge of interest in automatically describing images or videos in a natural language. These descriptions are useful for image/video search, etc. In this paper, we focus on procedure execution videos, in which a human makes or repairs something and propose a method for generating procedural texts from them. Since available video/text pairs are limited in size, the direct application of end-to-end deep learning is not feasible. Thus we propose to train Faster R-CNN network for object recognition and LSTM for text generation and combine them at run time. We took pairs of recipe and cooking video as an example, generated a recipe from a video, and compared it with the original recipe. The experimental results showed that our method can produce a recipe as accurate as the state-of-the-art scene descriptions.

1 Introduction

Massive effort has been done to develop a method for generating text from vision in the field of natural language processing and computer vision. More specifically, there are number of studies on generating captions for given images or videos (Yang et al., 2011; Rohrbach et al., 2013; Li et al., 2015; Donahue et al., 2015; Karpathy and Fei-Fei, 2015; Shetty and Laaksonen, 2016; Johnson et al., 2016). Most of the existing researches for video captioning, however, deal with simple and short videos (Li et al., 2015; Donahue et al., 2015; Shetty and Laaksonen, 2016) such as a ten second video in which a man playing guitar in a park.

In this paper, we propose a new problem in this field: generating a procedural text from an execu-

tion video such as cooking or machine assembly. The goal is to develop a method that takes video of a chef cooking a dish from ingredients or a mechanic assembling a machine from parts as the input, and outputs a procedural text that helps another person reproduce the same product.

We also give an initial solution to the problem, taking cooking recipe generation as an example. Because no large scale corpus consisting of related execution video and procedural text is available for now, we divide the problem into two sub-problems, object recognition and text generation, and train two modules independently using different resources as their training set. Then we combine them and search for the best text. The object recognition module is designed to spot the changes in state of progress of the procedure from video and texts are generated at each time. Finally, some of the generated sentences are selected to cover the entire procedure with discarding redundant sentences.

In the experiments, we use KUSK Dataset (Hashimoto et al., 2014), which consists of pairs of recipes submitted by users to a recipe hosting service Cookpad and video of cooking according to that recipe in a laboratory. The experimental results showed that our method is capable of producing a recipe of reasonable quality.

2 Related Work

Recent studies on automatic caption generation have reported great results both in images (Xu et al., 2015; Karpathy and Fei-Fei, 2015; Johnson et al., 2016) and short video clips (Li et al., 2015; Donahue et al., 2015; Shetty and Laaksonen, 2016) by using convolutional neural network (CNN), recurrent neural network, and LSTM. (Venugopalan et al., 2015) improved the accuracy with a sequence to sequence model (Sutskever et al., 2014). In addi-

tion, (Laokulrat et al., 2016; Guo et al., 2016) also improved the accuracy of automatic caption generation by introducing an LSTM equipped with an attention mechanism. One of the features of these end-to-end models is that they directly generate sentences from videos without determining content words such as subjects and predicates. Common datasets (Lin et al., 2014; Chen and Dolan, 2011; Torabi et al., 2015; Rohrbach et al., 2015) made research on automatic caption generation popular.

Before the above end-to-end models succeeded, many researchers concentrated models generating sentences via content words or intermediate states (Guadarrama et al., 2013; Rohrbach et al., 2013). As an advantage of the technique of using intermediate states, object recognition or motion recognition model can be diverted as it is. Thus data of pairs of a medium and a caption have not been particularly required. These methods with intermediate states are inferior in accuracy to the end-to-end models using CNN and LSTM in case that enough size of training data are available. On the other hand, since creation of medium-caption pairs is expensive, methods using intermediate states are also considered to be sufficiently practical for a problem where we have insufficient size of data available for model training.

Unlike conventional methods using intermediate states such as subjects, objects, and predicates, for procedure execution videos, there is a problem that the use of recognition results of general actions is not appropriate because of the abstraction level. It is considered preparing tailored data for motion recognition for each kind of procedure execution videos have high cost because it is often vague even for human annotators to assign every concrete motions into text-level motion categories. In contrast, objects directly appear in texts and there is much less ambiguity than motions. Therefore, it is reasonable for the procedural text generation to focus more on object recognition than motion recognition. In addition, the procedure execution videos generally show works performed by one person, thus subject recognition is not necessary. It is preferable to set the object recognition results as an intermediate state and generate sentences from it. Since predicates are not easy to be recognized, they are estimated or supplemented from recognized objects using language knowledge.

Many studies generate a caption consisting of

Table 1: Definition of r-NE tags.

r-NE tag	meaning
F	Food
T	Tool
D	Duration
Q	Quantity
Ac	Action by the chef
Af	Action by foods
Sf	State of foods
St	State of tools

one sentence for a video clip. Studies on the automatic caption generation of documents consisting of multiple sentences like procedural text do not attract much attention as far as we know. One similar study is done by (Kaufman et al., 2016), which gives captions for a movie that is divided into scenes beforehand.

3 Task Definition

In this section, we describe our novel task in detail. Then we present prerequisites of our solution.

3.1 Procedural Text Generation from Video

We propose a task of generating a procedural text from an execution video. Figure 1 shows the overview of the task. In general, an execution video records a sequence of activities to make or repair something from the beginning to the end. As the first trial, we deal with cooking videos in which only one person appears (mainly the hands only). In the beginning, there are some ingredients and tools on the cooking table and some appear in the video later. Then it finishes with a completed dish. This is the input of the task.

The output of our task is a procedural text, consisting of some sentences in a natural language, which explains procedures to be conducted by workers to make or repair something. The counterpart of cooking videos of the first trial is recipes. A recipe describes how to cook a certain dish. In general, a recipe includes the dish name and an ingredient list in addition to the instruction text part. In our task, however, we focus on generating the text part only. Thus, this is the output of the task. In the subsequent sections, we refer to that text part by the term recipe.

As an evaluation metrics, it is preferable to measure how much the output text helps another chef produce the same dish. Thus, the ideal may be

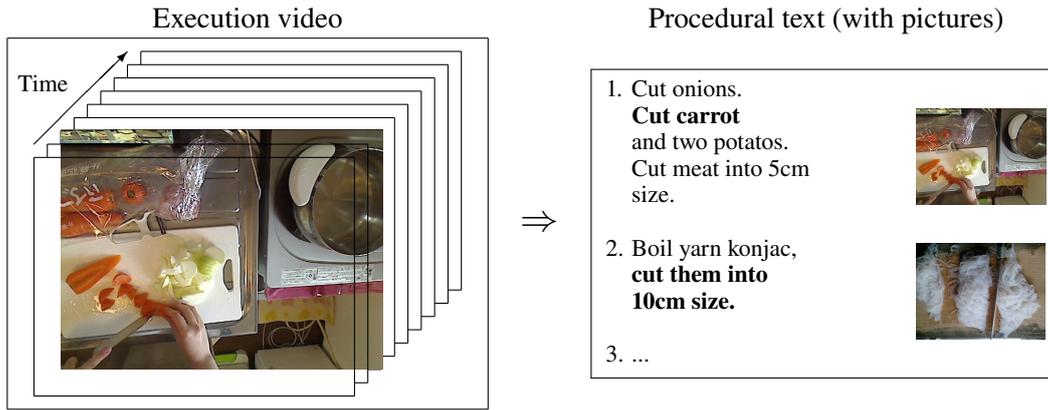

Figure 1: Task overview.

objective evaluation over the dishes produced by chefs reading the generated recipes. We propose, however, to adopt BLEU score as a metric of procedural text for the convenience of automated evaluation.

One of the advantages to choose the cooking domain as a benchmark of procedural text generation from video is that there are a huge number of recipes available on the Web. Therefore it is easy to develop a generative model of recipes for the task. In addition, there are recipe/video pairs available for various researches. For example, the KUSK Dataset (Hashimoto et al., 2014), which we use in the experiments, contains recipes and their cooking videos. Note that the lengths of these cooking videos are about 20 minutes or more, which are much longer than video clips used in automatic video captioning researches. And also note that the texts are kinds of summaries mentioning only the necessary objects and actions to complete a certain mission. Such texts are intrinsically different from scene descriptions in automatic video (or image) captioning researches.

3.2 Prerequisites

To solve the problem above, we enumerate the pre-conditions necessary for our method in the recipe generation case.

3.2.1 Domain Specific Named Entity

First we assume a set of terms (word sequences) called named entities (x -NEs) representing important object names in the target domain x . They are the objects to be recognized by computer vision (CV).

In the recipe case, noun phrases for ingredients and tools are important object names. In this paper, we adopt the recipe named entities (**r-NEs**) defined

in (Mori et al., 2014), whose types are listed in Table 1. There are eight r-NE tag types, but our CV part recognizes only foods (F) and tools (T). We use the notation “チンゲン 菜/F” (“qing-geng-cai/F”) to indicate that “チンゲン 菜” is an r-NE and its type is food (F)¹.

3.2.2 Named Entity Recognizer

In order to develop a useful generative model we must locate x -NEs in given sentences. So-called named entity recognizer (**NER**) is suitable for this task. In this paper, we adopt NERs based on sequence labeling techniques that can be trained by an annotated corpus.

3.2.3 Object Recognition

Our method requires the module that can detect the appearance and the disappearance of materials and tools involved in the procedure. In the cooking video case, we use Faster R-CNN model (Ren et al., 2015) fine-tuned with relatively small set of images of foods and cooking tools.

3.2.4 Procedural Text Examples

As we mentioned in Section 1, there is no large amount of video/sentence pairs available for our problem. But instead, in some cases, large text-only corpus is available in the domain. The corpus will allow us to train a generative model of the instruction sentences.

4 Proposed Method

In this section, we explain the proposed method for recipe generation from cooking videos. The out-

¹The language resources used in our experiments are in Japanese. Thus our system outputs recipes in Japanese. However, our method can generate recipes in another language by preparing the prerequisites in that language.

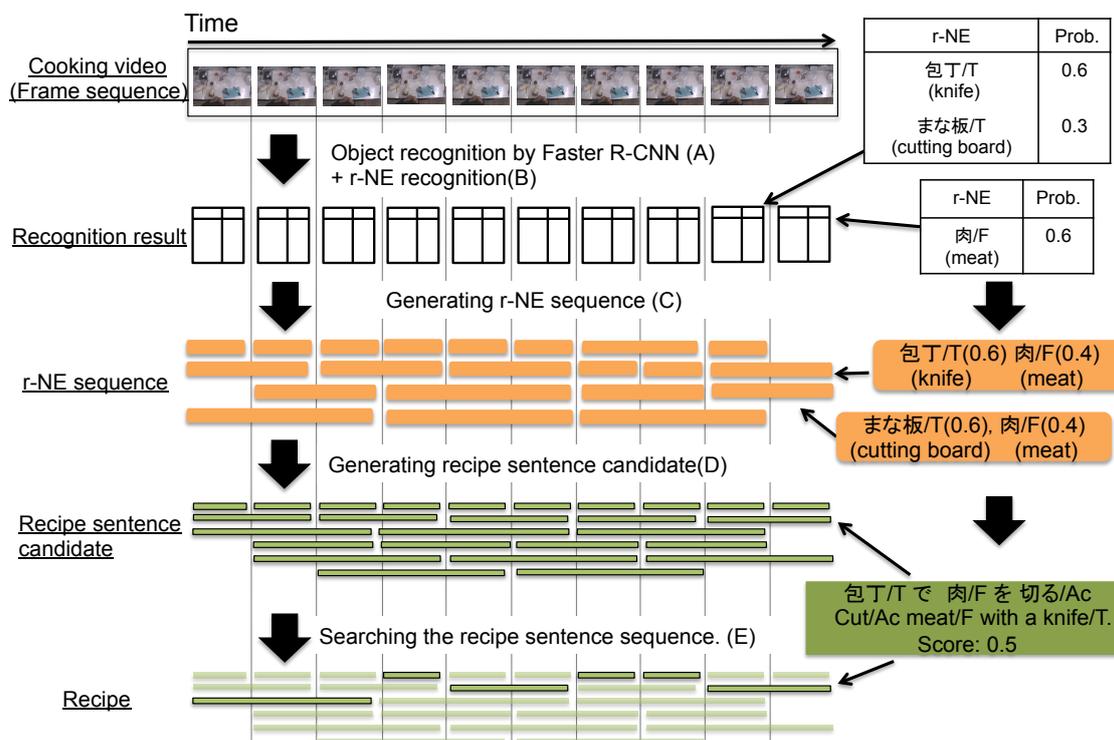

Figure 2: Overview of the proposed method.

line of this method is shown in Figure 2. First, we recognize objects in the video as a sequence of frames with a CNN and give an r-NE tag to each object (Figure 2 A, B). Next, we create an r-NE sequence from each partial frame sequence (Figure 2 C) and generate a candidate recipe sentence for each corresponding r-NE sequence (Figure 2 D). Each candidate recipe sentence is the one which maximizes the score indicating the likelihood of a sentence as a procedural text within the partial frame sequence. Finally, we select the sequence of recipe candidate sequences that maximizes the total score through the entire video based on Viterbi search. We output that sentence sequence as the procedural text for the input procedure execution video (Figure 2 E).

4.1 Object Recognition

Object recognition is performed only on the frames at which the chef picks up an object or places it, that is provided in KUSK Object Dataset (Hashimoto et al., 2016) with the object regions. Note that the provided frames and regions can contain plural objects because the method used in (Hashimoto et al., 2016) is based on background subtraction. To divide the detected region into object-wise regions, we adopted Faster R-CNN

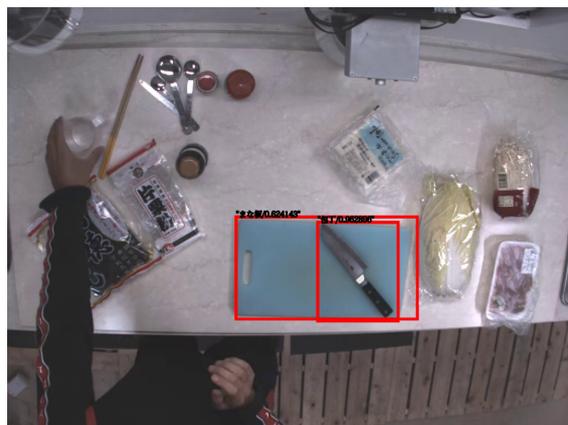

Figure 3: An example of object recognition by Faster R-CNN.

(Ren et al., 2015). This neural network outputs identified object region as a rectangular area while recognizing its category (Figure 2 A). It also provides confidence as a probability. An example of visualization of object recognition is shown in Figure 3, where a cutting board and a knife are in the region detected by (Hashimoto et al., 2016).

We utilized Faster R-CNN's ability of object region identification to suppress another type of false detection. The regions provided in (Hashimoto et al., 2016) contains objects that are moved only

slightly by coming in contact with the hands. Such objects should not be related to the procedure. To suppress such detection but spot only objects obviously related to the procedure, we compare the location of object-wise regions before and after the contact, and ignore object regions if they have the same object name and have a certain score in Jaccard index, which is general method to measure the size of intersection of two regions. After the test of region intersection, only the objects with an obvious location change are regarded as procedure-related. This module passes only procedure-related objects to the second module. Note also that we discarded objects whose name is not listed in x -NEs before passing them to the second module.

Hereafter, we only focus the frames with the procedure-related objects listed in x -NEs, and describe the sequence of such frames as follows:

$$\mathbf{f} = f_1, f_2, \dots, f_{|\mathbf{f}|}, \quad (1)$$

where f_i is the i -th frame and $|\mathbf{f}|$ is the length of the sequence.

4.2 Recipe Named Entity Recognition

We use the named entity recognizer (Sasada et al., 2015) to the object in the i -th frame f_i (Figure 2 B). Let \mathcal{E}_i be the object set whose tags are F or T in f_i . Then, we denote the number of elements in this set as $|\mathcal{E}_i|$. The j -th r-NE of \mathcal{E}_i is denoted as e_i^j . Then $P(e_i^j|f_i)$ denotes the conditional probability in which the element e_i^j (a food or a tool) is estimated to exist in the frame f_i .

4.3 Recipe Named Entity Sequence

Let $\mathbf{f}_i^{i+(l-1)} = f_i, f_{i+1}, \dots, f_{i+(l-1)}$ be a substring, of length l , of \mathbf{f} that corresponds to a single recipe sentence. A frame f_i may contain some r-NEs \mathcal{E}_i . Then a sequence of r-NEs contained in $\mathbf{f}_i^{i+(l-1)}$ can be expressed by $e \in \mathcal{E}_i \times \mathcal{E}_{i+1} \times \dots \times \mathcal{E}_{i+(l-1)}$. Note that the number of all the possible sequences is $\prod_{k=i}^{i+(l-1)} |\mathcal{E}_k|$. For example in Figure 2, e is (cutting board/T, meat/F) or (knife/T, meat/F).

In addition, in order to treat a sequence as a set, we introduce the following notation:

$$\{e\} = \{e_k^{j_k} | i \leq k \leq i + (l - 1)\}. \quad (2)$$

Note that j_k depends on k .

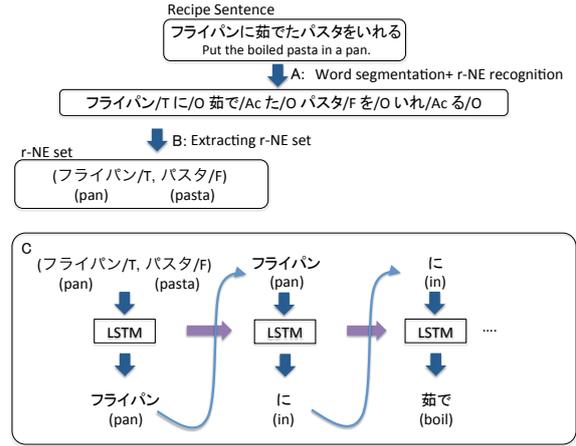

Figure 4: LSTM language model training. This model generates a sentence given an r-NE set.

Considering the likelihood of object recognition and the likelihood of a combination of r-NEs included in the sequence, we set the likelihood $P(e)$ that e appears as follows:

$$P(e) = \bar{P}(e) \times P(\{e\})^{-l}, \quad (3)$$

where $\bar{P}(e)$ is the average of the probability of the result of object recognition:

$$\bar{P}(e) = \frac{1}{l} \sum_{k=i}^{i+(l-1)} P(e_k^{j_k} | f_k). \quad (4)$$

This value indicates the likelihood of object recognition. Also $P(\{e\})^{-l}$ is the likelihood of a combination of r-NEs determined from the frequency of a sentence in which all the elements of $\{e\}$ appear in the corpus.

$$P(\{e\}) = \left(\frac{\text{count}(\{e\})}{C} \right), \quad (5)$$

where C is the number of sentences in the recipe corpus and $\text{count}(\{e\})$ is the frequency of sentences in which all the elements of $\{e\}$ appear at the same time. Thus, this value indicates the likelihood of the r-NE combination. In addition as the number of elements in the r-NE set increases, the frequency decreases. This is the reason why we introduce $P(\{e\})^{-l}$ considering the sequence length l .

4.4 Recipe Sentence Candidate Generation

For each partial frame sequence, we generate the most likely sentence and its score without referring

to the neighboring sentences. Some of these sentences may, however, be discarded in the next step. Thus we call it a recipe sentence candidate. The input to this process is the r-NE sequence and the scores of the r-NEs. And the output is the recipe sentence candidate that maximizes the score for the given partial frame sequence (Figure 2 D).

For the sentence candidate generation we use an LSTM language model. It outputs a sentence and its likelihood. Different from the ordinary LSTM, it takes a set of r-NEs as the input, but not a sequence. In addition, it is trained on the corpus in which r-NEs are recognized and replaced with r-NE tags as summarized in Figure 4. The first step of its training is preprocessing, in which we conduct word segmentation (Neubig et al., 2011) (not necessary for English or some other languages) and r-NE recognition (Sasada et al., 2015) for each recipe sentence in the recipe corpus (Figure 4 A). Then we filter out sentences containing r-NEs other than Ac, F and T and delete Ac tags for the reasons below:

- We cannot get information about r-NEs other than F and T by the object recognition module.
- A predicate denoting an action (Ac) is necessary for a complete sentence.

Putting it in another way, our method guesses a suitable predicate (verb) from the objects (foods and/or tools) and the corpus. From each of the resultant sentences, we generate a sentence in which F and T are replaced with tags and the set of the r-NEs contained in it (Figure 4 B). Finally we train the LSTM language model on the corpus. The LSTM can map a set of r-NEs to a recipe sentence with its likelihood (Figure 4 C).

As the likelihood of this module, our method returns the following score:

$$Score(e) = P_{LSTM}(r_{max}(e)|e) \times P(e),$$

where $r(e)$ is the sentence generated by the LSTM language model given e as the input. $P_{LSTM}(r(e)|e)$ is the generation probability of $r(e)$. $r_{max}(e)$ is the sentence that maximizes $P_{LSTM}(r(e)|e)$ with the beam search decoder given e .

$$r_{max}(e) = \underset{r(e) \in \mathcal{R}(e)}{\operatorname{argmax}} P_{LSTM}(r(e)|e),$$

where $\mathcal{R}(e)$ is a set of sentences that can be generated by beam search when e is the input and $r(e)$

is the sentence corresponding to it. The generation probability of a sentence is calculated by the following formula:

$$P_{LSTM}(r(e)|e) = \prod_{k=1}^{N_d} P(d_k|d_1, d_2, \dots, d_{k-1}; e),$$

where $r(e) = d_1, d_2, \dots, d_{N_d}$ is a word string and N_d is the length of the word string. And $P(d_k|d_1, d_2, \dots, d_{k-1}; e)$ denotes the generation probability of the k -th word d_k , when the input is e . The sentence is generated by the LSTM language model by beam search. The sentence is, however, aborted when the word length exceeds 20 or the terminal symbol appears. $P(e)$ is introduced to reflect the likelihood that the r-NE sequences e appear (see Equation (3)).

Calculating the above scores for all the possible e of a partial frame sequence, we define e_{max} as the r-NE sequences which maximize the score. At this stage, the generated sentence is no more than a recipe sentence candidate $r_{max}(e_{max})$, whose score is $Score(e_{max})$. When the scores earned by partial frame sequences are all 0, no recipe sentence candidate is generated.

4.5 Generating Recipe

As we see above, a set of recipe sentence candidates is generated from the partial frame sequences. The frame sequence is divided into partial sequences so that the overall score of the division, which is the sum of the $Score(e)$ in each partial sequence, is maximized (Figure 2 E). The partial sequences cover the entire video, thus the corresponding sentences, sequences of $r(e)$, form a complete recipe.

Since it is almost impossible for one chef to perform two operations in parallel, the corresponding partial frame sequences of the recipe sentence candidates must not overlap. In addition, in order to prevent the same recipe sentence from appearing more than once, the score of the recipe sentence candidate which has appeared once in the recipe is set to be 0. Under this condition, the score of a recipe sentence candidate can change. Although it should be totally searched for score maximization, we use the Viterbi algorithm for the calculation, because the change of the score is limited at the time of generation of the same sentence and it is considered that it does not occur so much.

By calculating the path of the recipe sentence candidate sequence for increasing the score, the

Table 2: The BLEU scores.

Configuration	BLEU			
	$N = 1$	$N = 2$	$N = 3$	$N = 4$
w/o $P(\{e\})^{-l}$	22.73	13.13	7.48	4.11
with $P(\{e\})^{-l}$	26.73	15.42	9.09	5.50

generated recipe sentence sequence is output as a recipe. The higher the score, the more recipe-like the sentences are.

5 Experiments and Evaluation

In this section we evaluate our method experimentally. We first describe the settings of the experiments, then report the experimental results, and finally evaluate our method.²

5.1 Experimental Setting

We used the following dataset to train and evaluate our model.

5.1.1 Test Dataset

KUSK Dataset This dataset contains 20 recipes and corresponding cooking videos.

5.1.2 Train Dataset

KUSK Object Dataset This dataset contains 180 categories of objects in total, which comprise ingredients, cooking tools, and others (bottle cap, dish cloth, and so on), observed in cooking videos in KUSK Dataset. Since all videos are recorded at the same kitchen, exactly the same cooking tools appear through all videos, including ones in the test set. More detailed information and examples are available in (Hashimoto et al., 2016).

Cookpad NII corpus This corpus contains 1720000 recipes collected from cookpad website. 187700 sentences are extracted for training.

Flow Graph Corpus This corpus contains randomly chosen 208 recipes (867 sentences) from Cookpad NII corpus. The text is annotated with the r-NE tags. (Mori et al., 2014).

5.1.3 Training Faster-RNN and Named Entity Recognizer

As the first module, an object recognizer for frames, we use Faster R-CNN (Ren et al., 2015).

²The code used in our experiment is available on our website. <http://www.ar.media.kyoto-u.ac.jp/member/hayato/procedural-text-generation/>

We fine-tuned Faster R-CNN with KUSK Object Dataset. The dataset contains 180 categories in total, but some categories, for example dish clothes or bottle caps, will not appear in recipe texts. Thus we ignored such categories and used 95 categories to fine-tune the Faster R-CNN model, which is done in the manner of leave-one-video-out.

Because this module is a pre-process of the second module, to achieve higher recall rather than a higher precision, we used any detection proposals from Faster R-CNN with more than 0.01% in confidence score, and set the intersection threshold of Jaccard Index 0.5. This setting earned 78.8% of recall and 22.3% of the precision on average through the 95 categories.

For the second module we trained an NE recognizer POWNER (Sasada et al., 2015), which is based on support vector machines and Viterbi best path search, with Flow Graph Corpus. Its accuracy is about 90% in F-measure (Mori et al., 2014).

5.1.4 Recipe Named Entity Sequence and Recipe Sentence Candidate Generation

When generating the r-NE sequences, we should specify the sequence length l . Most of the sentences in our recipe corpus contain no more than three r-NEs of F or T³. So we set the length of frame sequences as $l = 1 \sim 3$.

The training data of the LSTM language model consists of 11,705 sentences and the number of r-NE tokens is 4,025. These training data are a set of recipe sentences extracted so as to satisfy the following conditions:

- The total number of F and T is between 1 and 3,
- Each sentence does not contain any r-NE other than Ac, F, and T (see Section 4.4).

As a result the LSTM language model has a tendency not to generate sentences containing 4 or more r-NEs.

The setting of the LSTM language model training is as follows. The epoch number is 100, the batch size is 100, and the number of units of LSTM is 1,000. The objective function is the softmax cross entropy and the optimization algorithm is Adam (Kingma and Ba, 2014). The beam width for recipe sentence candidate generation is set to be 1.

³The percentage is slightly less than 75%.

<p>ミンチをいためて、色が変わったら、 Sauté the meat mince until the color changes, 他の野菜も入れていためて、 put another vegetable and sauté it. 火が通ったら小麦粉をいれて、 After heating them well, put the flour in the pan. 粘り気がすこしでるまでいためて、味をつける Sauté it until it gets a little sticky, season it. 卵をといて、1をいれて、フライパンをクルってして、 まく。 Beat an egg, add 1 to the pan and start rolling it by the pan. お皿にもりつけてできあがり。 Serve the dish. It's ready to eat.</p>	<p>フライパンに熱を入れ、炒めを炒 (砂糖を使う方は、ここで一緒に。 める。 If you like sugar, please add it. The original recipe	The result of the proposed method

Figure 5: The original recipe for a cooking video and the generated recipe by the proposed method.

5.1.5 Evaluation Metrics

We generated a recipe for each of 16 cooking videos corresponding to seven recipes in KUSK Dataset. As we mentioned in Section 3 they are excluded from the training data. In order to investigate the effectiveness of $P(\{e\})^{-l}$, we compared the results of the models with and without it.

The evaluation metrics is BLEU ($N = 1 \sim 4$) (Papineni et al., 2002) taking the original human-written recipes as the reference. The cooking actions in the KUSK Dataset video part were performed with following these recipes. Unlike BLEU calculation in MT, we treat the entire recipe, a sequence of sentences, as the unit instead of a single sentence. This is because one can describe the same actions in various ways with different number of sentences. An example pair is “cut onions and potatoes.” and “cut onions. then cut potatoes.”

5.2 Results and Discussion

Since our task is quite novel and existing end-to-end video captioning methods do not obviously work because of lack of large training data, there is no direct baseline. Thus we discuss absolute BLEU scores of some settings and examples of generated sentences.

Table 2 shows the BLEU scores. The absolute BLEU values (ex. 5.50 for $N = 4$) are much higher than the results of cinema caption generation (Kaufman et al., 2016) (0.8 for $N = 4$), which is regarded as one of the state-of-the-arts of text generation for videos longer than video clips. This result is worth noting considering that cooking videos are raw recording of execution and not edited nor divided into scenes, while input of

cinema caption generation is an *edited* video and scene segmentation is available. Our higher accuracy may be due to a large amount of text data in the target domain.

We then examined generated recipes and the original recipes. Figure 5 presents a recipe example actually generated by the proposed method and its original recipe used in the cooking video recording. We see that there are suitable sentences such as “挽肉を炒める。” (“Stir-fry minced meat.”), “卵はほぐしておく。” (“Beat an egg.”) in the result. These sentences correspond to “ミンチをいためて、色が変わったら、” (“Sauté the meat mince until the color changes”) and “卵をといて、” (“Beat an egg,”) in the original recipe. On the other hand, the result contains some unnecessary sentences. For example, in the third line of the generation result, “包丁ですを使” (“Use the knife is.”). The sentence itself is semantically correct, but is not suitable for a recipe (and grammatically wrong). This is actually the difference from the existing video clip description research.

Even if the object recognition functions perfectly, the sentence generation part has to ignore some objects focusing only on the actions to be taken. Such errors can be alleviated by considering the recipe structure such as relations of r-NEs. There are also ungrammatical sentences such as “お好みででを” (“pour over it that if if you like and serve”) in the result. This sort of errors are caused by the LSTM language model. We may need a language model incorporating grammatical structures (Chelba and Jelinek, 2000).

Despite the errors mentioned above, our method

solves the novel problem, procedural text generation from execution video in a certain accuracy. As it is clear from the explanation of our method, it has the correspondence between the sentence and the video frame region. Thus one can use our method for various practical multimedia applications, such as multimedia document generation from an execution video.

6 Conclusion

In this paper, we have proposed a novel task of procedural text generation from an execution video and the first attempt at solving it. Contrary to the ordinary video captioning task, it requires some kind of abstraction, that is, selecting objects to be mentioned. In addition, no existing end-to-end method is applicable due to the limited amount of video/text pairs for training. Instead, our method decomposes the problem into object recognition and sentence generation. Then we train the models for them independently with maximum available resources for each one. Finally we search for the best procedural text referring to them at once. For evaluation, we conduct recipe generation from cooking videos as an example case. The quality was as good as or better than the state-of-the-art scenario description for cinemas. Thus we can say that our method is promising to solve this novel task. We also gave some error analyses to allow further improvements in solutions of this difficult but interesting task.

Abstract

Tree-structured Long Short-Term Memory (Tree-LSTM) has been proved to be an effective method in the sentiment analysis task. It extracts structural information on text, and uses Long Short-Term Memory (LSTM) cell to prevent gradient vanish. However, though combining the LSTM cell, it is still a kind of model that extracts the structural information and almost not extracts serialization information. In this paper, we propose three new models in order to combine those two kinds of information: the structural information generated by the Constituency Tree-LSTM and the serialization information generated by Long-Short Term Memory neural network. Our experiments show that combining those two kinds of information can give contributes to the performance of the sentiment analysis task compared with the single Constituency Tree-LSTM model and the LSTM model.

1 Introduction

Text sentiment analysis, namely Opinion mining, is an important research direction in the field of Natural Language Processing (NLP). It aims to extract the author's subjective information from text and provide useful values for us. In recent years, there were more and more researchers paying attention to the study of text sentiment analysis.

Up to date, a variety of methods have been developed for improving the performance of sentiment analysis models. The distributed representation for words has been proposed in 2003 (Bengio et al., 2003). This model trained by two kinds of three-layer neural networks generates vectors to represent words. Glove, which is

the improvement of the model mentioned above, has been proposed in 2014 (Pennington et al., 2014). The improved representation of words gives contribution to the research of NLP tasks including sentiment analysis, and are used as the input of sentiment analysis models. There are several kinds of deep learning methods to extract text features. Sequential models such as Recurrent Neural Network (Schmidhuber, 1990), Bidirectional Recurrent Neural Networks (Member et al., 1997), Long Short-Term Memory (Hochreiter and Schmidhuber, 2012) and Gated Recurrent Unit (Cho et al., 2014) mainly extract serialization information of text. Multi-layer sequential models have also been proposed for sentiment analysis (Wang et al., 2016)(Tang et al., 2015)(He et al., 2016)(Yang et al., 2016). Tree-structured models extract structural information. The first tree-structured model named Recursive Neural Network has been proposed in 2012 (Socher et al., 2012b), followed by more models such as Matrix-Vector Recursive Neural Network (Socher et al., 2012a) and Recursive Neural Tensor Network (Socher et al., 2013). In 2015, Tree-structured Long Short-Term Memory Neural Network (Tree-LSTM), which combines the LSTM cell and tree-structured models, has been proposed and it outperforms the traditional LSTM and tree-structured neural networks (Le and Zuidema, 2015)(Tai et al., 2015)(Zhu et al., 2015). Different from the traditional tree-structured model, Tree-LSTM uses the LSTM cell to control the information from bottom to top so that it can effectively prevent the vanishing gradient problem.

As mentioned above, though combining the LSTM cell, Tree-LSTM does not really combine the structural information and serialization information. In this paper, we introduce three models: Tree-Composition LSTM (TC-LSTM), Leaf-Tree LSTM (LT-LSTM) and Leaf-Composition-Tree L-

STM (LCT-LSTM). Those models combine those two kinds of information and experiments show that they perform better than the traditional LSTM and the Constituency Tree-LSTM model.

The remainder of this paper is organized as follows: Section 2 introduces the LSTM and Tree-LSTM model which are related to our work. Section 3 introduces the models proposed in this paper. Experimental results are shown in Section 4 and in Section 5 we give the conclusions and future work.

2 Background

2.1 Long Short-Term Memory

Recurrent Neural Network (RNN) (Schmidhuber, 1990) encodes text information according to time. Giving a sentence, its words are encoded by the model in chronological order. For example, x_t represents the vector of input word at time step t , the hidden unit of time step t can be calculated as follows:

$$h_t = \tanh(Wx_t + Uh_{t-1} + b). \quad (1)$$

h_t represents the hidden layer at time step t , h_{t-1} represents the hidden state at time step $t - 1$, W is the weight matrix of the input layer, U is the weight matrix between h_{t-1} and h_t , b represents the bias and \tanh is the activation function which can normalize output information:

$$\tanh(x) = \frac{\sinh(x)}{\cosh(x)} = \frac{e^x - e^{-x}}{e^x + e^{-x}}. \quad (2)$$

At each time step, the hidden layer produces an output layer:

$$o_t = \text{softmax}(Vh_t + b). \quad (3)$$

Usually, the output of the final time step can be used to represent the feature of a sentence. Then, after forward propagation, the weights of model are trained by the backward propagation. Traditional RNN model has the problem of gradient vanish. Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 2012) Neural Network has effectively solved the problem. The model has four gates which help to selectively forget or remember information. A memory cell has also been added to memory information transmitted over time steps. The information calculated by an LSTM unit can be shown as follows (Tai et al., 2015):

$$i_t = \sigma(W^{(i)}x_t + U^i h_{t-1} + b^i), \quad (4)$$

$$f_t = \sigma(W^{(f)}x_t + U^f h_{t-1} + b^f), \quad (5)$$

$$o_t = \sigma(W^{(o)}x_t + U^o h_{t-1} + b^o), \quad (6)$$

$$u_t = \tanh(W^{(u)}x_t + U^u h_{t-1} + b^u), \quad (7)$$

$$c_t = i_t * u_t + f_t * c_{t-1}, \quad (8)$$

$$h_t = o_t * \tanh(c_t). \quad (9)$$

Here, i_t , f_t , u_t , o_t denote the four gates, c_t is the memory cell, $*$ represents element-wise multiplication. Intuitively, input gate (i_t) and update gate (u_t) denote how much the memory cell update information, forget gate (f_t) determines how much the memory cell forget history information and output gate (o_t) controls how much the hidden unit get information from the cell. σ represents the sigmoid function. The weights of different layers are different but they are shared at each time step in the same layer.

2.2 Tree-LSTM

Dependency Tree-LSTM and Constituency Tree-LSTM are two types of Tree-LSTM structures. We discuss the latter because it achieves a better performance in the sentiment analysis task (Tai et al., 2015). Constituency Tree-LSTM includes three types of layers. Input layer includes the leaf nodes, it consists of the words in the sentence, each word is represented by a vector. Composition layer acts as the hidden layer which composes the information flowing from the leaf nodes to the root node. Each composition unit can be seen as the structural feature of its leaf nodes. The final composition node (root node) represents the structural feature of the whole sentence, it is the input of output layer. LSTM cell is used to control the information flowed bottom-up. Different from the cell in sequential models, the hidden information of a composition node comes from their two child nodes:

$$i_j = \sigma(W^{(i)}x_j + \sum_{l=1}^N U_l^{(i)} h_{jl} + b^{(i)}), \quad (10)$$

$$f_{jk} = \sigma(W^{(f)}x_j + \sum_{l=1}^N U_{kl}^{(f)} h_{jl} + b^{(f)}), \quad (11)$$

$$o_j = \sigma(W^{(o)}x_j + \sum_{l=1}^N U_l^{(o)} h_{jl} + b^{(o)}), \quad (12)$$

$$u_j = \tanh(W^{(u)}x_j + \sum_{l=1}^N U_l^{(u)}h_{jl} + b^{(u)}), \quad (13)$$

$$c_j = i_j * u_j + \sum_{l=1}^N f_{jl} * c_{jl}, \quad (14)$$

$$h_j = o_j * \tanh(c_j). \quad (15)$$

It is worth noting that, in the input layer, the information composing the gates only include the input words (x_j) but do not have hidden information (h_{jl}). In the composition layer and output layer, only hidden information from two sub nodes participates in the construction of gates. The structure of Constituency Tree-LSTM model is shown in Figure 1.

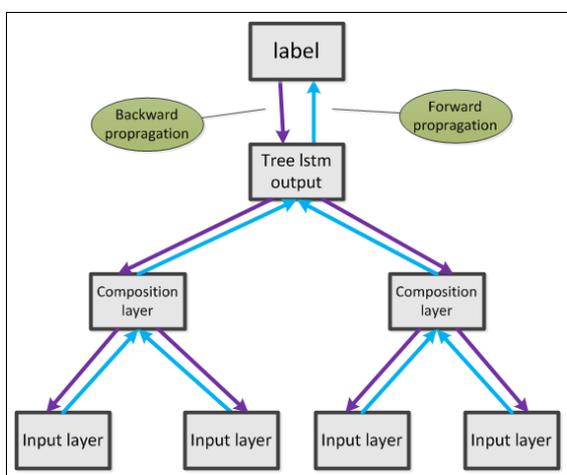

Figure 1: Constituency Tree-LSTM model. The upward arrows represent the direction of forward propagation, the downward arrows represent the direction of the backward propagation.

3 Our model

In this section, we discuss three new models which combine the structural information generated by tree-structured model (Constituency Tree-LSTM) and serialization information generated by sequential model (LSTM).

3.1 TC-LSTM

Constituency Tree-LSTM uses composition node at the root of the tree to represent the feature of sentence. We propose a new model named Tree-Composition LSTM (TC-LSTM) which generates a new feature taking all the leaf nodes, composition nodes and their sequential information into account. Firstly, we use postorder traversal to get all the nodes in the tree, and those nodes are

treated as a sequence. The sequence contains not only the words in the sentence, but also the structural information in their parent composition nodes. Then we put the sequence into LSTM model for training, thus obtaining the serialization information of those hidden nodes with structural information. It is worth noting that, though sharing the same hidden nodes, in our first proposed model, the weights of the original Tree-LSTM module and the new added LSTM module are trained independently. The input word vectors firstly perform forward propagation on the Tree-LSTM, and then, the sequence mentioned above is obtained. Then the forward propagation of the sequence is performed on the LSTM model. The output error and gradient of the two modules are obtained through the training label separately. Finally, the backward propagation performs independently of each other. The gradients of back propagation updating the word vectors of input layer only flows from Tree-LSTM module.

TC-LSTM model is shown in Figure 2. After training, we only use the output of LSTM module to test on test data in order to verify the performance of sequential information extracted from tree-structured model.

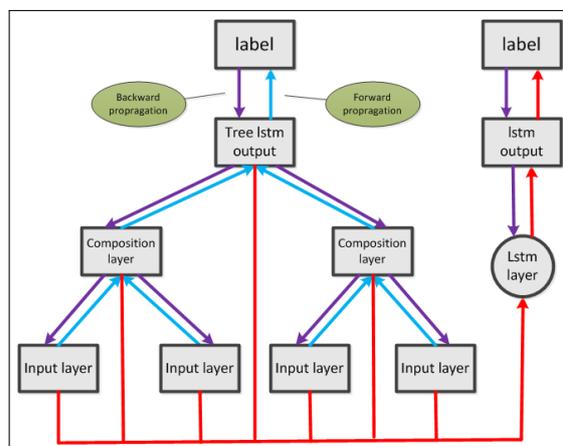

Figure 2: TC-LSTM model. New LSTM module is added to the original Tree-LSTM model. They shared the same hidden nodes but trained separately. Only the output of LSTM module is used to do the prediction.

3.2 LT-LSTM

We propose the Leaf-Tree LSTM (LT-LSTM) model to give a combination of the structural information and sequential information of a sentence. Similar to TC-LSTM, this model has t-

two modules but it only has one output. The first module is the same to Tree-LSTM, and the second module is the LSTM module which takes the leaf nodes of the tree, namely only the words of a sentence as input. During the forward propagation, we add the output of two modules and take the result as the output of the whole model. Gradient of the whole model is generated by the output, and then, assigned to the output of two modules for their backward propagation. Figure 3 shows the structure of the LT-LSTM model.

The output represents the combination of those two kinds of information: structural information and serialization information. Correspondingly, The gradient of the output layer contains the error information of the Tree-LSTM module and LSTM module. Letting the gradient propagate top-down through those two modules can make them learn from each other, thus having the chance to make the comprehensive performance of the whole model better.

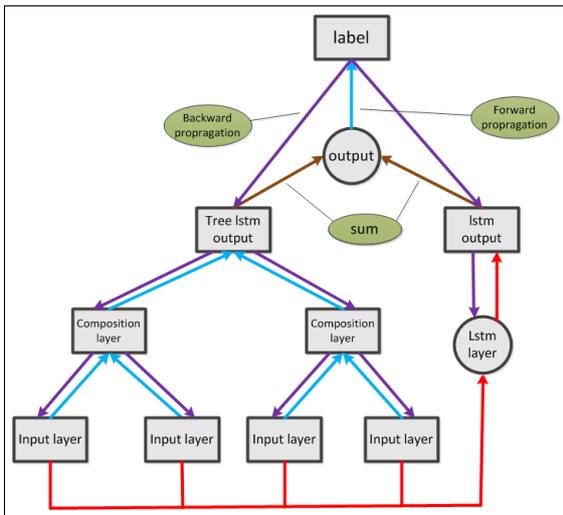

Figure 3: LT-LSTM model. The new added LSTM model only takes the leaf nodes as input. The output represent the fusion of two kinds of information, and its gradient trains the whole model.

3.3 LCT-LSTM

The third model proposed by us is Leaf-Composition-Tree LSTM (LCT-LSTM). Different from the LT-LSTM and TC-LSTM, this model not only takes the composition nodes into consideration when building the LSTM layer, but also makes sum of the outputs of two modules mentioned above. That is, LCT-LSTM can be seen as the composition of TC-LSTM and LT-LSTM for

the reason of not only building the sequential feature for the composition nodes which contain the structural information, but also combining the sequential feature and the structural feature of the input sentence. The structure of LCT-LSTM is shown in Figure 4.

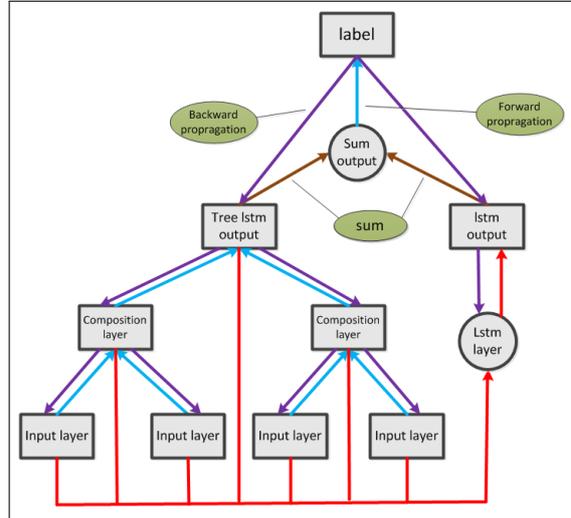

Figure 4: LCT-LSTM model.

4 Experiment

4.1 Dataset

We evaluate our proposed models on the Stanford Sentiment Tree Bank (SST) dataset, which contains sentences collected from movie reviews. The sentences in the dataset are split into three parts: 8544 for training, 1101 for development and 2210 for test. SST dataset has two classification tasks, one for fine-grained classification (five categories: very negative, negative, neutral, positive, and very positive) and the other for binary classification (two categories: negative and positive). The fine-grained subtask is evaluated on 8544/1101/2210 splits, and the binary classification is evaluated on 6920/872/1821 splits (there are fewer sentences because the neutral examples are excluded). Every sentence in the dataset is processed into tree structure, and every phrase (corresponding to the nodes in the tree) in the sentence is also labeled.

4.2 Hyperparameters and Training Details

We use the Glove vectors of 300 dimension (Pennington et al., 2014) to represent the input words. Word embeddings are fine-tuned during training and the learning rate used for the input layer is 0.1, for the other layers is 0.05. Adagrad

Models	$\theta - all$		$\theta - com$
	F	B	
LSTM	271955	271653	271200
Tree-LSTM	317555	317253	316800
TC-LSTM	499510	498906	498755
LT-LSTM	499510	498906	498755
LCT-LSTM	499510	498906	498755

Table 1: Parameters of models. $\theta - all$ represents the number of all the parameters in a model for F (fine-grained) tasks and B (binary tasks). $\theta - com$ represents parameters of composition layer. TC-LSTM, LT-LSTM and LCT-LSTM have the same number of parameters but they are trained in different ways.

algorithm is used for training, the minibatch size set by us is 25, L2-regularization is used for each batch using the value of 1e-4, and the dropout for the output layer is 0.5.

The dimension of the input layer is the same as the word vector, and the hidden layer consisted of tree nodes has the dimension of 150. For the sequential module, both of the inputs and the hidden layer have the dimension of 150, the vectors of leaf nodes are projected into the 150 dimension when put into the sequential part. The numbers of parameters for all the models are shown in Table 1.

Every model is trained on the training set for 20 epochs, and tested on the development set for validation after finishing every epoch. We choose the parameters performing best among them to do the evaluation on the test set. For every model, we repeat experiments for 8 times and take the average of their results as the final performance of the model.

4.3 Baseline

The models proposed by us fuse the structural information and serialization information, so we compare those models with other models which do not combine those two kinds of information. We choose the Constituency Tree-LSTM, LSTM and BiLSTM mentioned in 2015 (Tai et al., 2015) as the baseline models, other tree-structure models such as RNN, MV-RNN and RNTN are also used for comparison.

4.4 Result

The results of experiment are shown in Table 2. We use accuracy to measure the performance of models.

Models	Fine-grained	Binary
LSTM (Tai et al., 2015)	46.4	84.9
Bi-LSTM (Tai et al., 2015)	49.1	87.5
RNN (Socher et al., 2013)	43.2	82.4
MV-RNN (Socher et al., 2013)	44.4	82.9
RNTN (Socher et al., 2013)	45.7	85.4
Constituency Tree-LSTM	50.7	88.0
TC-LSTM	49.6	88.2
LT-LSTM	51.0	88.5
LCT-LSTM	50.9	88.7

Table 2: The result of accuracy on the test set. Fine-grained represents the five-category classification and the Binary represents the positive/negative classification.

From Table 2, we can see that on the whole, the models fusing structural and serialization information outperform other models which do not combine those two kinds of information. LT-LSTM achieves the best performance among our compared models in the fine-grained subtask and LCT-LSTM has the best performance in the binary subtask. TC-LSTM performs slightly better than Constituency Tree-LSTM in the binary subtask but worse than fine-grained subtask, but it still performs better than other single sequential models and tree-structured models.

We find that building the serialization feature for the nodes in tree-structure (TC-LSTM) does not really help the tree-structural models, but fusing the structural information and serialization information gives help to it. While fusing, adding the hidden nodes containing the structural information to the sequential model (LCT-LSTM) performs better in the binary subtask, but slightly worse in the fine-grained subtask compared to the model does not do so (LT-LSTM).

5 Conclusion

In this paper, we propose three new models in order to explore the effect of fusing the structural and sequential information. We evaluate our models on the Stanford Sentiment Tree Bank (SST). Experiments show that fusing the structural information and sequential information is an effective way to improve the performance of models proposed before. Future work can be focused on finding better ways to fusing those two features. Other models, such as the Bidirectional Long Short-Term Memory (BiLSTM), Bidirectional Tree-LSTM (Teng and Zhang, 2016) and TreeGRU (Kokkinos and Potamianos, 2017) can

be used in place of the tree-structured model and the sequential model used in our models. Attention mechanism (Luong et al., 2015) can also be used to do some improvement.

Length, Interchangeability, and External Knowledge: Observations from Predicting Argument Convincingness

Peter Potash, Robin Bhattacharya, Anna Rumshisky

Department of Computer Science

University of Massachusetts Lowell

{ppotash, rbhattach, arum}@cs.uml.edu

Abstract

In this work, we provide insight into three key aspects related to predicting argument convincingness. First, we explicitly display the power that text length possesses for predicting convincingness in an unsupervised setting. Second, we show that a bag-of-words embedding model posts state-of-the-art on a dataset of arguments annotated for convincingness, outperforming an SVM with numerous hand-crafted features as well as recurrent neural network models that attempt to capture semantic composition. Finally, we assess the feasibility of integrating external knowledge when predicting convincingness, as arguments are often more convincing when they contain abundant information and facts. We finish by analyzing the correlations between the various models we propose.

1 Introduction

Predicting argument convincingness has mostly been studied in relation to the overall quality of a persuasive essay (Attali and Burstein, 2004; Landauer, 2003; Shermis et al., 2010), with a recent focus specifically on predicting argument strength (Persing and Ng, 2015; Wachsmuth et al., 2016). Zhang et al. (2016) have also attempted to predict argument convincingness, in the form of predicting debate winners. Unfortunately, these are very rare argumentative formats that are seldom encountered in everyday life. In practice, at least at the moment, we tend to digest a large quantity of our information from social media and engage in a tremendous amount of interpersonal communication using it. Since, in social media, communications are roughly a single paragraph, analyzing

arguments in a persuasive essay or oxford-style debate is not applicable to our primary means of community engagement. Presenting an entire convincing argument within a single paragraph can be an invaluable skill in the modern world. This paper seeks to improve upon previous methodology for predicting argument convincingness.

Prompt: Is it better to have a lousy father or to be fatherless? **Stance:** It is better to have a lousy father.

Argument 1	Argument 2
It is better to have a lousy father because researchers at the McGill University have warned that growing up without a father can permanently change the structure of a child's brain and make him/her more aggressive and angry.	Having a lousy father is better because when a child does not have a father, it causes him/her to look for a father figure. During such searches, a child may end up getting sexual harassed or being emotionally exploited to various degrees.

Table 1: Example of an argument pair where Argument 1 is more convincing.

Habernal and Gurevych (2016b) have recently released a dataset of short, single-paragraph arguments annotated for convincingness, which we will refer to as UKPConvArg. For 16 issues, arguments with the *same* stance are compared with each other to determine, given a pair of arguments, which one is more convincing. Table 1 provides an example of an argument pair with arguments from the prompt ‘Is it better to have a lousy father or to be fatherless’; and the stance: ‘It is better to have a lousy father’. In this pair Argument 1 is chosen to be more convincing. Other such issues include: ‘Does India have the potential to

lead the world?’, ‘Which web browser is better, Internet Explorer or Mozilla Firefox?’, and ‘Should physical education be mandatory in schools’. In follow-up work, Habernal and Gurevych (2016a) examined the *reasoning* behind the annotations in their original corpus. That is, why arguments were selected as more convincing. Overwhelmingly, the reasons could be expressed by the following statement “Argument X has more details, information, facts or examples / more reasons / better reasoning / goes deeper / is more specific”. Although Habernal and Gurevych (2016b) experimented with two promising models, the models were not intended to directly take into account the reasons why an argument could be more convincing, as expressed in the previous quotation. The primary task of the dataset is, given two arguments with the same stance toward a topic, determine which argument is more convincing – this corresponds to outputting a binary label. Most of our experiments focus on this task, as it was the annotation directive for annotating convincingness in Habernal and Gurevych (2016b). From the pairwise annotation, they also derived convincingness scores for individual arguments, which is posed as a regression task. We evaluate on this task in Section 3.1.

In our work, we improve upon the initial experiments of Habernal and Gurevych in 3 ways: (1) we offer heuristic-based methods that requiring no training or fitting of a model to data; (2) we explore modifications of the initial ‘deep’ model used by Habernal and Gurevych (2016a), which was a Bidirectional Long Short-Term Memory (BLSTM) network; (3) we test the feasibility of offering factually relevant knowledge in the form of Wikipedia articles related to the argument topics.

In terms of heuristics, we examine the effectiveness of Metric Entropy (ME) of text to predict convincingness, which is inspired by the notion that written English language is well-formed, as opposed to random. Specifically, high ME corresponds to high randomness. The second heuristic uses a similarity to Wikipedia articles, with the hypothesis that the Wikipedia articles can act as a factual support reference for the arguments. We also hypothesize that Wikipedia articles have the potential to grade the quality of the writing in the arguments, on the assumption that arguments that better match the writing in Wikipedia articles are

more likely to exhibit the qualities that make an argument convincing. For all methods that use the presence of Wikipedia articles, we use several variations of a corpus to determine how well the methods leverage topic-specific articles, as opposed to randomly selected articles.

In terms of supervised techniques, we first follow previous approaches to classifying paired data that create separate learned representations of elements in a pair that are then concatenated for the final predictive model (Bowman et al., 2015; Mueller and Thyagarajan, 2016; Potash et al., 2016b). Specifically, we experiment with creating separate representations using either a BLSTM or summing individual token embeddings. We then propose modifications of the supervised models to leverage external data. The models grow with increasing complexity, approaching a form of Memory Network (Sukhbaatar et al., 2015) that computes a weighted sum of representations of Wikipedia articles.

Our experimental results reveal several important insights into how to approach predicting convincingness. We summarize our findings as follows: 1) Unsupervised text length is an extremely competitive baseline that performs on par with highly-engineered classifiers and deep learning models; 2) The current state-of-the-art approach treats tokens as interchangeable, bypassing the need to model compositionality; 3) Wikipedia articles can provide meaningful external knowledge, though, naive models have trouble dealing with the noise in a large corpus of documents, whereas a model that attends to the Wikipedia corpus is better equipped to handle the noise.

2 Related Work

Habernal and Gurevych (2016b) present two methods in their dataset paper: (1) an SVM with numerous hand-crafted features; (2) a BLSTM that only uses word embeddings as input. Aside from the original corpus authors, only one other work has tested on the UKPConvArg dataset. Chaluquine and Schulz (2017) use a feature-selection method to determine the raw feature representation that serves as input into a feed-forward neural network. The authors conduct a thorough ablation study of the performance of individual feature types. The authors’ best model records an accuracy of .766, compared to .781 and .757 of Habernal and Gurevych’s SVM and BLSTM, re-

spectively. Although the authors make an effort to determine the influence of individual feature type, their work continues to use supervised methods, which obscures the pure predictive power of individual features/metrics.

There are few datasets annotated for the convincingness of arguments. Zhang et al. (2016) published a dataset of debate transcripts, annotated with audience polling that occurs before and after the debate. In terms of argumentation, the key distinction between this dataset and that of Habernal and Gurevych (2016b) is that in the debate dataset, the debate teams have *opposing* stances on a topic, whereas Habernal and Gurevych’s dataset has labels for arguments with the same stance towards a topic. Persing and Ng (2015) constructed a corpus of persuasive essays annotated for the essays’ argument strength, which is slightly different to other annotated persuasive essay corpora, which have more of a focus on overall writing quality.

NLP datasets involving the processing of text pairs have become more prevalent. Examples include predicting textual entailment (Marelli et al., 2014; Bowman et al., 2015), predicting semantic relatedness/similarity (Marelli et al., 2014; Agirre et al., 2016), and predicting humor (Potash et al., 2016b; Shahaf et al., 2015). These tasks present interesting challenges from a modeling perspective, as methods must allow for semantic comparison between the texts.

Although relatively rare in the argument mining community, leveraging external knowledge sources is ubiquitous for the task of question-answering (Kolomiyets and Moens, 2011), using information retrieval techniques to mine the available documents for answers. Work such as Berant et al. (2013) forms a knowledge base from external documents, and maps queries to knowledge-base entries. Weston et al. (2014) have proposed a neural network-based approach for large-scale question-answering. In the argument mining community, Rinott et al. (2015) created a dataset for predicting potential support clauses for argumentative topics, while Braunstein et al. (2016) rank Wikipedia sentences for supporting answers made by online user answers. Conversely, Wachsmuth et al. (2017) approach the problem of measuring relevance amongst arguments themselves, proposing a methodology based on PageRank (Page et al., 1999).

3 Heuristic Methods

As Habernal and Gurevych (2016b) note in their paper, comparing the SVM and BLSTM systems, it is desirable for methodologies to require minimal preprocessing of text. Along those lines, methods that use heuristics can circumvent the need for supervised training. We refer to the models in this section as heuristic models, as opposed to unsupervised models, because they do not fit themselves to data – they merely compare various metric values to determine convincingness. We experiment with two types of heuristics: ME and Wikipedia similarity. The motivation of these heuristics is as follows: Metric Entropy has previously been applied to the task of predicting tweet deletion (Potash et al., 2016a), with the idea that tweets with high ME are likely to be spam. Moreover, ME conveys how well-formed the language is in a piece of text, since higher ME means a higher randomness in the language. Conversely, Wikipedia similarity attempts to use external knowledge to measure the factual validity of the arguments, but also potentially measuring the writing quality of the arguments.

3.1 Metric Entropy

The Shannon Entropy of a text T containing a set of characters C is defined as:

$$H(T) = - \sum_{c \in C} P(c) \log_2 P(c) \quad (1)$$

where

$$P(c) = \frac{freq(c)}{len(T)} \quad (2)$$

and $freq(c)$ is the number of times c appears in T . Consequently, ME is the Shannon entropy divided by the text length, $len(T)$. Since ME produces a continuous output, it is sensible to evaluate it using the regression task from Habernal and Gurevych (2016b). Because ME is a combination of Shannon Entropy and text length, we also evaluate their effectiveness separately as well. We admit, however, that our initial experiments only included ME and Shannon Entropy, but given the vastly different performance of the two metrics, we decided to test length on its own as well.

3.2 Wikipedia Similarity

Suppose we have vector representations of an argument a and a Wikipedia article w . The similarity score, $sim(a, w)$ is simply the dot product

of the two representations, aw^T . Therefore, given a corpus of Wikipedia articles W , we define the Wikipedia Similarity Score, WSS of an argument a as:

$$WSS(a) = \sum_{w \in W} aw^T \quad (3)$$

For pairwise prediction, we predict the argument with the higher score as the more convincing argument.

We consider two possible representations for texts: 1) term-frequency (TF) count, and 2) Summing the embeddings of all the tokens in the text. For the TF representation, we use the `CountVectorizer` class from Scikit-learn (Pedregosa et al., 2011) to process the text and create the appropriate representation. For the embedding representation, we use GloVe (Pennington et al., 2014) 300 dimensions learned from the Common Crawl corpus with 840 billion tokens.

Our Wikipedia data is from the May 20th, 2017 dump¹. We clean the raw Wikipedia data using *gensim* (Řehůřek and Sojka, 2010). We experiment with three different Wikipedia corpora. The first corpus has a set of 30 hand-picked Wikipedia articles, chosen to be of the same subject matter of the various topics in the argument convincingness corpora. We refer to this corpus as Wiki hand-picked (hp). The second corpus contains 38k random Wikipedia articles, chosen to be approximately the length of the hand-picked articles. The motivation behind the second corpus is to determine how valuable the topic-specific information is for assessing the validity of the arguments. The second corpus also simulates a situation where a model accesses an arbitrary knowledge base, as opposed to one that is hand-selected. We refer this corpus as Wiki random (ran). The third corpus combines the first two corpora, with the goal of determining how well the heuristic method can deal with the potential ‘noise’ of randomly chosen Wikipedia articles. We refer to this corpus as Wiki hp+ran.

4 Supervised Methods

Habernal and Gurevych (2016b) propose two supervised experiments for predicting argument convincingness: an SVM with numerous hand-crafted features, and a BLSTM that only uses word embeddings as input. While our heuristic methods

¹<https://dumps.wikimedia.org/enwiki/20170520/>

Model	Pearson	Spearman
SVM	0.351	0.402
BLSTM	0.270	0.354
SE	0.097	0.227
LEN	0.353	0.425
ME	0.358	0.422

Table 2: Results of the Metric Entropy experiments on the regression task. SE = Shannon Entropy, LEN = 1/text length, ME = Metric Entropy.

show promising results, they do not yet achieve state-of-the-art on the argument convincingness dataset. In this section, we motivate our supervised experiments with a combination of results from Section 3.2 and Habernal and Gurevych. All models have the same cost function, which is the binary cross-entropy of the training set, based on the sigmoid activation of a continuous value from a 1-dimensional dense layer.

4.1 Siamese BLSTM

The BSLTM model that Habernal and Gurevych (2016b) propose concatenates the text of the argument pairs, separated by a special delimiter. This single sequence is then run over by forward and backward LSTMs to produce the BLSTM embedding that is then used for logistic regression. We propose to model each argument in the argument pair separately, creating a representation for each argument pair that is then concatenated together for logistic regression output. The term ‘Siamese’ refers to the fact that the representations are created separately (we adopt the terminology from Mueller and Thyagarajan (2016)). Each argument goes through a BLSTM to produce its individual representation, using GloVe vectors as input to the BLSTM.

4.2 Siamese BOW Embedding

While a BLSTM model is very logical for most language tasks, given its sequential nature, work such as Joulin et al. (2016) shows that simply summing individual token embeddings can be extremely competitive for the task of text classification. Furthermore, in the current climate of increasingly complex deep learning models, it is important to continue to compare to simpler models. For this method, we represent an argument in an argument pair as the sum of its tokens’ embeddings. Given the TF representation of a set of texts

Table 3: Results of Wikipedia similarity experiments, using either a term-frequency representation (TF) or a sum of word embeddings (E). We experiment with three types of Wikipedia corpora: 30 hand-picked articles chosen to be highly relevant to the argument topics (hp); roughly 38k randomly chosen articles (ran); a combination of the first two corpora (hp+ran).

T in matrix format A and a corresponding embedding matrix E , the BOW Embedding, $BOWE$, representation is equivalent to:

$$BOWE(T) = AE \quad (4)$$

For our application, our input will have two matrices, T_l and T_r , representing the left and right arguments in the pair. Once the individual representations are created, as with the Siamese BLSTM, we concatenate them together as the input for lo-

gistic regression. Lastly, instead of continuing to train the initialized embedding matrix E , we fix E , calling it E_{fixed} , and pass it through a fully-connected layer, W_{emb} ,

$$E_{learned} = E_{fixed}W_{emb} \quad (5)$$

Thus, $E_{learned}$ replaces E in Equation 4. Because we are summing embedding vectors to create the representation, the values of representations' dimensions could become large, causing a dramati-

cally increased loss. While such methods as gradient clipping and gradient normalization could be used, we found it simple enough to divide the representation by 100.

4.3 Supervised Wikipedia Similarity

We now begin to modify the methodology described in Section 3.2 to add an increasing amount of complexity to better integrate the Wikipedia articles. The first model we propose uses the representations from Equation 4 to represent the arguments and Wikipedia articles, however, it is computed slightly differently for the arguments and wikipedia articles. While the argument representations use $E_{learned}$, the Wikipedia articles use E_{fixed} , and then the result of $BOWE(T)$ passes through a fully-connected layer, W_{wiki} . Just as we artificially normalized the argument representations, we divide the Wikipedia representations by 10,000, due to their greatly increased length compared to the argument text. Once we have the individual representations, we compute a similarity score as done in Equation 3. The one difference, though, is that we apply tanh to the result of the dot product to keep the summation in a manageable range, which aids training. The resulting similarity scores, one for each argument in the pair, become the features for a 2-dimensional logistic regression model. This model does not use dropout at the fully-connected layer.

4.4 Memory Network with Wikipedia

The model from Section 4.3 gives equal importance to the similarity scores from all Wikipedia articles. However, it’s more intuitive for more relevant articles to have more importance. Therefore, we construct a model similar to the end-to-end Memory Network from [Sukhbaatar et al. \(2015\)](#). We create a weight for each score (also interpretable as a probability score P^j) for each Wikipedia article, w_i , and argument, a_j , as²:

$$P^j(w_i) = \text{softmax}(a_j w_i^T) \quad (6)$$

which is used to create a weighted sum of the Wikipedia articles, s_j , for each argument j :

$$s_j = \sum_i^{|W|} P^j(w_i) w_i \quad (7)$$

²We note that we also experimented with an attention mechanism more akin that of [Bahdanau et al. \(2014\)](#), which uses a latent vector v to dot product with the sum $a_j + w_i$. However, this yielded the same results as the currently presented model.

We create the final representation, o_j , for argument j as follows:

$$o_j = a_j + s_j \quad (8)$$

which is the representation that is the input to the logistic regression layer (one for each argument in the pair).

5 Results

In each table that presents results, bold face indicates that a given system performed highest on a given topic within that table. An asterisk indicates that a given system performed highest on a given topic across *all* tables.

5.1 Heuristic Methods

Results of our ME experiments are shown in Table 2. We present the results on the regression task. The results of the Wikipedia similarity experiments are shown in Table 3.

5.2 Supervised Methods

Results of our supervised experiments are shown in Tables 4 and 5. We present the results of the Siamese BLSTM (SBLSTM), Siamese BOW Embeddings (SBOWE), Supervised Wikipedia similarity (SWS), and Memory Network with Wikipedia (MNW). Each model that uses Wikipedia articles is run with Wiki hp, Wiki ran, and Wiki hp+ran, as described in Section 3.2. All reported results are the average of three different runs. We report the accuracy on each topic, as well as the macro average across all topics. We compare our results with the SVM and BLSTM models from [Habernal and Gurevych \(2016b\)](#) in Table 4.

All models have dropout ([Srivastava et al., 2014](#)) of 0.5 at the dense layer (except for the model described in Section 4.3) and use a batch size of 32, as done by [Habernal and Gurevych \(2016b\)](#) in their BLSTM model. All models are implemented in TensorFlow ([Abadi et al., 2016](#)) and train for four epochs. The entire dataset has 11,650 argument pairs across all 32 topics. Since one topic is held-out for testing at a time, there is on average an 11,286/364 train/test split.

6 Discussion

6.1 Heuristic Methods

First, it is rather remarkable that text length alone, as a stand-alone metric, is able to record state-of-

Table 4: Results of supervised models that do not use Wikipedia. SVM and BLSTM results are reported from Habernal and Gurevych (2016b).

the-art results on the regression task. Although Chalaguine and Schulz (2017) directly showed the power of text length in a supervised setting, our results show an even simpler method for producing predictions on par with the previous state-of-the-art. There is intuitive reasoning for this result, since, as mentioned in Section 1, arguments are predominantly more convincing when they provide *more*; more facts, more information, more depth, etc. When evaluated on the pairwise binary prediction task, Metric Entropy and text length record 77.2% and 77.3% accuracy, respectively.

Reviewing the Wikipedia similarity results, it is

evident that the BOW embedding representation does offer greater predictive power when compared to the term-frequency representation. This unsupervised method even outperforms the supervised methods BLSTM and SBLSTM. Furthermore, compared to other methods that use Wikipedia articles, this method is more insensitive to the content of the articles, as it actually shows a very slight improvement when the hand-picked articles are not present, which is the opposite of all the other Wikipedia-based methods.

Table 5: We experiment with three types of Wikipedia corpora: 30 hand-picked articles chosen to be highly relevant to the argument topics (hp); roughly 38k randomly chosen articles (ran); a combining the first two corpora (hp+ran).

6.2 Supervised Methods

The first result to note is that the BOW Embedding model posts a new state-of-the-art on the dataset. This shows that the current best approach to predicting argument convincingness treats word order as interchangeable. Although, it is reasonable to surmise that facts and information are dependent on local compositionality, current methods to model such linguistic phenomena under-perform.

When comparing supervised models that integrate Wikipedia articles, we see that the MNW

model is better equipped to handle the noise from a large corpus of documents, when compared to the SWS results, which shows roughly a 1% drop in accuracy when the *ran* corpus is added to the *hp* corpus.

6.3 Model Correlations

Table 6 presents correlations between various models when comparing the accuracies of the individual topics. First, text length has a .96 correlation with the SVM model. This means that

	BLSTM	LEN	MNW	SBLSTM	SBOWE	SVM	SWS	WS-E	WS-TF
BLSTM	1.000	0.508	0.739	0.733	0.740	0.534	0.785	0.519	0.585
LEN	0.508	1.000	0.574	0.202	0.647	0.964	0.585	0.915	0.530
MNW	0.739	0.574	1.000	0.726	0.969	0.608	0.975	0.465	0.651
SBLSTM	0.733	0.202	0.726	1.000	0.722	0.277	0.723	0.173	0.528
SBOWE	0.740	0.647	0.969	0.722	1.000	0.681	0.948	0.552	0.683
SVM	0.534	0.964	0.608	0.277	0.681	1.000	0.615	0.904	0.584
SWS	0.785	0.585	0.975	0.723	0.948	0.615	1.000	0.528	0.630
WS-E	0.519	0.915	0.465	0.173	0.552	0.904	0.528	1.000	0.505
WS-TF	0.585	0.530	0.651	0.528	0.683	0.584	0.630	0.505	1.000

Table 6: Correlations between systems. Bold indicates the highest correlation for a given row.

the main predictive power of the SVM model can be distilled into using the text length to predict argument convincingness. What is perhaps more surprising is how high LEN correlates with WS-E. This could potentially be explained by the fact that articles with more words will sum together more embeddings, resulting in vectors with larger norms, which create larger dot-products when taken with the argument representations. However, the same argument can be made for the TF representation, so a more valid reason remains to be seen (note though that SBOWE and WS-TF have a low correlation with LEN). Secondly, we see that all models based on BOW embeddings have a very high correlation with each other, which is an intuitive finding.

7 Conclusion

In this work we have shown three key insights into the task of predicting argument convincingness: 1) Heuristic text length is an extremely competitive baseline that performs on par with highly-engineered classifiers and deep learning models; 2) The current state-of-the-art approach treats tokens as interchangeable, bypassing the need to model compositionality; 3) Wikipedia articles can provide meaningful external knowledge, though, naive models have trouble dealing with the noise in a large corpus of document, whereas a model that attends to the Wikipedia corpus is better equipped to handle the noise. Future work can focus on models that better handle compositionality, as well as integration of external knowledge, with an aim to surpass our new state-of-the-art on the corpus. One simple way to potentially enhance our MNW model is to perform multiple hops, a technique shown to greatly increase performance when using Memory Networks for other applica-

tions (Sukhbaatar et al., 2015).

Exploiting Document Level Information to Improve Event Detection via Recurrent Neural Networks

Abstract

This paper tackles the task of event detection, which involves identifying and categorizing events. The previous work mainly exists two problems: (1) the traditional feature-based methods apply cross-sentence information, yet need taking a large amount of human effort to design complicated feature sets and inference rules; (2) the representation-based methods though overcome the problem of manually extracting features, while just depend on local sentence representation. Considering local sentence context is insufficient to resolve ambiguities in identifying particular event types, therefore, we propose a novel document level Recurrent Neural Networks (DLRNN) model, which can automatically extract cross-sentence clues to improve sentence level event detection without designing complex reasoning rules. Experiment results show that our approach outperforms other state-of-the-art methods on ACE 2005 dataset neither the external knowledge base nor the event arguments are used explicitly.

1 Introduction

Event detection is a crucial subtask of event extraction, which aims to extract event triggers (most often a single verb or noun) and classify them into specific types in text. For instance, according to the ACE 2005 annotation guideline¹, in the sentence “central command says **troops** were involved in a **gun battle yesterday**”, an event detection system should be able to detect an **Attack** event with the trigger word “battle”. However, this

task is very challenging, as the same event might appear with various trigger words and a trigger expression might evoke different event types in different context.

Most of the existing methods either employed feature-based models with cross-sentence level information (Ji and Grishman, 2008)(Liao and Grishman, 2010)(Hong et al., 2011)(Huang and Riloff, 2012) or followed representation-based architectures with sentence level context (Chen et al., 2015)(Nguyen and Grishman, 2015)(Liu et al., 2016)(Nguyen and Grishman, 2016)(Nguyen et al., 2016)(Liu et al., 2017)(Chen et al., 2017). Both models have some inherent flaws: (1) feature-based approaches not only need to elaborately design rich features and often suffer error propagation from the existing natural language processing tools (i.e part of speech tags and dependency), but also the cross-sentence clues are embodied by devising complex inference rules, which is difficult to cover all the semantic laws; (2) though representation-based models can effectively alleviate the problem of manually extract features, local sentence context information may be insufficient for event detection models or even humans to classify events from isolated sentences. For example, consider the following sentences from ACE2005 dataset:

S1: Saba hasn't delivered yet.²

S2: I knew it was time to leave.³

It is very difficult to identify S1 as a Be-Born event with the trigger “delivered”, which means that a person entity is given birth to. Similarly, we have low confidence to tag “leave” as a trigger for End-Position event in the S2, which means that a person entity stops working for an organization. However, the wider context that “She wants to cal-

¹<https://www ldc.upenn.edu/sites/www ldc.upenn.edu/files/english-events-guidelines-v5.4.3.pdf>.

²Selected from the file “CNN_IP_20030414.1600.04”.

³Selected from the file “CNN_CF_20030303.1900.05”.

I her pregnant daughter Saba in Sweden to see if she has delivered.” would give us more confidence to tag “delivered” as a Be-Born event in the S1. It is easy to identify the “leave” as a trigger for End-Position event in the S2, if we know the previous information that “ this is when you were in the Senate – less and less information was new, fewer and fewer arguments were fresh, and the repetitiveness of the old arguments became tiresome. I was becoming almost as cynical as my constituents”.

In fact, each document often has a main content in ACE 2005 English corpus. For example, if the content of a document is about terrorist attack, the document is more likely to contain Injure events, Die events, Attack events, and is unlikely to describe Be-Born events. In other words, there is a strong association between events appearing in a document. In addition, event types contained in documents with the related topics are also consistent. Therefore how to use intra and inter document information becomes particularly important. Although there have been already some work to capture the clues beyond sentence to improve sentence level event detection (Ji and Grishman, 2008)(Liao and Grishman, 2010)(Hong et al., 2011), they still exist the following disadvantages: (1) inherent defects in feature-based models; (2) document level information was used by a large number of inference rules, this is not only complicated and time-consuming, but also difficult to cover all of the semantic laws.

In this paper, we propose a document level recurrent neural networks (DLRNN) model for event detection to solve the above problems. Firstly, to capture lexical-level clues and minimize the dependence on supervised tools and resources for features, we introduce a distributed word representation model (Mikolov et al., 2013a), which has been proved very effective for event detection (Chen et al., 2015)(Nguyen and Grishman, 2015)(Nguyen and Grishman, 2016). Secondly, we employ bidirectional recurrent networks to encode sentence level clues, which can effectively reserve the history clues and the following information of the current word. Thirdly, to capture document level and cross-document level clues without complicated inference rules. We introduce a document representation, which uses a distributed vector to represent a document and has been showed to be able to get better performance on text

classification and sentiment analysis tasks (Le and Mikolov, 2014). Finally, we use BILOU labeling method to solve the problem that a trigger contains multiple words.

In summary, our main contributions are as follows: (1) we prove the importance of document level information for event detection. (2) to capture document level clues, we devise a document level Recurrent Neural Networks (DLRNN) model for event detection, which can automatically learn features beyond sentence. (3) moreover, to solve the problem that a trigger word contains multiple words, we introduce BILOU labeling method. (4) finally, we improve the performance and achieve the best performance on ACE 2005 dataset neither the external knowledge base nor the event arguments are used explicitly.

2 Task Description

This paper focuses on addressing event detection task, which is a crucial subtask of event extraction. According to Automatic Context Extraction (ACE) evaluation⁴, which annotates 8 types and 33 subtypes for event mention. An event is defined as a specific occurrence involving one or more participants. Firstly, we introduce some ACE terminologies to facilitate the understanding of event extraction task:

Entity: an object or a set of objects in one of the semantic categories of interests.

Entity mention: a reference to an entity (typically, a noun phrase).

Event trigger: the main word that most clearly expresses an event occurrence.

Event arguments: the mentions that are involved in an event (participants).

Event mention: a phrase or sentence within which an event is described, including the trigger and arguments.

Given an English document, an event extraction system should identify event triggers and their corresponding arguments with specific subtypes or the roles for each sentence, but an event detection system only needs to identify event trigger and their subtype. For instance, for the sentence “central command says **troops** were involved in a **gun battle yesterday**”, an event extraction system is supposed to detect the word “battle” as the event trigger of **Attack** event and identify the word

⁴<https://project.ldc.upenn.edu/ace>

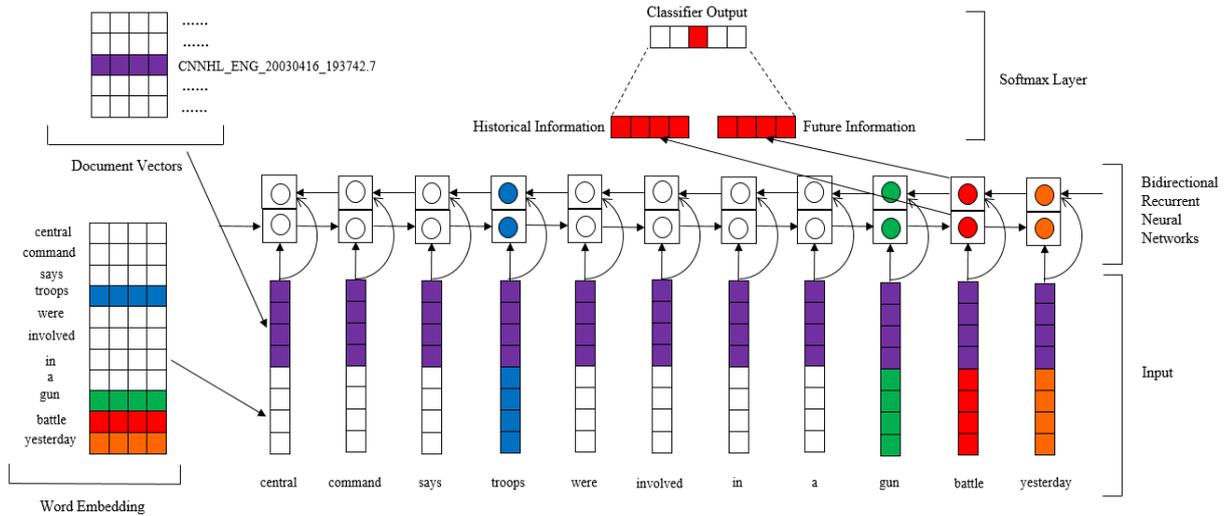

Figure 1: An illustration of our DLRNN model for detecting the trigger word “battle” in the input sentence “central command says troops were involved in a gun battle yesterday”.

“troops”, “gun” and “yesterday” as event argument whose roles are **Attacker**, **Instrument** and **Time-Within**. However, for an event detection system, identifying the word “troops”, “gun” and “yesterday” as event argument whose roles are **Attacker**, **Instrument** and **Time-Within** is not involved. Following previous work, we treat these simply as 33 separate event types and ignore the hierarchical structure among them.

3 Model

In this section, we give the details for the DLRNN model (shown in Figure 1). First of all, we formalize the event detection task as a multi-classes classification problem following previous work. More precisely, for each word in a sentence, our goal is to classify them into one of 34 classes (33 trigger types and None class).

Our DLRNN model primarily includes four parts: (i) word embedding, which contains lexical information for each word and is trained from external corpus in an unsupervised manner; (ii) document vector, which reveals the topic of a document is trained in an unsupervised mechanism; (iii) bidirectional recurrent neural networks encoding, which can learn the historical and future abstract representation of a candidate trigger; (iv) trigger prediction, which calculates a confidence score for each event subtype candidate.

3.1 Word Embedding

The representation of the words as continuous vectors (word embedding) are proved more powerful than discrete representation (Bengio et al., 2003)(Mikolov et al., 2013b). Word embedding not only addresses the problem of dimension disaster, but also makes the word vector contain richer semantic information. The closer the vector space, the closer the semantic. In addition, word embedding can automatically learn lexical-level clues in the process of pre-training. Not only does not require human ingenuity, but also effectively alleviates the error propagation brought by other NLP lexical analysis toolkits. Recent work has demonstrated that using word embedding can enhance the robustness of event detection model (Nguyen and Grishman, 2015)(Chen et al., 2015)(Nguyen and Grishman, 2016).

In this paper, we pre-trained word embedding via skip-gram model (Mikolov et al., 2013b) and New York Times corpus⁵. Given a sequence of training words $w_1, w_2, w_3, \dots, w_T$, the skip-gram model trains the embedding by maximizing the average log probability:

$$\frac{1}{T} \sum_{t=k}^{T-k} \log p(w_{t-k}, \dots, w_{t+k} | w_t) \quad (1)$$

where w_{t-k}, \dots, w_{t+k} is the context of w_t and the window size is k , usually it is expressed by the concatenation or sum of all word vectors in the

⁵<https://catalog.ldc.upenn.edu/LDC2008T19>

context; $p(w_{t-k}, \dots, w_{t+k} | w_t)$ is calculated via softmax. There, we have:

$$p(w_{t-k}, \dots, w_{t+k} | w_t) = \frac{e^{y_{w_{t-k}, \dots, w_{t+k}}}}{\sum_i e^{y_i}} \quad (2)$$

where each of y_i is un-normalized log-probability for each output context of the word i , computed as

$$y = b + U w_t \quad (3)$$

where U, b are the softmax parameters.

3.2 Document Vector

In order to illustrate the importance of the document vector for event detection in terms of disambiguity, we propose three hypotheses from intra and inter document context perspectives.

H1: As we all know, the same word in different context often has different meanings. For instance, the word “delivered” in S1 can mean that someone is born or bring something to a destination, when given different context.

H2: Events in a document exist consistency. For example, Die events and Marry events almost never appear in the same document, but Die events often occur with Attack events and Injure events in a document.

H3: The event types in documents with the related topics exist consistency. For instance, if the document that describing a financial crisis contains End-Position events and End-Org events, and then another document related to the financial crisis topic is more likely to happen End-Position events and End-Org events.

Based on the above three assumptions, we introduced an advanced document representation method. Documents are represented by the distributed vector like word embedding, which not only contains the main content of a document, but also the more relevant documents, the closer the document vector. For all the words in a document, the document vector is shared and is concatenated with word embedding, serving as the semantic representation of a word, as shown in Figure 1. Concatenating the document vector to word embedding has the following advantages: (i) a word is no longer represented by a unique word vector, but expressed by different vector in different documents. This can help event detection model to disambiguate event type; (ii) the consistency of events in a document is guaranteed. Since all the words in a document share a document vector,

which passes the identified event subtype information. For example, if some candidate triggers containing a particular document vector are mostly identified as Attack events, Die events, and Injuries events, and then the other candidate triggers that containing the document vector will be less likely to be identified as Marry events or Be-Born events. (iii) documents with related topic almost contain the same event types. Due to the fact that the more relevant topic of the documents, the closer document vectors, the model will be given high confidence to label candidate trigger in a document as the types that appearing in the relevant topic of the documents.

In this paper, we trained document vectors by using the PV-DM model (Le and Mikolov, 2014), which is very similar to the CBOW model that is another word embedding model (Mikolov et al., 2013a). Unlike the skip-gram model, given a document that contains training words $w_1, w_2, w_3, \dots, w_T$, document vector is trained by maximizing the average log probability:

$$\frac{1}{T} \sum_{t=k}^{T-k} \log p(w_t | w_{t-k}, \dots, w_{t+k}, doc) \quad (4)$$

where w_{t-k}, \dots, w_{t+k} is the context of w_t and the window size is k ; doc is the document vector containing the training words, which can be randomly initialized to a fixed dimension of vector like word embedding, see (Le and Mikolov, 2014) for details.

3.3 Bidirectional Recurrent Neural Networks Encoding

Recurrent neural networks (RNN) has been shown to perform considerably better than standard feed-forward architecture (Hammerton, 2003)(Sutskever et al., 2011)(Liu et al., 2014)(Sundermeyer et al., 2014). In this paper, we used RNN to encode word level information and document level clues. In the following, we describe our encoding model in detail.

The traditional RNN predicts the current tag with the consideration of the current input and history information before the current input. It loses the following information after the current input. In order to address this problem, we ran two RNNs, one of the RNNs is responsible for encoding the history information, and the other one is responsible for encoding the future information. In addition, the standard RNN often suf-

fers from gradient vanishing or gradient exploding problems during training via backpropagation (Bengio et al., 1994). To remedy this problem, we used long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) that is a variant of RNN to replace the standard RNN.

Formally, given candidate input sequence $X = \{x_1, x_2, \dots, x_n\}$. We run LSTM1 to get the hidden representation $\{h_{f_1}, h_{f_2}, \dots, h_{f_n}\}$ and run LSTM2 to get the hidden representation $\{h_{b_1}, h_{b_2}, \dots, h_{b_n}\}$. Each h_{f_i} and h_{b_i} are computed by:

$$h_{f_i} = \overrightarrow{LSTM}(x_i, h_{f_{i-1}}) \quad (5)$$

$$h_{b_i} = \overleftarrow{LSTM}(x_i, h_{b_{i+1}}) \quad (6)$$

where x_i is the concatenation of the word embedding of token i in candidate sentence and document vector that contains token i , as shown in Figure 1; $h_{f_{i-1}}$ contains the historical information before x_i ; $h_{b_{i+1}}$ contains the future clues after x_i . Eventually, we obtain the context information over the whole sentence $\{h_1, h_2, \dots, h_n\}$ with a greater focus on the position i by concentrating $\{h_{f_1}, h_{f_2}, \dots, h_{f_n}\}$ and $\{h_{b_1}, h_{b_2}, \dots, h_{b_n}\}$, where $h_i = [h_{f_i}, h_{b_i}]$.

3.4 Trigger Prediction

In the actual situation, due to the fact that a trigger may contain multiple words, we introduce the BILOU labeling method, which has been shown to be able to achieve better results than BIO labeling in entity recognition tasks (Gupta et al., 2016). In the BILOU labeling method, B represents the beginning of a trigger word, I indicates that the word is inside a trigger word, L represents that the word is the last word for a trigger word, O signifies that the word is not a trigger word, U denotes the trigger word contains unique word.

After bidirectional long short-term memory (BiLSTM) encoding, we get the global abstract representation h_i that encapsulates all context of the input sentence (see in section 3.3). And then, we feed h_i into a feed-forward neural network with a softmax layer (as shown in Figure 1). In the end, we get a 34 dimensions vector⁶, where the k -th term o_k is the probability value for classifying x_i to the k -th event type.

Given all of our (suppose T) training samples $(x^{(i)}; y^{(i)})$, we can then define the loss function as

⁶As a result of the BILOU tag, the actual dimension is more than 34 dimensions, but it is described as 34 dimensions for ease of understanding.

the average negative log-likelihood:

$$J(\theta) = -\frac{1}{T} \sum_{i=1}^T \log p(y^{(i)} | x^{(i)}, \theta) \quad (7)$$

In order to compute the network parameter θ , we minimize the average negative log-likelihood $J(\theta)$ via stochastic gradient descent (SGD) over shuffled mini-batches with Adam update rule (Kingma and Ba, 2014) and the dropout regularization (Zaremba et al., 2014).

4 Experiments

4.1 Dataset and Experimental Setup

We evaluate our DLRNN model on the ACE2005 English corpus. For fair comparisons, the same with (Ji and Grishman, 2008)(Liao and Grishman, 2010)(Hong et al., 2011)(Liu et al., 2017)(Chen et al., 2017), we select the same 40 newswire documents as the test set, the same 30 documents from different genres as development set and the remaining 529 documents are used as training set. Furthermore, we also follow the criteria of the previous work (Ji and Grishman, 2008)(Liao and Grishman, 2010)(Hong et al., 2011)(Li et al., 2013)(Liu et al., 2017)(Chen et al., 2017) to judge the correctness of the predicted event mentions and use *Precision* (P), *Recall* (R), *F-measure* (F_1) as the evaluation metrics.

We set the the dimension of word embedding to 200, the dimension of document vectors to 100, the size of hidden layer to 300, the size of mini-batch to 100, the dropout rate to 0.5, the learning rate to 0.002. All of the above hyper-parameter are adjusted on the development set.

4.2 Baseline Methods

In order to validate our DLRNN model, we choose the following models as our baselines, which are the state-of-the-art methods in sentence level and cross-sentence level event detection models.

Cross-Sentence Level Baselines:

1) **Cross-Document Inference:** It is the feature-based model proposed by (Ji and Grishman, 2008), which is the first time to use document information to assist in sentence level event detection. They employed document theme clustering and designed a lot of reasoning rules to ensure event consistency within the scope of the document and clustering.

2) **Cross-Event Inference:** This is the feature-based method proposed by (Liao and Grishman,

Methods	P	R	F_1
Ji’s cross-document†	60.2	76.4	67.3
Liao’s cross-event†	68.7	68.9	68.8
Hong’s cross-entity†	72.9	64.3	68.3
Li’s joint model	73.7	62.3	67.5
Nguyen’s JRNN	66.0	73.0	69.3
Chen’s DMCNN	75.6	63.6	69.1
Chen’s DMCNN+DS	75.7	66.0	70.5
Liu’s ANN	79.5	60.7	68.8
Liu’s ANN+Attention	78.0	66.3	71.7
Our DLRNN†	77.2	64.9	70.5

Table 1: Overall Performance on Blind Test Data. “†” designates the model that employs the evidences beyond sentence level. The boldface indicates that the model is representation-based model.

2010), which not only used the consistency information of the same type events in a document, but also explored the clues from the co-occurrence of different event types in the same document.

3) **Cross-Entity Inference:** It is the feature-based approach proposed by (Hong et al., 2011), which used the entity co-occurrence as a key feature to predict event mention.

Sentence Level Baselines:

4) **Joint Model:** It is the feature-based model proposed by (Li et al., 2013), which exploited argument information implicitly and captured the dependencies between two triggers within the same sentence.

5) **Joint RNN:** It is the representation-based method proposed by (Gupta et al., 2016), which exploited the inter-dependence of event trigger and event argument.

6) **DMCNN + Distant Supervision:** It is the representation-based method proposed by (Chen et al., 2017), which used the Freebase and FrameNet to extend the training corpus through distant supervision.

7) **ANN + Attention:** It is the representation-based approach proposed by (Liu et al., 2017), which exploited argument information explicitly for event detection via supervised attention mechanisms.

4.3 Performance Comparison

Table 1 are the comparisons of experimental results of our method with the baseline methods on the same blind test dataset. Seen from Table 1, we

make the following observations:

1) The performance of representation-based models is better than that of feature-based models. It indicates the artificially well-designed features are not sufficient for event detection, and automatically extracting features based on neural networks can capture richer semantic clues. In detail, the F_1 score of our DLRNN model is higher than state-of-the-arts feature-based model (Liao’s cross-event) by 1.7%; the other three representation-based models achieved better experimental results than that of Liao’s cross-event model, which gain 0.5%, 1.7% and 2.9% improvement, respectively.

2) The feature-based models that using cross-sentence information is more advantageous than the sentence level model. More accurately, in the cross-sentence models, only the performance of the Ji’s cross-document method is slightly lower than Li’s joint model (-0.2%), but the performance of the remaining models is better than Li’s joint model (an improvement of 0.8% and 1.3% in F_1 score). It proves the clues beyond sentence are very important for event detection.

3) Our DLRNN method outperforms all cross-sentence level feature-based event detection models. In detail, DLRNN gains 3.2% improvement on F_1 score than Ji’s cross-document, gains 1.7% improvement on F_1 score than Liao’s cross-event and gains 2.2% improvement on F_1 score than Hong’s cross-entity. The reasons are as follows: on the one hand, artificially constructed inference rules are difficult to cover all semantic laws; on the other hand, our DLRNN is better able to capture document level clues (including intra and inter-document context).

4) In spite that the performance of our DLRNN model does not improve the F_1 score compared with Chen’s DMCNN+DS model, even the performance is not as good as Liu’s ANN+Attention model. However, our method neither explicitly utilized event argument information, nor extended training data through using world knowledge (Freebase) and linguistic knowledge (FrameNet). If removed the event argument information and the knowledge base (Chen’s DMCNN and Liu’s ANN), the F_1 score of our DLRNN model is superior to the DMCNN and ANN methods, which are -1.4% and -1.7% lower, respectively. This not only illustrates that document level clues are very effective for the representation-based model, but

also prove that the effectiveness of the proposed method.

4.4 The Effectiveness of Document Vector

In order to verify the effectiveness of the document vector trained by PV-DM model for event detection, we design four experiments as baselines for comparison with our DLRNN (as shown in Table 2): BiLSTM, BiLSTM+TF-IDF, BiLSTM+AVE and BiLSTM+LDA.

1) **BiLSTM**: BiLSTM is similar to DLRNN except for removing the document vectors, only uses word embedding as the input of model.

2) **BiLSTM+TF-IDF**: Selected the word vector of the most important word for each document as the document vector for the document.

3) **BiLSTM+AVE**: The document vector is obtained by averaging the vector of each word in the document.

4) **BiLSTM+LDA**: The probability that each document corresponds to each topic is the document vector of the document.

5) **DLRNN**: DLRNN model uses the document vector, which is trained by PV-DM approach instead of averaging the word vector in the document⁷.

Methods	P	R	F_1
BiLSTM	76.1	63.5	69.3
BiLSTM+TF-IDF [†]	74.2	64.6	69.1
BiLSTM+AVE [†]	75.4	64.7	69.6
BiLSTM+LDA [†]	74.3	66.1	70.0
DLRNN [†]	77.2	64.9	70.5

Table 2: Overall Performance on Blind Test Data. “[†]” designates the model that employs the evidences beyond sentence level. “+TF-IDF” represents the document vector was obtained by TF-IDF. “+LDA” represents the document vector was obtained by LDA. “+AVE” represents the document vector was obtained by averaging the word vector in the document.

Seen from Table 2, we get the following observations: 1) in addition to BiLSTM+TF-IDF, the event detection models with the document vector can achieve better experimental results. In detail, BiLSTM+AVE, BiLSTM+LDA and DLRNN are 0.3%, 0.7% as well as 1.2% better than

⁷we clean the documents up by converting everything to lower case and removing punctuation and the stop words.

BiLSTM on F_1 score, respectively. This indicates that document level clues can contribute to sentence level event detection model. 2) compared to BiLSTM+TF-IDF, BiLSTM+AVE, BiLSTM+LDA, DLRNN gains 1.4%, 0.9%, 0.5% on F_1 score. This illustrates PV-DM model is able to capture richer semantic information.

In addition, in order to illustrate the documents that their vectors are similar contain the consistent event types. We visualize the document vectors. In detail, we randomly selected a document containing the events from ACE2005 English corpus, and found a document that is most similar to the selected document by calculating the cosine similarity of document vectors. Finally, we systematically compared the events contained in the two documents.

We randomly selected the document CNNHL_ENG_20030624_133331.33 as a source document, and found the document CNNHL_ENG_20030624_230338.34 is most similar to it by computing the cosine similarity of document vectors⁸. Seen from Figure 2, we observe that the two documents contain the same event types, except that the document CNNHL_ENG_20030624_133331.33 does not contain Attack event. Event type overlapping rate is up to 80%. This proves that there is correlation between the documents of similar document vectors.

Selected document	Most similar document

SUBTYPE="Phone-Write"	SUBTYPE="Phone-Write"
SUBTYPE="Injure"	SUBTYPE="Injure"

Figure 2: The comparison of event types on the most similar documents.

4.5 The Event Consistency in a Document

Seen from the Table 3, we observe that the Injure event often appears along with the Attack events, the Die events, and the Transport events

⁸The cosine similarity is 0.992

Event Subtype	Conditional Probability
Attack	0.4399
Die	0.2018
Transport	0.1555
Meet	0.0287
Demonstrate	0.0221
.....
Nominate	0.0
Elect	0.0

Table 3: The ranking probability of events co-occurrence with Injure events.

in the same document. The total probability of the above three types of events concurrence with Injure event is about 0.797. Furthermore, the Nominate events, the Elect events, and so on, have never been appeared in the same document containing the Injure events. This indicates that only certain types of events can occur in the same document, therefore the introduction of the document vector will help to predict event types in a document. Thus, the inter-document information reflected in document vector is useful to event detection.

4.6 The Effectiveness of BILOU Labeling

According to statistics, ACE2005 English corpus contains 235 trigger words, which are composed of multiple words, about 4.39% of the total trigger words. It is not appropriate to treat identifying the triggers that contains multiple words as a word classification task, because most of the triggers of multiple words contain prepositions. However, the prepositions in such triggers do not trigger event independently. Therefore, using BILOU encoding helps to treat the multiple words trigger as a whole. Table 3 demonstrates the effectiveness of the BILOU encoding (an improvement of 0.2% on F_1 score).

Methods	P	R	F_1
DLRNN-BILOU	78.8	63.5	70.3
DLRNN	77.2	64.9	70.5

5 Related Work

Event detection is a challenging task in the field of natural language processing, which has attract-

ed more and more researchers’ attention in recent years. The current event detection models can roughly be divided into: (1) the sentence level event detection models and (2) the cross-sentence level event detection models.

(1) The sentence level event detection models: they are designed to use the sentence information for event classification. According to the differences in how to use sentence information, they can be divided into two categories: the feature-based models and the representation-based models. The early event detection models are almost all feature-based models, which transformed lexical features, syntactic features and semantic features into one-hot vectors by other natural language processing toolkits, and then sended these well-designed features into the classifiers (eg: structure perceptron or support vector machine) and eventually completed the event classification (Ahn, 2006)(Li et al., 2013). With the success of deep learning in entity identification and relationship classification (Collobert and Weston, 2008)(Zeng et al., 2014), many event detection researchers turned to focus on the representation-based models. This kind of models do not need to extract the features manually. They used the distributed word vector as the input and encoded the word vector into low-dimensional abstractive representation by the neural network to complete event detection (Nguyen and Grishman, 2015)(Chen et al., 2015)(Nguyen et al., 2016)(Nguyen and Grishman, 2016)(Liu et al., 2016)(Liu et al., 2017)(Chen et al., 2017).

(2) The cross-sentence level event detection models: they aim to explore the clues beyond sentence to improve sentence level event detection. Remarkable researches are cross-document inference (Ji and Grishman, 2008), cross-event inference (Liao and Grishman, 2010), cross-entity inference (Hong et al., 2011) and modeling textual cohesion (Huang and Riloff, 2012). There mainly have two disadvantages: 1) The existing cross-sentence event detection models are feature-based models, which not only need to construct complex manual features and lack generalization ability; 2) utilizing the clues beyond sentence through designing complex and numerous reasoning rules, is not only complex, but also can not cover all semantic phenomenon. Different from the above methods, our approach makes the machine automatically learn the document level information by the representation based way to improve the per-

formance of event detection.

6 Conclusion

In this paper, we propose a novel model (DLRN-N) to automatically extract cross-sentence level clues for event detection by concatenating word vector and document vector. Moreover, we use BILOU encoding to solve the problem that contains multiple words in a trigger word. In order to prove the effectiveness of the proposed method, we systematically conduct a series of experiments on ACE2005 dataset. Experimental results show that the proposed method is better than state-of-the-arts cross-sentence level feature-based models and the sentence level representation-based models without using argument information and external corpus, such as Freebase and FrameNet (Liu et al., 2017)(Chen et al., 2017), which demonstrates that intra and inter-document context is effective for event detection.

Abstract

Current supervised name tagging approaches are inadequate for most low-resource languages due to the lack of annotated data and actionable linguistic knowledge. All supervised learning methods (including deep neural networks (DNN)) are sensitive to noise and thus they are not quite portable without massive clean annotations. We found that the F-scores of DNN-based name taggers drop rapidly (20%-30%) when we replace clean manual annotations with noisy annotations in the training data. We propose a new solution to incorporate many *non-traditional* language universal resources that are readily available but rarely explored in the Natural Language Processing (NLP) community, such as the World Atlas of Linguistic Structure, CIA names, PanLex and survival guides. We acquire and encode various types of non-traditional linguistic resources into a DNN name tagger. Experiments on three low-resource languages show that feeding linguistic knowledge can make DNN significantly more robust to noise, achieving 8%-22% absolute F-score gains on name tagging without using any human annotation¹.

1 Introduction

There is a general agreement that Deep Neural Networks provides a general, powerful underlying model for Information Extraction (IE), confirmed by improved state-of-the-art performance on many tasks such as name tagging (Chiu and Nichols, 2016; Lample et al., 2016), relation classification (Zeng et al., 2014; Liu et al., 2015; Nguyen

and Grishman, 2015b; Yang et al., 2016) and event detection (Nguyen and Grishman, 2015b; Chen et al., 2015; Nguyen and Grishman, 2015a, 2016; Feng et al., 2016). For example, our experiments on several languages show that a DNN-based name tagger generally outperforms (up to 6% F-score gain) a Conditional Random Fields (CRFs) model trained from the same labeled data and feature set. DNN architecture is attractive to couple with character/word embeddings for IE tasks because it is easy to learn and usually effective enough to eliminate the need of explicit linguistic feature design.

However, training general models like DNN usually requires a massive amount of clean annotated data, which is often not available for low-resource languages and difficult to obtain during emergent settings (Zhang et al., 2016a). In order to compensate this data requirement, various automatic annotation generation methods have been proposed, including knowledge base driven distant supervision (An et al., 2003; Mintz et al., 2009; Ren et al., 2015), cross-lingual projection (Li et al., 2012; Kim et al., 2012; Che et al., 2013; Wang et al., 2013; Wang and Manning, 2014; Zhang et al., 2016b), and leveraging naturally existing noisy annotations such as Wikipedia markups (Nothman et al., 2008; Dakka and Cucerzan, 2008; Ringland et al., 2009; Alotaibi and Lee, 2012; Nothman et al., 2012; Althobaiti et al., 2014; Pan et al., 2017). Annotations produced from these methods are usually very noisy, while DNN is sensitive to noise just like many other machine learning methods. Our name tagging experiment shows that the F-score of the same DNN model learned from noisy training data is 20-30% lower than that trained from clean data. One major reason is that most of these methods solely rely on implicit embedding features in order to be (almost) language-independent.

Moreover, certain types of linguistic properties

¹We make all cleaned resources and converted linguistic features publicly available at <http://nlp.cs.rpi.edu/denoise>

are difficult to be captured by embeddings, such as: (1) language-specific structures. For example, the Subject (S), Verb (V) and Object (O) orders in Tagalog are VS, VO, and VSO, which indicates that the word at the beginning of a sentence is usually a verb and thus unlikely to be a name. (2) culture-specific knowledge. For example, a Uyghur person’s last name is the same as his/her father’s first name.

On an almost parallel research avenue, linguists and domain experts have created a wide variety of multi-lingual resources, such as World Atlas of Linguistic Structure (WALS) (Dryer and Haspelmath, 2013b), Central Intelligence Agency (CIA) Names, grammar books, and survival guides. Such resources have been largely ignored by the mainstream statistical NLP research, because they were not specifically designed for NLP purpose at the first place and they are often far from complete. Thus they are not immediately actionable - converted into features, rules or patterns for a target NLP application. In this paper we design various methods to convert them into machine readable features for a new DNN architecture. Very little work has used non-traditional resources mentioned in this paper for practical downstream NLP applications. Limited work only used them for resource building (e.g., (Sarma et al., 2012)) or studying word order typology (Ostling, 2015). To the best of our knowledge, our work is the first to encode them as actionable knowledge for IE.

We aim to answer the following research questions: How to effectively acquire linguistic knowledge from non-traditional resources, and represent them for computational models? How much further gain can be obtained in addition to traditional resources?

2 Approach Overview

2.1 A Typical Baseline DNN Model

A typical supervised name tagger is presented in (Lample et al., 2016), consisted of Bi-directional Long Short-Term Memory networks (Bi-LSTM) and CRFs. We can consider name tagging as a sequence labeling problem, to tag each token in a sentence as the Beginning (B), Inside (I) or Outside (O) of a name mention with a certain type. In this paper we classify names into three types: person (PER), organization (ORG) and location (LOC). Predicting the tag for each token needs evidence from both of its previous context and future context

Languages	# of Documents		# of Names		# of Sentences	
	Train	Test	Train	Test	Train	Test
Hausa	137	100	3,414	1,320	3,156	1,130
Turkish	128	100	2,341	2,173	1,973	2,119
Uzbek	127	100	3,577	3,137	3,588	3,037

Table 1: Data Statistics.

in the entire sentence. Bi-LSTM networks (Graves et al., 2013) meet this need by processing each sequence in both directions with two separate hidden layers, which are then fed into the same output layer. Moreover, there are strong classification dependencies among name tags in a sequence. For example, “I-LOC” cannot follow “B-ORG”. CRFs model, which is particularly good at jointly modeling tagging decisions, can be built on top of the Bi-LSTM networks.

2.2 Baseline’s Sensitiveness to Noise

In low-resource settings where few clean annotations are available, we could try to automatically generate some annotations to train the above model. For instance, we can project automatic annotations from a high-resource language (HL) to a low-resource language (LL) through parallel data. Figure 1 shows an example of projecting English automatic name annotations to Hausa through a parallel sentence pair.

We are interested in studying how sensitive DNN is to noise in such automatically generated training data. For our experiments we use English as the HL and use three LLs with different linguistic properties: Turkish, Uzbek and Hausa. We evaluate our approaches using the ground-truth name tagging annotations from the DARPA LORELEI program². For fair comparison with previous LORELEI work (Tsai et al., 2016; Zhang et al., 2016a; Pan et al., 2017), we use the same 100 test documents. Table 1 shows detailed data statistics.

We use 80% of the name annotated LL documents for training and 20% for development, and parallel sentences to artificially create noisy training data as follows. We use S to denote the sentences in LL and T to denote the sentences in HL. We apply Stanford English name tagger (Manning et al., 2014) on T and project English names onto S , using the following measurements to determine whether a candidate LL name string n_l matches an expected English name n_e : (1) If the edit distance

²<http://www.darpa.mil/program/low-resource-languages-for-emergent-incidents>

English While speaking on the launch, the [AU]ORG president, [Nkosazana Dlamini-Zuma]PER, expressed her joy over the assistance coming from different parts of [Africa]LOC for the fight against Ebola virus in [West Africa]LOC.

Hausa Da take jawabi albarƙacin bikin kaddamarwa, shugabar kungiyar [AU]ORG, [Nkosazana Dlamini-Zuma]PER, ta bayyana jin-dadinta kan wannan tallafi dake fitowa daga yankunan [Afrika]LOC daban daban domin yaki da annobar cutar Ebola a [Yammacin Afrika]LOC.

* Projection 1 is incorrect and results in a noisy instance in the automatically generated Hausa annotations. The correct name mention is “kungiyar AU (Africa Union)” instead of “AU”.

Figure 1: Noisy Training Data Generation by Projecting English Automatic Name Annotations to Hausa.

between n_e and n_l is not greater than two. (2) We check the pronunciations of n_e and n_l based on Soundex (Odell, 1956), Metaphone (Philips, 1990) and NYSIIS (Taft, 1970) algorithms. We consider two codes match if their edit distance is not greater than two. (3) If n_e and n_l are aligned in the parallel data by running GIZA++ word alignment tool (Och and Ney, 2003).

In this way we obtain an automatically generated noisy training data set $Train_{noise}$. We denote $Train_{clean}$ as the ground truth which is manually created by human annotators on set S . We mix $Train_{noise}$ and $Train_{clean}$ in different proportions to obtain a training set $Train_{mix}$ on various noise levels. We define **noise level** as $1 - fscore(Train_{mix})$ where the f-score of $Train_{mix}$ is computed against $Train_{clean}$. For example, when $Train_{mix}$ is full of manually created clean data, the noise level is 0; when we mix half $Train_{noise}$ and half $Train_{clean}$ of the Hausa data, the f-score of $Train_{mix}$ is 80.1%, and the noise level is 19.9%.

To learn embeddings, we use 12,624 Hausa documents from the LORELEI program, and use 288,444 Turkish documents and 128,763 Uzbek documents from a June 2015 Wikipedia dump. Figure 2 shows the performance of the baseline tagger trained from $Train_{mix}$ for three languages. We can clearly see that the performance drops rapidly as the training data includes more noise.

2.3 A New Improved Model

We propose to acquire non-traditional linguistic resources and encode them as new actionable features (Section 3). In Figure 3, we design three integration methods to incorporate explicit linguistic features into Bi-LSTM networks: (1) concatenate the linguistic features and word embeddings at the input level, (2) concatenate the linguistic features and the bidirectional encodings of each token before feeding them into the output layer that computes the tag probability, and (3) use an additional Bi-LSTM to consume the feature embeddings of

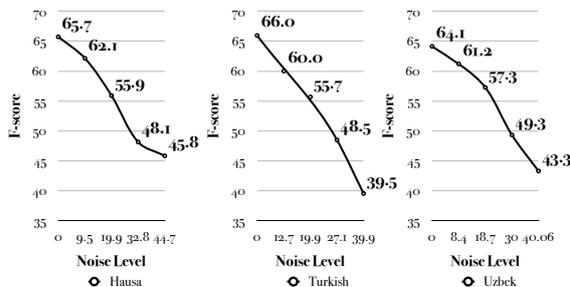

Figure 2: Performance of baseline DNN Name Taggers Trained from Data with Various Noise Levels (The noise level is created by assigning the proportion of $Train_{noise}$ in $Train_{mix}$ as 0%, 25%, 50%, 75% and 100% respectively.)

each token and concatenate both Bi-LSTM encodings of feature embeddings and word embeddings before the output layer. We set the word input dimension to 100, word LSTM hidden layer dimension to 100, character input dimension to 50, character LSTM hidden layer dimension to 25, input dropout rate to 0.5, and use stochastic gradient descent with learning rate 0.01 for optimization.

3 Incorporating Non-traditional Linguistic Knowledge

In this section we will describe the detailed methods to acquire and encode various types of non-traditional resources. We call them as *non-traditional* because they have been rarely used in previous NLP research.

3.1 Basic Knowledge about the Language

Wikipedia Description. An English Wikipedia page about a language usually provides us general descriptions of the language. In particular, the list of usable characters, gender indicators, capitalization information, transliteration and number spelling rules are most useful for name tagging. The list of usable characters for regular words in a particular language can help us detect foreign borrow words, which are likely to be names. For example, “*th*” usually does not appear at the begin-

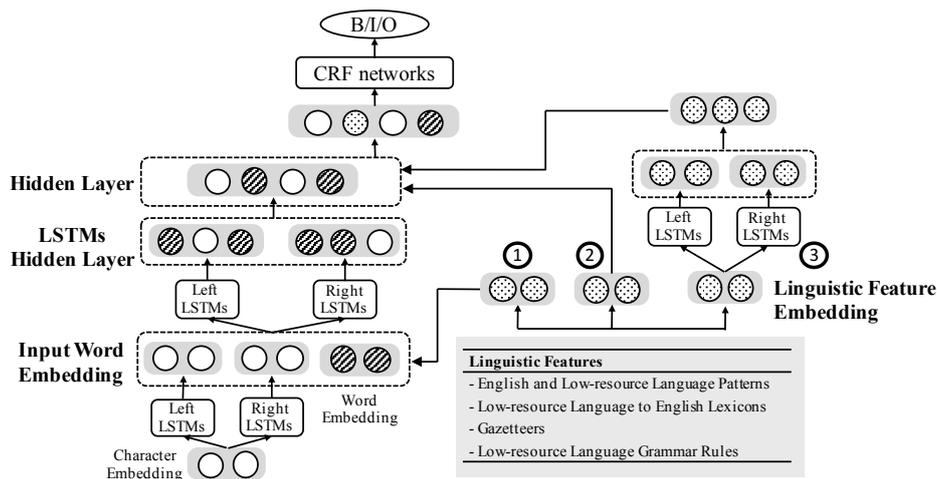

Figure 3: Three Integration Methods to Incorporate Explicit Linguistic Features into DNN.

ning of a Turkish word. Thus “*Thomas Marek*” is likely to be a foreign name.

Grammar Book. From grammar books we can also extract more language-specific contextual words, prefixes, suffixes and stemming rules. Name related lists contain: case suffix, preposition, postposition, ordinal number, definite article, negation, conjunction, pronoun, quantifier, numeral, time, locative, question particle, demonstrative, degree word, plural prefix/suffix, subordinator, reduplication, possessive, situational and epistemic markers. Table 2 shows some examples of name related suffix features.

3.2 Linguistic Structure

Recently linguists have made great efforts at building linguistic knowledge bases for thousands of languages in the world. Two such examples are WALS database (Dryer and Haspelmath, 2013a) and Syntactic Structures of the World’s Languages³. These databases classify languages according to a large number of topological properties (phonological, lexical and grammatical). For example, WALS consists of 141 maps with accompanying text on diverse properties, gathered from descriptive materials (such as reference grammars). Altogether there are 2,676 languages and more than 58,000 data points; each data point is a (language, feature, feature value) tuple that specifies the value of the feature in a particular language. (e.g., (English, canonical word order, SVO)). In total we extract 188 linguistic properties related to name tagging, belonging to 20 Phonology, 13 Lexicon, 12 Morphology, 29 Nominal, 8 Nominal Syntax, 17 Verbal Categories, 56 Word Order,

³<http://sswl.railsplayground.net/>

26 Simple Clauses, and 7 Complex Sentences categories respectively. Table 3 shows some examples.

3.3 Multi-lingual Dictionaries

CIA Names. We utilize the CIA Name Files⁴, which include biographical sketches, memorandums, telegrams, legislative records, legal documents, statements, and other records. We used the version cleaned up by Lawson et al.⁵ that includes documents about names in 41 languages. Besides, person names in certain regions often include some common syllable patterns. Table 4 presents some examples. In languages such as Turkish, Uzbek and Uyghur, a person’s last name inherits from his or her father’s first name. In Uyghur, there are no additional suffixes. In Uzbek, additional suffixes include “-ov”, “-ev”, “-yev”, “-eva” and “-yeva”. In Turkish, a male’s first name often ends with a consonant, and his last name consists of his father’s first name and a suffix “-oğlu (son of)”. We exploit this kind of knowledge to improve gazetteer match and name boundary identification.

Unicode CLDR. Unicode Common Locale Data Repository (CLDR)⁶ is a data collection for 194 languages, maintained by the Unicode Consortium to support software internationalization and localization. We extract bi-lingual location gazetteers, and exploit patterns and lists of currencies, months, weekdays, day periods and time units to remove them from name candidates because they share some features with names (e.g., capitalization, “*Ocak*” in Turkish means “*January*”).

Languages	Features	Description	Examples
Uzbek	Name	-ni (accusative), -ning (possessive), -da (locative), -dan (ablative)	Turkiyaning (of Turkey), Turkiyada (in Turkey), Turkiyaga (to Turkey), Turkiyadan (from Turkey).
	Non-Name	Suffix -roq indicates adjectives Suffixes -lar/-ler indicate plurals	qoraroq (darker) qizlar (daughters)
Hungarian	Name	Foreign name with >1 tokens and an adjective marker	New York- i (from New York)
		Most names with adjective or verbal suffix are lowercased	Balzac + -os ⇒ balzacos
	Possession relation	Péter- ék (Peter and his group), Péter- é (that of Peter)	
	Affixes associated with names	Sartre- nak (to Sartre), Bordeaux- ban (in Bordeaux), Smith- ért (for Smith)	
Non-Name	Non-Name POS tag	adjectives (-tlen : “-less”), verbs tense (-meg- : “completed”), conjunctions (-ért : “because of”)	
Uyghur	Name	Complete inflectional for nominals	karoknak (for arms) → karok (arms) → kar (arm)
		Animacy suffixes	ning, ni, luq, and lik
Turkish	Name	Geopolitical or location suffixes	ke, ge, qa, gha, te, de, ta, da, tin, din, tiki, diki, kiche, giche, qiche, and ghiche.
		Postpositions	karaköy de (in Karaköy)

Table 2: Name-related Knowledge Summarized from Grammar Books.

Languages	Categories	Description	Name Related Characteristics
Tagalog	Subject, Verb, Object Order	VS, VO, VSO	the word at the beginning of a sentence is unlikely to be a name
Turkish	Negation	Suffix -me at the root of a verb indicates negations	not a name
Bengali	Animacy	-ta is a case that indicates inanimacy	
Thai	Nested Name Structure	Delimiter between modifier and head, [ORG กระทรวงต่างประเทศ] ของ [LOC อินโดนีเซีย] ([ORG Foreign Ministry] of [LOC Indonesia])	Name boundary
Tamil	Conjunction Structure	Name1- yum Name2- yum (Name1 and Name2)	Name type consistency

Table 3: Name-related Knowledge Extracted from WALS.

Languages	Frequent Syllable Patterns	Examples
Slavic	Suffixes: -ov, -ev, -ova, -eva; -ovich, -ich, -enko, -ko, -chuk, -yuk, -ak, -chenko, -skiy, -ski, -vych, -vich	Karimov, Yuriy Yarov, Abdulaziz Komilov, Yamonkulov Yaxshiboyevich, Shevchenko
Arabic	Prefixes: al-, Ahl, Abdul-, Abdu- Suffixes: -allah, -ullah	Abdul Khaliq, Abdul Latif, Abdul Maajid Daifallah, Dhikrullah, Faizullah, Fathallah
Uzbek	Suffixes: -ov, -ova, -ev, -yev, -eva, -yeva; -ovich, -evich, -ich	Karim Ahmedov, Ahmed Aliyev, Zulfiya Karimova, Karmm Sharafovich Rashidov

Table 4: Common Syllable Patterns Extracted from CIA Names.

Wiktionary. Wiktionary ⁷ is a web-based collaborative project to create an English content dictionary of all words in many languages. We collected dictionaries in 1,247 languages.

Panlex. Panlex ⁸ (Baldwin et al., 2010; Kamholz et al., 2014) database contains 1.1 billion pairwise translations among 21 million expressions in about 10,000 language varieties.

Multilingual WordNet. We leverage three versions of multi-lingual WordNet: (1) Open Multilingual WordNet (Bond and Paik, 2012) which links words in many languages to English WordNet based on Wiktionary and CLDR; (2) Universal WordNet (de Melo and Weikum, 2019) which au-

tomatically extends English WordNet with around 1.5 million meaning links for 800,000 words in over 200 languages, based on WordNets, translation dictionaries and parallel corpora; and (3) Etymological WordNet (de Melo and Weikum, 2010; de Melo, 2014) that provides information about how words in various languages are etymologically related based on Wiktionary.

Phrase Pairs Mined from Wikipedia. From Wikipedia we extracted all pairs of titles that are connected by cross-lingual links. And we extracted more phrase translation pairs using parenthesis patterns from the beginning sentences of Wikipedia pages. For example, from the first sentence of the English Wikipedia page about Ürümqi: “*Ürümqi (ئۈرۈمچى) is the capital of the*

⁷<https://en.wiktionary.org>

⁸<http://panlex.org/>

Xinjiang Uyghur Autonomous Region of the People's Republic of China in Northwest China," we can extract an Uyghur-English name translation pair of “ئۈرۈمچى” and “Ürümqi”. Moreover, we retrieved related Wikipedia articles, and mined common names in many languages and regions.

GeoNames. We exploit the geo-political and location entities in multilingual GeoNames database⁹. It contains over 10 million geographical names and over 9 million unique features of the following properties: id, name, asciiname, alternate names, latitude, longitude, feature class, feature code, country code, administrative code, population, elevation and time zone.

JRC Names. Finally we include the JRC Names (Steinberger et al., 20011), a large list of person and organization names (about 205,000 entries) in over 20 different scripts. Some entries include additional information such as frequency, title and date ranges.

Grounding to KB and Typing. For names that we are able to acquire English translations, we further ground (“wikify”) them to an external knowledge base (KB, DBpedia in our work) if they are linkable. We use two measures (Pan et al., 2015) for linking: (1) Popularity: we prefer popular entities in the KB; (2) Coherence: we link a pair of a foreign name and its English translation simultaneously and favor their candidate entities that are also strongly connected in the KB through a direct cross-lingual page link, a common neighbor, or sharing similar properties. After linking, we assign an entity type to each pair based on their properties in the KB (e.g., an entity with a birth-date and a death-date is likely to be a person). The typing component is a Maximum Entropy model learned from the Abstract Meaning Representation (Banarescu et al., 2013) corpus that includes both entity type and Wikipedia link for each entity mention, using KB properties as features.

3.4 Phrase Books

Finally we exploit phrase books that include phrase translations between many languages and English.

Language Survival Kits. FAMiliarization¹⁰ offers language survival kits (LSKs) for 100 languages, each of which has up to 10 kits of different topics. LSK encodes phrases, translations, and romanizations and is available for 55 languages. FAMiliarization also provides translations of name-

⁹<http://www.geonames.org/>

¹⁰<http://fieldsupport.dliffc.edu/>

Language	Gazetteer			Title	Non-Name	Suffix
	PER	LOC	ORG			
Hausa	1,174	5,123	199	42	391	21
Turkish	2,819	7,271	262	231	411	181
Uzbek	1,771	5,331	103	178	271	209

Table 5: Name Related List Statistics (# of entries).

related words and phrases.

For each language, we first extracted 2,000 to 3,000 parallel sentence/phrase pairs. Then we ran GIZA++ over these pairs and combined structure rules from WALS to obtain word translation pairs. We also extracted translations of the following English lists: cardinal number, currency, disease, location affixes, title, nationalities, topical keywords, organization suffixes, temporal words, locations and people, and stop words which are unlikely to be names.

Elicitation Corpus. An elicitation corpus is a controlled corpus translated by a bilingual consultant in order to produce high quality word aligned sentence pairs. During the elicitation process, the user will translate a subset of these sentences that is dynamically determined to be sufficient for learning the desired grammar rules. We extracted word and phrase translation pairs from the Elicitation corpus developed by CMU (Probst et al., 2001; Alvarez et al., 2005)¹¹ for the DARPA LORELEI which contains pairs of sentences in a low-resource language and English.

3.5 Encoding Linguistic Features

We merged the linguistic resources collected above into three types of features: (1) name gazetteers; (2) list of suffixes and contextual words (e.g., titles) that indicate names; and (3) list of words that indicate non-names (e.g., time expressions). Ultimately we obtained 30 explicit linguistic feature categories. Table 5 shows the statistics of the encoded features.

For each token w_i in a sentence, we check whether w_i , its previous token w_{i-1} and its next token w_{i+1} exist in these lists, and concatenate them into an initial feature vector for w_i . For any resources (e.g., lexicons and phrase books) that contain English translations, we also use them to translate each w_i , and check whether its translation is capitalized or exists in English name tagging resources (contextual words, gazetteers), whether its contexts match any English patterns as described

¹¹http://www.cs.cmu.edu/afs/cs.cmu.edu/project/cmt-40/Nice/Elicitation/Elicitation_Corpus-LDC/

in (Zhang et al., 2016a).

4 Experiments

Using the data sets mentioned in Section 2.2, we conduct experiments for three languages: Hausa, Turkish and Uzbek.

4.1 Overall Performance

Table 6 compares the results of three feature integration methods described in Section 2.3 and Figure 3. We can see that the third integration method (Integration 3) consistently outperforms the others for all three languages.

Models	Hausa	Turkish	Uzbek
Bi-LSTMs	65.7	65.9	64.1
+ Integration 1	71.1	71.8	67.4
+ Integration 2	71.5	73.1	67.2
+ Integration 3	72.2	74.3	68.4

Table 6: Feature Integration Methods Comparison.

We compare the following models: a baseline model that uses only character and word embedding features, a model adding traditional linguistic features as described in (Zhang et al., 2016a), and a model further adding non-traditional linguistic features using the third integration method. Figure 4 presents the results. Clearly models trained with linguistic features substantially outperform the baseline models on all noise levels for all languages. As the noise level increases, the performance of the baseline model drops drastically while the model trained with linguistic features successfully curbs the downward trend and forms a relatively flat curve at last. Adding non-traditional linguistic features provides further gains in almost all settings. Notably for Turkish, adding linguistic features and using 100% automatically generated noisy training data, our approach achieves the same performance as the baseline model using 75% manually created clean data and 25% automatically created noisy data. In other words, explicit linguistic knowledge has significantly saved annotation cost (2,367 sentences). Our results without using any manually labeled training data are much better than state-of-the-art reported in our previous work (Zhang et al., 2016a) which used most traditional resources mentioned in this paper and (Pan et al., 2017) which derived noisy training data from Wikipedia markups. On the same test sets we achieved 5.5% higher F-score for Hausa than (Zhang et al., 2016a), 27.7% higher F-score

Category	Hausa	Turkish	Uzbek
A Embedding feature	45.8	39.5	43.3
B (A)+Pattern mining and projection	46.7	40.9	45.4
C (B)+Basic knowledge and linguistic structure	50.4	53.3	52.4
D (C)+Dictionaries	52.0	57.7	56.1
E (D)+Phrase books	53.8	60.0	57.8

Table 7: Contributions of Various Categories of Linguistic Knowledge (F-score (%)).

for Turkish and 13.6% higher F-score for Uzbek than (Pan et al., 2017).

4.2 Detailed Analysis

Table 7 presents the contribution of each linguistic feature category when using 100% automatically created training data. Figure 5 shows some examples of errors corrected by each category. Some remaining challenges pertain to the lack of contextual clues for identifying the boundaries of long organizations, especially when they include nested or conjunction structures (e.g., “*Uluslararası ve Stratejik Araştırmalar Merkezi’nde (International and Strategic Research Center)*” in Turkish). The performance of organization tagging is 16%-31% lower than that of persons and locations. We also observe a “*popularity bias*” challenge, especially because we don’t have enough resources and tools to perform a deep understanding of the contexts. For example, when a journal name “*New England*” appears in Hausa texts, all of its mentions are mistakenly labeled as location instead of organization, because the dominant type label of “*New England*” is location in all of our resources.

5 Related Work

The major novel contribution of this paper is to systematically explore many non-traditional linguistic resources which have been largely neglected by the mainstream NLP community. Some previous efforts used WALS to study the typological relations across languages (Rama and Prasanth, 2012; O’Horan et al., 2016; Yamauchi and Murawaki, 2016) but very little work used it for practical NLP applications. Most DNN methods solely relied on character embeddings and word embeddings as features for name tagging (e.g., (Huang et al., 2015; Lample et al., 2016; Chiu and Nichols, 2016)). (Shimaoka et al., 2017) used hand-crafted features to improve the performance of DNN on fine-grained entity typing. (Chiu and Nichols, 2016) attempted to incorporate gazetteers as ex-

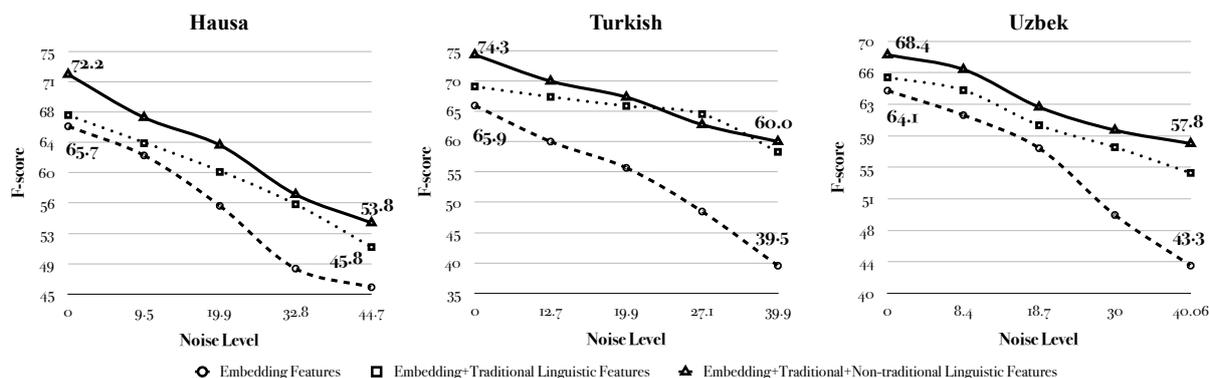

Figure 4: Name Tagging Performance.

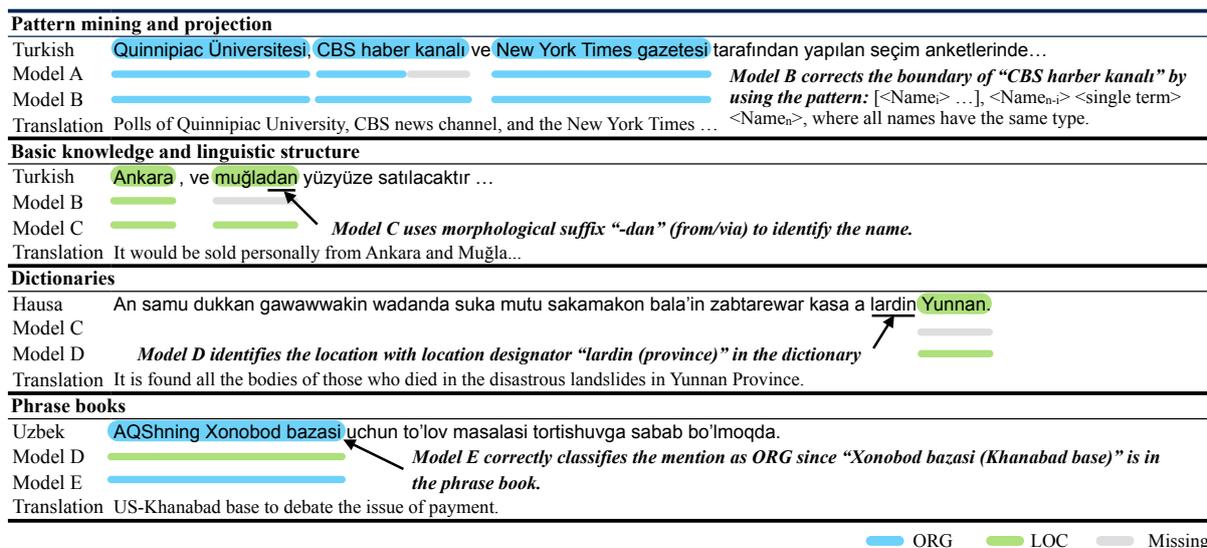

Figure 5: Examples of Corrections Made by Each Category of Linguistic Knowledge.

PLICIT linguistic features, and found that gazetteers are not very effective when they have a low coverage of name variants or when they contain many ambiguous entries. We addressed this challenge by integrating gazetteers gathered from a much wider range of sources.

Some recent studies (Zhang et al., 2016a; Littell et al., 2016a; Tsai et al., 2016; Pan et al., 2017) under the DARPA LORELEI program focused on name tagging for low-resource languages. Most noise tolerant supervised learning algorithms (Bylander, 1994; Dredze et al., 2008; Crammer et al., 2009; Kalapanidas et al., 2003; Scott et al., 2013) have been applied for improving image classification (Mnih and Hinton, 2012; Natarajan et al., 2013; Sukhbaatar et al., 2014; Xiao et al., 2015). Coupling our idea with these algorithms is also likely to yield further improvement.

6 Conclusions and Future Work

Using name tagging as a case study, we demonstrated the power of acquiring and encoding non-traditional linguistic resources. Experiments showed that they can significantly improve the quality of supervised models like DNNs and make them much more robust to noise in automatically created training data. Recent trend of DNN research in the NLP community boasts getting rid of explicit feature design. Our work argues that data-driven implicit knowledge like word embeddings cannot cover all linguistic phenomena in low-resource settings. We propose to embrace the readily available universal resources for many languages, and proved this process of making them actionable is not costly and does not require a system developer to "know" the language. Many more non-traditional linguistic resources remain to explore in the future, including Lexvo (de Melo, 2015), Multilingual Entity Taxonomy (de Melo and Weikum, 2010), EZGlott, URIEL knowledge

base (Littell et al., 2016b), travel phrase books and yellow phone books. We will also investigate whether these linguistic resources can make DNN more robust to other factors such as data size and topical relatedness.

NMT or SMT: Case Study of a Narrow-domain English-Latvian Post-editing Project

Inguna Skadiņa and **Mārcis Pinnis**

Tilde, Vienības gatve 75A, Rīga, Latvia

{inguna.skadina,marcis.pinnis}@tilde.lv

Abstract

The recent technological shift in machine translation from statistical machine translation (SMT) to neural machine translation (NMT) raises the question of the strengths and weaknesses of NMT. In this paper, we present an analysis of NMT and SMT systems' outputs from narrow domain English-Latvian MT systems that were trained on a rather small amount of data. We analyze post-edits produced by professional translators and manually annotated errors in these outputs. Analysis of post-edits allowed us to conclude that both approaches are comparably successful, allowing for an increase in translators' productivity, with the NMT system showing slightly worse results. Through the analysis of annotated errors, we found that NMT translations are more fluent than SMT translations. However, errors related to accuracy, especially, mistranslation and omission errors, occur more often in NMT outputs. The word form errors, that characterize the morphological richness of Latvian, are frequent for both systems, but slightly fewer in NMT outputs.

1 Introduction

For many years, the central problem in machine translation (MT) has been the quality. MT quality has been recognized as a complicated research question when translation is performed into a morphologically rich (and also under-resourced) language with a relatively free word order, e.g., Bulgarian, Croatian, Estonian, Finnish, Greek or Latvian. Possible solutions for widely used statistical machine translation have been studied for many years (e.g., Koehn and Hoang 2007; Tamchyna

and Bojar 2013; Burlot and Yvon 2015).

Today machine translation is experiencing a paradigm shift from (phrase-based) statistical machine translation (SMT) to neural machine translation (NMT). The first results obtained in recent years are promising, as it can be seen from the results of WMT 2016 (Bojar et al., 2016) and WMT 2017 (Bojar et al., 2017).

As NMT becomes more and more popular, the question of what can we expect from NMT in terms of quality becomes very important. Recent analysis of English to German SMT and NMT outputs of manual transcripts of short speeches showed that NMT can decrease the post-editing effort (Bentivogli et al., 2016). A comparison of NMT and SMT systems for nine language directions (English to and from Czech, German, Romanian, Russian, and English to Finnish) on news stories made by Toral and Sánchez-Cartagena (2017) showed that translations produced by NMT systems are more fluent and more accurate in terms of word order compared to translations produced by SMT systems. By analyzing of manually error-annotated outputs of generic English-Croatian MT systems, Klubička et al. (2017) found that NMT handles all types of agreement better than SMT (including factored models).

In this paper, we delve further into analyzing the strengths and weaknesses of NMT from the perspective of translation quality and the needs of the localization industry. We analyze translations of good quality domain-specific (medicine related) English-Latvian SMT and NMT systems that were trained on a rather small (ca. 325K sentences) data set. The target language - Latvian - is a morphologically rich under-resourced language (about 1.5 million speakers). As it is a synthetically inflected language, words change their form according to their grammatical function. In Latvian only half of the word endings are unambiguous, while for

the rest, multiple base forms may be derived from the inflected form (Skadiņa et al., 2012).

We analyze outputs of NMT and SMT systems in a post-editing (PE) scenario. Data on PE time, keystrokes, and typical operations were collected during the PE process. Analysis of these data allowed us to conclude that both approaches (SMT and NMT) are comparably successful allowing to increase translator productivity, with the NMT system showing slightly worse results. We believe that the reason translations from the SMT system are better in our case, is that from the small amount of data, SMT learns better terminology and phrases which are specific for the particular narrow domain. The situation could be different for broad domain MT systems, as it can be seen from recent WMT 2017 English-Latvian news domain results, where NMT and hybrid approaches were better (Bojar et al., 2017; Pinnis et al., 2017).

In addition, for a small sub-set of the MT system translations, manual error annotation was performed. This allowed us to identify the main error categories for each MT system. Through analysis of annotated errors, we found that NMT translations are more fluent than SMT translations, NMT produces significantly fewer typography errors than SMT. At the same time errors related to accuracy, especially, mistranslation and omission errors, occur more often in NMT outputs. The word form errors, which characterize the morphological richness of Latvian, are slightly fewer in NMT outputs.

2 Related work

Questions on how to evaluate the quality and usefulness of machine translation have been studied for several decades. For localization industry needs, MT quality and PE productivity have been analyzed by Flournoy and Duran (2009); Groves and Schmidtke (2009); Plitt and Masselot (2010); Skadiņš et al. (2011); Pinnis et al. (2016) and others. These studies report significant productivity increase when good quality SMT systems are used. Recently, for English-Spanish Sanchez-Torron and Koehn (2016) reported that "for 1-point increase in BLEU, there is a PE time decrease of 0.16 seconds per word, about 3-4%".

Several studies have recently compared SMT and NMT systems. Bentivogli et al. (2016) conducted a detailed analysis of SMT and NMT output for the English-German language pair on

translations of manual transcripts of TED talks¹. They found that NMT decreases post-editing effort, but degrades faster than SMT for longer sentences. They also found that NMT output contains fewer morphology errors, lexical errors and substantially fewer word order errors. Toral and Sánchez-Cartagena (2017) compared NMT and SMT systems submitted to WMT16 news translation task for nine translation directions (English to and from Czech, German, Romanian, Russian, and English to Finnish). The authors found that the translations produced by NMT systems were more fluent and more accurate in terms of word order compared to translations produced by SMT systems. They observed that NMT systems are also more accurate at producing inflected forms, but they perform poorly when translating very long sentences.

However, when Farajian et al. (2017) compared the performance of generic English-French NMT and SMT systems, that were trained on a generic parallel corpus composed of data from different domains, they found that on such multi-domain data SMT outperforms its neural counterpart. Moreover, Castilho et al. (2017) in their study, in which human evaluators compared NMT and SMT output for a range of language pairs, reported mixed results from the human evaluation. Similarly to the previous authors, they reported an increase in fluency, but inconsistent results for adequacy (the neural model showed a greater number of errors of omission, addition, and mistranslation) for NMT when compared to SMT. They argue that, although "NMT shows significant improvements for some language pairs and specific domains, there is still much room for research and improvement before broad generalizations can be made."

Analysis of NMT and SMT errors was recently made by Klubička et al. (2017) for English-Croatian MT systems. The authors analyzed manual error annotations of SMT and NMT system translations in the news domain and concluded that the NMT system reduces the errors produced by the SMT system by 54%.

3 Data and MT Systems

The SMT and NMT systems were trained on the parallel corpus from the European Medicines Agency (EMA), which is a part of the OPUS cor-

¹<http://www.ted.com/>

Corpus	Sentences before filtering	Sentences after filtering
Parallel	378,869	325,332
Monolingual	378,869	332,652

Table 1: Statistics of the training corpora

pus (Tiedemann, 2009), and the latest documents from the EMEA website (years 2009-2014)².

Prior to the training of the MT systems, we pre-processed the training data using tools for corpora cleaning, filtering, non-translatable token (e.g., URL, e-mail address, different code, etc.) identification, tokenization, and true-casing. The statistics of the training corpora before and after pre-processing are given in Table 1.

3.1 Statistical Machine Translation System

The SMT system is a standard phrase-based system that was trained on the Tilde MT platform (Vasijjevs et al., 2012) with Moses (Koehn et al., 2007). The system features a 7-gram translation model and a 5-gram language model. The language model was trained with KenLM (Heafield, 2011). The system was tuned with MERT (Bertoldi et al., 2009) using a held-out set of 2,000 sentence pairs.

3.2 Neural Machine Translation System

We used the sub-word neural machine translation toolkit Nematus (Sennrich et al., 2017) for training the NMT system. The toolkit allows training attention-based encoder-decoder models with gated recurrent units in the recurrent layers. For word splitting in sub-word units, we use the byte pair encoding tools from the subword-nmt toolkit (Sennrich et al., 2015). The NMT system was trained using a vocabulary of 40,000 word parts (39,500 for byte pair encoding), a projection (embedding) layer of 500 dimensions, recurrent units of 1024 dimensions, a batch size of 20 and dropout enabled. All other parameters were set to the default parameters as used by the developers of Nematus for their WMT 2016 submissions (Sennrich et al., 2016).

3.3 MT System Evaluation

SMT and NMT systems were evaluated on a held-out set of 1000 randomly selected sentence pairs.

²<http://www.ema.europa.eu/>

System	BLEU	NIST	ChrF2
SMT	46.57±1.46	9.45±0.18	0.7586
NMT	38.44±1.62	8.63±0.15	0.7065

Table 2: Automatic evaluation results

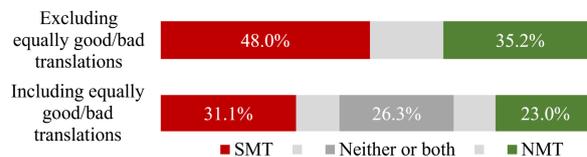

Figure 1: Human comparative evaluation results for SMT and NMT systems

The automatic evaluation results are given in Table 2. The results show that the SMT system achieves better results than the NMT system. This could be explained by the relatively small size of the parallel corpus and a very narrow domain, i.e., from the small amount of data, SMT learns better terminology and phrases which are specific for the particular narrow domain.

When translation is performed into a morphologically rich language, such as Latvian, automatic metrics (e.g. BLEU score) are not always good indicators of translation quality. Table 3 illustrates a case, where both translations have the same quality, but because of different word order the SMT translation received 41.38 BLEU points, while the NMT translation - only 24.42 points. To validate the automatic evaluation results, we performed a small blind comparative evaluation task. The task was performed by 5 professional translators who evaluated 198 segments in total. The results of the comparative evaluation show that the translations of the SMT system are preferred more often by evaluators than the translations of the NMT system (see Figure 1). However, the difference is not statistically significant according to the methodology by Skadiņš et al. (2010). Therefore, both systems were further used in the post-editing and error annotation experiments.

4 What Can Be Learned from Post-edits?

4.1 Post-editing process

For post-editing, we compiled a list of 22,500 segments (360,000 words) from EMEA documents. Then, we split the list into documents consisting of 100 segments so that the original sequence of sentences is preserved, and translated the documents

Sentence	BLEU	Text
Source	-	Seek medical advice straight away if you develop a severe rash, itching or shortness of breath or difficulty breathing.
Human	100.00	Nekavējoties meklējiet medicīnisku palīdzību , ja Jums parādās izsitumi , rodas nieze vai elpas trūkums , vai apgrūtināta elpošana .
SMT	41.38	Nekavējoties meklējiet medicīnisko palīdzību , ja Jums rodas smagi izsitumi , nieze vai elpas trūkums vai apgrūtināta elpošana .
NMT	24.42	Ja Jums rodas smagi izsitumi, nieze vai elpas trūkums vai apgrūtināta elpošana , nekavējoties meklējiet medicīnisko palīdzību .

Table 3: Influence of word order on BLEU score for similar translations by SMT and NMT systems

with both MT systems.

At first, translators were asked to post-edit SMT translations. Then, three months later, they were asked to post-edit NMT translations. For the NMT post-editing task, the documents were redistributed to translators, to ensure that each translator has different set of documents in SMT and NMT post-editing tasks.

We asked translators to post-edit translated segments with the post-editing tool PET (Aziz et al. 2012). It allowed us to track the time spent on each segment and to log all keystrokes that the translator performed while post-editing each segment. Translators were asked not to spend excessive amounts of time on each segment because the quality expectations were not "human translation quality", but rather "post-editing quality".

To assist post-editing, translators were provided with an automatically extracted in-domain term collection that was integrated into PET and provided translation suggestions for known terms.

After post-editing each segment, translators were asked to evaluate the quality of the MT translation, marking it as one of the following: "near perfect", "very good", "poor", and "very poor". If the translator did not apply any changes, the system automatically assigned the highest quality rating - "Unchanged".

Five professional translators were involved in the SMT post-editing task and seven in the NMT post-editing task. Finally, we asked the translators who participated in both tasks (4 in total) to translate two documents without pre-translated segments in order to measure each translator's pure translation productivity.

4.2 Post-editing Results

Most of the translators involved in this experiment post-edited 20 documents (in each post-editing

	Doc.	Segments	Tokens
Translation	8	797	14,924
SMT	80	5,280	99,375
NMT	80	4,688	86,651
Total	168	10,765	200,950

Table 4: Statistics of post-edited data

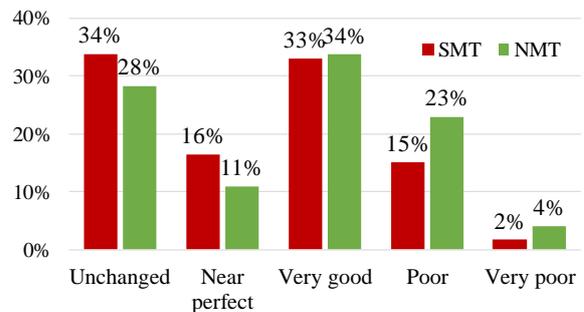

Figure 2: Distribution of rankings for MT segments

task). To perform a fair comparison between SMT and NMT post-editing tasks, we limit our analysis to the first 20 documents post-edited by each translator participating in both post-editing tasks. We perform the analysis only on segments that were not found in the MT system training data (approximately 36% of segments were discarded). The statistics of the post-edited data that are used for the further analysis is given in Table 4.

We start the analysis by examining the MT quality assessments produced by translators during post-editing. The Figure 2 summarizes the distribution of rankings showing that the SMT system produced a larger proportion of near perfect and perfect translations than the NMT system - 50.2% compared to just 39.3%.

The detailed logs of each translators work allowed to measure the time spent on post-editing

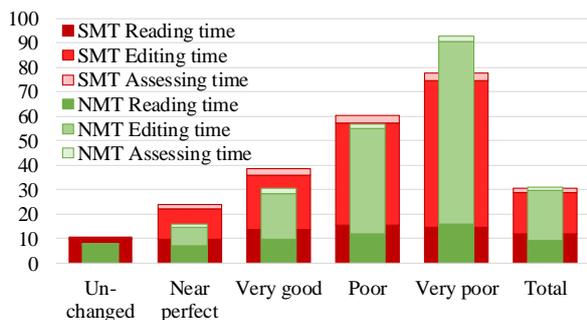

Figure 3: Average time in seconds spent on a segment

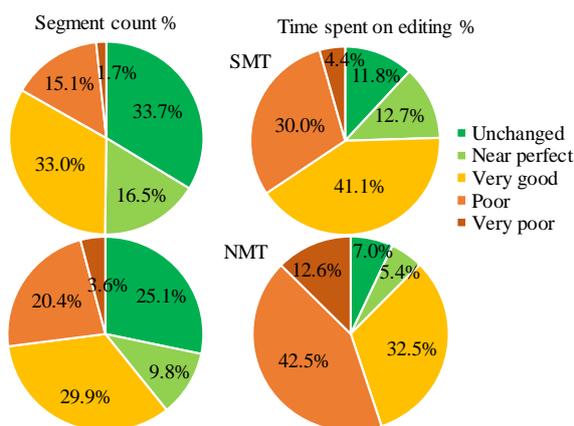

Figure 4: Segment count and editing time distribution for different quality MT segments

in three distinct intervals: the amount of time that elapsed between the appearance of an MT segment and the first click, or "reading time"; the amount of time between the first edit and approval of the segment, or "editing time"; and the amount of time spent between approval of the segment and completion of the quality assessment, referred to as "assessment time". The results of the log data analysis in Figure 3 show that on average it takes 30% more time for translators to start editing SMT translations. It is also obvious that editing of good, very good and near perfect SMT translations requires 16-62% more time than for NMT translations. However, the situation is opposite for poor and very poor translations - it requires 3-25% more time to post-edit NMT translations. This difference is more noticeable in Figure 4, which shows that post-editing poor and very poor NMT translations (24% of all post-edited NMT translations) required more than half of the editing time (55.1%). In comparison post-editing of poor SMT translations (16.8% of all post-edited SMT translations)

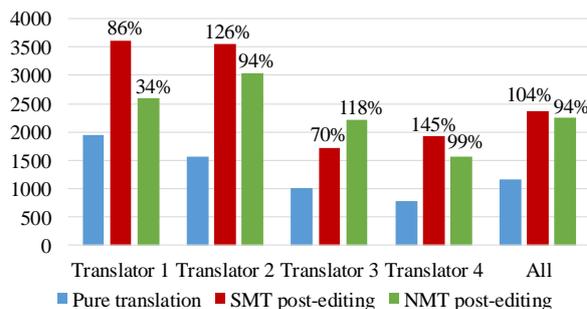

Figure 5: Individual translator productivity (tokens translated/post-edited per hour) based on actually measured numbers

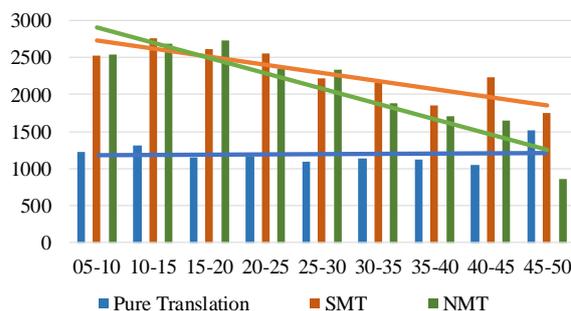

Figure 6: Translation and post-editing productivity (tokens translated/post-edited per hour) for segments with different length with linear trend-lines

required just 34.4% of time.

In terms of productivity (see Figure 5), it is evident that both tasks (SMT and NMT post-editing) obtain higher productivity than pure translation. However, the productivity is higher for post-editing SMT translations (104% compared to 94%).

When analyzing the effect of the length of segments on productivity (tokens translated/post-edited per hour), the results in Figure 6 showed that there is an obvious decrease in post-editing productivity for longer segments, with the NMT post-editing productivity decreasing faster than for SMT post-editing. It is interesting that there is almost no change in productivity when translating without MT support.

The information on the time spent on each segment allows us to analyze the relationship between the post-editing productivity and the post-editing effort that is expressed with the help of the Human-targeted Translation Edit Rate (HTER; Snover et al. 2006). Figure 7 depicts the aver-

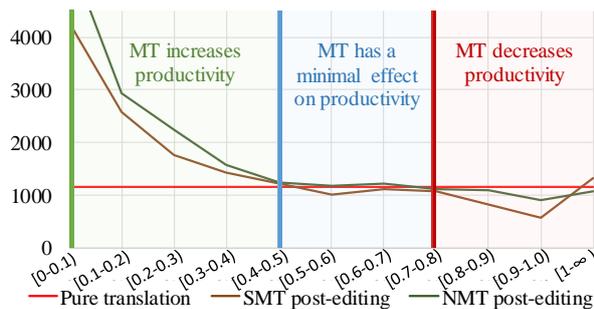

Figure 7: Average productivity (tokens translated/post-edited per hour; y axis) at different MT suggestion quality thresholds (HTER; x axis)

age productivity for different MT translation quality intervals. It shows that we can identify average MT system quality thresholds, at which post-editing becomes productive (HTER of 0.4 or less) and at which it stops being productive (HTER of 0.7 or higher). The average HTER scores of the SMT and NMT systems are 0.22 and 0.31 respectively. The figure also shows that there is little difference between SMT and NMT post-editing, with the NMT post-editing being faster at individual quality levels. Still, because the NMT system produced more poor translations, the overall post-editing productivity is higher for the SMT post-editing task.

To validate, whether the post-edits are of good quality, we performed quality assessment of the post-edits according to the LISA Quality Assurance model³. The quality assessment was performed by professional editors from our localization department. The results in Figure 8 show that even though the task for translators was to perform light post-editing, the quality of the post-edited translations is rated as excellent (i.e., the average error score for both SMT and NMT post-edits is below 10 per 1000 words).

5 MT Error Annotation

The aim of the error annotation task was to identify common and specific errors for both MT architectures and their influence on the overall quality of MT output.

5.1 Error Annotation Task

For error annotation (EA), 1800 English segments and their translations into Latvian by SMT and

³LISA QA model: <http://web.archive.org/web/20080124014404/http://www.lisa.org/products/qamodel/>

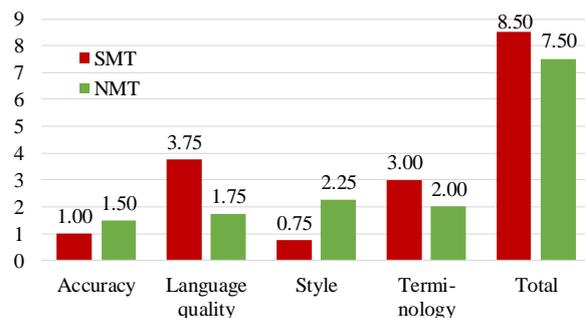

Figure 8: Average error score (per 1000 words)

NMT systems were selected. Only translations that were marked as "Very good" during post-editing for both MT systems were included. The main reason for including only segments that have good translations was the necessity to avoid wrong annotations due to very bad input.

The error classification used, in this task, is based on Multidimensional Quality Metrics (MQM; Lommel et al. 2014). More specifically, the subset that is defined by Burchardt and Lommel (2014) was used. In this classification, errors are divided into three top categories: accuracy, fluency, and terminology. These top level categories then include more detailed categories from the MQM issue type hierarchy.

The EA was performed four months after finishing both post-editing tasks. Two translators, who participated in both post-editing tasks, were involved to ensure consistency between post-editing and error annotation tasks and to avoid a situation when translators annotate errors, which were not requested to be corrected during post-editing.

The error annotation was performed in the Translate5⁴ platform. Before translators started the error annotation, they were introduced to a video tutorial, written guidelines, and the decision process. During annotation, translators saw the source segment, MT output, and post-edited MT output.

Each translator annotated 1000 segments translated by the SMT system and the same 1000 segments translated by the NMT system. Although inter-annotator agreement was not our main interest, 200 translations from each system were annotated by both translators.

Error type	SMT error annotation			NMT error annotation		
	Count	Total	%	Count	Total	%

Table 5: Summary of error annotation task (count - number of errors for particular category; total - sum of errors, including subcategories)

5.2 Observations from the Error Annotation Task

The overall results of the error annotation task are summarized in Table 5. Results show that although the segments were ranked as good, most of them contain more than one error per segment. The total number of errors is higher for SMT. There are twice as many errors related to fluency (77%) as to accuracy (28%) for SMT, while for NMT the fluency errors comprise 55% of errors, but accuracy errors - 44%.

The complexity of Latvian morphology is a reason why more than 1/4 of errors are grammar errors (35% for SMT and 27% for NMT), from which almost 1/5 of errors are word form errors (SMT 21%, NMT - 19%). For instance, both MT systems generate the wrong form for the word "aerosols (*spray*)" when translating the sentence "How to use the nasal spray": the SMT system generates the singular nominative form *aerosols* (*spray*), while the NMT system generates singular genitive form *aerosola* (*spray*).

A significant difference between SMT and

NMT outputs has been observed for three error subcategories - typography (the subcategory of fluency), mistranslation (the subcategory of accuracy) and omission (the subcategory of accuracy).

Typography errors are much more widespread in SMT (21.70%) than in NMT (11%). Usually these are cases where spaces are wrongly used (e.g. "beta - 2 - agonisti" instead of "beta-2-agonisti" (beta-2-agonists), or wrong separators appear in numbers (e.g. "3,644" instead of "3644", or "0.5" instead of "0,5"). These errors, especially wrong separators, are not frequent in NMT translations.

The Latvian language has a very rich, morphology-based word-building potential (words are usually built by adding affixes to the stem). This feature resulted in a high number (19%) of mistranslations from the NMT system. Typical cases of mistranslation from the NMT system include the incorrect translation of numbers (e.g., 30 July 2012 is translated as 2008. gada 30. jūlijs), terms (e.g., drop (*piliens*) is translated as *injekcija* (*injection*)) and named entities (e.g., *Naglazyme* (*Naglazyme*) is translated

⁴<http://translate5-metashare.dfki.de>

as *MabCampath*).

Latvian also has a relatively free word order. In the case of a formal, narrow domain, where usually the word order is strict, it has a rather small influence even for the SMT system (9% of errors), while in the case of more general systems this could have much greater impact.

Errors of omission are much more frequent for NMT (15%) than for SMT outputs (10%). NMT also produces fewer (4%) word order errors than SMT (9%), while SMT has fewer (8%) spelling errors than NMT (11%).

5.3 Inter-annotator Agreement

Although the aim of this research was not to study consistency between annotations, but to identify and analyze the main error categories, 200 segments translated by SMT and NMT systems were annotated by two translators. The reason for having only two annotators was seriously debated in the consortium of the QT21 project⁵ by a number of leading MT researchers. It was agreed that, to show inconsistencies/issues, common understanding of the annotation task, it is enough to have two annotators. The inter-annotator agreement is more like a sanity check for the fine-grained annotation levels (whether annotators have common understanding or not). Table 6 presents the summary on errors annotated in these segments.

Similarly to the whole error annotation task, slightly more errors are found in the SMT system's output. Table 6 also confirms the finding from the overall error annotation task, that NMT produces less typography and word order errors than SMT, but it produces more mistranslation and omission errors.

There are several error categories where translators have different opinions about the applicability of the particular categories. The table clearly demonstrates that the most complicated case was the identification of a correct subcategory for wrong word form errors. The annotator A1 mostly assigned the top category "word form" for such errors, while the annotator A2 marked them as agreement errors.

Another case of significant disagreement between annotators can be observed for fluency errors in the NMT post-editing task. As there was no consistent correspondence between an error category assigned by annotator A2 for cases where an-

notator A1 marked fluency errors, we asked annotator A1 to explain her reasoning. She told us that she marked fluency errors where a post-editor during post-editing applied just stylistic corrections. After inspecting these cases, we agreed with her explanation.

For inter-annotator agreement, we calculated free-marginal kappa under three different conditions (see Table 7): perfect match analysis (i.e., by taking the precise positions and (sub)categories of errors into account), error count analysis (i.e., by ignoring error positions), and error presence analysis (i.e., by just looking at whether both annotators identified that a segment contains a certain (sub)category of errors)⁶. The results show that when taking positions into account, there is just slight agreement between the annotators. This is explained by the different understanding of where errors need to be marked: one translator annotated errors at the character level, while the other - at the token level. For instance, in the case of wrong

⁶Free-marginal kappa is interpreted as: 0.01-0.20 = slight agreement, 0.21-0.40 = fair agreement, 0.41-0.60 = moderate agreement, 0.61-0.80 = substantial agreement, 0.81-1.00 = almost perfect agreement (Landis and Koch, 1977)

Table 7: Inter-annotator agreement (free-marginal kappa) on the 200 segment data sets

separators in numbers (e.g. 7.5), one annotator marked only the punctuation mark, while the other - the whole number. If we analyze the agreement on just error count and error presence levels, we see that the annotators reached moderate agreement for the annotation of errors for the SMT system’s translations, but only fair agreement for the NMT system’s translations. This is mainly due to the disagreement on how to annotate fluency errors.

The inter-annotator agreement scores highlight the necessity for improvements in the general guidelines to mitigate the potential for disagreement. That being said, the inter-annotator agreement in the higher error levels (i.e., if we do not split errors up in 4 levels of sub-categories, but analyze only the top 2 levels) is good (over 0.6) for SMT and moderate (over 0.4) for NMT.

6 Conclusion

In this paper, we presented an analysis of narrow domain English-Latvian SMT and NMT systems, that were trained on a rather small in-domain corpus.

Translations of both systems were post-edited by professional translators and ranked depending on the complexity of editing. 83% of SMT translations and 73% of NMT translations were ranked as perfect, near perfect or very good, thus confirming the fact that in-domain MT systems can produce good quality translations even when the

amount of training data is limited. The analysis of post-edited data allowed us to conclude that both approaches allow for an increase in translator productivity, with the NMT system showing slightly worse results in general, but better for good quality MT output. We believe that the lower results for the NMT system are linked to the relatively small size of the parallel corpus and the narrow domain.

By analysis of the manually annotated errors, we found that the SMT system produced twice as many errors related to fluency (77%) in comparison to those related to accuracy (28%), while for the NMT system the fluency errors comprise 55% of all errors, but accuracy errors - 44%. In terms of error subcategories, widespread errors for both systems are grammar errors (35% for SMT and 27% for NMT), especially wrong word form errors (21% for SMT and 19% for NMT), indicating that morphologically rich languages, e.g., Latvian, are problematic for both MT systems, while improving with NMT. A significant difference between SMT and NMT outputs has been observed for three error subcategories - typography (22% for SMT and 11% for NMT), mistranslation (7% for SMT and 19% for NMT) and omission (10% for SMT and 15% for NMT).

The obtained results show that in the case of a narrow domain, if MT systems are trained on a small amount of data, the SMT system performs better than the NMT system. The reason why the SMT system in our case is better, is that from the small amount of data, SMT learns better terminology and phrases which are specific for the particular narrow domain. The situation differs for broad domain MT systems, as it has been demonstrated by recent WMT 2017 English-Latvian news domain results, where NMT and hybrid approaches were better.

Acknowledgments

We would like to thank Tilde’s Localization Department for the hard work they did to prepare material for the analysis presented in this paper. The work within the QT21 project has received funding from the European Union under grant agreement n° 645452. The research has been supported by the ICT Competence Centre (www.itkc.lv) within the project ”2.2. Prototype of a Software and Hardware Platform for Integration of Machine Translation in Corporate Infrastructure” of EU Structural funds, ID n° 1.2.1.1/16/A/007.

Abstract

While neural machine translation (NMT) has become the new paradigm, the parameter optimization requires large-scale parallel data which is scarce in many domains and language pairs. In this paper, we address a new translation scenario in which there only exists monolingual corpora and phrase pairs. We propose a new method towards translation with partially aligned sentence pairs which are derived from the phrase pairs and monolingual corpora. To make full use of the partially aligned corpora, we adapt the conventional NMT training method in two aspects. On one hand, different generation strategies are designed for aligned and unaligned target words. On the other hand, a different objective function is designed to model the partially aligned parts. The experiments demonstrate that our method can achieve a relatively good result in such a translation scenario, and tiny bitexts can boost translation quality to a large extent.

1 Introduction

Neural machine translation (NMT) proposed by Kalchbrenner et al.(2013), Sutskever et al.(2014) and Cho et al.(2014) has achieved significant progress in recent years. Different from traditional statistical machine translation(SMT) (Koehn et al., 2003; Chiang, 2005; Liu et al., 2006; Zhai et al., 2012) which contains multiple separately tuned components, NMT builds an end-to-end framework to model the whole translation process. For several language pairs, NMT is reaching significantly better translation performance than SMT (Luong et al., 2015b; Wu et al., 2016).

In general, in order to obtain an NMT model

Figure 1: An example of our partially aligned training data, in which the source sentence and target sentence are not parallel but they include two parallel parts (highlight in blue and red respectively).

of great translation quality, we usually need large-scale parallel data. Unfortunately, the large-scale parallel data is always insufficient in many domains and language pairs. Without sufficient parallel sentence pairs, NMT tends to learn poor estimates on low-count events.

Actually, there have been some effective methods to deal with the situation of translating language pairs with limited resource under different scenarios (Johnson et al., 2016; Cheng et al., 2017; Sennrich et al., 2016a; Zhang and Zong, 2016). In this paper, we address a new translation scenario in which we do not have any parallel sentences but have massive monolingual corpora and phrase pairs. The previous methods are hard to be used to learn an NMT model under this situation. In this paper, we propose a novel method to learn an NMT model using only monolingual data and phrase pairs.

Our main idea is that although there does not exist the parallel sentences, we can derive the sentence pairs which are non-parallel but contain the parallel parts (in this paper, we call these sentences as **partially aligned sentences**) with the

monolingual data and phrase pairs. Then we can utilize these partially aligned sentences to train an NMT model. Figure 1 shows an example of our data. Source sentence and target sentence are not fully aligned but contain two translation fragments: (“外交部发言人”, “foreign ministry deputy”) and (“在例行的记者招待会上说”, “speaking at a regular press”). Intuitively, these kinds of sentence pairs are useful in building an NMT model.

To use these partially aligned sentences, the training method should be different from the original methods which are designed for parallel corpora. In this work, we adapt the conventional NMT training method mainly from two perspectives. On one hand, different generation strategies are designed for aligned and unaligned target words. For aligned words, our method guides the translation process based on both the context of source side and previously predicted words. When generating the unaligned target words, our model only depends on the words previously generated without considering the context of source side. On the other hand, we redesign the objective function so as to emphasize the partially aligned parts in addition to maximizing the log-likelihood of the target sentence.

The contributions of our paper are twofold:

- 1) Our approach addresses a new translation scenario, where there only exists monolingual data and phrase pairs. We propose a method to train an NMT model under this scenario. The method is simple and easy to implement, which can be used in arbitrary attention-based NMT framework.
- 2) Empirical experiments on the Chinese-English translation tasks under this scenario show that our method can achieve a relatively good result. Moreover, if we only add a tiny parallel corpus, the method can obtain significant improvements in terms of translation quality.

2 Review of Neural Machine Translation

Our approach can be easily applied to any end-to-end attention-based NMT framework. In this work, we follow the neural machine translation architecture by Bahdanau et al. (2015), which we will summarize in this section.

Given the source sentence $X = \{x_1, x_2, \dots, x_{T_x}\}$ and the target sentence

$Y = \{y_1, y_2, \dots, y_{T_y}\}$. The goal of machine translation is to transform source sentence into the target sentence. The end-to-end NMT framework consists of two recurrent neural networks, which are respectively called encoder and decoder. First, the encoder network encodes the X into context vectors C . Then, the decoder network generates the target translation sentences one word each time based on the context vectors C and target words previously generated. More specifically, that is $p(y_i|y_{<i}, C)$.

In encoding stage, it transforms X into a sequence of vectors $h_{enc} = \{h_1^k, h_2^k, h_3^k, \dots, h_T^k\}$ using m stacked LSTM (Hochreiter and Schmidhuber, 1997) layers. Finally, the encoder chooses the hidden states of the top encoder layer as $h_{top} = \{h_1^m, h_2^m, h_3^m, \dots, h_T^m\}$ that we will use in attention mechanism to calculate context vector later.

In decoding stage, it generates one target word at a time from conditional probability $p(y_i|y_{<i}, C; \theta)$ also via m stacked LSTM layers parameterized by θ . Supposing we have obtained the context vector, the conditional probability $p(y_i|y_{<i}, C; \theta)$ is calculated as follows:

$$\begin{aligned} p(y_i|y_{<i}, C; \theta) &= p(y_i|y_{<i}, c_i) \\ &= \text{softmax}(g(W_{y_i}, z_i^m, c_i)) \end{aligned} \quad (1)$$

Where W_{y_i} is embedding of the target word, z_i^m is current hidden states of top layer in decoder network. Note that the first hidden states of decoder z_0^k are set to the last hidden states of encoder as follows:

$$z_0^k = h_T^k \quad (2)$$

c_i can be computed as a weighted sum of the source-side h_s as follows:

$$c_i = \sum_{j=1}^{T_x} a_{ij} h_j^m \quad (3)$$

Where a_{ij} is alignment probability, which can be calculated in multiple ways (Luong et al., 2015a). In our method, we use a simple single-layer feed forward network. This alignment probability measures how relevant i -th context vector of source sentence is in deciding the current symbol in translation. The probability will be further normalized:

$$a_{ij} = \frac{\exp(e_{ij})}{\sum_{k=1}^{T_x} \exp(e_{ik})} \quad (4)$$

A detailed introduction of the encoder-decoder framework is described in Bahdanau et al. (2015). In order to train NMT system, we use parallel data to optimize the network parameters by maximizing the conditional log-likelihood:

$$L(\theta, D) = \frac{1}{N} \sum_{n=1}^N \sum_i^{T_y} \log(p(y_i^{(n)} | p(y_{<i}^{(n)}), X^{(n)}, \theta)) \quad (5)$$

3 NMT with Partially Aligned Data

In §2 we gave a brief description of the attention-based NMT models whose network parameters are trained using parallel sentence pairs. However, in the translation scenario where there only exists monolingual corpora and phrase pairs, the conventional NMT framework is hard to be used in training a model. In this section, we first explain how we actually obtain the partially aligned corpora with aligned positions using phrase pairs and monolingual corpora, then introduce our method to train the NMT models using the partially aligned sentences according to the particular properties of the corpora.

3.1 Constructing partially Aligned Corpora

Assuming there exists abundant phrase pairs and monolingual sentences in source and target languages, we define our approach to extract partially aligned sentence pairs for training.

Given a phrase pair (ph.s, ph.t), ph.s may appear in a source-side monolingual sentence X, and ph.t may appear in a target-side monolingual sentence Y. Then, X and Y are non-parallel but contain the parallel part. We call these kinds of data the partially aligned sentences. In this work, we collect the partially aligned sentences by searching the phrase pairs in both of the source and target monolingual data simultaneously. In order to reduce the time of the searching process, the monolingual training corpora are first split into many parts. Then, we retrieve the source phrase in each part to restrict the source range of partially aligned corpus. With the retrieved results, we can search the final results of the partially aligned sentences pairs easily. In this way we can construct our corpora, in which only one or more phrases are aligned in every sentence pairs. We denote a partially aligned sentence ($X = x_1, x_2, \dots, x_{T_x}, Y = y_1, y_2, \dots, y_{T_y}$), in which a set of the phrase pairs

aligned with each other. We call these pairs partially aligned part:

$$\begin{aligned} P_x^{(k)} &= x_{k1}, \dots, x_{kp} \\ P_y^{(k)} &= y_{k1}, \dots, y_{kp} \end{aligned} \quad (6)$$

$P_x^{(k)}$ and $P_y^{(k)}$ are the phrases in the source and target sentences respectively, and they are translation equivalents.

3.2 Model Descriptions

In §3.1, we acquired the partially aligned corpora with the phrase pairs and monolingual sentences. Now, we need to use them to train the NMT model. As the traditional NMT model is designed for the parallel sentences, it is not suitable for partially aligned sentences. Thus we redesign the traditional NMT model as follows. Figure 2 shows the basic framework of our training method. Our model has 4 different parts from conventional NMT model, including initial states, generation process, objective functions and vocabulary size.

3.2.1 Initial States

The first difference is the initial hidden states of decoder. In the conventional NMT model, the initial hidden states of decoder z_0^k is set to the last hidden state in encoder $h_{T_x}^k$, including initial states, generation process, objective functions and vocabulary size. shown in Eq. (2). For parallel sentences, this setting is reasonable, while for partially aligned sentence, this initial method is inappropriate. The reason is that the hidden state of last word in source sentence is irrelevant to the target sentence, considering the fact that under our scenario, the target side sentences may entirely uncorrelated to the source sentences. Thus, in our model, z_0^k is set to a zero vector as follows:

$$Z_0^k = \mathbf{0} \quad (7)$$

In Figure 2, the hidden state of "<start>" symbol is set to zero vector when y_1 does not belong to parallel part of the sentence pair.

3.2.2 Generation Process

The second difference is the generation process. In the conventional NMT system, the model generates each target word based on the context vector c_i and previously predicted words $y_{<i}$ as shown in Eq. (1). This generation strategy is unsuitable for the partially aligned corpora, since there exists many unaligned target words. Intuitively,

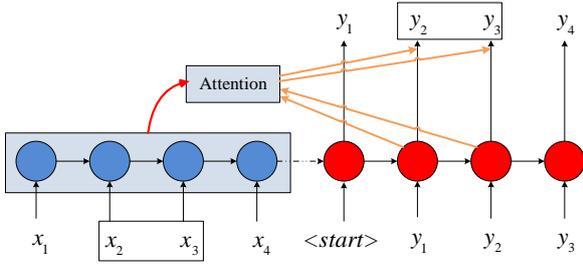

Figure 2: The framework of our training method for partially aligned sentence, in which (x_2, x_3) and (y_2, y_3) are parallel parts.

when the model generates the non-parallel parts, it is unnecessary to take the context vector c_i into consideration. As Figure 2 illustrated, (x_2, x_3) and (y_2, y_3) are parallel parts in this partially aligned sentence pair, and we use context vector which is generated by attention mechanism only when the decoder outputs y_2 and y_3 . Therefore, the decoder in our model can be described as follows:

$$c_i = \begin{cases} \sum_j^{T_x} a_{ij} h_i & \text{if } y_i \in P_y^{(k)} \\ 0 & \text{if } y_i \notin P_y^{(k)} \end{cases} \quad (8)$$

where a_{ij} is calculated as Eq. (2), $P_y^{(k)}$ is the target partial part, as shown in Eq. (5). In Eq. (8), our model generates the aligned target words based on the context vector c_i and previously predicted words $y_{<i}$. When generating the unaligned target words, the model sets the context vector c_i to zero, indicating that the model generates these words only based on the LSTM-based RNN language model.

3.2.3 Objective Function

Third, we redesign the objective function. Given the parallel data, the objective function is to maximize the log-likelihood of each target word as shown in Eq. (5). For the partially aligned sentence, besides the source and target sentence, we know the phrase alignment information. Hence, apart from maximizing the log-likelihood of each target word, we also hope to make the source and target words in partially aligned part align to each other. As shown in Figure 2, when predicting the words y_2 and y_3 , we want to attend more information of corresponding words x_2 and x_3 . Thus, we inject an auxiliary object function to achieve it. More specifically, our objective function is de-

signed as follows:

$$L_P(\theta, D) = \frac{1}{N} \sum_{n=1}^N \left\{ \sum_i^{T_y} \log(p(y_i^{(n)} | p(y_{<i}^{(n)}), X^{(n)}; \theta)) \right. \\ \left. + \lambda \times \Delta(a^{(n)}, \hat{a}^{(n)}; \theta) \right\} \quad (9)$$

Where $a^{(n)}$ is defined in Eq. (4), Δ is a loss function that encourages the agreement between $a^{(n)}$ and $\hat{a}^{(n)}$. $\hat{a}^{(n)}$ is the supervised attention determined by alignment relationship between P_X and P_Y , and can be calculated as follows:

$$\hat{a}_{i,j}^{(n)} = \begin{cases} 1 & \text{if } x_j \in P_X \text{ and } y_i \in P_Y \\ 0 & \text{others} \end{cases} \quad (10)$$

$\lambda > 0$ is a hyper-parameter that balances the preference between likelihood and agreement. In this paper, it is set to 0.3.

As shown in Eq. (8), our objective function does not only consider to maximize the log-likelihood of the target sentence, but also encourages the alignment a_{ij} produced by NMT to have a larger agreement with the prior alignment information. This objective function is similar to that used by the supervised attention method (Mi et al., 2016a; Liu et al., 2016). Inspired by Liu et al. (2016), the agreement between $a^{(n)}$ and $\hat{a}^{(n)}$ can be defined in different ways:

- Multiplication (MUL)

$$\Delta(a^{(n)}, \hat{a}_{i,j}^{(n)}; \theta) = - \sum_{i=0}^{T_y} \sum_{j=0}^{T_x} a(\theta)_{i,j}^{(n)} \times \hat{a}_{i,j}^{(n)} \quad (11)$$

where $\hat{a}_{i,j}^{(n)}$ is computed by Eq. (10)

- Mean Squared Error (MSE)

$$\Delta(a^{(n)}, \hat{a}_{i,j}^{(n)}; \theta) = - \sum_{i=0}^{T_y} \sum_{j=0}^{T_x} \frac{1}{2} (a(\theta)_{i,j}^{(n)} - \hat{a}_{i,j}^{(n)})^2 \quad (12)$$

3.2.4 Limited Vocabulary

The last difference is the vocabulary size during decoding. To make use of phrase pairs as much as possible, we extract a number of special phrase pairs whose source and target are both one word.

In decoding phase, as what Mi et al. (2016b) have done, we can use these special phrase pairs to reduce the vocabulary size when computing the final score distribution. In this way, we can not only acquire more accurate translation of each word, but also accelerate the decoding speed. The vocabulary size can be reduced as follows:

$$V = V_1 \cup V_2 \quad (13)$$

Where V_1 contains the most frequently target words and V_2 is a target words set. This set V_2 is made up of all the target words of the special phrase pairs whose corresponding source words belong to the source sentence.

4 Experiment

In this section, we perform the experiment on Chinese-English translation tasks to test our method.

4.1 Dataset

We evaluate our approach on large-scale monolingual data set from LDC corpus, which includes 13M Chinese sentences and 10M English sentences. Table 1 shows the detailed statistics of our training data. To test our model, we use NIST 2003(MT03) as development set, and NIST 2004-2006(MT04-06) as test set. The evaluation metric is case-insensitive BLEU (Papineni et al., 2002) as calculated by the *multi-bleu.perl*.

Corpus		Chinese	English
monolingual	#Sent.	13.33M	10.03M
	#Word	327.10M	276.07M
	Vocab	1.83M	1.07M

Table 1: The statistics of monolingual dataset on the LDC corpus.

4.2 Data Preparing and Preprocessing

Considering the fact that the amount of manually annotated phrase pairs is not enough, in order to imitate the environment of experiment, we extract phrase pairs from parallel corpora automatically to make up for the shortage of quantity. To do this, we use Moses (Koehn et al., 2007) in its training step to learn a phrase table from LDC corpus, which includes 0.63M sentence pairs. In order to simulate the experiment as far as possible, we adopt three strategies to filter low quality

phrase pairs: 1) the phrases containing the punctuation should be filtered out. (The special phrase pairs introduced in §3.2.4 should be retain) 2) the length of source phrase and target phrase should be greater than 3. 3) only the phrase pairs whose translation probability exceed 0.5 should be retain. In this way, we can get 3M phrase pairs in our experiment. According to our analysis, the average length of phrases are 4.15 and 4.70 on source and target side respectively.

When we search the phrase pairs in monolingual sentences, an obstacle is that one phrase pair will get different source sentences with same target sentence or same source sentence with different target sentences. Therefore, for one phrase pair, we have to restrict the number n of both source sentences and target sentences. To balance the search speed of the phrase pairs in monolingual corpora and the amount of partially aligned sentences, we set the hyper-parameter n to 7. We can search for 5M partially aligned sentences in our experiment. We also calculate the average length ratio of aligned phrases against the whole sentence, which is only 21% and 23% respectively on source and target side.

To ensure the quality of the partially aligned corpora, we also set the number of phrases that aligned to each other in one sentence pair must be greater than a threshold. Here, the threshold is set to 2. That is to say the partially aligned sentence pair should contain at least two aligned phrase pairs.

4.3 Training Details

We build our described method based on the Zoph_RNN toolkit¹ written in C++/CUDA. Both encoder and decoder consist of two stacked LSTM layers. We set minibatch size to 128. The word embedding dimension of both source and target sides is 1000, and the dimensions of hidden layers unit is set to 1000. In our baseline model, we limit the vocabulary of both source and target languages to 30K most frequent words, and other words are replaced by a special symbol “UNK” . We run our model on the training corpus 20 iterations in total with stochastic gradient decent algorithm. We set learning rate to 0.1 at the beginning and halve the threshold while the perplexity increases on the development set. Dropout is applied to our model, and the rate is set to 0.2. For

testing, we employ beam search algorithm, and the beam size is 12.

4.4 Training Methods

We conduct our experiment on the dataset mentioned above, and we list the training methods used as follows:

- 1) **Phrase NMT Model:** As mentioned above, the only parallel resource is phrase pairs. We use attention-based NMT system to train only on the 3M phrase pairs to get our baseline result.
- 2) **Partially Aligned Model(MUL):** We train our NMT model using the objective function of multiplication method on the partially aligned sentences.
- 3) **Partially Aligned Model(MSE):** We train our NMT model using the objective function of Mean Squared Error(MSE) method.
- 4) **Partially Aligned Model(MSE) + Limited-Vocab:** It is similar to Partially Aligned Model(MSE) and the only difference is that we restrict the final score distribution on a limited target vocabulary, which is described in §3.2.4.
- 5) **Phrase NMT Model + LimitedVocab:** It is the method that LimitedVocab is used in Phrase NMT model.

5 Results and Analysis

5.1 Phrase NMT Model vs. Partially Aligned Method

We present the translation results in BLEU scores of different systems in Table 2. Our first concern is whether the proposed model can actually improve the translation quality. As Table 2 shows, we find that our partially aligned model (both MUL supervised method and MSE supervised method) is superior to the Phrase NMT Model, which indicates

that our Partially Aligned method is effective in improving the translation quality.

Source sentence:	布什说：“此项计划将对劳动大众提供减税优惠。”
Phrase NMT model:	The bush says the <UNK> tax concessions be made a possible member
Our model:	Bush said, the scheme will provide tax concessions to the community.

Figure 3: A translation example comparing between phrase NMT model and our partially aligned method.

Figure 3 lists a comparison example of Phrase NMT model and our model. Obviously, our model can achieve the correct translation while the Phrase NMT model generates the unfaithful result. It demonstrates that our model is actually having the ability to learn translation adequacy from aligned parts and fluency from both aligned and unaligned parts.

In §3.2, we described two objective functions in our model. We focus on the difference of these two approaches. As a comparison, MSE method (Row 3) outperforms the MUL method (Row 2) with an average improvement of 0.8 BLEU points, indicating that MSE method is more effective as an object function for our partially aligned model. In the following experiment, we adopt the MSE method as the new objective function used in our model.

5.2 Effect of Limited Vocabulary

In Table 2, an interesting result is that using a reduced vocabulary can significantly improve the performance (+1.36 BLEU points), but it can only achieve 0.12 BLEU points improvement for Phrase NMT model. According to Mi et al. (2016b), this approach is useful in conventional

NMT model. Our result is in agreement with their findings, and the improvement is more prominent in our partially aligned model. Under our scenario, compared to the parallel corpora, fewer parallel parts appear in sentence pairs. The faithfulness of our translation result is relatively poor while the fluency is relatively good. With the limited relevant vocabulary, the faithfulness of the translation results is much improved.

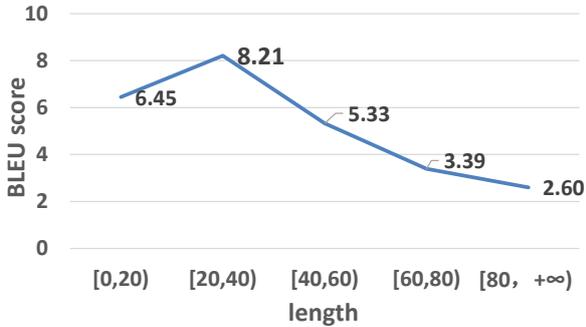

Figure 4: Translation results (BLEU score) of different lengths.

5.3 Result of Different Sentence Lengths

The performance of our partially aligned model with different lengths is another problem we care about. We randomly select 1000 sentences from translation results of test set (MT03-08), which are trained by the Partially Aligned Model(MSE)+ReduceDict method. We classify them into five categories according to the length. Figure 4 shows the results of the experiment.

We find that the sentences with shorter length (lower than 40) yield better results than the long sentences. When the length of sentences exceeds 80, the quality of translation is rather poor. The reason is that we mainly use phrase pairs in our method, and the length of phrase is relative short compared to whole sentence. So our model is more suitable for the translation of short sentences. When we translate long sentences, the parameters in our model are not adjusted for tuning, and our approach can not produce translation of high quality.

5.4 Effect of Adding Small Parallel Corpus

We concern that when we have a tiny parallel corpus, whether the small scale parallel corpus can boost the translation performance of the partially aligned method. Here, we fine-tune the partially

aligned translation model on these corpora. The details of these corpora are introduced in Table 3.

Corpus		Chinese	English
parallel	#Sent.	0.1M	
	#Word	3.00M	3.86M
	Vocab	0.07M	0.04M

Table 3: The statistics of small-scale parallel datasets.

The result is presented in Table 4. We can observe that the translation result tends to be poor by only using a small-scale parallel corpora. It indicates that conventional NMT system cannot learn a good model on the small-scale datasets. However, when fine-tuning our partially aligned model with this small parallel corpus, we can get a surprising improvement. The results suggest that when under a scenario in which we only have monolingual corpora and phrase pairs, even a few bitexts can boost translation quality to a large extent.

We investigate the effect of the different corpora size on the final translation results. According to Table 4, when the number of parallel sentences is quite small (lower than 60K), we can acquire a measurable improvement (more than 10 BLEU) compared to the conventional NMT system result. Especially, when the size of sentence pairs is 40K and 60K, our method obtains the enormous improvement over the NMT model by +13.82 BLEU points and +13.21 BLEU points respectively. When using more than 60K sentence pairs, we still get a relatively high promotion of translation quality. However, the promotion is not very remarkable as Row 1-3 reveal in Table 4. We can see when the number of parallel corpora is 100K(Row 5), the improvement over NMT Model is +3.95 BLEU points, which indicates that as the size of parallel corpora increases, the improvement of fine-tuning model is decreasing.

6 Related Work

Most of existing work in neural machine translation focus on integrating SMT strategies (He et al., 2016; Zhou et al., 2017; Wang et al., 2017; Shen et al., 2015), handling rare words (Li et al., 2016; Sennrich et al., 2016b; Luong et al., 2015b) and designing the better framework (Tu et al., 2016; Luong et al., 2015a; Meng et al., 2016). As for translation scenarios, training NMT model under

#Sent.	Method	MT03	MT04	MT05	MT06	Ave

Table 4: Effect of different data size of parallel corpus. Method NMT Model means the result of conventional NMT system trained on these low-count parallel sentences. Partially Aligned Model(MSE) + Para means the result of our model fine-tuned by these parallel sentences.

different scenarios has drawn intensive attention in recent years. Actually, there have been some effective methods to deal with them. We divide the related work into three categories:

6.1 Pivot-based Scenario

Pivot-based scenario assumes that there only exists source-pivot and pivot-target parallel corpora, which can be used to train source-to-pivot and pivot-to-target translation models. Cheng et al. (2017) propose to translate source language into pivot language, and then the pivot language will be translated into target language. According to the fact that parallel sentences should have close probabilities of generating a sentence in a third language, Chen et al. (2017) construct a Teacher-Student framework, in which existing pivot-target NMT model guides the learning process of the source-target model.

6.2 Multilingual Scenario

In multilingual scenario, there exists multiple language pairs but no source-target sentence pairs. Johnson et al. (2016) use parallel corpora of multiple languages to train a universal NMT model. This universal model learns translation knowledge from multiple different languages, which makes zero-shot translation feasible. Firat et al. (2016) present a multi-way, multilingual model to resolve the zero-resource translation. They use other language to train a multi-way NMT model. The model generates pseudo parallel corpora to fine-tune attention mechanism, so as to achieve better

translation.

6.3 Monolingual Data Scenario

In this scenario, an NMT model of good quality has been trained on existing parallel corpora, but a preferable translation result is still in need by incorporating additional data resource. Gülçehre et al. (2015) propose to incorporate target-side corpora as a language model. Sennrich et al. (2016a) attempt to enhance the decoder network model of NMT by incorporating the target-side monolingual data. Luong et al. (2016) explore the sequence autoencoders and skip-thought vectors method to exploit the monolingual data of source language. Zhang and Zong (2016) propose two approaches, self-training algorithm and multi-task learning framework, to incorporate source-side monolingual data. Besides that, Cheng et al. (2016) have explored the usage of both source and target monolingual data using a semi-supervised method to reconstruct both source and target side monolingual language, where two NMT frameworks will be used.

Above methods are designed for different scenarios, and their work can achieve great results on these scenarios. However, when in the scenario we propose in this work, that is we only have monolingual sentences and some phrase pairs, their methods are hard to be utilized to train an NMT model. Under this scenario, monolingual data can be acquired easily, and high quality phrase pairs can be obtained using some effective methods (Zhang et al., 2014). To learn a good NMT

model in our translation scenario, we adapt the conventional training procedure by designing a different generation mechanism and a different objective function.

7 Conclusion

In this paper, we have presented a new translation scenario for NMT in which we have only monolingual data and bilingual phrase pairs. We obtain large-scale partially aligned sentence pairs from the monolingual data and phrase pairs by an information retrieval algorithm. The generation process and objective function are specially designed in NMT training to take full advantage of the partially aligned corpora. The empirical experiments show that the proposed method is capable to achieve a relatively good result. We further find that only a little amount of parallel sentences can significantly boost the translation quality.

We also notice that the proposed approach with only partially aligned data cannot obtain high translation quality. In the future, we plan to design better approaches to model the partially aligned corpus. We also attempt to evaluate our approach on other language pairs, especially low-resource language pairs.

Identifying Usage Expression Sentences in Consumer Product Reviews

Shibamouli Lahiri and V. G. Vinod Vydiswaran and Rada Mihalcea

University of Michigan

{lahiri, vgvinodv, mihalcea}@umich.edu

Abstract

In this paper we introduce the problem of identifying usage expression sentences in a consumer product review. We create a human-annotated gold standard dataset of 565 reviews spanning five distinct product categories. Our dataset consists of more than 3,000 annotated sentences. We further introduce a classification system to label sentences according to whether or not they describe some “usage.” The system combines lexical, syntactic, and semantic features in a product-agnostic fashion to yield good classification performance. We show the effectiveness of our approach using importance ranking of features, error analysis, and cross-product classification experiments.

1 Introduction

Identification of *usage expressions* — phrases or sentence snippets describing product use in reviews — is an important problem in mining consumer product reviews. Identifying such usage expressions accurately allows us to view the relationship between consumers and products more clearly (e.g., by indicating how frequently a consumer uses a product). Further, the language and style employed in describing product use bring relevant and unseen aspects of the products to the fore (e.g., describing usage of a product in non-traditional and unique ways).

Usage expressions can take several forms, such as which aspects of the product are used, why the product is used, where it is used, how it is used, when it is used, and so forth (c.f. Section 3 for specific examples). The product could be used by a consumer in a number of ways, sometimes in unique ways not intended for originally. Hence

enumerating all possible uses of a product is computationally intractable. In this paper, therefore, we focus on four specific cases of product usage: why the product is used, where it is used, how it is used, and if there are any non-standard or non-traditional use (cf. Section 3).

While the relationship between product usage and consumer behavior has mostly been discussed by marketing researchers and psychologists, the question of whether the phenomenon of *usage* has any detectable signature in terms of the *language* used by consumers has not been addressed thus far. In this paper, we introduce the task of identifying usage expressions from consumer product reviews. In particular, we focus on classifying review sentences as to whether they contain a *usage expression* or not. We create our own human-annotated corpus of 565 reviews on five distinct product categories containing more than 3000 sentences. We introduce a system that classifies sentences according to whether they contain a usage expression or not with 87.2% accuracy. We also show that an appropriate combination of lexical, syntactic, and semantic features performs better than individual feature categories.

2 Related Work

Existing research could be organized into six self-consistent psycho-sociological theories, namely psycho-analysis, social theories, stimulus-response theories, trait and factor theories, self-theories, and life style theories. Kassarijan (1971) offers a comprehensive review of the literature on consumer behavior and psychological traits. Robertson and Myers (1969) found weak relationships between opinion leadership and innovative buying behavior, but observed that the relationship *strength* varied by product category. Tucker and Painter (1961), and Sparks and Tucker

(1971) showed that there were correlations between personality traits and the *types* of products used. Dolich (1969) posited that products as *symbols* were organized into congruent relationships with the consumer’s *self-image*. More recently, Govers and Schoormans (2005) found that people preferred products with a *product personality* that matched their self-image, and the positive effect of product-personality congruence was independent of user-image congruence.

In natural language processing research, the closest problem to usage expressions is perhaps that of opinion mining from product reviews and product aspects. Dave et al. (2003) classified reviews as expressing positive or negative sentiment. They identified four problems with review classification, including rating inconsistency, ambivalence, data sparseness, and skewed distribution. Hu and Liu (2004) extracted product features from the reviews of a single product, taking user opinion into account. Opinion/product features were mined if a reviewer had commented on them. Popescu and Etzioni (2005) presented OPINE, an unsupervised information extraction system that mined reviews in order to build a model of important product features, their evaluation by reviewers, and their relative quality across products. OPINE’s use of *relaxation labeling* led to strong performance on the tasks of finding opinion phrases and their polarity. Ding et al. (2008) presented a “*holistic lexicon-based approach*” for mining *context-dependent* opinion words. The proposed method used an aggregating function for multiple conflicting opinion words in a sentence. The authors further implemented a system called “Opinion Observer” based on their method. Lastly, Wu et al. (2009) implemented a special dependency parser for opinion mining that used phrases (rather than words) as the primitive building blocks. Since many product features are in fact phrases, this approach led to good results for extracting relations between product features and opinion expressions.

Yet another related task is that of mining *semantic affordances* (Chao et al., 2015). In this task, “usage” of a product can be viewed as an *action* performed on an *object* with the help of the *product*. Relationships between such actions and objects are known as “semantic affordances”. As Chao et al. showed, text mining can be very effective at ascertaining affordance relationships

between verb and noun classes. Similar verb-noun relationships have also been formulated in the problem of learning *selectional preferences* from text (Resnik, 1997; Brockmann and Lapata, 2003; Erk, 2007; Pantel et al., 2007; Bergsma et al., 2008; Van de Cruys, 2014), and more generally, in the problem of *probabilistic frame induction* (Chambers and Jurafsky, 2011; Cheung et al., 2013; Chen et al., 2013).

Another topic of research related to our work is the problem of *research idea extraction* from academic papers. Gupta and Manning (2011) took the first stab at this problem by implementing a bootstrapping algorithm on dependency tree kernels. Gupta and Manning’s method was later refined by Tsai et al. (2013) who worked with a more crisp set of *idea categories*. We view this problem as conceptually parallel to ours; however, a key difference is that usage expressions are typically more obscure in text as compared to research ideas.

3 Building a Usage Expression Dataset

Product reviews often contain usage information. Specifically, in addition to opinions on product quality, reviewers often share how, where, or why they use the product. We therefore build our dataset of product usage expressions starting with a collection of product reviews.

We collect Amazon product reviews for five different product categories, as shown in Table 1. The particular product lines we use are: a *laundry product*: specifically, Downy Unstopables In Wash Fresh Scent Booster 13.2 Oz; two kinds of *cooking agents*, namely, *Olive oil*: Baja Precious Extra Virgin Olive Oil from Baja California (750ml Bottle) and *Vinegar*: Raw Organic Apple Cider Vinegar by Bragg (1 gallon); a *Medicine*: Kirkland Signature Low Dose Aspirin, 2 bottles – 365-Count Enteric Coated Tablets each; and a *household item*, namely *Toothpaste*: Colgate Optic White Toothpaste, 4 Ounce (Pack of 2). The reviews are split into sentences, with the total number of sentences and average number of sentences per review as shown in Table 1. In all, there are 3020 sentences in 565 reviews, with an average of 5.34 sentences per review.

With the help of three linguistics undergraduate students, each sentence in the dataset was annotated as containing a usage expression or not. Initially, as an early trial, we asked the annota-

Product category	Product	# Reviews	# Sentences	Avg # Sentences per Review
Laundry product	Scent booster	125	695	5.56
Cooking agent	Olive oil	110	588	5.35
Cooking agent	Vinegar	110	623	5.66
Medicine	Aspirin	110	463	4.21
Household item	Toothpaste	110	651	5.92
Total	–	565	3020	5.34

Table 1: Product categories in our dataset.

tors to indicate if a sentence contained a usage expression. This approach led to low inter-annotator agreement, so we refined the annotation process to a two-step process as follows.

In the first step, we instructed the annotators to read each product review carefully, identify all usage expressions in the review (examples below), and write them in a given textbox, one usage expression per line. Annotators were requested to write the usage expressions in their own words. This component was employed to make sure annotators carefully read and understood the review.

The second step involved answering the following four questions on usage types:

- (A) Does the sentence describe why the product was being used? (usage reason/purpose) E.g., “*I used unstopables to freshen my room.*”
- (B) Does the sentence describe where the product was used? E.g., “*I used unstopables with my cat litter.*”
- (C) Does the sentence describe how the product was used? E.g., “*I use three cups of Downy Unstopables in every wash.*”
- (D) Does the sentence describe any non-traditional or non-standard usage of the product? E.g., “*I always love to add some hot water to unstopables and make my own DIY air freshener!*”

If a sentence had a positive answer to one or more of these four questions, then it was labeled as containing a usage expression.¹

Additionally, several specific instructions were added to deal with potentially difficult or complex cases, by asking annotators to (1) consider the context (one sentence before and after the target sentence) before deciding whether to mark a

¹Note that in this paper, we ignore the different ways of product usage (why, where, how, non-traditional), but we plan to utilize the detailed annotations in future work.

sentence or not. (2) determine if a sentence contains an opinion (“*Love it*”, “*Hate it*”, etc.) or a recommendation (“*I’d recommend this product to all aspiring gardeners*”), and if so, pairing it with an explicit usage expression in some form. (3) determine if a sentence talks about usage of another product that is not the primary focus of the review (i.e., a secondary product), then mark the sentence only if the primary product is being used in addition to the secondary product. (4) determine if the secondary product is used instead of the primary product: “*Unstopables were not good, so I used sheets instead.*”, or if only the secondary product was used: “*I used sheets, they are better.*” then do not label the sentence. (5) focus only on products, and ignore other (named) entities like persons, organizations, locations, and dates.

Table 2 shows an example product review, and sentences that were agreed upon by all annotators to contain, or not, a usage expression. We also show sentences on which there was no consensus. Note that such sentences have a fair amount of ambiguity. For example, the sentence “*I do recommend this for times when you may want extra freshness for your clothes or towels.*” does not seem to contain an explicit usage expression, but it does indicate that the consumer used the product to obtain extra freshness for clothes or towels. Sentences like this demonstrate the difficulty of identifying usage expressions in product reviews.

Inter-annotator agreement values, shown in Table 3, indicate that the task is moderately difficult. We can see that different products have different difficulty levels, with Vinegar being the least difficult (highest A_3 agreement as well as highest κ), while for the other four products, κ was between 0.43 and 0.48. This is presumably owing to the fact that Vinegar is a cooking agent and used in many different ways, thus providing more opportunity to find a usage sentence (by several people) in a product review.

To construct a gold standard, we took the majority of the three votes assigned by the three anno-

Sample Review
I used this recently when I washed my blankets and towels, and I was definitely impressed. Just a small amount (half a capful) was necessary to give my blankets and towels an extra burst of freshness. The scent is a little bit floral and lasts for a few days. I put the Downy booster directly into the washer. (Instructions say NOT to put in your dispenser) And it does work fine with high efficiency washers. I do recommend this for times when you may want extra freshness for your clothes or towels.
Usage annotations (agreed by all)
I used this recently when I washed my blankets and towels, and I was definitely impressed. Just a small amount (half a capful) was necessary to give my blankets and towels an extra burst of freshness.
Non-usage annotations (agreed by all)
The scent is a little bit floral and lasts for a few days.
Mixed usage/non-usage annotations
I put the Downy booster directly into the washer. (Instructions say NOT to put in your dispenser) And it does work fine with high efficiency washers. I do recommend this for times when you may want extra freshness for your clothes or towels.

Table 2: An example review and its annotations.

tators to each sentence. There were 36 sentences (1.19% of all sentences) that did not have a majority. One of the authors manually arbitrated these sentences into “usage” ($n = 22$) and “not usage” ($n = 14$) classes.

4 Finding Usage Expression Sentences

Once the annotated dataset was finalized, our primary goal was to build a classifier to predict if a given sentence contains usage expressions or not. We learn the classifier over five categories of features extracted from the sentence and neighboring context. In this paper, we show the performance using a logistic regression classifier, chosen based on its performance on a small development dataset of usage-annotated sentences drawn from 20 product reviews. The following features are included:

(A) Lexical features: As n-grams are usually very helpful in document classification, we explore their utility on the task of usage expression sentence classification. We use word unigrams and bigrams, part-of-speech (POS) bigrams, and character trigrams. We use the CRFTagger (Phan, 2006) for POS tagging.

(B) Embeddings: Embeddings encode *latent semantics* and could reflect usage patterns. We train a word embedding using word2vec (Mikolov et al., 2013) over a large corpus of 55,463 product reviews. This corpus is constructed from all Amazon reviews associated with any product that

has “Unstoppables”, “Olive oil”, “Vinegar”, “Aspirin”, or “Toothpaste” in its title. Once the word embedding is trained, a sentence is represented by the weighted average of the embeddings of all the unique words in it.

(C) Syntax: We use bags of constituency and dependency production rules, obtained from the output of the Stanford parser (Klein and Manning, 2003; Chen and Manning, 2014). For constituency grammar, we use terminal and non-terminal rules separately as well as together. For the dependency grammar, we use the (collapsed) dependency types (*amod*, *nsubj*, etc.), and the lexicalized dependencies (e.g., (*nsubj*, *Kirkland*, *seems*)) as separate features.

(D) Style: We extract thirteen shallow surface-level and style features to encode the stylistic properties of a sentence, in the hope that they would be predictive of whether the sentence contains a usage expression. These features are: sentence position, average word length (in chars), sentence length (in words and characters), type-token ratio, Flesch Reading Ease (Flesch, 1948; Farr et al., 1951), Automated Readability Index (Senter and Smith, 1967), Flesch-Kincaid Grade Level (Kincaid et al., 1975), Coleman-Liau Index (Coleman and Liau, 1975), Gunning Fog Index (Gunning, 1968), SMOG Score (McLaughlin, 1969), Formality (Heylighen and Dewaele, 1999), and Lexical Density (Ure, 1971).

(E) Semantics: Since *usage* is above all a semantic phenomenon, a *semantic space* should be able to capture the dominant properties of the usage expression. We use the following feature sets to capture a semantic space for a sentence. Each feature set effectively describes a *lexicon*, and we turn “on” the features in the lexicon that are present in the target sentence.

- 1. Product categories:** This feature set consists of the list of product categories obtained from the Walmart API.² We use both main categories and sub-categories.
- 2. Concreteness:** The set of words, along with their concreteness scores, available as part of the Free Association Norms Database (Nelson et al., 1998). There are more than 3,000 words available as part of the database.
- 3. Levin classes:** The set of coarse and fine-grained variations of Levin verb classes and

²<https://developer.walmartlabs.com/>

Product type	Majority Yes	Majority No	Majority Not Sure	All Yes	All No	A_3	κ
Scent booster	201	494	0	80	385	66.91	0.46
Olive oil	91	493	4	40	395	73.98	0.43
Vinegar	190	430	3	139	369	81.54	0.71
Aspirin	94	366	3	47	282	71.06	0.48
Toothpaste	137	514	0	56	411	71.74	0.46
Overall	713	2297	10	362	1842	72.98	0.52

Table 3: Majority label statistics, and three-way inter-annotator agreement. A_3 is the % of sentences where all three annotators agreed. κ is the Fleiss’ kappa among three annotators (Fleiss, 1971).

verb alternations, leading to four types of features (Levin, 1993).

4. **LIWC:** Like Levin classes, we included another set of features derived from the LIWC dictionary of psychological word categories (Tausczik and Pennebaker, 2010).
5. **Semantic lexicons:** Like Levin classes, we use the Roget thesaurus and WordNet Affect word categories, with a binary feature representation. If a word falls under any of the Roget word categories, the corresponding feature is set.
6. **Named Entities:** We use the Stanford NER (Finkel et al., 2005) to identify named entities in our corpus, and then use these entities as bag-of-features. We use the terms, the entity types, and the lexicalized entity types (terms + entities) as our bags. Standard tf, tfidf, and binary representations are used. We use the seven-class typology of named entities (Location, Person, Organization, Money, Percent, Date, Time).
7. **Spatial Prepositions:** Recent studies have shown prepositions to be a precious source of semantic information (Srikumar and Roth, 2013; Schneider et al., 2015, 2016). We use a lexicon of *spatial prepositions*³ as a bag-of-words feature. The rationale was to observe if spatial properties of usage of objects (“use olive oil **with** celery”, “put detergent **in** washer”) can be captured in terms of prepositions such as *on*, *in*, *by*, *with*, etc.
8. **Semantic Distance:** Finally, we added the

³Obtained by combining the two lists at <https://owl.english.purdue.edu/owl/resource/594/04/> and <http://www.firstschoolyears.com/literacy/sentence/grammar/prepositions/resources/Spatial%20Prepositions%20word%20bank.pdf>.

(weighted) WordNet distance⁴ between all words and the verb *use*, where weights are set as binary, tf, and tfidf, as before. The rationale behind this feature is that it captures words similar to the verb *use* in the sentence, and their relative importance.

5 Evaluation

We use the dataset introduced in Section 3 to evaluate the accuracy of the usage detection classifier. 20% of the data for each product is held out as test data, and the remaining 80% is used for training.

We start by evaluating each individual feature using a ten-fold cross-validation on the training data. We then explore three combination methods, applied on a subset of seven feature sets, selected based on their performance and diversity: word unigrams, POS bigrams, character trigrams, embeddings, constituency rules, product categories, and concreteness. We combine these features through: classifier voting, where we assign the class predicted by the majority of the classifiers; feature fusion, where we join all the individual features into one feature vector used in the classification; and meta-learning, where we use the output of the individual classifiers as input into another classifier (again using logistic regression for the meta-learner). Table 4 shows the results of these evaluations. As seen in the table, while simple features, such as word n-grams and character trigrams, lead to the best performance among the individual features, better performance is obtained when they are combined with other features (bottom rows of Table 4).

The meta-learner based combination strategy resulted in the best performing classifier during the cross-validation experiments on training data. We next evaluate this classifier on the test data consisting of 20% reviews of all five products. Table 5 shows the results obtained on the test data. For

⁴We use the Wu-Palmer similarity (Wu and Palmer, 1994).

Feature Type	Prec.	Rec.	F-score	Accu.
Word unigrams	71.56	54.94	62.16	83.88
Word bigrams	77.06	30.85	44.06	81.13
Character trigrams	70.06	57.19	62.98	83.80

Spatial prepositions	41.67	3.47	6.40	75.57
Semantic distance	66.29	20.45	31.26	78.33
Classifier voting	66.84	67.76	67.30	84.13
Feature fusion	63.92	60.49	62.15	82.25
Meta learner	73.61	59.45	65.77	85.09

Table 4: Micro-averaged sentence-level results (%) under 10-fold cross-validation on the training data. Maximum value in each column (within each section) is boldfaced.

Feature Type	Prec.	Rec.	F-score	Accu.
Majority	0.00	0.00	0.00	76.13
Word unigrams	71.82	58.09	64.23	85.92
Meta learner	76.92	58.82	66.67	87.20

Table 5: Micro-averaged sentence-level results (%) on the **test set** (20% of all products). Maximum value in each column is boldfaced.

comparison, the table also shows the performance of the word unigram classifier, as well as a majority class baseline that labels every sentence as “non-usage.” As before, the meta-learner significantly improves over the unigram classifier,⁵ and also over the majority class baseline.⁶

We also report the performance of the meta-learner classifier on individual products in Table 6. Across all the products, vinegar appears to have the highest F-score. This can be partly explained by the high inter-annotator agreement: the same product had the highest three-way agreement in the manual annotations, as shown in Table 3, likely an indication of a less difficult dataset.

6 Additional Analyses

To gain further insights, we perform several additional analyses, to determine: the role played by different features; the relation between classifier performance and amount of training data; the role of in-domain vs. cross-domain classification; and

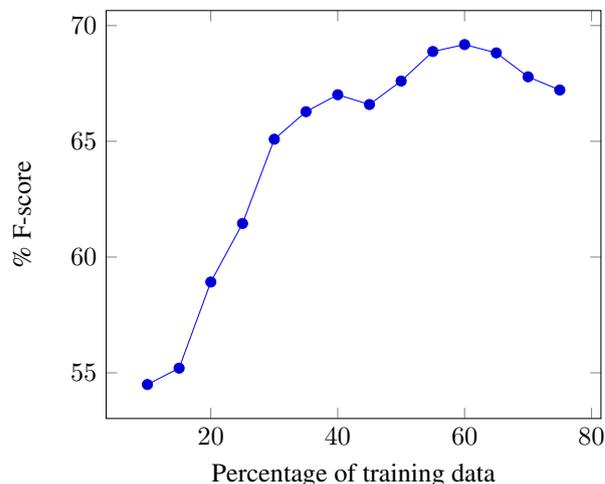

Figure 1: Learning curve using micro-averaged sentence-level results for the meta-learner classifier.

finally the types of errors produced by the system.

6.1 Feature Importance Ranking

Table 7 shows the top features (ranked by their Gini importance (Breiman et al., 1984)) for three prominent individual feature-based classifiers — viz. word unigrams, category words, and concreteness — and the meta-learner. Note that top-ranking words include product properties (*smell*), secondary objects on which the product was used (*clothes*), how the product was used (*day, daily, drink, water*), usage verbs (*use*), prepositions and conjunctions (*and, for, with*), pronouns (*i, it, this*), and articles (*a, the*). For the meta learner, lexical features (character trigrams and word unigrams) and embedding features (Word2vec) are among the top-ranked feature classes.

6.2 Learning Curve

Next, we experiment with varying the size of the training data to understand the learning curve. We gradually increased the amount of training data from 10% to 80%, in steps of 5%; and evaluated on the full test data. Figure 1 shows the variation of F-score achieved by the meta-learner as

Word unigrams		Category words		Concreteness		Meta learner	
and	0.023	the	0.040	smell	0.025	Character trigrams	0.309
my	0.019	my	0.036	use	0.024	Word2vec	0.236
smell	0.014	smell	0.029	day	0.023	Word unigrams	0.171
day	0.014	a	0.028	for	0.019	Constituency	0.119
use	0.014	use	0.025	clothes	0.017	Concreteness	0.077
it	0.011	day	0.023	i	0.016	Category words	0.053
clothes	0.010	this	0.020	with	0.014	POS bigrams	0.035
a	0.010	clothes	0.018	drink	0.014		
bought	0.009	daily	0.015	water	0.013		
drink	0.009	drink	0.013	daily	0.013		

Table 7: Feature importance ranking for four feature types. We show ten top-ranked features along with their importance scores. For the meta-learner, we show the ranking over the subset of seven feature sets used in this classifier.

Feature Type	Prec.	Rec.	F-score	Accu.
Baseline	0.00	0.00	0.00	76.39
Word unigrams	69.15	35.20	46.65	80.99
Meta-learner	70.62	38.43	49.77	81.69

Table 8: Cross-domain classification: Micro-averaged sentence-level results (%), where test set is an individual product, and training set is four other products. Maximum value in each column is boldfaced.

the training data is increased, smoothed over three consecutive data points. The test performance was the highest when trained on 60% of training data and then decreased gradually, which suggests that the system might not benefit from additional training data.

6.3 The Role of In-Domain Data

To understand the role played by in-domain data, we further experiment with two different configurations of training and test sets.

In one configuration, we train on four products, and test on the remaining product (*cross-domain training*). As can be seen from Table 8, this results in lower F-scores than Table 5. This suggests that identifying usage expressions of a product is intimately related to the identity of the product, echoing the findings by Govers and Schoormans (2005).

In the second configuration, we train on 80% of a product, and test on 20% of the same product (*in-domain training*). The results, averaged over the five products, are shown in Table 9. Note that the F-score values are much improved compared to the previous configuration, and are comparable to the results shown in Table 5. This suggests that when storage/memory might be a concern, we could simply use training data from *within the do-*

Feature Type	Prec.	Rec.	F-score	Accu.
Baseline	0.00	0.00	0.00	78.24
Word unigrams	74.19	50.74	60.26	85.44
Meta-learner	76.53	55.15	64.10	86.56

Table 9: In-domain classification: Micro-averaged sentence-level results (%), where test set is 20% of an individual product, and training set is 80% of the same product. Maximum value in each column is boldfaced.

main to achieve comparable performance. This strategy also results in a faster training time and a smaller model, similar to the findings in (Bucilua et al., 2006).

6.4 Error Analysis

Finally, we also conducted a manual inspection of two broad categories of errors – **false positives**, i.e. “not usage” sentences marked as “usage” ($n = 25$), and **false negatives**, i.e. “usage” sentences marked as “not usage” ($n = 56$). This analysis revealed the following sub-categories for the false positives:

- **Number expressions:** Seven instances (29.17%) of errors can be attributed to numeric expressions occurring within sentences (“two years”, “3am”, “third bottle”, etc.).
- **Erroneous gold labels:** Six instances (25%) were actually correctly labeled as “usage” by the system, whereas the gold label was wrong (“*I really love the smell of fresh laundry, and the smell of Downy.*”).
- **Shortcomings:** Six examples (25%) talk about actual or perceived shortcoming(s) of a product. “*Olive oil used for healthy properties doesn’t keep well in plastic.[sic]*”

- **Others:** Five instances (20.83%) were not captured by the above categories: “*I used to drink a small shot each day, but haven’t for a while.*”

False negatives have the following sub-categories:

- **Positive adjectives and adverbs:** 21 instances (37.5%) can be attributed to positive adjectives (“good”, “great”, “excellent”), and/or positive adverbs (“really”, “impressively”, “well”). “*It smells amazing and lasts forever.*”
- **Use-related verb in primary clause:** Eleven examples (19.64%) contain a use-related verb (“use”, “help”, “need”) in the primary clause: “*I use this to eat, not to cook with.*”
- **Erroneous gold labels:** Nine instances (16.07%) are actually correctly labeled as “not usage” by the system, but the gold label was wrong (“*When I have to hang dry clothes, they get this horrible egg water odor.*”).
- **Non-traditional usage:** There are three instances (5.36%) that talk about non-traditional or innovative usage of a product: “*I have since made small sachet bags for my closets, car and as gifts.*”
- **Others:** Twelve instances (21.43%) were not captured by the above categories: “*I actually saw results after the first use.*”

7 Conclusion

In this paper, we introduced the task of identifying usage expression sentences in consumer product reviews. A dataset comprising more than 3,000 annotated sentences was created from reviews of five products. We also trained a binary classifier to identify sentences that talk about the usage of a product. Extensive feature tuning and fusion experiments resulted in performance values comparable to the inter-annotator agreement. Detailed feature ranking, error analysis, and per-product performance numbers have been reported. Directions for future research include: experiments on a larger dataset of reviews with more diverse product types, expanding to other genres of reviews such as product blogs, and identifying types

of usage expressions (how, where, why, and non-traditional uses). The work can also be extended to model the “personality” of a product with the “personality” of users – perhaps measured by the average personality of all people using the target product.

The annotated dataset is publicly available for research use from <http://lit.eecs.umich.edu/downloads.html>.

Between Reading Time and Syntactic/Semantic Categories

Masayuki Asahara † and Sachi Kato ‡

National Institute for Japanese Language and Linguistics, Japan †, ‡

masayu-a@ninja1.ac.jp †

Abstract

This article presents a contrastive analysis between reading time and syntactic/semantic categories in Japanese. We overlaid the reading time annotation of BCCWJ-EyeTrack and a syntactic/semantic category information annotation on the ‘Balanced Corpus of Contemporary Written Japanese’. Statistical analysis based on a mixed linear model showed that verbal phrases tend to have shorter reading times than adjectives, adverbial phrases, or nominal phrases. The results suggest that the preceding phrases associated with the presenting phrases promote the reading process to shorten the gazing time.

1 Introduction

Most of the studies on sentence processing by humans are based on confirmatory data analysis. The methodology involves developing a hypothesis, constructing sample sentences, including the target language phenomena, and performing a psycholinguistic experiment, such as recording reading time or event-related potentials. In recent times, the ‘Balanced Corpus of Contemporary Written Japanese’ (hereafter ‘BCCWJ’) (Maekawa et al., 2014) was compiled and published. The reading time annotation on BCCWJ: BCCWJ-EyeTrack (Asahara et al., 2016) is available for the linguistic research community. The data in the BCCWJ enable us to perform exploratory data analysis in fair and reproducible environments.

We measured the readability of humans. More concretely, we performed a contrast comparison between reading time and syntactic/semantic categories of words. We prepared the annotation

of word senses on BCCWJ based on ‘Word List by Semantic Principles’ (国立国語研究所, 1964, 2004). The original WLSP label annotation is on both short unit words and long unit words in the BCCWJ. We then mapped these annotations into *Bunsetsu*(base phrase)-units.

The statistical analysis using a mixed linear model shows that verbal phrases tend to have shorter reading times than adjective/adverbial phrases or nominal phrases.

Section 2 presents the related research. Section 3 shows the data and methods. Section 4 presents the results, and Section 5 is the discussion. Section 6 concludes this article and presents the implications of our current work and the future work we plan to conduct.

2 Related Work

First, we present related work on eye tracking. The Dundee Eyetracking Corpus (Kennedy and Pynte, 2005) contains reading times for English and French newspaper editorials from 10 native speakers of each language that were recorded using eye-tracking equipment. The corpus does not target a specific set of linguistic phenomena but instead provides naturally occurring texts for testing diverse hypotheses. For example, (Demberg and Keller, 2008) used the corpus to test Gibson’s dependency locality theory (DLT) (Gibson, 2008) and Hale’s surprisal theory (Hale, 2001). The corpus also allows for replications to be conducted; for example, (Roland et al., 2012) concluded that previous analyses (Demberg and Keller, 2007) had been distorted by the presence of a few outlier data points.

Second, we present language analyses or models with reading time or eye tracking gaze information. (Barrett et al., 2016) presented a POS tagging model with gaze patterns. (Klerke et al.,

Table 1: Data format of BCCWJ-EyeTrack

2015) presented a grammaticality detection model for machine-processed sentences. (Iida et al., 2013) presented an analysis of eye-tracking data for the annotation of predicate-argument relations.

Our paper is slightly different from these preceding papers. We present a corpus-based psycholinguistic research on the relationship between reading time and syntactic/semantic categories.

3 Data and Method

We used the overlaid data of BCCWJ-EyeTrack and syntactic/semantic categories, as given in Table 1. We present the data below in detail.

3.1 BCCWJ and its annotation

We used BCCWJ (Maekawa et al., 2014) and its annotation data. BCCWJ is a balanced corpus of Japanese. We used newspaper articles from the core data. The data were sampled by their production. The sentences were segmented into word unit boundaries of short unit words, long unit words, and *bunsetsu*. The morphological information for the short unit words and long unit words was annotated by human annotators.

We also used *bunsetsu*-based syntactic depen-

ency annotation (Asahara and Matsumoto, 2016) for the data to investigate the correlation between syntactic dependency attachments and reading time.

3.2 Reading Time Data: BCCWJ-EyeTrack

We now explain the two methods used for measuring the reading time: eye tracking and self-paced reading. The order of tasks was fixed with eye tracking in the first session and self-paced reading in the second session. Each participant saw each text once with the task and segmentation of the texts counterbalanced across participants.

Eye tracking was recorded with a tower-mounted EyeLink 1000 (SR Research Ltd). The view was binocular, but data were collected from each participant’s right eye at a resolution of 1000 Hz. Participants looked at the display using a half-mirror; their heads were fixed with their chins on a chin rest. Unlike self-paced reading, during eye tracking all segments were shown simultaneously. This allowed more natural reading because each participant could freely return and reread earlier parts of the text on the same screen. However, participants were not allowed to return to previous screens. Stimulus texts were shown in a fixed full-width font (MS Mincho 24 point) and displayed horizontally as is customary with computer displays for Japanese; there were five lines per screen on a 21.5-in display.¹ Under the segmented condition, a half-width space was used to indicate the boundary between segments. In order to improve vertical tracking accuracy, three empty lines were placed between the lines of text. A line break was inserted at the end of a sentence or when the maximum 53 full-width characters per line was attained. Moreover, line breaks were inserted at the same points in the segmented and unsegmented conditions to guarantee that the same number of non-space characters was shown under both conditions.

The same procedure was adopted for the self-paced reading presentation except that the chin rest was not used, and participants could move their heads freely while looking directly at the display. Doug Rohde’s Linger program Version 2.94² was used to record keyboard-press latencies while sentences were shown using a non-cumulative self-paced moving-window presenta-

¹EIZO FlexScan EV2116W (resolution: 1920×1080 pixels) set at 50 cm from the chin rest.

²<http://tedlab.mit.edu/~dr/Linger/>

tion. This had the best correlation with eye-tracking data when different styles of presentation were compared for English (Just et al., 1982). Sentence segments were initially shown masked with dashes. Participants pressed the space key of the keyboard to reveal each subsequent segment of the sentence, while all other segments reverted to dashes. Participants were not allowed to go back and reread earlier segments.

Twenty-four native Japanese speakers, who were 18 years or older at the time, participated in the experiment with due financial compensation. The experiments were conducted from September to December 2015. The collected profile data included the age (in 5-year brackets), gender, educational background, eyesight (all participants had uncorrected vision or vision corrected with soft contact lenses or prescription glasses), geographical linguistic background (i.e., the prefecture within Japan where they lived until the age of 15), and parents' place of birth. The vocabulary size of the participants was measured using a Japanese language vocabulary evaluation test (Amano and Kondo, 1998). Participants indicated words they knew from a list of 50 words, and scores were calculated by taking word-familiarity estimates into consideration. As a measure of the working memory capacity, the Japanese version of a reading span test was conducted (Osaka and Osaka, 1994). Each participant read sentences aloud, each of which contained an underlined content word. After each set of sentences, the participants recalled the underlined words. If they successfully recalled all the words, the set size was increased by one sentence (sets of two to five sentences were used). The final score was the largest set for which all words were correctly recalled; a half point was added if half the number of words were recalled in the last trial.

Reading times were collected for a subset of the core data of the BCCWJ (Maekawa et al., 2014), which consisted of newspaper article (PN: published newspaper) samples. Articles were chosen if they were annotated with information such as syntactic dependencies, predicative clausal structures, co-references, focus of negation, and similar details following the list of articles that were given annotation priority in the BCCWJ.

The 21 newspaper articles³ chosen were divided

³The original BCCWJ-EyeTrack paper (Asahara et al., 2016) presented 20 articles. However, there were two con-

into four data sets containing five articles each: A, B, C, and D. Table 2 presents the numbers of words, sentences, and screens (i.e., pages) for each data set. Each article was presented starting on a new screen.

Table 2: Data set sizes

Data set	Segments	Sentences	Screens
A	470	66	19
B	455	67	21
C	355	44	16
D	363	41	15

Articles were shown segmented or unsegmented (i.e., with or without a half-width space to mark the boundary between segments). Segments conformed to the definition for *bunsetsu* units (a content word followed by functional morphology, e.g., a noun with a case marker) in the BCCWJ as prescribed by the National Institute for Japanese Language and Linguistics. Each participant was assigned to one of eight groups of three participants each. Each group was subjected to one of the eight experimental conditions with varying combinations of measurement methods, and boundary marking for different data sets was presented in different orders.

During the self-paced reading session, each segment was displayed separately, and participants could not return to reread earlier parts of the text. Therefore, the latencies for the button presses are straightforward measures of the time spent on each segment.

With regard to data from eye tracking, five types of measurements were used: first fixation time (FFT), first pass time (FPT), regression path time (RPT), second pass time (SPT), and total time (TOTAL). These are explained in Figure 1.

The FFT is the duration of fixation measured when the gaze first enters the area of interest. In the figure, the FFT for “the first fiscal year settling of accounts also” (hereafter “the area of interest”) is the duration of fixation 5.

The FPT is the total duration of fixation from the moment the gaze first stops within the area of interest until it leaves the focus area by moving to the right or left of this area. In the figure, the FPT

secutive articles in data set C. These two articles were presented on separate screens. Thus, we split them into two for statistical analysis.

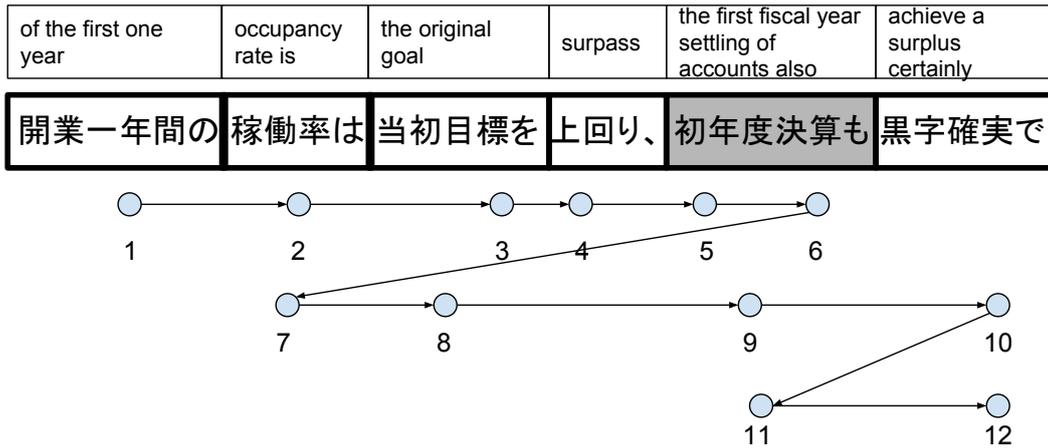

Figure 1: Example of fixations

is the sum of the durations of fixations 5 and 6.

The RPT is the total span of time from the moment the gaze enters the area of interest until it crosses the right boundary of this area for the first time. In the figure, the RPT is the sum of the durations for fixations 5–9. The RPT can include fixations to the left of the left boundary (e.g., 7 and 8) and the durations of fixations when the gaze returns to the area of interest (e.g., 9).

The SPT is the total span of time the gaze rests in the area of interest excluding the FPT. In the figure, the SPT is the sum of the durations of fixations 9 and 11.

The TOTAL is the total duration the gaze rests within the area of interest. In other words, it is the sum of SPT and FPT. In the figure, TOTAL is the sum of the durations of fixations 5, 6, 9, and 11.

Table 1 presents the data. `surface` is the surface form of the word. The reading time (i.e., `time`) is converted into log scale (i.e., `logtime`). `measure` is the reading type {SELF, FFT, FPT, RPT, SPT, TOTAL}. `sample`, `article`, `metadata_orig`, `metadata` are information related to the article. `length` is the number of characters in the surface form. `space` denotes spaces, if they are present between segments. `subj` is the participant ID, which is used as a random effect for the statistical analysis. `dependent` is the number of dependents for the segments. The dependency relation is annotated by humans (Asahara and Matsumoto, 2016). `sessionN`, `articleN`, `screenN`, `lineN`, `segmentN` are the display order of the elements. `is_first`, `is_last`, `is_second_first`

are the layout features on the screen. `WLSPLUWFALSE`, `WLSPLUWA`, `WLSPLUWB` are described in the next subsection.

3.3 WLSP and annotation

‘Word List by Semantic Principles’ (*Bunrui Goi-hyo*) (国立国語研究所, 1964) is ‘a A collection of words classified and arranged by their meanings’. The first published version of WLSP in 1964 includes around 33,000 words. The revised and enlarged version of WLSP (国立国語研究所, 2004) was published in 2004. The data include around 79,000 word tokens with 100,000 word sense tokens.

Table 3 shows an example entry ‘この (*kono*: this)’ in WLSP. The article number ‘3.1010’ identifies a word belonging to the syntactic/semantic category. The first digit of the article number refers to ‘class’, which is a syntactic category of the entry: class ‘1’ represents a ‘体’ nominal entry; class ‘2’ represents a ‘用’ verbal entry; class ‘3’ is an ‘相’ adjective entry; and class ‘4’ is a ‘他’ other entry including conjunctive and interjection. This category classification is originally from the ‘Awakening of Faith in the Mahayana’ (大乘起信論; 大乘起信論) in Mahayana Buddhism.

The digits to the right of a period identify the semantic category. The first decimal digit represents a ‘division’, which is a major semantic category: division ‘.1’ is a ‘抽象的關係 (関係)’ relation entry; division ‘.2’ is a ‘人間活動の主体 (主体)’ subject entry; division ‘.3’ is a ‘精神および行為 (活動)’ action entry; division ‘.4’ is a ‘生産物および用具 (生産物)’ product entry; and division ‘.5’ is a ‘自然物および自然現象 (自然)’ nature entry. The

Table 3: WLSP example entry ‘この (*kono*)’ (article number 3.1010)

class	division	section	article
相 (3)	関係 (.1)	真偽 (.10)	こそあど (.1010)
Adj/adv	Relation	Boolean	Demonstrative

first two decimal digits refer to the ‘section’. Four decimal digits refer to the ‘article’, which is article number 895, of the finest semantic categories.

We annotated the words from these WLSP article numbers based on the BCCWJ core samples. The annotation was carried out for content words for short unit words and long unit words of BCCWJ. Functional words were not annotated in the WLSP category. Now, the samples of BCCWJ-EyeTrack have already been annotated. We defined the set of right-most long unit words as the category of the *bunsetsu*. The semantic category (class) and syntactic category (division) were reassigned on segments. We called them WLSPLUWA and WLSPLUWB, respectively. We note that, there are still unassigned entries for the segment even if all the words have been manually checked. We assigned the boolean value of WLSPLUWFALSE for the unassigned words.

3.4 Statistical Analysis

We investigated the reading time (*logtime*) of NPs that were annotated with the WLSP labels. Whereas Asahara et al.’s paper was based on *time*, ours was based on *logtime* to reduce the outliers in the model. During the preprocessing, we excluded data {*authorsData*, *caption*, *listItem*, *profile*, *titleBlock*} of metadata. We also excluded zero-millisecond data points from the eye tracking data. The number of data points were 17,628 for SELF (100.0%); 13,232 for FFT, FPT, RPT, and TOTAL (75.0%); and 4,769 for SPT (27.0%). After model-based trimming was used to eliminate points beyond 3.0 standard deviations, the model was rebuilt (Baayen, 2008). *subj* and *article* were considered as random effects, as expressed in the formula in Figure 2. We used the *lme4* package on R.

4 Results

Table 4 shows the results. Each number shows the coefficient with the standard error in brackets. A negative value of the coefficient indicates that the factor shortens the reading time.

A positive value of the coefficient indicates that the factor lengthens the reading time. The base fixed effect of the syntactic category is the nominal phrase (WLSPLUWA1), and the base fixed effect of the semantic category is the relation (WLSPLUWB1). Note that the time is based on logarithm.

First, we confirm the results of the non-WLSP related terms. The presentation with spaces between segments makes the reading time of FPT, RPT, SPT, and TOTAL faster than the one without spaces for eye tracking methods. To improve the readability of texts, one should simply introduce spaces at *Bunsetsu* boundaries. The longer length of the segment makes reading times long except for FFT, because the gazing area in this case is correlated to the probability of the fixation. More dependency arcs make shorter reading times for the segment. This fact supports *Anti-locality* (Konieczny, 2000). The layout information (*is_first*, *is_last*, *is_second_last*) is for the eye movement at the text wrap. All reading times other than SPT is longer at the left most segment (*is_first*). The reading time of FPT, RPT, and Total is longer at the right most and the second right most segments (*is_last*, *is_second_last*). With regard to the presentation order (*sessionN*, *articleN*, *screenN*, *lineN*, *segmentN*), As the experiment progressed, the reading time became shorter. This means that the subject participants become more familiar with the experiment.

Next, we confirm the results related to the WLSP syntactic categories. For all types of reading times, the verbal segments (WLSPLUWA2) had significantly shorter reading times than the nominal segments (WLSPLUWA1). For reading time types other than FFT, the adjective/adverbial segments (WLSPLUWA3) had significantly shorter reading times than the nominal segments (WLSPLUWA1). For reading time types other than SPT, the adjective/adverbial segments (WLSPLUWA3) had significantly longer reading times than the verbal segments (WLSPLUWA1).

```

logtime ~ space * sessionN + length + dependent
+ is_first + is_last + is_second_last
+ articleN + screenN + lineN + segmentN
+ WLSPLUWFALSE + WLSPLUWA + WLSPLUWB
+ (1 | subj) + (1 | article)

```

Finally, we confirm the result related to WLS semantic categories. The abstract relation (WLSPLUWB.1) shows significantly longer reading times of FFT and TOTAL than of

others such as subject (WLSPLUWB.2), action (WLSPLUWB.3), and product (WLSPLUWB.4).

5 Discussions

In this section, we discuss why reading time varies in syntactic and semantic categories.

Anti-locality is the term used to describe the phenomenon in which segments with more dependents in their preceding context have shorter reading times (Konieczny, 2000). This phenomenon was reported for German double objects (Konieczny and Döring, 2003). It was then investigated for Japanese double objects (Uchida et al., 2014). These shortened reading times cannot be explained by the predictions of the working memory models, in which segments with more dependents load for the reading (Gibson, 2008), or in which the number of dependents do not affect the reading time of the succeeding segments.

This phenomenon is compatible with surprisal theory (Hale, 2001; Levy and Gibson, 2013). It explains how double objects of head final languages, in which the predicate has both a direct and an indirect object tend to have shorter reading times than one that has only a direct object. Asahara et al. (2016) investigated the *anti-locality* phenomenon in more general settings with the dependency from BCCWJ-DepPara (Asahara and Matsumoto, 2016). The results show that the segment with higher dependency has a shorter reading time than a segment with a lower dependency.

In this research, the reading time tends to be shorter in the order of Noun (体, WLSPLUWA1) > Adjective/Adverb (相, WLSPLUWA3) > Verb (用, WLSPLUWA2) in the syntactic categories. The noun (WLSPLUWA1) tends to indicate the object and to become the argument of a predicate such as a verb or an adjective. Although the noun can also become a predicate with a copula verb, the modifier or argument for the noun is limited. The category (WLSPLUWA3) includes a predicative adjective with arguments. The verb (WLSPLUWA2) tends to be a predicate with arguments at the clause end. The tendency is reliable because the standard errors of the coefficients are very small. Though we included dependency as a fixed factor, we observed these tendencies for the reading time, in which the syntactic category with more argument tends to have a shorter reading time than the others. It indicates that arguments of a predicate in Japanese tend not to be overtly appearing in the context. The omitted arguments may help predict the upcoming predicate, although the ar-

guments tend to be omitted in the context. Therefore, the results do not support the working memory model, in which the load to memorize the preceding contexts interferes with the reading. The prediction model is a more plausible hypothesis than the working memory model.

In the semantic category, the abstract relation has a shorter reading time than others. The relation has at least two arguments. The existence of the arguments helps to promote the reading time.

6 Conclusions

This article explores the correlation between reading time and the syntactic/semantic category of the text. The reading time tends to be shorter in the order of Noun (1) > Adjective/Adverb (3) > Verb (2) in the syntactic categories. The relation (WLSPLUWB.1) tends to be the shortest in the semantic categories. The results show that the *bunsetsu* with arguments tend to have shorter reading times than the ones without arguments. This fact supports the *anti-locality* (Konieczny and Döring, 2003) and Hale’s surprisal theory (Hale, 2001).

Our current work comprises two analyses. The first one is a contrastive analysis between reading time and information structure annotation. We overlaid the annotation of information structures (Miyachi et al., 2017) on the reading time data. The result showed that reading time can reveal the difference in whether the target nominal phrase is hearer-new or bridging (Asahara, 2017). The second one is contrastive analysis between reading time and the clause boundary category annotation. The result shows that the clause end segments tend to have shorter reading times. Furthermore, the reading time of clause boundaries vary according to the classification of the clauses.

In our future work, we plan to introduce Bayesian linear mixed model (Sorensen et al., 2016) for the statistical modelling. We also hope to investigate the correlation between reading time and word familiarity rate. Word familiarity rate is the fundamental data to estimate Japanese language vocabulary evaluation test (Amano and Kondo, 1998). However, word-familiarity-rate data were constructed around 20 years ago. We now plan to reconstruct word-familiarity-rate data on WLSPL entries by crowd sourcing using a Bayesian linear mixed model.

Abstract

We revisit the idea of mining Wikipedia in order to generate named-entity annotations. We propose a new methodology that we applied to the English Wikipedia to build WiNER, a large, high quality, annotated corpus. We evaluate its usefulness on 6 NER tasks, comparing 4 popular state-of-the-art approaches. We show that LSTM-CRF is the approach that benefits the most from our corpus. We report impressive gains with this model when using a small portion of WiNER on top of the CONLL training material. Last, we propose a simple but efficient method for exploiting the full range of WiNER, leading to further improvements.

1 Introduction

Named-Entity Recognition (NER) is the task of identifying textual mentions and classifying them into a predefined set of types. It is an important pre-processing step in NLP and Information Extraction. Various approaches have been proposed to tackle the task, including conditional random fields (Finkel et al., 2005), perceptrons (Ratinov and Roth, 2009), and neural network approaches (Collobert et al., 2011; Lample et al., 2016; Chiu and Nichols, 2016).

One issue with NER is the small amount of annotated data available for training, and their limited scope (see Section 4.1). Furthermore, some studies (Onal and Karagoz, 2015; Augenstein et al., 2017) have demonstrated that named-entity systems trained on news-wire data perform poorly when tested on other text genres. This motivated some researchers to create a named-entity labelled corpus from Wikipedia. This was notably attempted by Nothman et al. (2008) and more re-

cently revisited by Al-Rfou et al. (2015) in a multilingual context. Both studies leverage the link structure of Wikipedia to generate named-entity annotations. Because only a tiny portion of texts in Wikipedia are anchored, some strategies are typically needed to infer more annotations (Ghaddar and Langlais, 2016b). Such a process typically yields a noisy corpus for which filtering is required.

In this paper, we revisit the idea of automatically extracting named-entity annotations out of Wikipedia. Similarly to the aforementioned works, we gather anchored strings in a page as well as their type according to Freebase (Bollacker et al., 2008) but, more importantly, we also generate annotations for texts not anchored in Wikipedia. We do this by considering coreference mentions of anchored strings as candidate annotations, and by exploiting the out-link structure of Wikipedia. We applied our methodology on a 2013 English Wikipedia dump, leading to a large annotated corpus called WiNER, which contains more annotations than similar corpora and, as we shall see, is more useful for training NER systems.

We discuss related work in Section 2 and present the methodology we used to automatically extract annotations from Wikipedia in Section 3. The remainder of the article describes the experiment we conducted to measure the impact of WiNER for training NER systems. We describe the datasets and the different NER systems we trained in Section 4. We report the experiments we conducted in Section 5. We propose a simple but efficient two stage strategy we designed in order to benefit the full WiNER corpus in Section 6. We report error analysis in Section 7 and conclude in Section 8.

2 Related Work

Turning Wikipedia into a corpus of named entities annotated with types is a task that received some attention in a monolingual setting (Toral and Munoz, 2006; Nothman et al., 2008), as well as in a multilingual one (Richman and Schone, 2004; Al-Rfou et al., 2015).

In (Nothman et al., 2008) the authors describe an approach that exploits links between articles in Wikipedia in order to detect entity mentions. They describe a pipeline able to detect their types (ORG, PER, LOC, MISC), making use of hand-crafted rules specific to Wikipedia, and a bootstrapping approach for identifying a subset of Wikipedia articles where the type of the entity can be predicted with confidence. Since anchored strings in Wikipedia lack coverage (in part because Wikipedia rules recommend that only the first mention of a given concept be anchored in a page), the authors also describe heuristics based on redirects to identify more named-entity mentions. They tested several variants of their corpus on three NER benchmarks and showed that systems trained on Wikipedia data may perform better than domain-specific systems in an out-domain setting.

Al-Rfou et al. (2015), follow a similar path albeit in a multilingual setting. They use Freebase to identify categories (PER, LOC, ORG), and trained a neural network on the annotations extracted. In order to deal with non-anchored mentions in Wikipedia, they propose a first-order coreference resolution algorithm where they link mentions in a text using exact string matching (thus *Obama* will be linked to the concept *Barack Obama* and labelled PER). They still had to perform some sentence selection, based on an oversampling strategy, in order to construct a subset of the original training data.

Our work revisits the idea developed in these two studies. Our main contribution consists in dealing specifically with non anchored strings in Wikipedia pages. We do this by analyzing the out-link structure in Wikipedia, coupled to the information of all the surface forms that have been used in a Wikipedia article to mention the main concept being described by this article. This process, detailed in the next section, leads to a much larger set of annotations, whose quality obviates the need for ad-hoc filtering or oversampling strategies.

3 WiNER

We applied the pipeline described hereafter to a dump of English Wikipedia from 2013, and obtained WiNER, a resource built out of 3.2M Wikipedia articles, comprising more than 1.3G tokens accounting for 54M sentences, 41M of which contain at least one named-entity annotation. We generated a total of 106M annotations (an average of 2 entities per sentence).

3.1 Annotation Pipeline

The pipeline used to extract named-entity annotations from Wikipedia is illustrated in Figure 1, for an excerpt of the Wikipedia article *Chilly_Gonzales*, hereafter named the target article. Similarly to (Nothman et al., 2008; Al-Rfou et al., 2015), the anchored strings of out-links in the target article are elected mentions of named entities. For instance, we identify *Warner Bros. Records* and *Paris* as mentions in our target article. In general, a Wikipedia article has an equivalent page in Freebase. We remove mentions that do not have such a page. This way, we filter out anchored strings that are not named entities (such as *List of Presidents of the United States*). We associate a category with each mention by a simple strategy, similar to (Al-Rfou et al., 2015), which consists in mapping Freebase attributes to entity types. For instance, we map *organization/organization*, *location/location* and *people/person* attributes to ORG, LOC and PER, respectively. If an entry does not belong to any of the previous classes, we tag it as MISC.

Because the number of anchored strings in Wikipedia is rather small — less than 3% of the text tokens according to (Al-Rfou et al., 2015) — we propose to leverage: (1) the out-link structure of Wikipedia, (2) the information of all the surface strings used to describe the main concept of a Wikipedia article. For the latter, we rely on the resource¹ described in (Ghaddar and Langlais, 2016a) that lists, for all the articles in Wikipedia (those that have a Freebase counterpart), all the text mentions that are corefering to the main concept of an article. For instance, for the article *Chilly_Gonzales*, the resource lists proper names (e.g. Gonzales, Beck), nominal (e.g. the per-

¹<http://rali.iro.umontreal.ca/rali/en/wikipedia-main-concept>

[Chilly Gonzales]_{PER} (born [Jason Charles Beck]_{PER}; 20 March 1972) is a [Canadian]_{MISC} musician who resided in [Paris]_{LOC}, [France]_{LOC} for several years, and now lives in [Cologne]_{LOC}, [Germany]_{LOC}. Though best known for his first MC [...], he is a pianist, producer, and songwriter. He was signed to a three-album deal with Warner Music Canada in 1995, a subsidiary of [Warner Bros. Records]_{ORG} ... While the album's production values were limited [Warner Bros.]_{ORG} simply ...

France _{LOC}	CT
↪ French Republic, Kingdom. ...	

Figure 1: Illustration of the process with which we gather annotations into WiNER for the target page https://en.wikipedia.org/wiki/Chilly_Gonzales. Bracketed segments are the annotations, underlined text are anchored strings in the corresponding Wikipedia page. OLT represents the out-link table (which is compiled from the Wikipedia out-link graph structure), and CT represents the coreference table we gathered from the resource.

former) and pronominal (e.g. he) mentions that refer to Chilly Gonzales. From this resource, we consider proper name mentions, along with their Freebase type.

Our strategy for collecting extra annotations is a 3-step process, where:

1. We consider direct out-links of the target article. We search in its text the titles of the articles we reach that way. We also search for their coreferences as listed in the aforementioned resource. For instance, we search (exact match) *Warner Bros. Records* and its coreferences (e.g. *Warner*, *Warner Bros.*) in the target article. Each match is labelled with the type associated (in Freebase) with the out-linked article (in our example, *ORG*).
2. We follow out-links of out-links, and search in the target article (by an exact string match) the titles of the articles reached. For instance, we search for the strings *Europe*, *France*, *Napoleon*, as well as other article titles from the out-link list of the article *Paris*. The matched strings are elected named entities and are labeled with their Freebase type.
3. For the titles matched at step 2, we also match their coreferent mentions. For instance, because we matched *France*, we also search its coreferences as listed in the coreference table (*CT*).

During this process, some collisions may occur. We solve the issue of overlapping annotations by applying the steps exactly in the order presented above. Our steps have been ordered in such a

way that the earlier the step, the more confidence we have in the strings matched at that step. It may also happen that two out-link articles contain the same mention (for instance *Washington State* and *George Washington* both contain the mention *Washington*), in which case we annotate this ambiguous mention with the type of the closest² unambiguous mention.

Step 1 of our pipeline raises the coverage³ from less than 3% to 9.5%, while step 2 and 3 increase it to 11.3% and 15% respectively. This is actually very close to the coverage of the manually annotated CONLL-2003 dataset, which is 17%. Considering that we do not apply any specific filtering, as is done for instance in (Nothman et al., 2008), our corpus contains many more annotations than existing Wikipedia-based named-entity annotated corpora.

3.2 Manual Evaluation

We assessed the annotation quality of a random subset of 1000 mentions. While we measure an accuracy of 92% for mentions detected during step 1, the accuracy decreases to 88% and 77% during step 2 and 3 respectively. We identified two main sources for errors in the coreferent mentions detection procedure. One source of error comes from the resource used to identify the mentions of the main concept. We measured in a previous work (Ghaddar and Langlais, 2016a), that the process we rely on for this (a binary classifier) has an accuracy of 89%. Example (a) of Figure 2 illus-

²Before or after the named-entity.

³Ratio of annotated tokens.

trates such a mistake where the family name *Pope* is wrongly assumed coreferent to the brewery *Eldridge Pope*. We also found that our 3-step process and the disambiguation rule fails in 15% of the cases. Figure 2 illustrates an example where we erroneously recognize the mention *Toronto* (referring to the town) as a coreferent of the (non ambiguous mention) *Toronto FC*, simply because the latter is close to the former.

- a) [*Eldridge Pope*]_{ORG} was a traditional brewery.....Sixteen years later the [*Pope*]_{ORG*} brothers floated the business...
- b) Montreal Impact’s biggest rival is [*Toronto FC*]_{ORG} because Canada’s two largest cities have rivalries in and out of sport. Montreal and [*Toronto*]_{ORG*} professional soccer teams have competed against each other for over 40 years.
- c) I didn’t want to open up my [*Rolodex*]_{ORG*} and get everyone to sing for me.

Figure 2: Examples of errors in our annotation pipeline. Faulty annotations are marked with a star.

Table 1 shows the counts of token strings annotated with at least two types. For instance, there are 230k entities that are annotated in WiNER as PER and LOC. It is reassuring that different mentions with the same string are labelled differently. The cells on the diagonal indicate the number of mentions labelled with a given tag.

	PER	LOC	ORG	MISC
PER	28M	230k	80k	250k
LOC	-	29M	120k	190k
ORG	-	-	13M	206k
MISC	-	-	-	36M

Table 1: Number of times a text string (mention) is labelled with (at least) two types in WiNER. The cells on the diagonal indicate the number of annotations.

We further examined a random subset of 100 strings that were annotated differently (in different contexts) and found that 89% of the time, the correct type was identified. For instance, in example Figure 2c) — a sentence of the *Chilly_Gonzales* article — the mention *Rolodex* is labelled as ORG,

while the correct type is MISC. Our pipeline fails to disambiguate the company from its product.

4 Protocol

4.1 Data Sets

We used a number of datasets in our experiments. For CONLL, MUC and ONTO, that are often used to benchmark NER, we used the test sets distributed in official splits. For the other test sets, that are typically smaller, we used the full dataset as a test material.

CONLL the CONLL-2003 NER Shared Task dataset (Tjong Kim Sang and De Meulder, 2003) is a well known collection of Reuters newswire articles that contains a large portion of sports news. It is annotated with four entity types (PER, LOC, ORG and MISC).

MUC the MUC-6 (Chinchor and Sundheim, 2003) dataset consists of newswire articles from the Wall Street Journal annotated with PER, LOC, ORG, as well as a number of temporal and numerical entities that we excluded from our evaluation for the sake of homogeneity.

ONTO the OntoNotes 5.0 dataset (Pradhan et al., 2012) includes texts from five different text genres: broadcast conversation (200k), broadcast news (200k), magazine (120k), newswire (625k), and web data (300k). This dataset is annotated with 18 fine grained NE categories. Following (Nothman, 2008), we applied the procedure for mapping annotations to the CONLL tag set. We used the CONLL 2012 (Pradhan et al., 2013) standard test set for evaluation.

WGOLD WikiGold (Balasuriya et al., 2009) is a set of Wikipedia articles (40k tokens) manually annotated with CONLL-2003 NE classes. The articles were randomly selected from a 2008 English dump and cover a number of topics.

WEB Ratnov and Roth (2009) annotated 20 web pages (8k tokens) on different topics with the CONLL-2003 tag set.

TWEET Ritter et al. (2011) annotated 2400 tweets (comprising 34k tokens) with 10 named-entity classes, which we mapped to the CONLL-2003 NE classes.

4.2 Metrics

Since we use many test sets in this work, we are confronted with a number of inconsistencies. One is the definition of the MISC class, which differs from a dataset to another, in addition to not being annotated in MUC. This led us to report token-level F1 score for 3 classes only (LOC, ORG and PER). We computed this metric with the `conlleval` script.⁴

We further report OD_{F1} , a score that measures how well a named-entity recognizer performs on out-domain material. We compute it by randomly sampling 500 sentences⁵ for each out-domain test set, on which we measure the token-level F1. Sampling the same number of sentences per test set allows to weight each corpus equally. This process is repeated 10 times, and we report the average over those 10 folds. On average, the newly assembled test set contains 50k tokens and roughly 3.5k entity mentions. We excluded the CONLL-2003 test set from the computation since this corpus is in-domain⁶ (see section 5.2).

4.3 Reference systems

We chose two feature-based models: the StanfordNER (Finkel et al., 2005) CRF classifier, and the perceptron-based Illinois NE Tagger (Ratinov and Roth, 2009). Those systems have been shown to yield good performance overall. Both systems use handcrafted features; the latter includes gazetteer features as well.

We also deployed two neural network systems: the one of (Collobert et al., 2011), as implemented by Attardi (2015), and the LSTM-CRF system of Lample et al. (2016). Both systems capitalize on representations learnt from large quantities of unlabeled text⁷. We use the default configuration for each system.

5 Evaluation of WiNER

5.1 Other Wikipedia-based corpora

We compare WiNER to existing Wikipedia-based annotated corpora. Nothman et al. (2008) released two versions of their corpus, WP2 and WP3, each containing 3.5 million tokens. Both

⁴<http://www.cnts.ua.ac.be/conll2000/chunking/conlleval.txt>

⁵The smallest test set has 617 sentences.

⁶Figures including this test set do not change drastically from what we observe hereafter.

⁷We use the pre-trained representations.

versions enrich the annotations deduced from anchored strings in Wikipedia by identifying coreferences among NE mentions. They differ by the rules used to conduct coreference resolution. We randomly generated 10 equally-sized subsets of WiNER (of 3.5 million tokens each). On each subset, we trained the Illinois NER tagger and compared the performances obtained on the CONLL test set by the resulting models, compared to those trained on WP2 and WP3. Phrase-level F1 score are reported in Table 2. We also report the results published in (Al-Rfou et al., 2015) with the Polyglot corpus, which is unfortunately not available.

	with MISC	w/o MISC
WP2	68.2	72.8
WP3	68.3	72.9
Polyglot	-	71.3
WiNER	71.2 [70.3,71.6]	74.5 [73.4,75.2]

Table 2: Performance of the Illinois toolkit on CONLL, as a function of the Wikipedia-based training material used. The figures on the last line are averaged over the 10 subsets of WiNER we randomly sampled. Bracketed figures indicate the minimum and maximum values.

Using WiNER as a source of annotations systematically leads to better performance, which validates the approach we described in Section 3. Note that in order to generate WP2 and WP3, the authors applied filtering rules that are responsible for the loss of 60% of the annotations. Al-Rfou et al. (2015) also perform sentence selection. We have no such heuristics here, but we still observe a competitive performance. This is a satisfactory result considering that WiNER is much larger.

5.2 Cross-domain evaluation

In this experiment, we conduct a cross-domain evaluation of the reference systems described in Section 4.3 on the six different test sets presented in Section 4.1. Following a common trend in the field, we evaluate the performance of those systems when they are trained on the CONLL material. We also consider systems trained on CONLL plus a subset of WiNER. We report results obtained with a subset of randomly chosen sentences summing up to 3 million tokens, as well as a variant where we use as much as possible of the training material available in WiNER. Larger datasets

Table 3: Cross-domain evaluation of NER systems trained on different mixes of CONLL and WiNER. Figures are token-level F1 score on 3 classes, while figures in parentheses indicate absolute gains over the configuration using only the CONLL training material. Bold figures highlight column-wise best results.

were created by randomly appending material to smaller ones. Datasets were chosen once (no cross-validation, as that would have required too much time for some models). Moreover, for the comparison to be meaningful, each model was trained on the same 3M dataset. The results are reported in Table 3.

First, we observe the best overall performance with the LSTM-CRF system (73% OD_{F1}), the second best system being a variant of the `Illinois` system (69.5% OD_{F1}). We also observe that the former system is the one that benefits the most from WiNER (an absolute gain of 8% in OD_{F1}). This may be attributed to the fact that this model can explore the context on both sides of a word with (at least in theory) no limit on the context size considered. Still, it is outperformed by the `Illinois` system on the `WEB` and the `TWEET` test sets. Arguably, those two test sets have a NE distribution which differs greatly from the training material.

Second, on the `CONLL` setting, our results are satisfyingly similar to those reported in (Ratinov and Roth, 2009) and (Lample et al., 2016). The former reports 91.06 phrasal-level F1 score on 4 classes, while our score is 90.8. The latter reports an F1 score of 90.94 while we have 90.76. The best results reported far on the `CONLL` setting are those of (Chiu and Nichols, 2016) with a BiLSTM-CNN model, and a phrasal-level F1 score of 91.62 on 4 classes. So while the models

we tested are slightly behind on `CONLL`, they definitely are competitive. For other tasks, the comparison with other studies is difficult since the performance is typically reported with the full tagset.

Third, the best performances are obtained by configurations that use WiNER, with the exception of `CONLL`. That this does not carry over to `CONLL` confirms the observations made by several authors (Finkel et al., 2005; Al-Rfou et al., 2015), who highlight the specificity of `CONLL`'s annotation guidelines as well as the very nature of the annotated text, where sport teams are overrepresented. These teams add to the confusion because they are often referred to with a city name. We observe that, on `CONLL`, the `LSTM-CRF` model is the one that registers the lowest drop in performance. The drop is also modest for the `CRF` model. The WiNER's impact is particularly observable on `TWEET` (an absolute gain of 8.8 points) and `WEB` (a gain of 5.5), again two very different test sets. This suggests that WiNER helps models to generalize.

Last, we observe that systems differ in their ability to exploit large training sets. For the two feature-based models we tested, the bottleneck is memory. We did train models with less features, but with a significantly lower performance. With the `CRF` model, we could only digest a subset of WiNER of 1 million tokens, while `Illinois` could handle 30 times more. As far as neural network systems are concerned, the is-

sue is training time. On the computer we used for this work — a Linux cluster equipped with a GPU — training Senna and LSTM-CRF required over a month each for 7 and 5 millions WiNER tokens respectively. This prevents us from measuring the benefit of the complete WiNER resource.

6 Scaling up to WiNER

6.1 Our 2-stage approach

Because we were not able to employ the full WiNER corpus with the NER systems mentioned above, we resorted to a simple method to leverage all the annotations available in the corpus. It consists in decoupling the segmentation of NEs in a sentence — we leave this to a reference NER system — from their labelling, for which we train a local classifier based on contextual features computed from WiNER. Decoupling the two decision processes is not exactly satisfying, but allows us to scale very efficiently to the full size of WiNER, our main motivation here.

6.1.1 Contextual representations

Our classifier exploits a small number of features computed from two representations of WiNER. In one of them, each named-entity is bounded by a beginning and end token tags — both encoding its type — as illustrated on line MIX of Figure 3. In the second representation, the words of the named-entity are replaced with its type, as illustrated on line CONT. The former representation encodes information from both the context and the the words of the segment we wish to label while the second one only encodes the context of a segment.

WiNER [Gonzales]_{PER} will be featured on [Daft Punk]_{MISC} .

MIX ⟨B-PER⟩ Gonzales ⟨L-PER⟩ will be featured on ⟨B-MISC⟩ Daft Punk ⟨L-MISC⟩

CONT ⟨PER⟩ will be featured on ⟨MISC⟩ .

Figure 3: Two representations of WiNER’s annotation used for feature extraction.

With each representation, we train a 6-gram backoff language model using kenLM (Heafield et al., 2013). For the MIX one, we also train word embeddings of dimension 50 using Glove (Pennington et al., 2014).⁸ Thus, we have the embed-

⁸We used a window size of 5 in this work.

dings of plain words, as well as those of token tags. The language and embedding models are used to provide features to our classifier.

6.1.2 Features

Given a sentence and its hypothesized segmentation into named-entities (as provided by another NER system), we compute with the Viterbi algorithm the sequence of token tags that leads to the smallest perplexity according to each language model. Given this sequence, we modify the tagging of each segment in turn, leading to a total of 4 perplexity values per segment and per language model. We normalize those perplexity values so as to interpret them as probabilities. Table 4 shows the probability given by both language models to the segment *Gonzales* of the sentence of our running example. We observe that both models agree that the segment should be labelled PER. We also generate features thanks to the embedding model. This time, however, this is done without considering the context: we represent a segment as the sum of the representation of its words. We then compute the cosine similarity between this segment representation and that of each of the 4 possible tag pairs (the sum of the representation of the begin and end tags); leading to 4 similarity scores per segment. Those similarities are reported on line EMB in Table 4.

	LOC	MISC	ORG	PER
CONT	0.11	0.35	0.06	0.48
MIX	0.26	0.19	0.18	0.37
EMB	0.39	0.23	0.258	0.46

Table 4: Features for the segment *Gonzales* in the sentence *Gonzales will be featured on Daft Punk*.

To these 4 scores provided by each model, we add 16 binary features that encode the rank of each token tag according to one model (does ⟨tag⟩ have rank ⟨i⟩ ?). We also compute the score difference given by a model to any two possible tag pairs, leading to 6 more scores. Since we have 3 models, we end up with 78 features.

6.1.3 Training

We use scikit-learn (Pedregosa et al., 2011) to train a Random Forest classifier⁹ on the 29k mentions of the CONLL training data. We

⁹We tried other algorithms provided by the platform with less success.

adopted this training material to ensure a fair comparison with other systems that are typically trained on this dataset. Another possibility would be to split WiNER into two parts, one for computing features, and the other for training the classifier. We leave this investigation as future work. Because of the small feature set we have, training such a classifier is very fast.

6.2 Results

We measure the usefulness of the complete WiNER resource by varying the size of the training material of both language models and word embeddings, from 5M tokens (the maximum size the LSTM-CRF mode could process) to the full WiNER resource size.

	CO	ON	MU	TW	WE	WG	OD _{F1}
5M	84.3	72.0	78.7	39.8	61.9	70.2	68.1
50M	86.8	75.6	82.3	44.9	64.7	73.8	71.7
500M	88.9	76.2	84.8	45.8	66.6	75.5	74.1
All	90.5	76.9	85.9	46.6	65.3	77.0	74.7

Table 5: Influence of the portion of WiNER used in our 2-stage approach for the CONLL test set, using the segmentation produced by LSTM-CRF+WiNER(5M). These results have to be contrasted with the last line of Table 3.

To this end, we provide the performance of our 2-stage approach on CONLL, using the segmentation output by LSTM-CRF+WiNER(5M)¹⁰. Results are reported in Table 5. As expected, we observe that computing features on the same WiNER(5M) dataset exploited by LSTM-CRF leads to a notable loss overall (OD_{F1} of 68.1 versus 73.0), while still outperforming LSTM-CRF trained on CONLL only (OD_{F1} of 65.0). More interestingly, we observe that for all test sets, using more of WiNER leads to better performance, even if a plateau effect emerges. Our approach does improve systematically across all test sets by considering 100 times more WiNER data than what LSTM-CRF can handle in our case. Using all of WiNER leads to an OD_{F1} score of 74.7, an increase of 1.7 absolute points over LSTM-CRF+WiNER(5M).

Table 6 reports the improvements in OD_{F1} of our 2-stage approach (RF), which uses all of

¹⁰The best configuration according to Table 3.

	Native	RF
CRF		
CONLL	67.0	73.6 (+6.6)
+WiNER(3M)	-	-
+WiNER(1M)	69.2	73.0 (+2.8)
Illinois		
CONLL	68.3	74.4 (+6.1)
+WiNER(3M)	69.5	74.2 (+4.7)
+WiNER(30M)	69.0	74.3 (+4.3)
Senna		
CONLL	64.3	70.1 (+5.8)
+WiNER(3M)	67.0	70.8 (+3.8)
+WiNER(7M)	66.2	72.0 (+5.8)
LSTM-CRF		
CONLL	65.0	69.7 (+4.7)
+WiNER(3M)	72.0	74.8 (+2.8)
+WiNER(5M)	73.0	74.7 (+1.7)

Table 6: OD_{F1} score of native configurations, and of our two-stage approach (RF) which exploits the full WiNER corpus. Figures in parenthesis indicate absolute gains over the native configuration.

the WiNER material and the segmentation produced by several native systems. Applying our 2-stage approach systematically improves the performance of the native configuration. Gains are larger for native configurations that cannot exploit a large quantity of WiNER. We also observe that the 2-stage approach delivers roughly the same level of performance (OD_{F1} \simeq 74) when using the segmentation produced by the Illinois or the LSTM-CRF systems.

7 Error Analysis

Table 7 indicates the number of disagreements between the LSTM-CRF+WiNER(5M) system (columns) and the 2-stage approach (rows). The table also shows the percentage of times the latter system was correct. For instance, the bottom left cell indicates that, on 38 distinct occasions, the classifier changed the tag PER proposed by the native system to ORG and that it was right in 85% of these occasions. We exclude errors made by both systems, which explains the low counts observed (1.7% is the absolute difference between the two approaches).

We observe that in most cases the classifier makes the right decision when an entity tag is changed from PER to either LOC or ORG (86% and

	PER	LOC	ORG
PER	-	50% [12]	25% [12]
LOC	86% [20]	-	21% [28]
ORG	85% [38]	81% [19]	-

Table 7: Percentage of correctness of the 2-stage system (rows) when tagging a named-entity differently than the LSTM-CRF+WiNER(5M) (columns). Bracketed figures indicate the average number of differences over the out-domain test sets.

85% respectively). Most often, re-classified entities are ambiguous ones. Our approach chooses correctly mostly by examining the context of the mention. For instance, the entity *Olin* in example (a) of Figure 4 is commonly known as a last name. It was correctly re-classified as ORG thanks to its surrounding context. Replacing *its* by *his* in the sentence makes the classifier tag the entity as PER. Similarly, the entity *Piedmont* in example (b) was re-classified as ORG, although it is mostly used as the region name (even in Wikipedia), thanks to the context-based CONT and MIX features that identify the entity as ORG (0.61 and 0.63 respectively).

- (a) ... would give [Olin]_{PER→ORG} access to its production processes ...
- (b) Wall Street traders said [Piedmont]_{LOC→ORG} shares fell partly ...
- (c) ★ ... performed as a tenor at New York City 's [Carnegie Hall]_{ORG→LOC}.

Figure 4: Example of entities re-classified by our 2-stage approach.

Misclassification errors do occur, especially when the native system tagged an entity as ORG. In such cases, the classifier is often misled by a strong signal emerging from one family of features. For instance, in example (c) of Figure 4, both MIX — $p(\text{ORG}) = 0.39$ vs. $p(\text{LOC}) = 0.33$ — and EMB — $p(\text{ORG}) = 0.39$ vs. $p(\text{LOC}) = 0.38$ — features are suggesting that the entity should be tagged as LOC, but the CONT signal — $p(\text{LOC}) = 0.63$ vs. $p(\text{ORG}) = 0.1$ — strongly impacts the final decision. This was to be expected considering the simplicity of our classifier, and leaves room for further improvements.

8 Conclusion and Future Work

We revisited the task of using Wikipedia for generating annotated data suitable for training NER systems. We significantly extended the number of annotations of non anchored strings, thanks to coreference information and an analysis of the Wikipedia's link structure. We applied our approach to a dump of English Wikipedia from 2013, leading to WiNER, a corpus which surpasses other similar corpora, both in terms of quantity and of annotation quality. We evaluated the impact of our corpus on 4 reference NER systems with 6 different NER benchmarks. The LSTM-CRF system of (Lample et al., 2016) seems to be the one that benefits the most from WiNER overall. Still, shortage of memory or lengthy training times prevent us from measuring the full potential of our corpus. Thus, we proposed an entity-type classifier that exploits a set of features computed over an arbitrary large part of WiNER. Using this classifier for labelling the types of segments identified by a reference NER system yields a 2-stage process that further improves overall performance. WiNER and the classifier we trained are available at <http://rali.iro.umontreal.ca/rali/en/winer-wikipedia-for-ner>. As future work, we want to study the usefulness of WiNER on a fine-grained entity type task, possibly revisiting the simple classifier we resorted to in this work, and testing its benefits for other currently successful models.

Abstract

Acoustic emotion recognition aims to categorize the affective state of the speaker and is still a difficult task for machine learning models. The difficulties come from the scarcity of training data, general subjectivity in emotion perception resulting in low annotator agreement, and the uncertainty about which features are the most relevant and robust ones for classification. In this paper, we will tackle the latter problem. Inspired by the recent success of transfer learning methods we propose a set of architectures which utilize neural representations inferred by training on large speech databases for the acoustic emotion recognition task. Our experiments on the IEMOCAP dataset show 10% relative improvements in the accuracy and F1-score over the baseline recurrent neural network which is trained end-to-end for emotion recognition.

1 Introduction

Speech emotion recognition (SER) has received growing interest and attention in recent years. Being able to predict the affective state of a person gives valuable information which could improve dialog systems in human-computer interaction. To fully understand a current emotion expressed by a person, also knowledge of the context is required, like facial expressions, the semantics of a spoken text, gestures and body language, and cultural peculiarities. This makes it challenging even for people that have all this information to accurately predict the affective state. In this work, we are focusing solely on inferring the speaker's emotional state by analysing acoustic signals which are also the only source of information in situations when

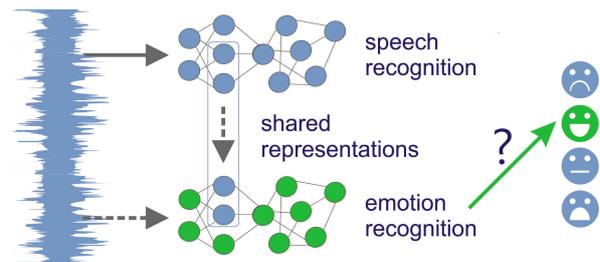

Figure 1: High-level system architecture. Acoustic emotion recognition system uses neural speech representations for affective state classification.

the speaker is not directly observable.

With recent advances in deep learning, which made it possible to train large end-to-end models for image classification (Simonyan and Zisserman, 2014), speech recognition (Hannun et al., 2014) and natural language understanding (Sutskever et al., 2014), the majority of the current work in the area of acoustic emotion recognition is neural network-based. Diverse neural architectures were investigated based on convolutional and recurrent neural networks (Fayek et al., 2017; Trigeorgis et al., 2016). Alternatively, methods based on linear models, like SVM with careful feature engineering, still show competitive performance on the benchmark datasets (Schuller et al., 2013, 2009). Such methods were popular in computer vision until the AlexNet approach (Krizhevsky et al., 2012) made automatic feature learning more wide-spread. The low availability of annotated auditory emotion data is probably one of the main reasons for traditional methods being competitive. The appealing property of neural networks compared to SVM-like methods is their ability to identify automatically useful patterns in the data and to scale linearly with the number of training samples. These properties drive the research community to investigate different neural architectures.

In this paper, we present a model that neither solely learns feature representations from scratch nor uses complex feature engineering but uses the features learned by a speech recognition network.

Even though the automatic speech recognition (ASR) task is agnostic to the speaker’s emotion and focuses only on the accuracy of the language transcription, low-level neural network layers trained for ASR might still extract useful information for the task of SER. Given that the size of the data suitable for training ASR systems is significantly larger than SER data, we can expect that trained ASR systems are more robust to speaker and condition variations. Recently, a method of transferring knowledge learned by the neural network from one task to another has been proposed (Rusu et al., 2016; Anderson et al., 2016). This strategy also potentially prevents a neural network from overfitting to the smaller of the two datasets and could work as an additional regularizer. Moreover, in many applications, such as dialog systems, we would need to transcribe spoken text and identify its emotion jointly.

In this paper, we evaluate several dual architectures which integrate representations of the ASR network: a fine-tuning and a progressive network. The fine-tuning architecture reuses features learnt by the recurrent layers of a speech recognition network and can use them directly for emotion classification by feeding them to a softmax classifier or can add additional hidden SER layers to tune ASR representations. Additionally, the ASR layers can be static for the whole training process or can be updated as well by allowing to backpropagate through them. The progressive architecture complements information from the ASR network with SER representations trained end-to-end. Therefore, in contrast to the fine-tuning model, a progressive network allows learning such low-level emotion-relevant features which the ASR network never learns since they are irrelevant to the speech recognition task. Our contribution in this paper is two-fold: 1) we propose several neural architectures allowing to model speech and emotion recognition jointly, and 2) we present a simple variant of a fine-tuning and a progressive network which improves the performance of the existing end-to-end models.

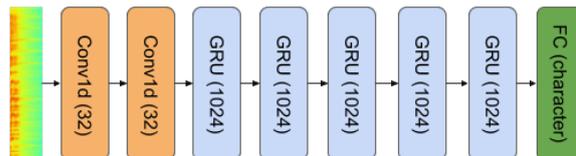

Figure 2: Architecture of the ASR model used in this work, following the DeepSpeech 2 architecture.

2 Related work

The majority of recent research is aimed at searching for optimal neural architectures that learn emotion-specific features from little or not processed data. An autoencoder network (Ghosh et al., 2016) was demonstrated to learn to compress the speech frames before the emotion classification. An attention mechanism (Huang and Narayanan, 2016) was proposed to adjust weights for each of the speech frames depending on their importance. As there are many speech frames that are not relevant to an expressed emotion, such as silence, the attention mechanism allows focusing only on the significant part of the acoustic signal. Another approach probabilistically labeling each speech frame as emotional and non-emotional was proposed by (Chernykh et al., 2017). A combination of convolutional and recurrent neural networks was demonstrated by (Trigeorgis et al., 2016) by training a model directly from the raw, unprocessed waveform, significantly outperforming manual feature engineering methods.

One of the first examples of the knowledge transfer among neural networks was demonstrated by (Bengio, 2012) and (Yosinski et al., 2014). Eventually, fine-tuning became the de-facto standard for computer vision tasks that have a small number of annotated samples, leveraging the ability of trained convolutional filters to be applicable to different tasks. Our work is mainly inspired by recently introduced architectures with an ability to transfer knowledge between recurrent neural networks in a domain different from computer vision (Rusu et al., 2016; Anderson et al., 2016).

Previously, to our knowledge, there was only one attempt to analyze the correlation between automatic speech and emotion recognition (Fayek et al., 2016). This approach showed the possibility of knowledge transfer from the convolutional neural acoustic model trained on the TIMIT corpus (Garofolo et al., 1993) for the emotion recog-

dition task. The authors proposed several variants of fine-tuning. They reported a significant drop in the performance by using the ASR network as a feature extractor and training only the output softmax layer, compared to an end-to-end convolution neural network model. Gradual improvements were observed by allowing more ASR layers to be updated during back-propagation but, overall, using ASR for feature extraction affected the performance negatively.

3 Models and experiment setup

3.1 Models

We introduce two models that use a pre-trained ASR network for acoustic emotion recognition. The first one is the fine-tuning model which only takes representations of the ASR network and learns how to combine them to predict an emotion category. We compare two variants of tuning ASR representations: simply feeding them into a softmax classifier or adding a new Gated Recurrent Units (GRU) layer trained on top of the ASR features. The second is the progressive network which allows us to train a neural network branch parallel to the ASR network which can capture additional emotion-specific information. We present all SER models used in this work in Figure 3.

3.1.1 ASR model

Our ASR model (see Figure 2) is a combination of convolutional and recurrent layers inspired by the DeepSpeech (Hannun et al., 2014) architecture for speech recognition. Our model contains two convolutional layers for feature extraction from power FFT spectrograms, followed by five recurrent bi-directional GRU layers with the softmax layer on top, predicting the character distribution for each speech frame (ASR network in all our experiments, left branch of the network in the Figures 3b, 3c and 3d). The ASR network is trained on pairs of utterances and the corresponding transcribed texts (see 3.2.2 “Speech data“ section for details). Connectionist Temporal classification (CTC) loss (Graves et al., 2006) was used as a metric to measure how good the alignment produced by the network is compared to the ground truth transcription. Power spectrograms were extracted using a Hamming window of 20ms width and 10 ms stride, resulting in 161 features for each speech frame. We trained the ASR network with Stochastic Gradient Descent with a learning rate of

0.0003 divided by 1.1 after every epoch until the character error rate stopped improving on the validation set (resulting in 35 epochs overall). In all our experiments we keep the ASR network static by freezing its weights during training for SER.

3.1.2 Baseline

As a baseline (see Figure 3a), we used a two-layer bi-directional GRU neural network. Utterances were represented by averaging hidden vector representations obtained on the second GRU layer and fed to a softmax layer for emotion classification. Dropout with the probability of 0.25 was applied to the utterance representation during training to prevent overfitting. We evaluate this architecture as a baseline as it was proven to yield strong results on the acoustic emotion recognition task (Huang and Narayanan, 2016). As there are significantly less emotion-annotated samples available the SER-specific network is limited to two layers compared to the ASR network.

3.1.3 Fine-tuning model

We propose several variants of reusing speech representations: 1) By averaging hidden memory representations of the layer number x of the ASR network (*Fine-tuning MP- x* later in the text where MP stands for *Mean Pooling*), we train only the output softmax layer to predict an emotion class. (2) We feed hidden memory representations as input to a new GRU network (emotion-specific) initialized randomly and trained for emotion classification (*Fine-tuning RNN- x*). The intuition is that bottom layers of the ASR network can be used as feature extractors and the top level GRU can combine them to predict the emotion class. Similar to the *Fine-tuning MP- x* setup we average representations of the newly attached GRU layer and feed them to the classifier. In both experiments, dropout with the rate of 0.25 was applied to averaged representations. Figure 3b shows the *Fine-tuning MP-1* model pooling ASR representation of the first ASR layer, and Figure 3c shows the *Fine-tuning RNN-1* setup.

3.1.4 Progressive neural network

The progressive network combines fine-tuning with end-to-end training. The scheme of the model is presented in Figure 3d. It contains two branches: first, a speech recognition branch (left in Figure 3d and identical to Figure 2) which is static and not updated, and second, an emotion recogni-

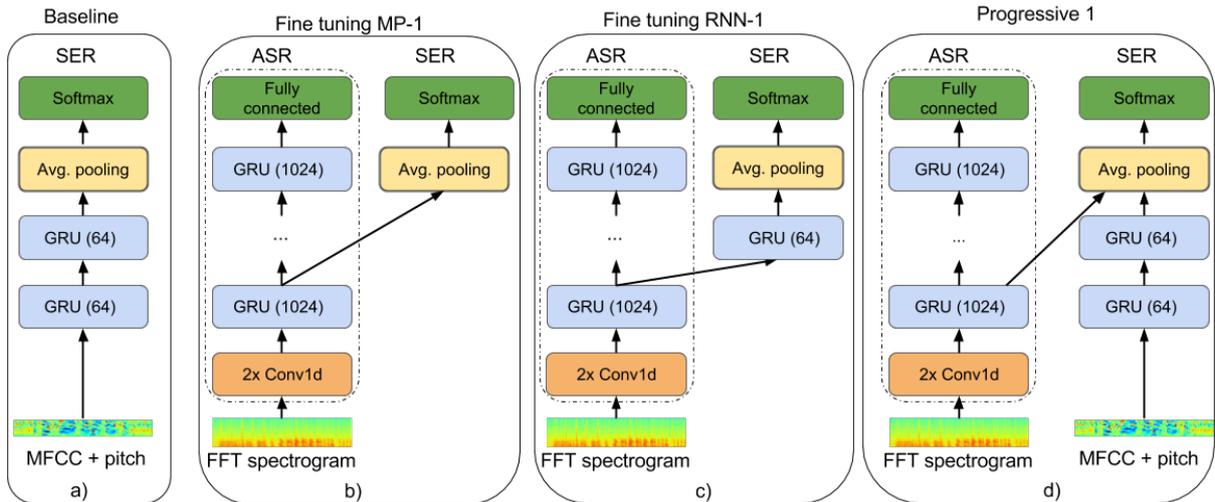

Figure 3: (a) Baseline speech emotion recognition (SER) model, containing two bi-directional GRU layers (b) A variant of the fine-tuning network (Fine-tuning MP-1) which uses the temporal pooled representations of the first recurrent layer of the ASR network. (c) A variant of the fine-tuning network (Fine-tuning RNN-1) which uses hidden memory representations of the first recurrent layer of the ASR network as input to a new emotion-specific GRU layer. (d) The progressive network combines representations from the emotion recognition path with the temporal pooled first layer representations of the ASR network (here Progressive net 1). A concatenated vector is fed into the softmax layer for the final emotion classification. The ASR branch of the network remains static and is not tuned during backpropagation in (b), (c) and (d).

tion branch (right), with the same architecture as the baseline model which we initialized randomly and trained from scratch. We feed the same features to the emotion recognition branch as to the baseline model for a fair comparison. Theoretically, a network of such type can learn task specific features while incorporating knowledge already utilized in the ASR network if it contributes positively to the prediction.

3.2 Data

3.2.1 Emotion data

The Interactive Emotional Dyadic Motion Capture dataset IEMOCAP (Busso et al., 2008) contains five recorded sessions of conversations between two actors, one from each gender. The total amount of data is 12 hours of audio-visual information from ten speakers annotated with categorical emotion labels (Anger, Happiness, Sadness, Neutral, Surprise, Fear, Frustration and Excited), and dimensional labels (values of the activation and valence from 1 to 5). Similarly as in previous work (Huang and Narayanan, 2016), we merged the *Excited* class with *Happiness*. We performed several data filtering steps: we kept samples where at least two annotators agreed on the emotion la-

bel, discarded samples where an utterance was annotated with 3 different emotions and used samples annotated with neutral, angry, happy and sad, resulting in 6,416 samples (1,104 of Anger, 2,496 of Happiness, 1,752 of Neutral and 1,064 of Sadness). We use 4 out of 5 sessions for training and the remaining one for validation and testing (as there are two speakers in the session, one was used for validation and the other for testing).

3.2.2 Speech data

We concatenated three datasets to train the ASR model: LibriSpeech, TED-LIUM v2, and VoxForge. LibriSpeech (Panayotov et al., 2015) contains around 1,000 hours of English-read speech from audiobooks. TED-LIUM v2 (Rousseau et al., 2014) is a dataset composed of transcribed TED talks, containing 200 hours of speech and 1495 speakers. VoxForge is an open-source collection of transcribed recordings collected using crowdsourcing. We downloaded all English recordings¹, which is around 100 hours of speech. Overall, 384,547 utterances containing 1,300 hours of speech from more than 3,000 speakers were used

¹http://www.repository.voxforge1.org/downloads/SpeechCorpus/Trunk/Audio/Original/48kHz_16bit/

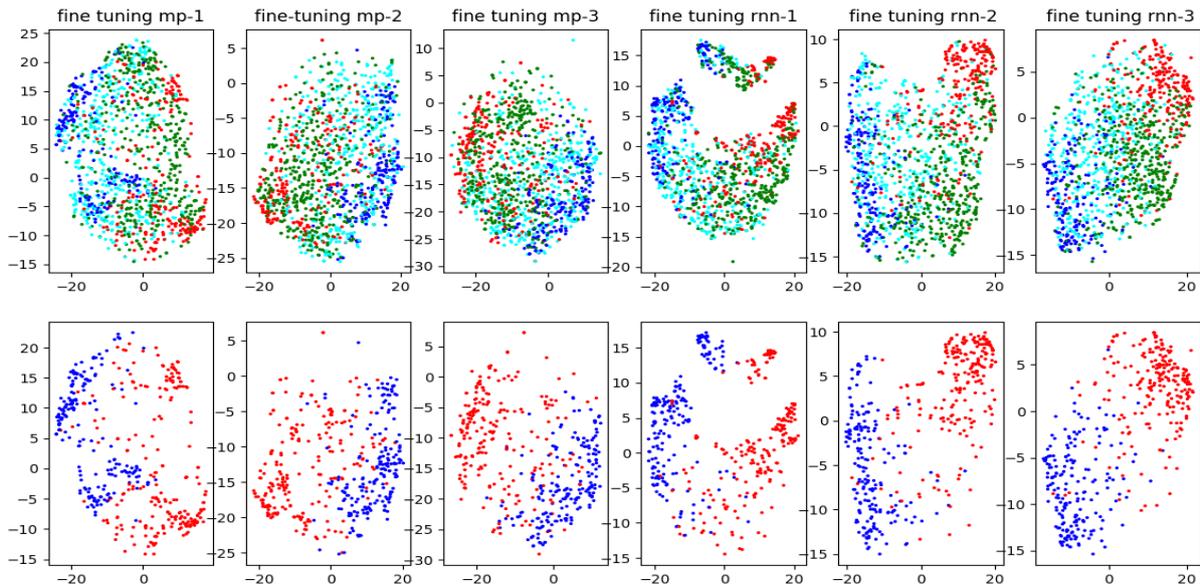

Figure 4: Representations of the IEMOCAP utterances generated by the *Fine-tuning MP- x* and *Fine-tuning RNN- x* networks (x stands for the ASR layer number of which the representation *MP* is used) projected into 2-dimensional space using the t-SNE technique. Top: all four classes, bottom: only *Sadness* and *Anger*. Color mapping: *Anger* - red, *Sadness* - blue, *Neutral* - cyan, *Happiness* - green. We can observe that *Fine-tuning MP-2* and *MP-3* networks can separate *Anger* and *Sadness* classes even though these representations are directly computed from the ASR network without any emotion-specific training. *Fine-tuning RNN* networks benefit from being trained directly for emotion recognition and form visually distinguishable clusters.

to train the ASR model. We conducted no preprocessing other than the conversion of recordings to WAV format with single channel 32-bit format and a sampling rate of 16,000. Utterances longer than 15 seconds were filtered out due to GPU memory constraints.

3.3 Extracted features

The ASR network was trained on power spectrograms with filter banks computed over windows of 20ms width and 10ms stride. For the progressive network, we used the same features as for the ASR branch, and for the SER-specific branch, we used 13 MFCC coefficients and their deltas extracted over windows of 20ms width and 10ms stride. We have extracted pitch values smoothed with moving average with a window size of 15 using the OpenSMILE toolkit (Eyben et al., 2013). The reason for the choice of high-level features like MFCC and pitch for the SER-branch was the limited size of emotion annotated data, as learning efficient emotion representation from low-level features like raw waveform or power-spectrograms might be difficult on the dataset of a size of IEMO-

CAP. In addition, such feature set showed state-of-the-art results (Huang and Narayanan, 2016). In both cases, we normalized each feature by subtracting the mean and dividing by standard deviation per utterance.

3.3.1 Training

The Adam optimizer (Kingma and Ba, 2014) was used in all experiments with a learning rate of 0.0001, clipping the norm of the gradient at the level of 15 with a batch size of 64. During the training, we applied learning rate annealing if the results on the validation set did not improve for two epochs and stopped it when the learning rate reaches the value of $1e-6$. We applied the Sorta-Grad algorithm (Amodei et al., 2015) during the first epoch by sorting utterances by the duration (Hannun et al., 2014). We performed data augmentation during the training phase by randomly changing tempo and gain of the utterance within the range of 0.85 to 1.15 and -3 to +6 dB respectively. The model with the lowest cross-entropy loss on the validation set was picked to evaluate the test set performance.

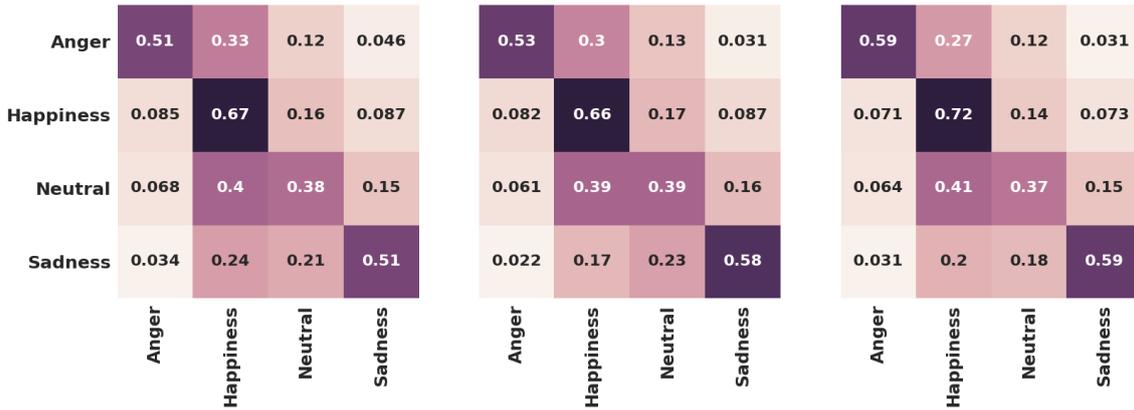

Figure 5: Confusion matrices for our best baseline, *Fine-tuning MP* and *Progressive* models averaged over 10-folds on the IEMOCAP dataset.

Table 1: Utterance-level emotion 4-way classification performance (unweighted and weighted accuracy and f1-score). Several variants of fine-tuning and progressive networks are evaluated: using first, second or third ASR layers as input for Fine-tuning MP, Fine-tuning RNN, and progressive networks.

4 Results

Table 1 summarizes the results obtained from ASR-SER transfer learning. We evaluate several baseline models by varying the number of GRU units in a network, and three variants for *Fine-tuning MP-x*, *Fine-tuning RNN-x* and *Progressive net-x* by utilizing representations of layer x of the ASR network. We report weighted and unweighted accuracy and f1-score to reflect imbalanced classes. These metrics were averaged over ten runs of a ten-fold leave-one-speaker-out cross-validation to monitor an effect of random initialization of a neural network. Also, our results reveal the difficulty of separating *Anger* and *Happiness* classes, and *Neutral* and *Happiness* (see

Figure 5). Our best *Fine-tuning MP-3* model achieved 55% unweighted and 56% weighted accuracy, which significantly outperforms the baseline (p-value ≤ 0.03) end-to-end 2-layer GRU neural network similar to (Huang and Narayanan, 2016) and (Ghosh et al., 2016). The fine-tuning model has around 30 times less trainable parameters (as only the softmax layer is trained) and achieves significantly better performance than the baseline. These results show that putting an additional GRU layer on top of ASR representations affects the performance positively and shows significantly better results than the baseline (p-value ≤ 0.0007). Results prove our hypothesis that intermediate features extracted by the ASR network

contain useful information for emotion classification.

The progressive network consistently outperforms baseline end-to-end models, reaching 58% unweighted and 61% weighted accuracy. In all variants, the addition of the second recurrent layer representations of the ASR’s network contributes positively to the performance compared to the baseline. Our results support the hypothesis that the progressive architecture of the network allows to combine the ASR low-level representations with the SER-specific ones and achieve the best accuracy result.

In addition to the quantitative results, we tried to analyze the reason of such effectiveness of the ASR representations, by visualizing the representations of the utterances by *Fine-tuning MP-x* and *Fine-tuning RNN-x* networks (see Figure 4). We observe that a prior ASR-trained network can separate *Sadness* and *Anger* samples even by pooling representations of the first ASR layer. On the 3rd layer, *Anger*, *Sadness* and *Happiness* form visually distinguishable clusters which could explain the surprising effectiveness of *Fine-tuning MP-2/3* models. *Fine-tuning RNN-x* networks can separate four classes better due to an additional trained GRU network on top of the ASR representations. Also, we found that activations of some neurons in the ASR network correlate significantly with the well-known prosodic features like loudness. Figure 6 shows the activation of the neuron number 840 of the second GRU layer of the ASR network and the loudness value of the speech frame for two audio files. We found that, on average, the Pearson’s correlation between loudness and activation of the 840th neuron calculated on the IEMOCAP dataset is greater than 0.64 which is an indicator that the ASR network is capable of learning prosodic features which is useful for emotion classification.

5 Discussion and conclusion

In this paper, various neural architectures were proposed utilizing speech recognition representations. Fine-tuning provides an ability to use the ASR network for the emotion recognition task quickly. A progressive network allows to combine speech and emotion representations and train them in parallel. Our experimental results confirm that trained speech representations, even though expected to be agnostic to a speaker’s emotion,

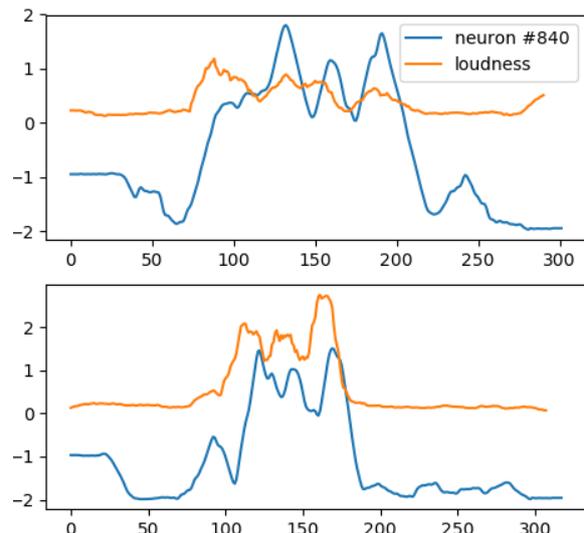

Figure 6: Activations of the neuron number 840 of the second GRU layer of the ASR model (blue) and loudness of two utterances selected randomly from IEMOCAP dataset (orange).

contain useful information for affective state predictions.

A possible future research direction would be to investigate the influence of linguistic knowledge on the speech representations and how it affects the system performance. Additionally, the ASR system can be fine-tuned in parallel with the emotion branch by updating the layers of the ASR network. Potentially, this could help the system to adapt better to the particular speakers and their emotion expression style. Furthermore, analyzing linguistic information of the spoken text produced by the ASR network could possibly alleviate the difficulty of separating *Anger* and *Happiness* classes, and *Neutral* and *Happiness*.

Abstract

Recently, encoder-decoder neural networks have shown impressive performance on many sequence-related tasks. The architecture commonly uses an attentional mechanism which allows the model to learn alignments between the source and the target sequence. Most attentional mechanisms used today is based on a global attention property which requires a computation of a weighted summarization of the whole input sequence generated by encoder states. However, it is computationally expensive and often produces misalignment on the longer input sequence. Furthermore, it does not fit with monotonous or left-to-right nature in several tasks, such as automatic speech recognition (ASR), grapheme-to-phoneme (G2P), etc. In this paper, we propose a novel attention mechanism that has local and monotonic properties. Various ways to control those properties are also explored. Experimental results on ASR, G2P and machine translation between two languages with similar sentence structures, demonstrate that the proposed encoder-decoder model with local monotonic attention could achieve significant performance improvements and reduce the computational complexity in comparison with the one that used the standard global attention architecture.

1 Introduction

End-to-end training is a newly emerging approach to sequence-to-sequence mapping tasks, that allows the model to directly learn the mapping between variable-length representation of different

modalities (i.e., text-to-text sequence (Bahdanau et al., 2014; Sutskever et al., 2014), speech-to-text sequence (Chorowski et al., 2014; Chan et al., 2016), image-to-text sequence (Xu et al., 2015), etc).

One popular approaches in the end-to-end mapping tasks of different modalities is based on encoder-decoder architecture. The earlier version of an encoder-decoder model is built with only two different components (Sutskever et al., 2014; Cho et al., 2014b): (1) an encoder that processes the source sequence and encodes them into a fixed-length vector; and (2) a decoder that produces the target sequence based on information from fixed-length vector given by encoder. Both the encoder and decoder are jointly trained to maximize the probability of a correct target sequence given a source sequence. This architecture has been applied in many applications such as machine translation (Sutskever et al., 2014; Cho et al., 2014b), image captioning (Karpathy and Fei-Fei, 2015), and so on.

However, such architecture encounters difficulties, especially for coping with long sequences. Because in order to generate the correct target sequence, the decoder solely depends only on the last hidden state of the encoder. In other words, the network needs to compress all of the information contained in the source sequence into a single fixed-length vector. (Cho et al., 2014a) demonstrated a decrease in the performance of the encoder-decoder model associated with an increase in the length of the input sentence sequence. Therefore, (Bahdanau et al., 2014) introduced attention mechanism to address these issues. Instead of relying on a fixed-length vector, the decoder is assisted by the attention module to get the related context from the encoder sides, depends on the current decoder states.

Most attention-based encoder-decoder model

used today has a “global” property (Bahdanau et al., 2014; Luong et al., 2015). Every time the decoder needs to predict the output given the previous output, it must compute a weighted summarization of the whole input sequence generated by the encoder states. This global property allows the decoder to address any parts of the source sequence at each step of the output generation and provides advantages in some cases like machine translation tasks. Specifically, when the source and the target languages have different sentence structures and the last part of the target sequence may depend on the first part of the source sequence. However, although the global attention mechanism has often improved performance in some tasks, it is very computationally expensive. For a case that requires mapping between long sequences, misalignments might happen in standard attention mechanism (Kim et al., 2017). Furthermore, it does not fit with monotonous or left-to-right natures in several tasks, such as ASR, G2P, etc.

In this paper, we propose a novel attention module that has two important characteristics to address those problems: local and monotonicity properties. The local property helps our attention module focus on certain parts from the source sequence that the decoder wants to transcribe, and the monotonicity property strictly generates alignment left-to-right from beginning to the end of the source sequence. In case of speech recognition task that need to produce a transcription given the speech signal, the attention module is now able to focus on the audio’s specific timing and always move in one direction from the start to the end of the audio. Similar way can be applied also for G2P or machine translation (MT) between two languages with similar sentences structure, i.e., Subject-Verb-Object (SVO) word order in English and French languages. Experimental results demonstrate that the proposed encoder-decoder model with local monotonic attention could achieve significant performance improvements and reduce the computational complexity in comparison with the one that used the standard global attention architecture.

2 Attention-based Encoder Decoder Neural Network

The encoder-decoder model is a neural network that directly models conditional probability

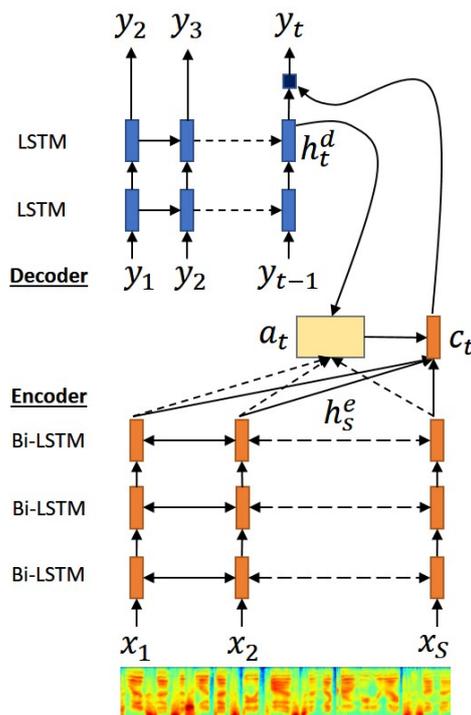

Figure 1: Attention-based encoder-decoder architecture.

$p(\mathbf{y}|\mathbf{x})$, where $\mathbf{x} = [x_1, \dots, x_S]$ is the source sequence with length S and $\mathbf{y} = [y_1, \dots, y_T]$ is the target sequence with length T . Figure 1 shows the overall structure of the attention-based encoder-decoder model that consists of encoder, decoder and attention modules.

The encoder task processes input sequence \mathbf{x} and outputs representative information $\mathbf{h}^e = [h_1^e, \dots, h_S^e]$ for the decoder. The attention module is an extension scheme for assisting the decoder to find relevant information on the encoder side based on the current decoder hidden states (Bahdanau et al., 2014; Luong et al., 2015). Usually, attention modules produces context information c_t at the time t based on the encoder and decoder hidden states:

$$c_t = \sum_{s=1}^S a_t(s) * h_s^e \quad (1)$$

$$a_t(s) = \text{Align}(h_s^e, h_t^d) = \frac{\exp(\text{Score}(h_s^e, h_t^d))}{\sum_{s=1}^S \exp(\text{Score}(h_s^e, h_t^d))} \quad (2)$$

There are several variations for score functions:

$$\text{Score}(h_s^e, h_t^d) = \begin{cases} \langle h_s^e, h_t^d \rangle, & \text{dot product} \\ h_s^{eT} W_s h_t^d, & \text{bilinear} \\ V_s^T \tanh(W_s [h_s^e, h_t^d]), & \text{MLP} \end{cases} \quad (3)$$

where $\text{Score} : (\mathbb{R}^M \times \mathbb{R}^N) \rightarrow \mathbb{R}$, M is the number of hidden units for encoder and N is the number of hidden units for decoder. Finally, the decoder task, which predicts the target sequence probability at time t based on previous output and context information c_t can be formulated:

$$\log p(\mathbf{y}|\mathbf{x}) = \sum_{t=1}^T \log p(y_t | y_{<t}, c_t) \quad (4)$$

For speech recognition task, most common input \mathbf{x} is a sequence of feature vectors like Mel-spectral filterbank and/or MFCC. Therefore, $\mathbf{x} \in \mathbb{R}^{S \times D}$ where D is the number of features and S is the total frame length for an utterance. Output \mathbf{y} , which is a speech transcription sequence, can be either phoneme or grapheme (character) sequence. In text-related task such as machine translation, \mathbf{x} and \mathbf{y} are a sequence of word or character indexes.

3 Locality and Monotonicity Properties

In the previous section, we explained the standard global attention-based encoder-decoder model. However, in order to control the area and focus attention given previous information, such mechanism requires to apply the scoring function into all the encoder states and normalizes them with a softmax function. Another problem is we cannot explicitly enforce the probability mass generated by the current attention modules that are always moving incrementally to the end of the source sequence. In this section, we discuss and explain how to model the locality and monotonicity properties on the attention module. This way, we could improve the sensitivity of capturing regularities and ensure to focus only an important subset instead of whole sequence.

Figure 2 illustrates the overall mechanism of our proposed local monotonic attention, and details are described below.

1. Monotonicity-based Prediction of Central Position

First, we define how to predict the next central position of the alignment illustrated in

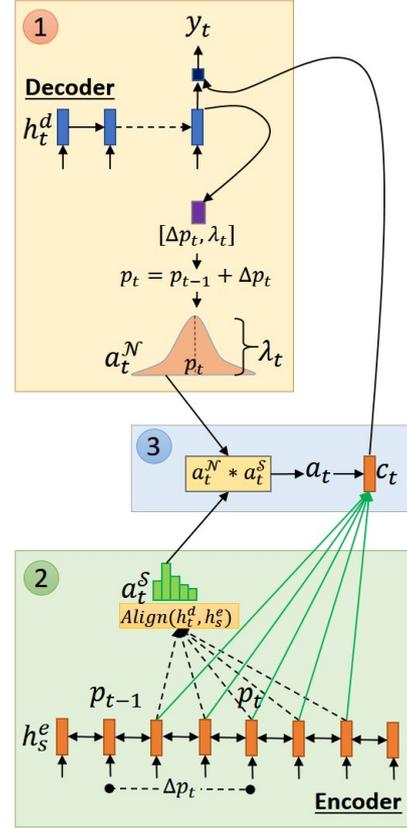

Figure 2: Local monotonic attention.

Part (1) of Figure 2. Assume we have source sequence with length S , which is encoded by the stack of Bi-LSTM (see Figure 1) into S encoded states $\mathbf{h}^e = [h_1^e, \dots, h_S^e]$. At time t , we want to decode the t -th target output given the source sequence, previous output y_{t-1} , and current decoder hidden states $h_t^d \in \mathbb{R}^N$. In standard approaches, we use hidden states h_t^d to predict the position difference Δp_t with a multilayer perceptron (MLP). We use variable Δp_t to determine how far we should move the center of the alignment compared to previous center p_{t-1} .

In this paper, we propose two different formulations for estimating Δp_t to ensure a forward or monotonicity movement:

- **Constrained position prediction:**

We limit maximum range from Δp_t with hyperparameter C_{max} with the following equation:

$$\Delta p_t = C_{max} * \text{sigmoid}(V_p^T \tanh(W_p h_t^d)) \quad (5)$$

Here we can control how far our next center of alignment position p_t

relies on our datasets and guarantee $0 \leq \Delta p_t \leq C_{max}$. However, it requires us to handle hyperparameter C_{max} .

- **Unconstrained position prediction:**

Compared to a previous formulation, since we do not limit the maximum range of Δp_t , here we can ignore hyperparameter C_{max} and use exponential (exp) function instead of sigmoid. We can also use another function (e.g softplus) as long as the function satisfy $f : \mathbb{R} \rightarrow \mathbb{R}_0^+$ and the result of $\Delta p_t \geq 0$. We formulate unconstrained position prediction with following equation:

$$\Delta p_t = \exp(V_p^T \tanh(W_p h_t^d)) \quad (6)$$

Here $V_p \in \mathbb{R}^{K \times 1}$, $W_p \in \mathbb{R}^{K \times N}$, N is the number of decoder hidden units and K is the number of hidden projection layer units. We omit the bias for simplicity. Both equations guarantee monotonicity properties since $\forall t \in [1..T], p_t \geq (p_{t-1} + \Delta p_t)$.

Additionally, we also used scaling variable λ_t to scale the unnormalized Gaussian distribution that depends on h_t . We calculated λ_t with following equation:

$$\lambda_t = \exp(V_\lambda^T \tanh(W_p h_t^d)) \quad (7)$$

where $V_\lambda \in \mathbb{R}^{K \times 1}$. In our initial experiments, we discovered that we improved our model performance by scaling with λ_t for each time-step. The main objective of this step is to generate a scaled Gaussian distribution a_t^N :

$$a_t^N(s) = \lambda_t * \exp\left(-\frac{(s - p_t)^2}{2\sigma^2}\right). \quad (8)$$

where p_t is the mean and σ is the standard deviation, both of which are used to calculate the weighted sum from the encoder states to generate context vector c_t later. In this paper, we treat σ as a hyperparameter.

2. Locality-based Alignment Generation

After calculating new position p_t , we generate locality-based alignment, as shown in Part (2) of Figure 2. Based on predicted position p_t , we follow (Luong et al., 2015) to generate

alignment a_t^S only within $[p_t - 2\sigma, p_t + 2\sigma]$:

$$a_t^S(s) = \text{Align}(h_s^e, h_t^d), \quad (9)$$

$$\forall s \in [p_t - 2\sigma, p_t + 2\sigma].$$

Since p_t is a real number and the indexes for the encoder states are integers, we convert p_t into an integer with floor operation. After we know the center of the position p_t , we only need to calculate the scores (Eq. 3) for each encoder states in $[p_t - 2\sigma, \dots, p_t + 2\sigma]$ then calculate the context alignment scores (Eq. 2).

Compared to the standard global attention, we can reduce the decoding computational complexity $O(T * S)$ into $O(T * \sigma)$ where $\sigma \ll S$ and σ is constant, T is total decoding step, S is the length of the encoder states.

3. Context Calculation

In the last step, we calculate context c_t with alignments a_t^N and a_t^S , as shown in Part (3) of Figure 2:

$$c_t = \sum_{s=(p_t-2\sigma)}^{(p_t+2\sigma)} (a_t^N(s) * a_t^S(s)) * h_s^e \quad (10)$$

Context c_t and current hidden state h_t^d will later be utilized for calculating current output y_t .

Overall, we can rephrase the first step as generating “prior” probabilities a_t^N based on the previous p_{t-1} position and the current decoder states. Then the second step task generates “likelihood” probabilities a_t^S by measuring the relevance of our encoder states with the current decoder states. In the third step, we combine our “prior” and “likelihood” probability into an unnormalized “posterior” probability a_t and calculate expected context c_t .

4 Experiment on Speech Recognition

We applied our proposed architecture on ASR task. The local property helps our attention module focus on certain parts from the speech that the decoder wants to transcribe, and the monotonicity property strictly generates alignment left-to-right from beginning to the end of the speech.

4.1 Speech Data

We conducted our experiments on the TIMIT ¹ (Garofolo et al., 1993) dataset with the same set-

¹<https://catalog.ldc.upenn.edu/ldc93s1>

up for training, development, and test sets as defined in the Kaldi s5 recipe (Povey et al., 2011). The training set contains 3696 sentences from 462 speakers. We also used another sets of 50 speakers for the development set and the test set contains 192 utterances, 8 each from 24 speakers. For every experiment, we used 40-dimensional fbank with delta and acceleration (total 120-dimension feature vector) extracted from the Kaldi toolkit. The input features were normalized by subtracting the mean and divided by the standard deviation from the training set. For our decoder target, we re-mapped the original target phoneme set from 61 into 39 phoneme class plus the end of sequence mark (eos).

4.2 Model Architectures

On the encoder sides, we projected our input features with a linear layer with 512 hidden units followed by tanh activation function. We used three bidirectional LSTMs (Bi-LSTM) for our encoder with 256 hidden units for each LSTM (total 512 hidden units for Bi-LSTM). To reduce the computational time, we used hierarchical subsampling (Graves, 2012; Bahdanau et al., 2016), applied it to the top two Bi-LSTM layers, and reduced their length by a factor of 4.

On the decoder sides, we used a 64-dimensional embedding matrix to transform the input phonemes into a continuous vector, followed by two unidirectional LSTMs with 512 hidden units. For every local monotonic model, we used an MLP with 256 hidden units to generate Δp_t and λ_t . Hyperparameter 2σ was set to 3, and C_{max} for constrained position prediction (see Eq. 5) was set to 5. Both hyperparameters were empirically selected and generally gave consistent results across various settings in our proposed model. For our scorer module, we used bilinear and MLP scorers (see Eq. 3) with 256 hidden units. We used an Adam (Kingma and Ba, 2014) optimizer with a learning rate of $5e - 4$.

In the recognition phase, we generated transcriptions with best-1 (greedy) search from the decoder. We did not use any language model in this work. All of our models were implemented on the Chainer framework (Tokui et al., 2015).

For comparison, we evaluated our proposed model with the standard global attention-based encoder-decoder model and *local-m* attention (Luong et al., 2015) as the baseline. Most of the con-

figurations follow the above descriptions, except the baseline model that does not have an MLP for generating Δp_t and λ_t .

5 Result and Discussion for Speech Recognition

Table 1 summarizes our experiments on our proposed local attention models and compares them to the baseline model using several possible scenarios.

5.1 Constrained vs Unconstrained Position Prediction

Considering the use of constrained and unconstrained position prediction Δp_t , our results show that the model with the unconstrained position prediction (exp) model gives better results than one based on the constrained position prediction (sigmoid) model on both MLP and bilinear scorers. We conclude that it is more beneficial to use the unconstrained position prediction formulation since it gives better performance and we do not need to handle the additional hyperparameter C_{max} .

5.2 Alignment Scorer vs Non-Scorer

Next we investigate the importance of the scorer module by comparing the results between a model with and without it. Our results reveal that, by only relying on Gaussian alignment a_t^N and set $a_t^S = 1$, our model performance’s was worse than one that used both the scorer and Gaussian alignment. This might be because the scorer modules are able to correct the details from the Gaussian alignment based on the relevance of the encoder states in the current decoder states. Thus, we conclude that alignment with the scorer is essential for our proposed models.

5.3 Overall comparison to the baseline

Overall, our proposed encoder-decoder model with local monotonic attention significantly improved the performance and reduced the computational complexity in comparison with one that used standard global attention mechanism (we cannot compare directly with (Chorowski et al., 2014) since its pretrained with HMM state alignment). We also tried *local-m* attention from (Luong et al., 2015), however our model cannot converge and we hypothesize the reason is because ratio length between the speech and their corresponding text is larger than 1, therefore the

Table 1: Results from baseline and proposed models on ASR task with TIMIT test set.

Model		Test PER (%)	
Global Attention Model (Baseline)			
Att Enc-Dec (pretrained with HMM align) (Chorowski et al., 2014)		18.6	
Att Enc-Dec (Pereyra et al., 2017)		23.2	
Att Enc-Dec (Luo et al., 2016)		24.5	
Att Enc-Dec with MLP Scorer (ours)		23.8	
Att Enc-Dec with <i>local-m</i> (ours) (Luong et al., 2015)		-	
Local Attention Model (Proposed)			
Monotonicity	Locality		Test PER (%)
Pos Prediction Δp_t	Alignment Score (h_s^e, h_t^d)	Func. Type	
Const (<i>sigmoid</i>)	No	-	23.2

Const (<i>sigmoid</i>)	Yes	MLP	21.7
Unconst (<i>exp</i>)	No	-	23.1
Unconst (<i>exp</i>)	Yes	Bilinear	20.9
Unconst (<i>exp</i>)	Yes	MLP	21.4

Δp_t cannot be represented by fixed value. The best performance achieved by our proposed model with unconstrained position prediction and bilinear scorer, and provided 12.2% relative error rate reduction to our baseline.

6 Experiment on Grapheme-to-Phoneme

We also investigated our proposed architecture on G2P conversion task. Here, the model need to generate corresponding phoneme given small segment of characters and its always moving from left to right. The local property helps our attention module focus on certain parts from the grapheme source sequence that the decoder wants to convert into phoneme, and the monotonicity property strictly generates alignment left-to-right from beginning to the end of the grapheme source sequence.

6.1 Dataset

Here, we used the CMUDict dataset². It contains 113438 words for training and 12753 for testing (12000 unique words). For validation, we randomly select 3000 sentences from the training set. The evaluation metrics for this task are phoneme error rate (PER) and word error rate (WER). In the evaluation process, there are some words has multiple references (pronunciations). Therefore, we

²CMUDict: <https://sourceforge.net/projects/cmuspinx/files/G2P%20Models/phonetisaurus-cmudict-split.tar.gz>

select one of the references that has lowest PER between compared to our hypothesis, and if the hypothesis completely match with one of those references, then the WER is not increasing. For our encoder input, we used 26 letter (A-Z) + single quotes ('). For our decoder target, we used 39 phonemes plus the end of sequence mark (eos).

6.2 Model Architectures

On the encoder sides, the characters input were projected into 256 dims using embedding matrix. We used two bidirectional LSTMs (Bi-LSTM) for our encoder with 512 hidden units for each LSTM (total 1024 hidden units for Bi-LSTM). On the decoder sides, the phonemes input were projected into 256 dims using embedding matrix, followed by two unidirectional LSTMs with 512 hidden units. For local monotonic model, we used an MLP with 256 hidden units to generate Δp_t and λ_t . For this task, we only used the unconstrained formulation because based on previous sections, we able to achieved better performance and we didn't need to find optimal hyperparameter for C_{max} . For our scorer module, we used MLP scorer with 256 hidden units.

In the decoding phase, we used beam search strategy with beam size 3 to generate the phonemes given the character sequences. For comparison, we evaluated our model with standard global attention and *local-m* attention model (Luong et al., 2015) as the baseline.

6.3 Result Discussion

Table 2 summarizes our experiment on proposed local attention models. We compared our proposed models with several baselines from other algorithm as well. Our model significantly improving the PER and WER compared to encoder-decoder, attention-based global softmax and *local-m* attention (fixed-step size). Compared to Bi-LSTM model which was trained with explicit alignment, we achieve slightly better PER and WER with larger window size ($2\sigma = 3$).

7 Experiment on Machine Translation

We also conducted experiment on machine translation task, specifically between two languages with similar sentences structure. By using our proposed method, we able to focus only to a small related segment on the source side and the target

Table 2: Results from baseline and proposed method on G2P task with CMUDict test set

Model	PER (%)	WER (%)
Baseline		
Enc-Dec LSTM (2 lyr) (Yao and Zweig, 2015)	7.63	28.61
Bi-LSTM (3 lyr) (Yao and Zweig, 2015)	5.45	23.55
Att Enc-Dec with Global MLP Scorer (ours)	5.96	25.55
Att Enc-Dec with <i>local-m</i> (ours) (Luong et al., 2015)	5.64	24.32
Proposed		
Att Enc-Dec + Unconst (exp) ($2\sigma = 2$)	5.45	23.15
Att Enc-Dec + Unconst (exp) ($2\sigma = 3$)	5.43	23.19

generation process usually follows the source sentence structure without many reordering process.

7.1 Dataset

We used BTEC dataset (Kikui et al., 2003) and chose English-to-France and Indonesian-to-English parallel corpus. From BTEC dataset, we extracted 162318 sentences for training and 510 sentences for test data. Because there are no default development set, we randomly sampled 1000 sentences from training data for validation set. For all language pairs, we preprocessed our dataset using Moses (Koehn et al., 2007) tokenizer. For training, we replaced any word that appear less than twice with unknown (unk) symbol. In details, we keep 10105 words for French corpus, 8265 words for English corpus and 9577 words for Indonesian corpus. We only used sentence pairs where the source is no longer than 60 words in training phase.

7.2 Model Architecture

On both encoder and decoder sides, the input words were projected into 256 dims using embedding matrix. We used three Bi-LSTM for our encoder with 512 hidden units for each LSTM (total 1024 hidden unit for Bi-LSTM). For our decoder, we used three LSTM with 512 hidden units. For local monotonic model, we used an MLP with 256 hidden units to generate Δp_t and λ_t . Same as previous section, we only used the unconstrained for-

mulation for local monotonic experiment. For our scorer module, we used MLP scorer with 256 hidden units. In the decoding phase, we used beam search strategy with beam size 5 and normalized length penalty with $\alpha = 1$ (Wu et al., 2016). For comparison, we evaluate our model with standard global attention and *local-m* attention model (Luo et al., 2016) as the baseline.

Table 3: Results from baseline and proposed method on English-to-France and Indonesian-to-English translation tasks.

7.3 Result Discussion

Table 3 summarizes our experiment on proposed local attention models compared to baseline global attention model and *local-m* attention model (Luong et al., 2015). Generally, local monotonic attention had better result compared to global attention on both English-to-France and Indonesian-to-English translation task. Our proposed model were able to improve the BLEU up to 2.2 points on English-to-France and 3.6 points on Indonesian-to-English translation task compared to standard global attention. Compared to *local-m* attention with fixed step size, our proposed model able to improve the performance up to 0.8 BLEU on

English-to-France and 2.0 BLEU on Indonesian-to-English translation task.

8 Related Work

Humans do not generally process all of the information that they encounter at once. Selective attention, which is a critical property in human perception, allows attention to be focused on particular information while filtering out a range of other information. The biological structure of the eye and the eye movement mechanism is one part of visual selective attention that provides the ability to focus attention selectively on parts of the visual space to acquire information when and where it is needed (Rensink, 2000). In the case of the cocktail party effect, humans can selectively focus their attentive hearing on a single speaker among various conversation and background noise sources (Cherry, 1953).

The attention mechanism in deep learning has been studied for many years. But, only recently have attention mechanisms made their way into the sequence-to-sequence deep learning architectures that were proposed to solve machine translation tasks. Such mechanisms provide a model with the ability to jointly align and translate (Bahdanau et al., 2014). With the attention-based model, the encoder-decoder model significantly improved the performance on machine translation (Bahdanau et al., 2014; Luong et al., 2015) and has successfully been applied to ASR tasks (Chorowski et al., 2014; Chan et al., 2016).

However, as we mentioned earlier, most of those attention mechanism are based on “global” property, where the attention module tries to match the current hidden states with all the states from the encoder sides. This approach is inefficient and computationally expensive on longer source sequences. A “local attention” was recently introduced by (Luong et al., 2015) which provided the capability to only focus small subset of the encoder sides. They also proposed monotonic attention but limited to fixed step-size and not suitable for a task where the length ratio between source and target sequence is vastly different. Our proposed method are able to elevated this problem by predicting the step size dynamically instead of using fixed step size. After we constructed our proposed framework, we found work by (Raffel et al., 2017) recently that also proposed a method for producing monotonic alignment by

using Bernoulli random variable to control when the alignment should stop and generate output. However, it cannot attend the source sequence outside the range between previous and current position. In contrast with our approach, we are able to control how large the area we want to attend based on the window size.

(Chorowski et al., 2014) also proposed a soft constraint to encourage monotonicity by invoking a penalty based on the current alignment and previous alignments. However, the methods still did not guarantee a monotonicity movement of the attention.

To the best of our knowledge, only few studies have explored about local and monotonicity properties on an attention-based model. This work presents a novel attention module with locality and monotonicity properties. Our proposed mechanism strictly enforces monotonicity and locality properties in their alignment by explicitly modeling them in mathematical equations. The observation on our proposed model can also possibly act as regularizer by only observed a subset of encoder states. Here, we also explore various ways to control both properties and evaluate the impact of each variations on our proposed model. Experimental results also demonstrate that the proposed encoder-decoder model with local monotonic attention could provide a better performances in comparison with the standard global attention architecture and *local-m* attention model (Luong et al., 2015).

9 Conclusion

This paper demonstrated a novel attention mechanism for encoder decoder model that ensures monotonicity and locality properties. We explored various ways to control these properties, including dynamic monotonicity-based position prediction and locality-based alignment generation. The results reveal our proposed encoder-decoder model with local monotonic attention significantly improved the performance on three different tasks and able to reduced the computational complexity more than one that used standard global attention architecture.

Abstract

In this paper, we extend Recurrent Neural Network Language Models (RNN-LMs) with an attention mechanism. We show that an *Attentive* RNN-LM (with 14.5M parameters) achieves a better perplexity than larger RNN-LMs (with 66M parameters) and achieves performance comparable to an ensemble of 10 similar sized RNN-LMs. We also show that an *Attentive* RNN-LM needs less contextual information to achieve similar results to the state-of-the-art on the wikitext2 dataset.

1 Introduction

Language Models (LMs) are an essential component in a range of Natural Language Processing applications, such as Statistical Machine Translation and Speech Recognition (Schwenk et al., 2012). An LM provides a probability for a sequence of words in a given language, reflecting fluency and the likelihood of that word sequence occurring in that language.

In recent years Recurrent Neural Networks (RNNs) have improved the state-of-the-art in LM research (Józefowicz et al., 2016). Sequential data prediction, however, is still considered a challenge in Artificial Intelligence (Mikolov et al., 2010) given that, in general, prediction accuracy degrades as the size of sequences increase.

RNN-LMs sequentially propagate forward a context vector by integrating the information generated by each prediction step into the context used for the next prediction. One consequence of this forward propagation of information is that older information tends to fade from the context as new information is integrated into the context. As a result, RNN-LMs struggle in situations where there is a long-distance dependency because the relevant

information from the start of the dependency has faded by the time the model has spanned the dependency. A second problem is that the context can be dominated by the more recent information so when an RNN-LM does make an error this error can be propagated forward resulting in a cascade of errors through the rest of the sequence.

In recent sequence-to-sequence research the concept of “attention” has been developed to enable RNNs to align different parts of the input and output sequences. Examples of attention based architectures include Neural Machine Translation (NMT) (Bahdanau et al., 2015; Luong et al., 2015) and image captioning (Xu et al., 2015).

In this paper we extend the RNN-LM context mechanism with an attention mechanism that enables the model to bring forward context information from different points in the context sequence history. We hypothesize that this attention mechanism enables RNN-LMs to: (a) bridge long-distance dependencies, thereby avoiding errors; and, (b) to overlook recent errors by choosing to focus on contextual information preceding the error, thereby avoiding error propagation.

We show that a medium sized¹ *Attentive* RNN-LM² achieves better performance than larger “standard” models and performance comparable to an ensemble of 10 “medium” sized LSTM RNN-LMs on the PTB. We also show that an *Attentive* RNN-LM needs less contextual information in order to achieve similar results to state-of-the-art results over the wikitext2 dataset.

Outline: §2 introduces RNN-LMs and related research, §3 outlines our approach, §4 describes our experiments, §5 presents our analysis of the models’ performance and §6 our conclusions.

¹We adopt the terminology of Zaremba et al. (2015) and Press and Wolf (2016) when referring to the size of the RNNs.

2 RNN-Language Models

RNN-LMs model the probability of a sequence of words by modelling the joint probability of the words in the sequence using the chain rule:

$$p(w_1, \dots, w_N) = \prod_{t=1}^N p(w_t | w_1, \dots, w_{t-1}) \quad (1)$$

where N is the number of words in the sequence. The context of the word sequence is modelled by an RNN and for each position in the sequence the probability distribution over the vocabulary is calculated using a softmax on the output related to that position of the RNN’s last layer (i.e., the last layer’s hidden state) (Józefowicz et al., 2016). Examples of such models include Zaremba et al. (2015) and Press and Wolf (2016). These models are composed of LSTM units (Hochreiter and Schmidhuber, 1997) and apply regularization to improve the RNN performance. In addition, Press and Wolf (2016) also uses the same embedding matrix that is used to transform the input words to transform the output of the last RNN layer to feed it to the softmax layer to make the next prediction.

Attention mechanisms were first proposed in “encoder-decoder” architectures for NMT systems. Bahdanau et al. (2015) proposed a model that stores all the encoder RNN’s outputs and uses them together with the decoder RNN’s state h_{t-1} to compute a context vector that, in turn, is used to compute the state h_t . In Luong et al. (2015) a generalization of the model of Bahdanau et al. (2015) is presented which uses the decoder RNN’s state, in this instance h_t rather than h_{t-1} , along with the outputs of the encoder RNN to compute a context vector that it then concatenated with h_t before making the next prediction. Both models have similar performance and achieve state-of-the-art performance for some language pairs; however, they suffer from repeating words or dropping translations at the output (Mi et al., 2016).

There is previous work on using past information to improve RNN-LMs. Tran et al. (2016) propose an extension to LSTM cells to include memory areas, which depend on input words, at the output of every hidden layer. The model produces good results but the dependency on input words expands the number of parameters in each LSTM cell in proportion to the vocabulary size in use.

Similarly, Cheng et al. (2016) propose storing the LSTM’s memory cells of every layer at each timestep and draw a context vector for each memory cell for each new input to attend to previous content and compute its output. Although their model requires fewer parameters than the model of Tran et al. (2016), the performance of the model is worse than regularized “standard” RNN-LM as in Zaremba et al. (2015) and Press and Wolf (2016).

Daniluk et al. (2017) propose an augmented version of the attention mechanism proposed by Bahdanau et al. (2015) on which their model outputs 3 vectors called *key-value-predict*. The *key* (a vector of real numbers) is used to retrieve a single hidden state from the past. Grave et al. (2017) propose an LM augmented with a “memory cache” that stores tuples of hidden-states plus word embeddings (for the word predicted from that hidden state). The memory cache is used to help the current prediction by retrieving the word embedding associated with the hidden state in the memory most similar to the current hidden state. Merity et al. (2017) proposed a mixture model that includes an RNN and a pointer network. This model computes one distribution for the softmax component and one distribution for the pointer network, using a sentinel gating function to combine both distributions. In spite of the fact that their model is similar to the model of Grave et al. (2017), their model requires an extra transformation between the current state of the RNN and those stored in the memory.

These recent models have a number of drawbacks. The systems that extend the architecture of LSTM units struggle to process large vocabularies because the system memory expands to the size of the vocabulary. For systems that retrieve a single hidden-state or word from memory, if the prediction is not correct, the RNN-LM will not receive the correct past information. Finally, the models of Merity et al. (2017) and Grave et al. (2017) use a fixed-length memory of L previous hidden states to store and retrieve information from the past (100 states in the case of Merity et al. (2017) and 2,000 states in the case of Grave et al. (2017)). As we shall explain in §3 our “attentive” RNN-LMs have a memory of dynamic-length that grows with the length of the input and therefore, in general, are computationally cheaper.

We see our “attentive” RNN-LM (see §3) as a generalized version of these models as we rely on the encoded information in the hidden state of the

RNN-LM to represent previous input words and we use a set of attention weights (instead of a *key*) to retrieve information from the past inputs. The main advantages of our approach are: (a) our model does not need vocabulary sized matrices in the computations of the attention mechanism and therefore has a reduced number of parameters; and (b) as we use all previous hidden states of the RNN-LM in the computation for the attention weights, all of those states will influence the next prediction based on the weights calculated.

3 Attentive Language Models

In this work we extend RNN-LMs to include an attention mechanism over previous inputs. We employ a multi-layered RNN to encode the input and, at each timestep, we store the output of the last recurrent layer (i.e., its hidden state \mathbf{h}_t) into a memory buffer. We compute a score for each hidden state \mathbf{h}_i ($\forall i \in \{1, \dots, t-1\}$) stored in memory and use these scores to weight each \mathbf{h}_i . From these weighted hidden states we generate a context vector \mathbf{c}_t that is concatenated with the current hidden state \mathbf{h}_t to predict the next word in the sequence. Figure 1 illustrates a step of our model when predicting the fourth word in a sequence.

We propose two different attention score functions that can be used to compute the context vector \mathbf{c}_t . One calculates the attention score of each \mathbf{h}_i using just the information in the state (the *single*(\mathbf{h}_i) score introduced below). The other calculates the attention scores for each \mathbf{h}_i by combining the information from that state with the information from the current state \mathbf{h}_t (the *combined*($\mathbf{h}_i, \mathbf{h}_t$) score described below). Each of these mechanisms defines a separate *Attentive* RNN-LMs and we report results for each of these LMs in our experiments.

More formally, each \mathbf{h}_t is computed as follows, where \mathbf{x}_t is the input at timestep t :

$$\mathbf{h}_t = \text{RNN}(\mathbf{x}_t, \mathbf{h}_{t-1}) \quad (2)$$

The context vector \mathbf{c}_t is then generated using Eq. (3) where each scalar weight a_i is a softmax (Eq. (4)) and the score for each hidden state (\mathbf{h}_i) in the memory buffer is one of Eq. (5) or Eq. (6).

$$\mathbf{c}_t = \sum_{i=1}^{t-1} a_i \mathbf{h}_i \quad (3)$$

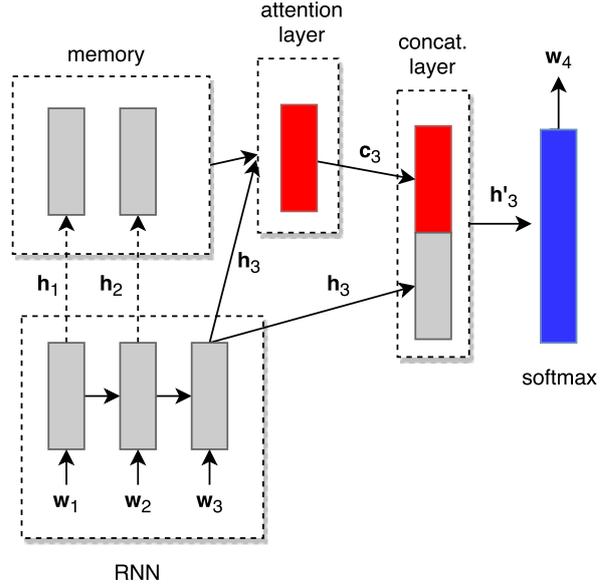

Figure 1: Illustration of a step of the *Attentive* RNN-LM with *combined* score. In this example, the model receives the third word as input (w_3) after storing the previous states (h_1 and h_2) in memory. After producing h_3 , the model computes the context vector (in this case c_3) that will be concatenated to h_3 before the softmax layer for the prediction of the fourth word w_4 . Note that if the *single* score is in use (Eq. (9)), the arrow from the RNN output for h_3 to the attention layer is dropped. Also note that h_3 is stored in memory only at the end of this process.

$$a_i = \frac{\exp(\text{score}(\mathbf{h}_i, \mathbf{h}_t))}{\sum_{j=1}^{t-1} \exp(\text{score}(\mathbf{h}_j, \mathbf{h}_t))} \quad (4)$$

$$\text{score}(\mathbf{h}_i, \mathbf{h}_t) = \begin{cases} \text{single}(\mathbf{h}_i) & (5) \\ \text{combined}(\mathbf{h}_i, \mathbf{h}_t) & (6) \end{cases}$$

We then merge \mathbf{c}_t with the current state \mathbf{h}_t using a concatenation layer³, where \mathbf{W}_c is a matrix of parameters and \mathbf{b}_t is a bias vector.

$$\mathbf{h}'_t = \tanh(\mathbf{W}_c[\mathbf{h}_t; \mathbf{c}_t] + \mathbf{b}_t) \quad (7)$$

We compute the next word probability using Eq. 8 where \mathbf{W} is a matrix of parameters and \mathbf{b} is a bias vector.

³We also have experimented with using a dot product and a feedforward layer to combine \mathbf{h}_t and \mathbf{c}_t and also using only \mathbf{c}_t , but those results were far below previous work in RNN-LM so we do not report them here.

$$p(w_t|w_{<t}, x) = \text{softmax}(\mathbf{W}\mathbf{h}'_t + \mathbf{b}) \quad (8)$$

Single score. This score is calculated for each \mathbf{h}_i using just the information stored the state in itself. The score $\text{single}(\mathbf{h}_i)$ is defined as

$$\text{single}(\mathbf{h}_i) = \mathbf{v}_s \odot \tanh(\mathbf{W}_s \mathbf{h}_i) \quad (9)$$

where the parameter matrix \mathbf{W}_s and vector \mathbf{v}_s are both learned by the attention mechanism and \odot represents the dot product.

When applying the $\text{single}(\mathbf{h}_i)$ score, we can think of the score a_i as a scalar summary of the “absolute relevance” of the state \mathbf{h}_i . When a new state \mathbf{h}_t is added to the buffer its scalar summary \mathbf{a}_i is calculated by first using Eq.9 to get the score for the state and then applying a softmax function over the set of state scores including the score for the new state. Although the scores for each state do not change from one timestep to the next, applying the softmax results in recalculation of the distribution of the scalar summaries for all the states $\mathbf{h}_0, \dots, \mathbf{h}_t$. As a result the \mathbf{a}_i ’s for each state in Eq.3 changes from one prediction to the next as new states are added and the weight mass is distributed across more states.

Combined score. This score is calculated for each \mathbf{h}_i by combining the information from that state with the information from the current state \mathbf{h}_t . The score $\text{combined}(\mathbf{h}_i, \mathbf{h}_t)$ is defined as

$$\text{combined}(\mathbf{h}_i, \mathbf{h}_t) = \mathbf{v}_s \odot \tanh(\mathbf{W}_s \mathbf{h}_i + \mathbf{W}_q \mathbf{h}_t) \quad (10)$$

where the parameter matrices \mathbf{W}_s and \mathbf{W}_q and vector \mathbf{v}_s are learned by the attention mechanism, and \odot is the same as in Eq. 9. Notice that because $\mathbf{W}_q \mathbf{h}_t$ does not depend on any other state and is used in the computations with all other \mathbf{h}_i , we can efficiently compute it once and use the results in Eq. 10, thus reducing computation time.

The score \mathbf{a}_i defined by $\text{combined}(\mathbf{h}_i, \mathbf{h}_t)$, can be understood as the “relative relevance” of state \mathbf{h}_i to the current state \mathbf{h}_t . Using this attention mechanism the score for each \mathbf{h}_i is different for each timestep according to its relevance to the current hidden state \mathbf{h}_t of the RNN. Consequently, the

scores for each \mathbf{h}_i and the distribution over these scores changes from one timestep to the next. Using this scoring, the model can decide whether it should pay more attention to the current state, to a previous state or use past states to “supplement” the information for the next prediction. In §5 we present and analysis of how the model attends to different parts of its history as it generates a sequence of predictions.

4 Experiments

To evaluate our *Attentive* RNN-LMs we conducted experiments over the PTB (Marcus et al., 1994) and wikitext2 (Merity et al., 2017) datasets. We first describe the setup of our *Attentive* RNN-LM for the PTB (§4.1) and wikitext2 (§4.2) datasets and then discuss the results (§4.3). We compare our results on PTB to Zaremba et al. (2015) and Press and Wolf (2016) the best performing LSTM-LMs on the PTB, two memory augmented networks (Grave et al. (2017) and Merity et al. (2017)) and PTB state-of-the-art ensemble models of Zaremba et al. (2015). On wikitext2 we take (Merity et al., 2017), the creators of the dataset, and (Grave et al., 2017), the current state-of-the-art, as our baselines.

4.1 PTB Setup

We evaluate our *Attentive* RNN-LM over the PTB dataset using the standard split which consists of 887K, 70K and 78K tokens on the training, validation and test sets respectively.

We follow, in part, the parameterization used by Zaremba et al. (2015) and Press and Wolf (2016) with some changes. We trained an *Attentive* RNN-LM with 2 layers of 650 LSTM units using Stochastic Gradient Descent (SGD) with an initial learning rate of 1.0, halving the learning rate at each epoch after 12 epochs, to minimize the average negative log probability of the target words.

We train the models until we do not get any perplexity improvements over the validation set with an early stop counter of 10 epochs (i.e., patience of 10 epochs). Once the model runs out of patience, we rollback its parameters and use the model that achieved the best validation perplexity to calculate the perplexity over the test set. We initialize the weight matrices of the network uniformly in $[-0.05, 0.05]$ while all biases are initialized to a constant value at 0.0. We also apply 50% dropout (Srivastava et al., 2014) to the non-recurrent con-

nections and clip the norm of the gradients, normalized by mini-batch size, at 5.0. In all our experiments, we follow Press and Wolf (2016) and tie the matrix \mathbf{W} in Eq. (8) to be the embedding matrix (which also has 650 dimensions) used to represent the input words.

Contrary to Zaremba et al. (2015) and Press and Wolf (2016), we do not allow successive mini-batches to sequentially traverse the dataset. In other words, we follow the standard practice to reinitialize the hidden state of the network at the beginning of each mini-batch, by setting it to all zeros. This way, we do not allow the attention window to span across sentence boundaries⁴. We use all sentences in the training set, we truncate all sentences longer than 35 words and pad all sentences shorter than 35 words with a special symbol so all sentences are the same size. We use a vocabulary size of 10K words and a batch size of 32. All UNK words (following the pre-processing of (2015)) were kept during the training, validation and testing phases.

4.2 wikitext2 Setup

We also evaluate our *Attentive* RNN-LM over the wikitext2 dataset (Merity et al., 2017). We use the standard train, validation and test splits which consists of around 2M, 217K tokens and 245k tokens respectively. This dataset is composed of “Good” and “Featured” articles on Wikipedia.

There is an important difference between how we trained and tested our models on the wikitext2 dataset and how the baseline systems were trained and tested. Both Merity et al. (2017) and Grave et al. (2017) permitted the memory buffers of their systems to span sentence boundaries (and, indeed, they also did mini-batch traversal which allowed the memory buffers to traverse mini-batch boundaries) whereas we reset our systems memory at each sentence boundary. This difference is important because in the wikitext2 dataset the sentences are not shuffled and, therefore, are sequentially related to each other. As a result, systems that carry sequential information from previous sentences into the current sentence have an advantage in that they utilise contextual cues from the preceding sentence to inform the predictions at the start of the new sentence. By compari-

⁴We also experimented to with successive mini-batches to sequentially traverse the dataset as in Zaremba et al. (2015) but the performance of the model dropped considerably so we do not report those results here.

son, systems that reset their memory at the start of each sentence must reconstruct their context models from scratch and face a “cold-start” problem for the early predictions in the sentence.

The core reason why (Merity et al., 2017) and (Grave et al., 2017) did not reset their memories across sentence boundaries and we do is that these baseline systems use a fixed length memory whereas our “attention” mechanism has a variable length memory. A variable length memory has benefits in terms of both computational cost and the fact that the memory size is dynamically fitted to the context. However, just as the system designer for a fixed length memory LM must fix the memory size hyper-parameter in some fashion, so to the designer of a variable length memory LM must decide when the memory buffer is reset. For our work, we have decided to reset our memory buffer at sentence boundaries because many of the tasks for which LMs are used (e.g. NMT) work on a sentence by sentence basis. If required it would be possible for us to extend the memory buffer to the start of the preceding sentence (or some other landmark is the sequence history). However, this would incur extra computational cost, and as we shall see our *Attentive* RNN-LMs are still competitive on the wikitext2 dataset despite the fact that the baselines systems are given access to longer context sequences.

We trained an *Attentive* RNN-LM with 2 layers of 1000 LSTM units using Stochastic Gradient Descent (SGD) with an initial learning rate of 1.0, decaying the learning rate by a factor of 1.15 at each epoch after 14 epochs, to minimize the average negative log probability of the target words.

Similarly to the PTB model we also train this model with an early stop counter of 10 epochs and we initialize the weight matrices of the network uniformly in $[-0.05, 0.05]$ while all biases are initialized to a constant value at 0.0. We apply 65% dropout to the non-recurrent connections and clip the norm of the gradients, normalized by mini-batch size, at 5.0. In all our experiments, we also follow Press and Wolf (2016) and tie the matrix \mathbf{W} in Eq. (8) to be the embedding matrix (which has 1000 dimensions for this model) used to represent the input words. We use all sentences in the training set, we truncate all sentences longer than 35 words and pad all sentences shorter than 35 words with a special symbol so all sentences are the same length. We use a vocabulary size of

33,278 and a batch size of 32. All UNK words (following the pre-processing of (2017)) were kept during the training, validation and testing phases.

4.3 Results

In Table 1 we report the results of our experiments on the PTB dataset. As we can see in this table, the *Attentive* RNN-LMs outperforms all other single models on the PTB dataset. Although *Attentive* RNN-LMs have less parameters (10M) than the large “regularized” LSTM-LMs (66M parameters), they were capable of reducing the perplexity over both validation and test sets. This result shows that using an *Attentive* RNN-LM it is possible to achieve better perplexity scores with far fewer model parameters. Furthermore, *Attentive* RNN-LMs are able to achieve roughly the same results as the averaging of 10 RNN-LM models (with no attention) of the same size.

In addition, there is little difference between the results of the *Attentive* RNN-LM with *single* score (Eq.9) and the *Attentive* RNN-LM with *combined* score (Eq.10) with the *single* score slightly outperforming the the *combined* score. We believe this is because the model using the *combined*($\mathbf{h}_i, \mathbf{h}_t$) score has more parameters to optimize and, thus, more difficulties in settling to a good local optima.

In Table 2 we report the results on the wikitext2 dataset. Despite the fact that we reset the memory for the *Attentive* RNN-LM at each sentence boundary whereas the caches for the baseline systems span sentence boundaries, our best *Attentive* RNN-LM is within 1 perplexity point of the system of (2017) (which is allowed to cache 2,000 previous hidden states), and has a lower perplexity than all of the other baselines.

5 Analysis of the Models

The purpose of our attention mechanism is to enable an RNN-LM to bridge long distance dependencies in language. Therefore, we expect the attention mechanism to select previous hidden states that are relevant to the current predictions. To analyse whether the attention mechanism is functioning as intend we analysed the evolution of attention weights in our *Attentive* RNN-LM as we calculated the perplexity for samples sentences using the models trained over the wikitext2⁵.

⁵The behaviour of the models on wikitext2 is similar to that of the models trained and evaluated on the PTB dataset, so for space reasons we only present the wikitext2 analysis here.

Figure 2 show the evolution of attention weights, using both single and combined scoring, when calculating perplexities for 2 sentences containing nominal modifiers. In addition, Figure 3 show the evolution of attention weights for two sentences containing relative clauses, once again using both single and combined scoring. The words in the X-axis (horizontal) are the inputs at each timestep and the words in the Y-axis (vertical) are the next (or predicted) words. We suppressed weights that either equal to 1.0 (black squares) or 0.0 (white squares). Note that given the rounding to 4 decimal places, weights in some rows of the matrices may not sum to 1.0.

None of the attention mechanisms worked as a proper attention mechanism. In other words, none of the mechanisms generated larger weights for specific words in the sentence, in comparison to the other words in the same sentence. Comparing the attention weights generated by both *combined* score and *single* score for both sentences, it is striking that the distribution of attention weights is very similar. For both *Attentive* RNN-LM models the attention spreads out across the history in a relatively equal fashion.

Indeed, both models seem to take into consideration all previous states, creating a *smoothing effect* for the hidden states in the buffer. Therefore, no single state dominates the context vector by receiving a much larger attention weight than the others. We believe that this behaviour enables the models to bring forward information from the beginning of the sentence at the time it is making a prediction. This way, the models do not let information fade away from the context as it progresses to subsequent steps in a sequence and all previous information about the words that preceded the current timestep is available to the classifier in a manner that disregards recency.

As a consequence of the *smoothing effect*, the model does not necessarily need to store information about the context of the sequence in the recurrent connections of the RNN. This behaviour enable the model to retrieve information from the buffer to remember past words without relying solely on the RNN’s internal “memory”. Therefore, the model can maximize the features extracted about an input word, creating an advantage over other RNN-LMs that need to both extract features and keep context regarding the sequence in its connections.

Model	Params	Valid. Set	Test Set
Single Models			
Medium Regularized LSTM (Zaremba et al., 2015)	20M	86.2	82.7
Large Regularized LSTM (Zaremba et al., 2015)	66M	82.2	78.4
Large + BD + WT (Press and Wolf, 2016)	51M	75.8	73.2
Neural cache model (size = 500) (Grave et al., 2017)	-	-	72.1
Medium Pointer Sentinel-LSTM (Merity et al., 2017)	21M	72.4	70.9
Attentive LM w/ <i>combined</i> score function	14.5M	72.6	70.7
Attentive LM w/ <i>single</i> score function	14.5M	71.7	70.1
Model Averaging			
2 Medium regularized LSTMs (Zaremba et al., 2015)	40M	80.6	77.0
5 Medium regularized LSTMs (Zaremba et al., 2015)	100M	76.7	73.3
10 Medium regularized LSTMs (Zaremba et al., 2015)	200M	75.2	72.0
2 Large regularized LSTMs (Zaremba et al., 2015)	122M	76.9	73.6
10 Large regularized LSTMs (Zaremba et al., 2015)	660M	72.8	69.5
38 Large regularized LSTMs (Zaremba et al., 2015)	2508M	71.9	68.7

Table 1: Perplexity results over the PTB. Symbols: WT = weight tying (Press and Wolf, 2016); WD = weight decay and BD = Bayesian Dropout, both suggested by Gal and Ghahramani (2015).

Model	Params	Valid. Set	Test Set
Zoneout + Variational LSTM (Merity et al., 2017)	20M	108.7	100.9
LSTM-LM (Grave et al., 2017)	-	-	99.3
Variational LSTM (Merity et al., 2017)	20M	101.7	96.3
Neural cache model (size = 100) (Grave et al., 2017)	-	-	81.6
Pointer LSTM (window = 100) (Merity et al., 2017)	21M	84.8	80.8
Attentive LM w/ <i>combined</i> score function	50M	74.3	70.8
Attentive LM w/ <i>single</i> score function	50M	73.7	69.7
Neural cache model (size = 2000) (Grave et al., 2017)	-	-	68.9

Table 2: Perplexity results over the wikitext2.

Another interpretation of the *smoothing effect* is that it “reinforces” the signal in a similar fashion to residual connections in other RNNs and Deep Neural Networks architectures. Other RNN architectures use these residual connections as a shortcut to “reinforce” the signal of the current input and, thus, it still considers the current input only. The *Attentive* RNN-LM, however, uses all the previous hidden states to achieve a similar effect and create a stronger signal to the softmax classifier.

6 Conclusions

This paper proposes the use of attention mechanisms in RNN-LMs. These attention mechanisms enable an RNN-LM to consider information from its past when it is predicting the next word. We believe that this can help the LM to overcome

the fading of relevant information as it traverses a long-distance dependency within a sequence and also to recover from a mistaken prediction by focusing on the context preceding the error.

Our results show that an *Attentive* RNN-LM outperforms both RNN-LM models that use and that do not use past information to predict the next word in a sequence when trained on the PTB dataset. Furthermore, our *Attentive* RNN-LM achieves this performance using far fewer units than the “standard” RNN-LM and, therefore, less model parameters. Our results also show that our *Attentive* RNN-LM achieves similar results to an ensemble that averages over 10 similar sized (in terms of number of LSTM units) RNN-LMs.

In addition, our results demonstrate that our *Attentive* RNN-LM achieves similar to state-of-the-

art results over the wikitext2 dataset. It is an interesting result given that we do not allow our model to look beyond the boundaries of the current sequence it is processing, whilst the state-of-the-art model is allowed to store 2,000 previous states in its cache.

In future work we plan to (a) test the performance of ensembles of *Attentive* RNN-LMs and (b) to study the use of the *Attentive* RNN-LM as the decoder within an NMT system.

Diachrony-aware Induction of Binary Latent Representations from Typological Features

Abstract

Although features of linguistic typology are a promising alternative to lexical evidence for tracing evolutionary history of languages, a large number of missing values in the dataset pose serious difficulties for statistical modeling. In this paper, we combine two existing approaches to the problem: (1) the synchronic approach that focuses on interdependencies between features and (2) the diachronic approach that exploits phylogenetically-and/or spatially-related languages. Specifically, we propose a Bayesian model that (1) represents each language as a sequence of binary latent *parameters* encoding inter-feature dependencies and (2) relates a language's parameters to those of its phylogenetic and spatial neighbors. Experiments show that the proposed model recovers missing values more accurately than others and that induced representations retain phylogenetic and spatial signals observed for surface features.

1 Introduction

Features of linguistic typology such as basic word order (examples are *SVO* and *SOV*) and the presence or absence of tone constitute a promising resource that can potentially be used to uncover the evolutionary history of languages. It has been argued that in exceptional cases, typological features can reflect a time span of 10,000 years or more (Nichols, 1994). Since typological features, by definition, allow us to compare an arbitrary pair of languages, they can be seen as the last hope for language isolates and tiny language families such as Ainu, Basque, and Japanese, for which lexicon-based historical-comparative lin-

guistics¹ has failed to identify genetic relatives. Fortunately, the publication of a large typology database (Haspelmath et al., 2005) made it possible to take computational approaches to this area of study (Daumé III and Campbell, 2007).

Murawaki (2015) pursued a pipeline approach to utilizing typological features for phylogenetic inference. Exploiting interdependencies found among features, Murawaki (2015) first mapped each language, represented as a sequence of surface features, into a sequence of continuous latent components. It was in this continuous space that phylogenetic relations among languages were subsequently inferred. Murawaki (2015) argued that since the conversion and the resulting latent representations were designed to reflect typological naturalness, reconstructed ancestral languages were also likely to be typologically natural.

In this paper, however, we show that Murawaki (2015) rests on fragile underpinnings so that they need to be rebuilt. One of the most important problems underestimated by Murawaki (2015) is an alarmingly large number of missing values. The dataset is a matrix where languages are represented as rows and features as columns, but only less than 30% of the items are present after a modest preprocessing. What is worse, the situation is unlikely to change in the foreseeable future because of the thousands of languages in the world, there is ample documentation for only a handful. These missing values pose serious difficulties for statistical modeling. Ignoring uncertainty in data, however, Murawaki (2015) relied on point estimates of missing values provided by an existing method of imputation when inducing latent representations. In this paper, we take a Bayesian approach because it is known for its robustness in

¹ By lexicon-based historical-comparative linguistics, we mean broad topics including sound laws, cognates, and historical changes in inflectional paradigms.

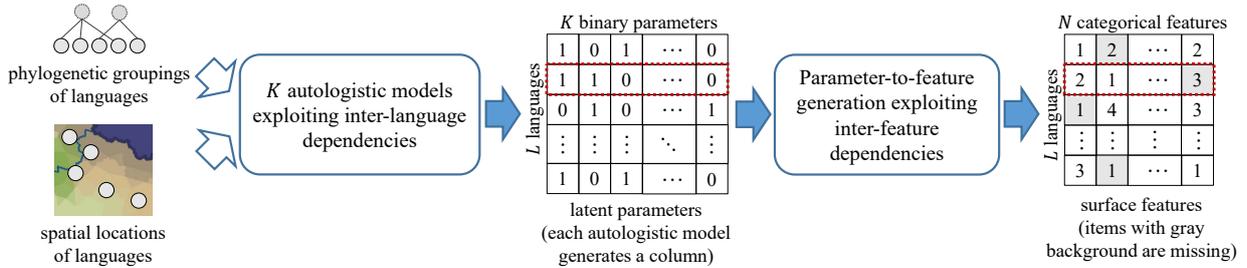

Figure 1: Overview of the proposed Bayesian generative model. Dotted boxes indicate the latent and surface representations of a language. Solid arrows show the direction of stochastic generation.

modeling uncertainties. We demonstrate that we can jointly infer missing values and latent representations.

Another question left unanswered is how good the induced representations are. In this paper, we present two quantitative analyses of the induced representations. The first one is rather indirect: we measure how well a model recovers missing values, with the assumption that good representations must capture regularity in surface features. We show that the proposed method outperformed the pipelined imputation method of Murawaki (2015) among others.

The second analysis involves geography. It is well known that the values of a surface feature do not distribute randomly in the world but reflect vertical (phylogenetic) transmissions from parents to children and horizontal (spatial or areal) transmissions between populations (Nichols, 1992). For example, languages of Mainland Southeast Asia are known for having similar tone systems even though they belong to different language families. To measure the degrees of the two modes of transmissions, we use an autologistic model that investigates dependencies among languages (Towner et al., 2012; Yamauchi and Murawaki, 2016). Since it requires the input to be discrete, we evaluate a new model that focuses on inter-feature dependencies in the same way as Murawaki (2015) but induces *binary* latent representations. We show that vertical and horizontal signals observed for surface features largely vanish from latent representations when only inter-feature dependencies are exploited. Although not directly applicable to the model of Murawaki (2015), our results suggest that the pipeline approach suffers from noise during phylogenetic inference. To address this problem, we extend the induction model to incorporate the autologistic model at the level of latent representations, rather

than surface features. With this integrated model, we manage to let induced representations retain surface signals.

In the end, the Bayesian generative model we propose induces binary latent representations by combining inter-feature dependencies and inter-language dependencies, with primacy given to the former (Figure 1). Whereas inter-feature dependencies are synchronic in nature, inter-language dependencies reflect diachrony. Thus we call the integrated model diachrony-aware induction.

Due to space limitation, we had to put technical details into the supplementary material. However, we would like to stress that the proposed model works only if it is armed with statistical techniques rarely found in the NLP literature. Together with missing values and binary representations, a large number of continuous variables that connect binary representations to surface features need to be inferred. Unfortunately, a naïve Metropolis-Hastings algorithm does not converge within realistic time scales. We solve this problem by adopting Hamiltonian Monte Carlo (Neal, 2011) since it enables us to efficiently sample a large number of continuous variables at once. Likewise, the autologistic model contains an intractable normalization term, which prevents the application of the standard Metropolis-Hastings sampler. We use an approximate sampler instead (Liang, 2010).

2 Related Work

2.1 Inter-feature Dependencies

Interdependencies among features have long been observed across the world’s languages. For example, OV (object-verb) languages tend to be AN for the order of adjective and noun. Greenberg (1963) proposed dozens of such patterns known as *linguistic universals*. A statistical model for discovering Greenbergian universals was presented by Daumé III and Campbell (2007). Itoh and Ueda (2004) used the Ising model to model the interac-

tion between features. Although these studies entirely focused on surface patterns, they imply the presence of some latent structure behind these surface features.

Some generative linguists argue for the existence of binary latent *parameters* behind surface features although they are controversial even among generative linguists (Boeckx, 2014). We borrow the term *parameter* from generative linguistics because the name of *feature* is reserved for surface variables.

Parameters are part of the *principles and parameters* (P&P) framework (Chomsky and Lasnik, 1993), where, the structure of a language is explained by (1) a set of universal principles that are common to all languages and (2) a set of parameters whose values vary among languages. Here we skip the former since our focus is on structural variability. According to P&P, if we set specific values to all the parameters, then we obtain a specific language. Each parameter is binary and, in general, sets the values of multiple surface features in a deterministic manner. For example, the head directionality parameter is either *head-initial* or *head-final*. If *head-initial* is chosen, then surface features are set to VO, NA and Prepositions; otherwise the language in question becomes OV, AN and Postpositions (Baker, 2002). Baker (2002) discussed a number of parameters such as head directionality, polysynthesis, and topic prominent parameters.

Partly inspired by the P&P framework, we use a sequence of binary variables as the latent representation of a language. However, there are non-negligible differences between P&P and ours, which are discussed in Section S.2 of the supplementary material.

What the structure behind surface features looks like is almost exclusively discussed by generative linguists, but it should be noted that they are not the only group who attempts to explain surface patterns. Roughly speaking, generative linguists are part of the *synchronist* camp, as contrasted with *diachronists*, who consider that at least some patterns observed in surface features arise from common paths of diachronic development (Anderson, 2016). An important factor of diachronic development is grammaticalization, by which content words change into function words (Heine and Kuteva, 2007). For example, the correlation be-

tween the order of adposition and noun and the order of genitive and noun might be explained by the fact that adpositions often derive from nouns.

2.2 Inter-language Dependencies

The standard model for phylogenetic inference is the tree model, where a trait is passed on from a parent to a child with occasional modifications. In fact, the recent success in the applications of statistical models to historical linguistic problems is largely attributed to the tree model (Gray and Atkinson, 2003; Bouckaert et al., 2012). In linguistic typology, however, a non-tree-like mode of evolution has emerged as one of the central topics (Trubetzkoy, 1928; Campbell, 2006). Typological features, like loanwords, can be borrowed from one language to another, and as a result, vertical (phylogenetic) signals are obscured by horizontal (spatial) transmission.

The task of incorporating both vertical and horizontal transmissions within a statistical model of evolution is notoriously challenging because of the excessive flexibility of horizontal transmissions. This is the reason why previously proposed models are coupled with some very strong assumptions, for example, that a reference tree is given a priori (Nelson-Sathi et al., 2010), and that horizontal transmissions can be modeled through time-invariant areal clusters (Daumé III, 2009).

Consequently, we pursue a line of research in linguistic typology that draws on information on the current distribution of typological features without explicitly requiring the reconstruction of previous states (Nichols, 1992, 1995; Parkvall, 2008; Wichmann and Holman, 2009). The basic assumption is that if the feature in question is vertically stable, then a phylogenetically defined group of languages will tend to share the same value. Similarly, if the feature in question is horizontally diffusible, then spatially close languages would be expected to frequently share the same feature value. Since the current distribution of typological features is more or less affected by these factors, we need to disentangle the effects of each of these factors. To do this, Yamauchi and Murawaki (2016) adopted a variant of the autologistic model, which had been widely used to model the spatial distribution of a feature (Besag, 1974; Towner et al., 2012). The model was also used to impute missing values because the phylogenetic and spatial neighbors of a language had some predictive power over its feature values.

3 Data and Preprocessing

The dataset we used in the present study is the online edition² of the *World Atlas of Language Structures* (WALS) (Haspelmath et al., 2005). While Greenberg (1963) and generative linguists have manually induced patterns and parameters, WALS makes it possible to take computational approaches to modeling features (Daumé III and Campbell, 2007; Daumé III, 2009; Murawaki, 2015; Takamura et al., 2016; Murawaki, 2016).

WALS is essentially a matrix where languages are represented as rows and features as columns. As of 2017, it contained 2,679 languages and 192 surface features. It covered less than 15% of items in the matrix, however.

We removed sign languages, pidgins and creoles from the matrix. We imputed some missing values that could trivially be inferred from other features. We then removed features that covered less than 10% of the languages. After the preprocessing, the number of languages L was 2,607 while the number of features N was reduced to 104. The coverage went up to 26.9%, but the rate was still alarmingly low.

In WALS, languages are accompanied by additional information. We used the following fields to model inter-language dependencies. (1) genera, the lower of the two-level phylogenetic groupings, and (2) single-point geographical coordinates (longitude and latitude). By connecting every pair of languages within a genus, we constructed a phylogenetic neighbor graph. A spatial neighbor graph was constructed by linking all language pairs that were located within a distance of $R = 1000$ km. On average, each language had 30.8 and 89.1 neighbors, respectively.

The features in WALS are categorical. For example, Feature 81A, “Order of Subject, Object and Verb” has seven possible values: SOV, SVO, VSO, VOS, OVS, OSV and No dominant order, and each language incorporates one of these seven values. For each language, we arranged its features into a sequence. A sequence of categorical features can alternatively be represented as a binary sequence using the 1-of- F_i coding scheme: Feature i with F_i possible values was converted into F_i binary items among which only one item takes 1. The number of binarized features M was 723.

²<http://wals.info/>

L	# of languages
K	# of parameters
M	# of binarized features
N	# of categorical features
$Z \in \{0, 1\}^{L \times K}$	Binary parameter matrix
$W \in \mathbb{R}^{K \times M}$	Weight matrix
$\tilde{\Theta} \in \mathbb{R}^{L \times M}$	Feature score matrix
$\Theta \in [0, 1]^{L \times M}$	Feature probability matrix
$X \in \mathbb{N}^{L \times N}$	Categorical feature matrix

Table 1: Notations.

4 Proposed Method

Since the proposed model is rather complicated, we present two key components before going into the integrated model. Table 1 shows notations used in this paper. Surface features have two ways of indexing. First, feature values are serialized as $(1, 1), \dots, (1, F_1), (2, 1), \dots, (i, j), \dots, (N, F_N)$, where (i, j) points to feature i ’s j -th value. Then they are given the flat index $1, \dots, m, \dots, M$ ($M = \sum_{i=1}^N F_i$). Two indices are mapped by the function $f(i, j) = m$. We need the flat representation because that is what latent parameters work on. A parameter is expected to capture the relation between one feature’s particular value (e.g., VO for the order of object and verb) and another feature’s particular value (NA for the order of adjective and noun).

4.1 Inter-feature Dependencies

Figure 2 illustrates how surface features are generated from binary latent parameters. We use matrix factorization (Srebro et al., 2005; Griffiths and Ghahramani, 2011) to capture inter-feature dependencies. Since categorical feature matrix X cannot directly be decomposed into two, we first construct (unnormalized) feature score matrix $\tilde{\Theta}$ and then stochastically generate X using $\tilde{\Theta}$.

$\tilde{\Theta}$ is a product of binary parameter matrix Z and weight matrix W . The generation of Z will be described in Section 4.2.³ Each item of $\tilde{\Theta}$, $\tilde{\theta}_{l,m}$, is a score for language l ’s m -th binarized feature. It is affected only by parameters with $z_{l,k} = 1$ because

$$\tilde{\theta}_{l,m} = \sum_{k=1}^K z_{l,k} w_{k,m}. \quad (1)$$

³ Although the natural choice for modeling binary latent matrices is an Indian buffet process (IBP) (Griffiths and Ghahramani, 2011), we do not take this approach for reasons we explain in Section S.1 of the supplementary material.

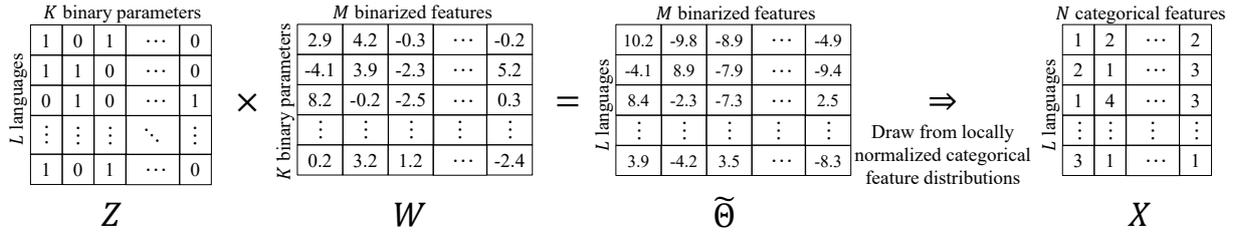

Figure 2: Stochastic parameter-to-feature generation. $\tilde{\Theta} = ZW$ encodes inter-feature dependencies.

We locally apply normalization to $\tilde{\Theta}$ to obtain Θ , in which $\theta_{l,i,j}$ is the probability of language l taking value j for categorical feature i

$$\theta_{l,i,j} = \frac{\exp(\tilde{\theta}_{l,f(i,j)})}{\sum_{j'} \exp(\tilde{\theta}_{l,f(i,j')})}. \quad (2)$$

Finally, language l 's i -th categorical feature, $x_{l,i}$, is generated from this distribution.

$$P(x_{l,i} | z_{l,*}, W) = \theta_{l,i,x_{l,i}}, \quad (3)$$

where $z_{l,*} = (z_{l,1}, \dots, z_{l,K})$.

Combining Eqs. (1) and (2), we obtain

$$\begin{aligned} \theta_{l,i,j} &\propto \exp\left(\sum_{k=1}^K z_{l,k} w_{k,f(i,j)}\right) \\ &= \prod_{k=1}^K \exp(z_{l,k} w_{k,f(i,j)}). \end{aligned} \quad (4)$$

We can see from Eq. (4) that this is a product-of-experts model (Hinton, 2002). If $z_{l,k} = 0$, parameter k has no effect on $\theta_{l,i,j}$ because $\exp(z_{l,k} w_{k,f(i,j)}) = 1$. Otherwise, if $w_{k,f(i,j)} > 0$, it makes $\theta_{l,i,j}$ larger, and if $w_{k,f(i,j)} < 0$, it lowers $\theta_{l,i,j}$.

Suppose that for parameter k , a certain group of languages takes $z_{l,k} = 1$. If two categorical feature values (i_1, j_1) and (i_2, j_2) have positive weights (i.e., $w_{k,f(i_1,j_1)} > 0$ and $w_{k,f(i_2,j_2)} > 0$), the pair must often co-occur in these languages. Likewise, the fact that two feature values do not co-occur can be encoded as a positive weight for one value and a negative weight for the other.

4.2 Inter-language Dependencies

The autologistic model is used to generate each column of Z , $z_{*,k} = (z_{1,k}, \dots, z_{L,k})$. To construct the model, we use two neighbor graphs and the corresponding three counting functions, as illustrated in Figure 3. $V(z_{*,k})$ returns the number

of pairs sharing the same value in the phylogenetic neighbor graph, and $H(z_{*,k})$ is the spatial equivalent of $V(z_{*,k})$. $U(z_{*,k})$ gives the number of languages that take the value 1.

We now introduce the following variables: vertical stability $v_k > 0$, horizontal diffusibility $h_k > 0$, and universality $-\infty < u_k < \infty$ for each feature k . Then the probability of $z_{*,k}$ conditioned on v_k, h_k and u_k is given as

$$P(z_{*,k} | v_k, h_k, u_k) = \frac{\exp\left(v_k V(z_{*,k}) + h_k H(z_{*,k}) + u_k U(z_{*,k})\right)}{\sum_{z'_{*,k}} \exp\left(v_k V(z'_{*,k}) + h_k H(z'_{*,k}) + u_k U(z'_{*,k})\right)}.$$

The denominator is a normalization term, ensuring that the sum of the distribution equals one.

The autologistic model can be interpreted in terms of the competition associated with possible assignments of $z_{*,k}$ for the probability mass 1. If a given value, $z_{*,k}$, has a relatively large $V(z_{*,k})$, then setting a large value for v_k enables it to appropriate fractions of the mass from its weaker rivals. However, if too large a value is set for v_k , then it will be overwhelmed by its stronger rivals.

To acquire further insights into the model, let us consider the probability of language l taking value $b \in \{0, 1\}$, conditioned on the rest of the languages, $z_{-l,k}$:

$$P(z_{l,k} = b | z_{-l,k}, v_k, h_k, u_k) \propto \exp(v_k V_{l,k,b} + h_k H_{l,k,b} + u_k b), \quad (5)$$

where $V_{l,k,b}$ is the number of language l 's phylogenetic neighbors that assume value b , and $H_{l,k,b}$ is its spatial counterpart. $P(z_{l,k} = b | z_{-l,k}, v_k, h_k, u_k)$ is expressed by the weighted linear combination of the three factors in the log-space. It will increase with a rise in the number of phylogenetic neighbors that assume value b . However, this probability depends not only on the phy-

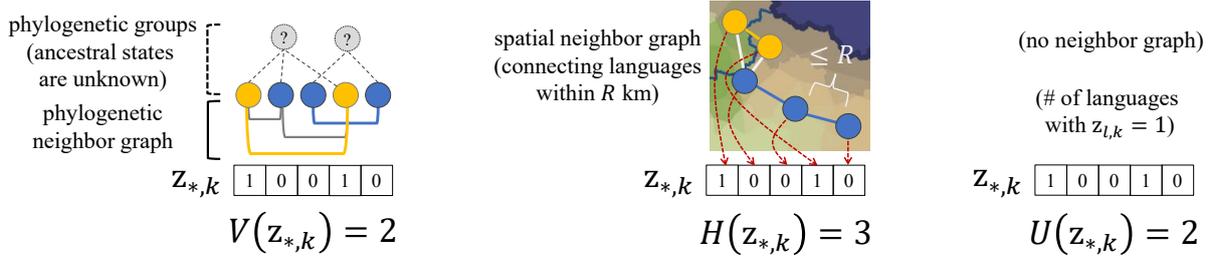

Figure 3: Neighbor graphs and counting functions used to encode inter-language dependencies.

logenetic neighbors of language l , but it also depends on its spatial neighbors and on universality. How strongly these factors affect the stochastic selection is controlled by v_k , h_k , and u_k .

4.3 Integrated Model

Now we complete the generative model by integrating the two types of dependencies. The joint distribution is defined as

$$P(A, Z, W, X) = P(A)P(Z|A)P(W)P(X|Z, W),$$

where hyperparameters are omitted for brevity and A is a set of latent variables that control the generation of Z :

$$P(A) = \prod_{k=1}^K P(v_k)P(h_k)P(u_k).$$

Their prior distributions are: $v_k \sim \text{Gamma}(\kappa, \theta)$, $h_k \sim \text{Gamma}(\kappa, \theta)$, and $u_k \sim \mathcal{N}(0, \sigma^2)$.⁴

Next, $z_{*,k}$'s are generated as described in Section 4.2:

$$P(Z | A) = \prod_{k=1}^K P(z_{*,k} | v_k, h_k, u_k).$$

The generation of Z is followed by that of the corresponding weight matrix $W \in \mathbb{R}^{K \times M}$, and then we obtain the feature score matrix $\tilde{\Theta} = ZW$. Each item of W , $w_{k,m}$, is generated from Student's t -distribution with 1 degree of freedom. We choose this distribution for two reasons. First, it has heavier tails than the Gaussian distribution and allows some weights to fall far from 0. Second, our inference algorithm demands that the negative logarithm of the probability density function be differentiable (see Section S.4 for details).

⁴ In the experiments, we set shape $\kappa = 1$, scale $\theta = 1$, and standard deviation $\sigma = 10$. These priors were not non-informative, but they were sufficiently gentle in the regions where these parameters typically resided.

The t -distribution satisfies the condition while the Laplace distribution does not.

Finally, X is generated using $\tilde{\Theta} = ZW$, as described in Section 4.1:

$$P(X | Z, W) = \prod_{l=1}^L \prod_{i=1}^N P(x_{l,i} | z_{l,*}, W).$$

4.4 Inference

As usual, we use Gibbs sampling to perform posterior inference. Given observed values $x_{l,i}$, we iteratively update $z_{l,k}$, v_k , h_k , u_k , and $w_{k,*}$ as well as missing values $x_{l,i}$.

Update $x_{l,i}$. $x_{l,i}$ is sampled from Eq. (3).

Update $z_{l,k}$. The posterior probability $P(z_{l,k} | -)$ is proportional to Eq. (5) times the product of Eq. (3) for all feature i 's of language l .

Update v_k , h_k and u_k . We want to sample v_k (and h_k and u_k) from $P(v_k | -) \propto P(v_k)P(z_{*,k} | v_k, h_k, u_k)$. This belongs to a class of problems known as sampling from doubly-intractable distributions (Møller et al., 2006; Murray et al., 2006). While it remains a challenging problem in statistics, it is not difficult to approximately sample the variables if we give up theoretical rigorosity (Liang, 2010). The details of the algorithm we use can be found in Section S.3 of the supplementary material.

Update $w_{k,*}$. The remaining problem is how to update $w_{k,m}$. Since the number of weights is very large ($K \times M$), the simple Metropolis-Hastings algorithm (Görür et al., 2006; Doyle et al., 2014) is not a workable option. To address this problem, we block-sample $w_{k,*} = (w_{k,1}, \dots, w_{k,M})$ using Hamiltonian Monte Carlo (HMC) (Neal, 2011). A sketch of the algorithm can be found in Section S.4 of the supplementary material.

5 Experiments

5.1 Missing Value Imputation

We indirectly evaluated the proposed model, called SYNDIA, by means of missing value imputation. If it predicts missing feature values better than reasonable baselines, we can say that the induced parameters are justified. Although no ground truth exists for the missing portion of the dataset, missing value imputation can be evaluated by hiding some observed values and verifying the effectiveness of their recovery. We conducted a 10-fold cross-validation.

We ran SYNDIA with two different settings: $K = 50$ and 100. We performed posterior inference for 500 iterations. After that, we collected 100 samples of $x_{l,i}$ for each language, one per iteration. For each missing value $x_{l,i}$, we output the most frequent value among the 100 samples. The HMC parameters ϵ and S were set to 0.05 and 10, respectively.

We applied simulated annealing to the sampling of $z_{l,k}$. For the first 100 iterations, the inverse temperature was increased from 0.1 to 1.0.

We compared SYNDIA with several baselines.

MFV For each categorical feature i , always output the most frequent value among observed $x_{l,i}$.

Surface-DIA An autologistic model applied to surface features (Yamauchi and Murawaki, 2016). The details of the model are presented in Section S.5 of the supplementary material.

DPMPM A Dirichlet process mixture of multinomial distributions with a truncated stick-breaking construction (Si and Reiter, 2013) used by Blasi et al. (2017). It assigns a single categorical latent variable to each language. As an implementation, we used the R package *NPBayesImpute*.

MCA A variant of multiple correspondence analysis (Josse et al., 2012) used by Murawaki (2015). We used the `imputeMCA` function of the R package *missMDA*.

SYN A simplified version of SYNDIA, with v_k and h_k removed from the model. See Section S.6 of the supplementary material for details.

MFV and Surface-DIA can be seen as the models of inter-language dependencies while DPMPM, MCA and SYN are these of inter-feature dependencies.

Table 2 shows the result. We can see that SYNDIA with $K = 50$ performed the best.

Type	Model	Accuracy
Lang.	MFV	60.95%
	Surface-DIA	66.22%
Feat.	DPMPM ($K^* = 50$)	69.08%
	MCA	69.88%
	SYN ($K = 50$)	73.83%
	SYN ($K = 100$)	72.87%
Both	SYNDIA ($K = 50$)	74.46%
	SYNDIA ($K = 100$)	74.00%

Table 2: Accuracy of missing value imputation. The first column indicates the types of dependencies the models exploit: inter-language dependencies, inter-feature dependencies and both.

Model	Accuracy
Full model (SYNDIA)	74.46%
-vertical	73.89%
-horizontal	74.47%
-vertical -horizontal (SYN)	73.83%

Table 3: Ablation experiments for missing value imputation. $K = 50$.

Smaller K yielded higher accuracy although the likelihood $P(X | Z, W)$ went up as K increased. Due to the high ratio of missing values, the model might have overfitted the data with larger K .

The fact that SYN outperformed Surface-DIA suggests that inter-feature dependencies have more predictive power than inter-language dependencies in the dataset. However, they are complimentary in nature as SYNDIA outperformed SYN.

We can confirm the limited expressive power of single categorical latent variables because DPMPM performed poorly even if a small value was set to the truncation level K^* to avoid overfitting. MCA employs more expressive representations of a sequence of continuous variables for each language. It slightly outperformed DPMPM but was beaten by SYN by a large margin. We conjecture that MCA was more sensitive to initialization than the Bayesian model armed with MCMC sampling. In any case, this result indicates that the latent representations Murawaki (2015) obtained were of poorer quality than those of SYN, not to mention those of SYNDIA.

We also conducted ablation experiments by removing either v_k or h_k from the model. The result is shown in Table 3. It turned out that the horizontal factor had stronger predictive power than the vertical factor, which has a negative implication on typology-based phylogenetic inference.

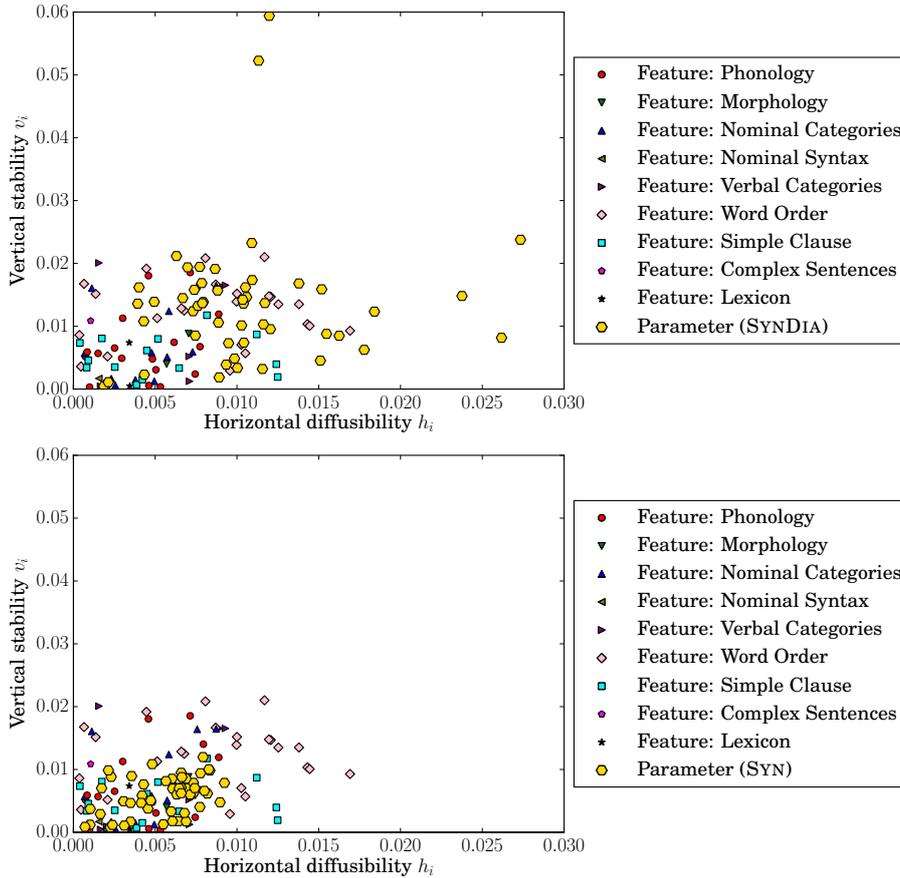

Figure 4: Scatter plots of surface features and induced parameters, with vertical stability v_i (v_k) as the y-axis and horizontal diffusibility h_i (h_k) as the x-axis. Larger v_i (h_i) indicates that feature i is more stable (diffusible). Comparing the absolute values of a v_i and an h_i makes no sense because they are tied with different neighbor graphs. Features are classified into 9 broad categories (called *Area* in WALS). v_k (and h_k) is the geometric mean of the 100 samples. The induction models are SYNDIA (Top) and SYN (Bottom). For both models, $K = 50$.

5.2 Vertical and Horizontal Signals

Hereafter we use all observed features to perform posterior inference. We examined how vertically stable and horizontally diffusible the induced parameters were. For SYNDIA, we simply extracted v_k and h_k from posterior samples. For comparison, we used Surface-DIA to estimate vertical stability and horizontal diffusibility of surface features. The same autologistic model was used to estimate v_k and h_k of SYN *after* the posterior inference. For details, see Sections S.5 and S.6.2 of the supplementary material.

Figure 4 summarizes the results. We can see that the most vertically stable latent parameters of SYNDIA are comparable to the most vertically stable surface features. The same holds for the most horizontally diffusible ones. Thus we can conclude that the induced representations retain ver-

tical and horizontal signals observed for surface features.

On the other hand, SYN halved vertical stability and horizontal diffusibility when transforming surface features into latent parameters. A plausible explanation of this failure is that for many scarcely documented languages, we simply did not have enough observed surface features to determine their latent representations only from inter-feature dependencies. Due to the inherent uncertainty, $z_{l,k}$ swung between 0 and 1 during posterior inference, regardless of the states of their neighbors. As a result, these languages seem to have blocked vertical and horizontal signals. By contrast, SYNDIA appears to have flipped $z_{l,k}$ without disrupting inter-language dependencies when there were.

In summary, the experimental results have neg-

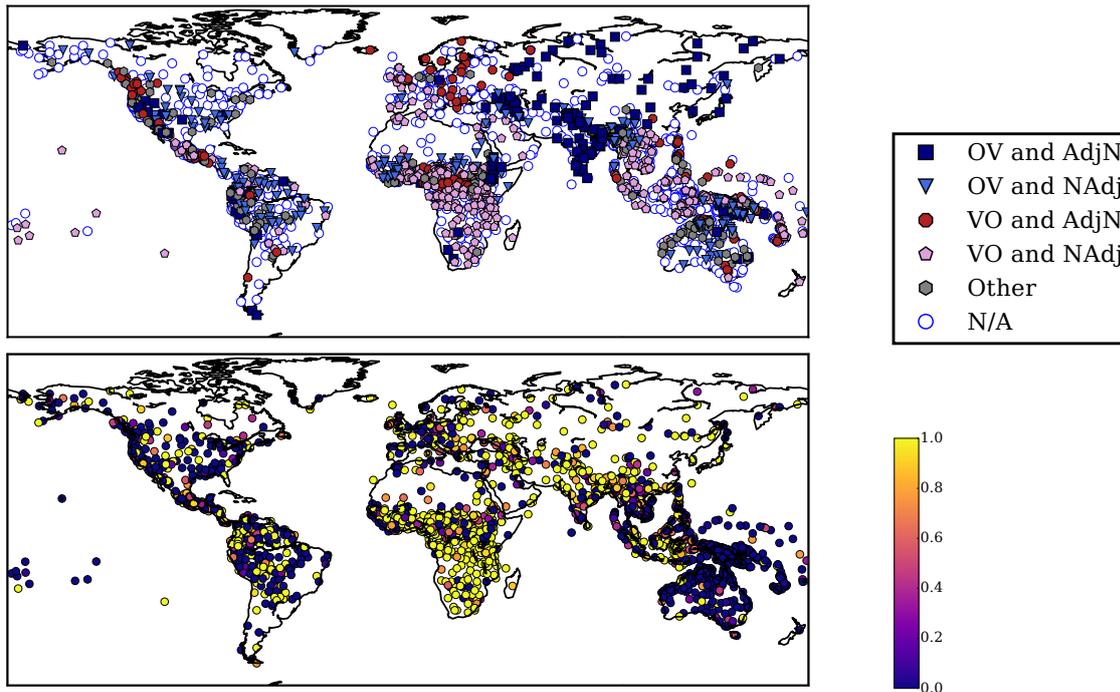

Figure 5: A comparison of a surface feature and a latent parameter in terms of geographical distribution. Each point denotes a language. (Top) Feature 97A, “Relationship between the Order of Object and Verb and the Order of Adjective and Noun.” Missing values are denoted as N/A. (Bottom) A parameter of SYNDIA with $K_0 = 50$. Lighter nodes indicate higher frequencies of $z_{l,k} = 1$ among 100 samples.

ative implications for the pipeline approach pursued by Murawaki (2015), where the inter-feature dependency-based induction of latent representations is followed by phylogenetic inference. Fortunately, evidence presented up to this point suggests that it can be readily replaced with the proposed model.

5.3 Discussion

Figure 5 compares a latent parameter of SYNDIA with a surface feature on the world map. Some surface features show several geographic clusters of large size, telling something about the evolutionary history of languages. Even with a large number of missing values, SYNDIA yielded comparable geographic clusters for some parameters. Some geographic clusters were also produced by SYN, especially when the estimation of $z_{l,k}$ was stable. In our subjective evaluation, SYNDIA appeared to show clearer patterns than SYN. Needless to say, not all surface features were associated with clear geographic patterns, and not all latent parameters were. Overall, the results shed a positive light on the applicability of the induced representations to phylogenetic inference.

We also checked the weight matrix W (Fig-

ure S.2). It is not easy to analyze qualitatively but it deserves future investigation.

6 Conclusion

In this paper, we presented a Bayesian model that induces binary latent parameters from surface features of linguistic typology. We combined inter-language dependencies with inter-feature dependencies to obtain the latent representations of better quality. Gathering various statistical techniques, we managed to create the complex but workable model. The source code is publicly available at <https://github.com/murawaki/latent-typology>.

We pointed out that typology-based phylogenetic inference proposed by Murawaki (2015) had weak foundations, and we rebuilt them from scratch. The whole long paper was needed to do so, but our ultimate goal is the same as the one stated by Murawaki (2015). In the future, we would like to utilize the new latent representations to uncover the evolutionary history of languages.

Abstract

The popularity of image sharing on social media and the engagement it creates between users reflect the important role that visual context plays in everyday conversations. We present a novel task, Image-Grounded Conversations (IGC), in which natural-sounding conversations are generated about a shared image. To benchmark progress, we introduce a new multiple-reference dataset of crowd-sourced, event-centric conversations on images. IGC falls on the continuum between chit-chat and goal-directed conversation models, where visual grounding constrains the topic of conversation to event-driven utterances. Experiments with models trained on social media data show that the combination of visual and textual context enhances the quality of generated conversational turns. In human evaluation, the gap between human performance and that of both neural and retrieval architectures suggests that multi-modal IGC presents an interesting challenge for dialog research.

1 Introduction

Bringing together vision & language in one intelligent conversational system has been one of the longest running goals in AI (Winograd, 1972). Advances in image captioning (Fang et al., 2014; Chen et al., 2015; Donahue et al., 2015) have enabled much interdisciplinary research in vision and language, from video transcription (Rohrbach et al., 2012; Venugopalan et al., 2015), to answering questions about images (Antol et al., 2015; Malinowski and Fritz, 2014), to storytelling around series of photographs (Huang et al., 2016).

* This work was performed at Microsoft.

User1: My son is ahead and surprised!
User2: Did he end up winning the race?
User1: Yes he won, he can't believe it!

Figure 1: A naturally-occurring Image-Grounded Conversation.

Most recent work on vision & language focuses on either describing (captioning) the image or answering questions about their visible content. Observing how people naturally engage with one another around images in social media, it is evident that it is often in the form of conversational threads. On Twitter, for example, uploading a photo with an accompanying tweet has become increasingly popular: in June 2015, 28% of tweets reportedly contained an image (Morris et al., 2016). Moreover, across social media, the conversations around shared images range beyond what is explicitly visible in the image. Figure 1 illustrates such a conversation. As this example shows, the conversation is grounded not only in the visible objects (e.g., the boys, the bikes) but more importantly, in the events and actions (e.g., the race, winning) implicit in the image that is accompanied by the textual utterance. To humans, it is these latter aspects that are likely to be the most interesting and most meaningful components of a natural conversation, and to the systems, inferring such implicit aspects can be the most challenging.

In this paper we shift the focus from image as an artifact (as is in the existing vision & language work, to be described in Section 2), to image as the context for interaction: we introduce the task of Image-Grounded Conversation (IGC) in which a system must generate conversational turns to proactively drive the interaction forward. IGC thus falls on a continuum between chit-chat

(open-ended) and goal-oriented task-completion dialog systems, where the visual context in IGC naturally serves as a detailed topic for a conversation. As conversational agents gain increasing ground in commercial settings (e.g., Siri and Alexa), they will increasingly need to engage humans in ways that seem intelligent and anticipatory of future needs. For example, a conversational agent might engage in a conversation with a user about a camera-roll image in order to elicit background information from the user (e.g., special celebrations, favorite food, the name of the friends and family, etc.).

This paper draws together two threads of investigation that have hitherto remained largely unrelated: vision & language and data-driven conversation modeling. Its contributions are three-fold: (1) we introduce multimodal conversational context for formulating questions and responses around images, and support benchmarking with a publicly-released, high-quality, crowd-sourced dataset of 4,222 multi-turn, multi-reference conversations grounded on event-centric images. We analyze various characteristics of this IGC dataset in Section 3.1. (2) We investigate the application of deep neural generation and retrieval approaches for question and response generation tasks (Section 5), trained on 250K 3-turn naturally-occurring image-grounded conversations found on Twitter. (3) Our experiments suggest that the combination of visual and textual context improves the quality of generated conversational turns (Section 6-7). We hope that this novel task will spark new interest in multimodal conversation modeling.

2 Related Work

2.1 Vision and Language

Visual features combined with language modeling have shown good performance both in image captioning (Devlin et al., 2015; Xu et al., 2015; Fang et al., 2014; Donahue et al., 2015) and in question answering on images (Antol et al., 2015; Ray et al., 2016; Malinowski and Fritz, 2014), when trained on large datasets, such as the COCO dataset (Lin et al., 2014). In Visual Question Answering (VQA) (Antol et al., 2015), a system is tasked with answering a question about a given image, where the questions are constrained to be answerable directly from the image. In other words, the VQA task primarily serves to evaluate the extent to which the system has recognized the explicit content of the image.

Figure 2: Typical crowdsourced conversations in IGC (left) and VisDial (right).

Das et al. (2017a) extend the VQA scenario by collecting sequential questions from people who are shown only an automatically generated caption, not the image itself. The utterances in this dataset, called ‘Visual Dialog’ (VisDial), are best viewed as simple one-sided QA exchanges in which humans ask questions and the system provides answers. Figure 2 contrasts an example IGC conversation with the VisDial dataset. As this example shows, IGC involves natural conversations with the image as the grounding, where the literal objects (e.g., the pumpkins) may not even be mentioned in the conversation at all, whereas VisDial targets explicit image understanding. More recently, Das et al. (2017b) have explored the VisDial dataset with richer models that incorporate deep-reinforcement learning.

Mostafazadeh et al. (2016b) introduce the task of visual question generation (VQG), in which the system itself outputs questions about a given image. Questions are required to be ‘natural and engaging’, i.e. a person would find them interesting to answer, but need not be answerable from the image alone. In this work, we introduce multimodal context, recognizing that images commonly come associated with a verbal commentary that can affect the interpretation. This is thus a broader, more complex task that involves implicit commonsense reasoning around both image and text.

2.2 Data-Driven Conversational Modeling

This work is also closely linked to research on data-driven conversation modeling. Ritter et al. (2011) posed response generation as a machine translation task, learning conversations from parallel message-response pairs found on social media. Their work has been successfully extended with the use of deep neural models (Sordoni et al., 2015; Shang et al., 2015; Serban et al., 2015a; Vinyals and Le, 2015; Li et al., 2016a,b). Sordoni et al. (2015) introduce a context-sensitive neural language model that selects the most probable response conditioned on the conversation history (i.e., a text-only context). In this paper, we extend the contextual approach with multimodal features to build models that are capable of asking questions on topics of interest to a human that might allow a conversational agent to proactively drive a conversation forward.

3 Image-Grounded Conversations

3.1 Task Definition

We define the current scope of IGC as the following two consecutive conversational steps:

- **Question Generation:** Given a visual context I and a textual context T (e.g., the first statement in Figure 1), generate a coherent, natural question Q about the image as the second utterance in the conversation. It has been shown that humans achieve greater consensus on what constitutes a natural question to ask given an image (the task of VQG) than on captioning or asking a visually verifiable question (VQA) (Mostafazadeh et al., 2016b). As seen in Figure 1, the question is not directly answerable from the image. Here we emphasize on questions as a way of potentially engaging a human in continuing the conversation.

- **Response Generation:** Given a visual context I , a textual context T , and a question Q , generate a coherent, natural, response R to the question as the third utterance in the conversation. In the interests of feasible multi-reference evaluation, we pose question and response generation as two separate tasks. However, all the models presented in this paper can be fed with their own generated question to generate a response.

3.2 The IGC Dataset

The majority of the available corpora for developing data-driven dialogue systems contain task-oriented and goal-driven conversational data (Serban et al., 2015b). For instance, the Ubuntu dia-

logue corpus (Lowe et al., 2015) is the largest corpus of dialogues (almost 1 million mainly 3-turn dialogues) for the specific topic of troubleshooting Ubuntu problems. On the other hand, for open-ended conversation modeling (chitchat), now a high demand application in AI, shared datasets with which to track progress are severely lacking. The IGC task presented here lies nicely in the continuum between the two, where the visual grounding of event-centric images constrains the topic of conversation to contentful utterances.

To enable benchmarking of progress in the IGC task, we constructed the IGC_{Crowd} dataset for validation and testing purposes. We first sampled eventful images from the VQG dataset (Mostafazadeh et al., 2016b) which has been extracted by querying a search engine using event-centric query terms. These were then served in a photo gallery of a crowd-sourcing platform we developed using the Turkserver toolkit (Mao et al., 2012), which enables synchronous and real-time interactions between crowd workers on Amazon Mechanical Turk. Multiple workers wait in a virtual lobby to be paired with a conversation partner. After being paired, one of the workers selects an image from the large photo gallery, after which the two workers enter a chat window in which they conduct a short conversation about the selected image. We prompted the workers to naturally drive the conversation forward without using informal/IM language. To enable multi-reference evaluation (Section 6), we crowd-sourced five additional questions and responses for the IGC_{Crowd} contexts and initial questions.

Table 1 shows three full conversations found in the IGC_{Crowd} dataset. These examples show that eventful images lead to conversations that are semantically rich and appear to involve commonsense reasoning. Table 2 summarizes basic dataset statistics. The IGC_{Crowd} dataset has been released as the Microsoft Research Image-Grounded Conversation dataset (<https://www.microsoft.com/en-us/download/details.aspx?id=55324&751be11f-ede8>).

4 Task Characteristics

In this Section, we analyze the IGC dataset to highlight a range of phenomena specific to this task. (Additional material pertaining to the lexical distributions of this dataset can be found in the Supplementary Material.)

Visual Context			
Textual Context	This wasn't the way I imagined my day starting.	I checked out the protest yesterday.	A terrible storm destroyed my house!
Question	do you think this happened on the highway?	Do you think America can ever overcome its racial divide?	OH NO, what are you going to do?
Response	Probably not, because I haven't driven anywhere except around town recently.	I can only hope so.	I will go live with my Dad until the insurance company sorts it out.
VQG Question	What caused that tire to go flat?	Where was the protest?	What caused the building to fall over?

Table 1: Example full conversations in our IGC_{Crowd} dataset. For comparison, we also include VQG questions in which the image is the only context.

IGC _{Crowd} (val and test sets, split: 40% and 60%)	
# conversations = # images	4,222
total # utterances	25,332
# all workers participated	308
Max # conversations by one worker	20
Average payment per worker (min)	1.8 dollars
Median work time per worker (min)	10.0
IGC _{Crowd-multiref} (val and test sets, split: 40% and 60%)	
# additional references per question/response	5
total # multi-reference utterances	42,220

Table 2: Basic Dataset Statistics.

4.1 The Effectiveness of Multimodal Context

The task of IGC emphasizes modeling of not only visual but also textual context. We presented human judges with a random sample of 600 triplets of image, textual context, and question (I, T, Q) from each IGC_{Twitter} and IGC_{Crowd} datasets and asked them to rate the effectiveness of the visual and the textual context. We define ‘effectiveness’ to be “the degree to which the image or text is required in order for the given question to sound natural”. The workers were prompted to make this judgment based on whether or not the question already makes sense without either the image or the text. As Figure 3 demonstrates, both visual and textual contexts are generally highly effective, and understanding of both would be required for the question that was asked. By way of comparison, Figure 3 also shows the effectiveness of image and text for a sample taken from Twitter data presented in Section 4.4. We note that the crowd-sourced dataset is more heavily reliant on understanding the textual context than is the Twitter set.

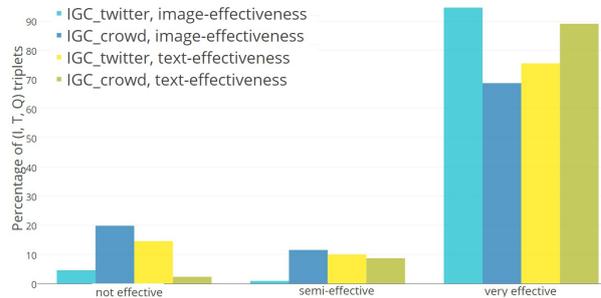

Figure 3: The effectiveness of textual and visual context for asking questions.

4.2 Frame Semantic Analysis of Questions

The grounded conversations starting with questions contain a considerable amount stereotypical commonsense knowledge. To get a better sense of the richness of our IGC_{Crowd} dataset, we manually annotated a random sample of 330 (I, T, Q) triplets in terms of Minsky’s Frames: Minsky defines ‘frame’ as follows: “When one encounters a new situation, one selects from memory a structure called a Frame” (Minsky, 1974). A frame is thus a commonsense knowledge representation data-structure for representing stereotypical situations, such as a wedding ceremony. Minsky further connects frames to the nature of questions: “[A Frame] is a collection of questions to be asked about a situation”. These questions can ask about the cause, intention, or side-effects of a presented situation.

We annotated¹ the FrameNet (Baker et al., 1998) frame evoked by the image I , to be called (I_{FN}), and the textual context T , (T_{FN}). Then, for the question asked, we annotated the frame

¹These annotations can be accessed through <https://goo.gl/MVyGzP>

Visual Context	Textual Context	Question
	Look at all this food I ordered!	Where is that from?
FN Food	Request-Entity	Supplier

Table 3: FrameNet (FN) annotation of an example.

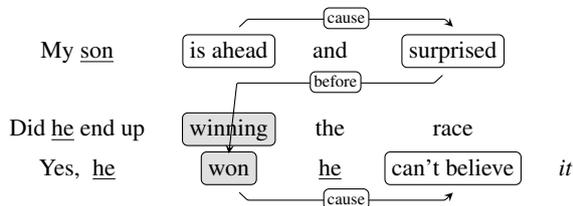

Figure 4: An example causal and temporal (CaTeRS) annotation on the conversation presented in Figure 1. The rectangular nodes show the event entities and the edges are the semantic links. For simplicity, we show the ‘identity’ relation between events using gray nodes. The coreference chain is depicted by the underlined words.

slot ($Q_{FN-slot}$) associated with a context frame (Q_{FN}). For 17% of cases, we were unable to identify a corresponding $Q_{FN-slot}$ in FrameNet. As the example in Table 3 shows, the image in isolation often does not evoke any uniquely contentful frame, whereas the textual context frequently does. In only 14% of cases does $I_{FN}=T_{FN}$, which further supports the complementary effect of our multimodal contexts. Moreover, $Q_{FN}=I_{FN}$ for 32% our annotations, whereas $Q_{FN}=T_{FN}$ for 47% of the triplets, again, showing the effectiveness of textual context in determining the question.

4.3 Event Analysis of Conversations

To further investigate the representation of events and any stereotypical causal and temporal relations between them in the IGC_{Crowd} dataset, we manually annotated a sample of 20 conversations with their causal and temporal event structures. Here, we followed the Causal and Temporal Relation Scheme (CaTeRS) (Mostafazadeh et al., 2016a) for event entity and event-event semantic relation annotations. Our analysis shows that the IGC utterances are indeed rich in events. On average, each utterance in IGC has 0.71 event entity mentions, such as ‘win’ or ‘remodel’. The semantic link annotation reflects commonsense relation between event mentions in the context of the ongoing conversation. Figure 4 shows an example CaTeRS annotation. The distribution of semantic

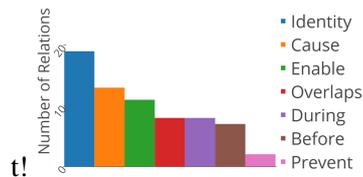

Figure 5: The frequency of event-event semantic links in a random sample of 20 IGC conversations.

links in the annotated sample can be found in Figure 5. These numbers further suggest that in addition to jointly understanding the visual and textual context (including multimodal anaphora resolution, among other challenges), capturing causal and temporal relations between events will likely be necessary for a system to perform the IGC task.

4.4 IGC_{Twitter} Training Dataset

Previous work in neural conversation modeling (Ritter et al., 2011; Sordoni et al., 2015) has successfully used Twitter as the source of natural conversations. As training data, we sampled 250K quadruples of {visual context, textual context, question, response} tweet threads from a larger dataset of 1.4 million, extracted from the Twitter Firehose over a 3-year period beginning in May 2013 and filtered to select just those conversations in which the initial turn was associated with an image and the second turn was a question.

Regular expressions were used to detect questions. To improve the likelihood that the authors are experienced Twitter conversationalists, we further limited extraction to those exchanges where users had actively engaged in at least 30 conversational exchanges during a 3-month period.

Twitter data is noisy: we performed simple normalizations, and filtered out tweets that contained mid-tweet hashtags, were longer than 80 characters² or contained URLs not linking to the image. (Sample conversations from this dataset can be found in the Supplementary Material.) A random sample of tweets suggests that about 46% of the Twitter conversations is affected by prior history between users, making response generation particularly difficult. In addition, the abundance of screenshots and non-photograph graphics is potentially a major source of noise in extracting features for neural generation, though we did not attempt to exclude these from the training set.

²Pilot studies showed that 80 character limit more effectively retains one-sentence utterances that are to the point.

5 Models

5.1 Generation Models

Figure 6 overviews our three generation models. Across all the models, we use the VGGNet architecture (Simonyan and Zisserman, 2015) for computing deep convolutional image features. We use the 4096-dimensional output of the last fully connected layer (*fc7*) as the input to all the models sensitive to visual context.

Visual Context Sensitive Model (*V-Gen*). Similar to Recurrent Neural Network (RNN) models for image captioning (Devlin et al., 2015; Vinyals et al., 2015), (*V-Gen*) transforms the image feature vector to a 500-dimensional vector that serves as the initial recurrent state to a 500-dimensional one-layer Gated Recurrent Unit (GRU) which is the decoder module. The output sentence is generated one word at a time until the $\langle \text{EOS} \rangle$ (end-of-sentence) token is generated. We set the vocabulary size to 6000 which yielded the best results on the validation set. For this model, we got better results by greedy decoding. Unknown words are mapped to an $\langle \text{UNK} \rangle$ token during training, which is not allowed to be generated at decoding time.

Textual Context Sensitive Model (*T-Gen*). This is a neural Machine Translation-like model that maps an input sequence to an output sequence (Seq2Seq model (Cho et al., 2014; Sutskever et al., 2014)) using an encoder and a decoder RNN. The decoder module is like the model described above, in this case the initial recurrent state being the 500-dimensional encoding of the textual context. For consistency, we use the same vocab size and number of layers as in the (*V-Gen*) model.

Visual & Textual Context Sensitive Model (*V&T-Gen*). This model fully leverages both textual and visual contexts. The vision feature is transformed to a 500-dimensional vector, and the textual context is likewise encoded into a 500-dimensional vector. The textual feature vector can be obtained using either a bag-of-words (*V&T.BOW-Gen*) representation, or an RNN (*V&T.RNN-Gen*), as depicted in Figure 7. The textual feature vector is then concatenated to the vision vector and fed into a fully connected (FC) feed forward neural network. As a result, we obtain a single 500-dimensional vector encoding both visual and textual context, which then serves as the initial recurrent state of the decoder RNN.

In order to generate the response (the third utterance in the conversation), we need to represent

the conversational turns in the textual context input. There are various ways to represent conversational history, including a bag of words model, or a concatenation of all textual utterances into one sentence (Sordoni et al., 2015). For response generation, we implement a more complex treatment in which utterances are fed into an RNN one word at a time (Figure 7) following their temporal order in the conversation. An $\langle \text{UTT} \rangle$ marker designates the boundary between successive utterances.

Decoding and Reranking. For all generation models, at decoding time we generate the N-best lists using left-to-right beam search with *beam-size* 25. We set the maximum number of tokens to 13 for the generated partial hypotheses. Any partial hypothesis that reaches $\langle \text{EOS} \rangle$ token becomes a viable full hypothesis for reranking. The first few hypotheses on top of the N-best lists generated by Seq2Seq models tend to be very generic,³ disregarding the input context. In order to address this issue we rerank the N-best list using the following score function:

$$\log p(h|C) + \lambda \text{idf}(h,D) + \mu|h| + \kappa V(h) \quad (1)$$

where $p(h|C)$ is the probability of the generated hypothesis h given the context C . The function V counts the number of verbs in the hypothesis and $|h|$ denotes the number of tokens in the hypothesis. The function idf is the inverse document frequency, computing how common a hypothesis is across all the generated N-best lists. Here D is the set of all N-best lists and d is a specific N-best list. We define $\text{idf}(h, D) = \log \frac{|D|}{|\{d \in D: h \in d\}|}$, where we set $N=10$ to cut short each N-best list. These parameters were selected following reranking experiments on the validation set. We optimize all the parameters of the scoring function towards maximizing the smoothed-BLEU score (Lin and Och, 2004) using the Pairwise Ranking Optimization algorithm (Hopkins and May, 2011).

5.2 Retrieval Models

In addition to generation, we implemented two retrieval models customized for the tasks of question and response generation. Work in vision and language has demonstrated the effectiveness of retrieval models, where one uses the annotation (e.g., caption) of a nearest neighbor in the training image set to annotate a given test image (Mostafazadeh et al., 2016b; Devlin et al., 2015;

³An example generic question is *where is this?* and a generic response is *I don't know*.

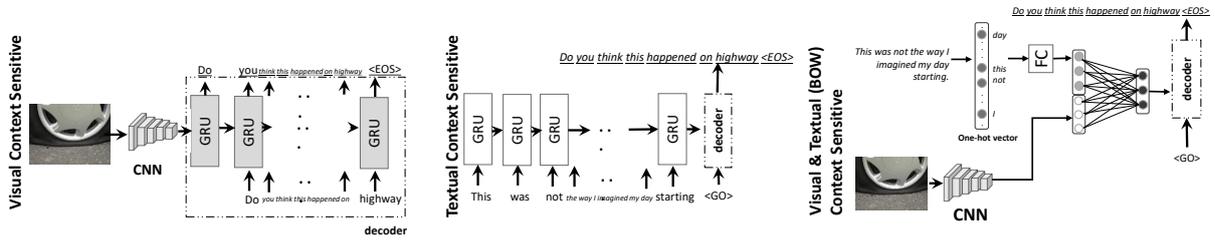

Figure 6: Question generation using the Visual Context Sensitive Model (*V-Gen*), Textual Context Sensitive Model (*T-Gen*), and the Visual & Textual Context Sensitive Model (*V&T.BOW-Gen*), respectively.

	Visual Context			
Question Generation	Textual Context	The weather was amazing at this baseball game.	I got in a car wreck today!	My cousins at the family reunion.
	Gold Question	Nice, which team won?	Did you get hurt?	What is the name of your cousin in the blue shirt?
	V&T-Ret	U at the game? or did someone take that pic for you?	You driving that today?	U had fun?
	V-Gen	Where are you?	Who's is that?	Who's that guy?
	V&T-Gen	Who's winning?	What happened?	Where's my invite?
Response Generation	Textual Context	The weather was amazing at this baseball game. <UTT> Nice, which team won?	I got in a car wreck today! <UTT> Did you get hurt?	My cousins at the family reunion. <UTT> What is the name of your cousin in the blue shirt?
	Gold Response	My team won this game.	No it wasn't too bad of a bang up.	His name is Eric.
	V&T-Ret	10 for me and 28 for my dad.	Yes.	lords cricket ground . beautiful.
	V&T-Gen	ding ding ding!	Nah, I'm at home now.	He's not mine!

Table 4: Example question and response generations on IGC_{Crowd} test set. All the generation models use beam search with reranking. In the textual context, <UTT> separates different utterances. The generations in bold are acceptable utterances given the underlying context.

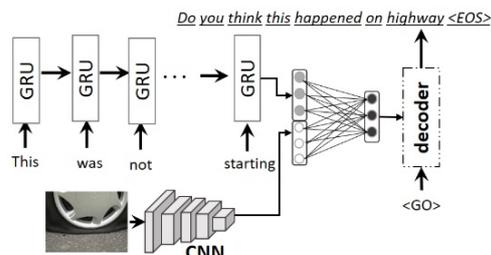

Figure 7: The visual & textual context sensitive model with RNN encoding (*V&T.RNN-Gen*).

Hodosh et al., 2013; Ordonez et al., 2011; Farhadi et al., 2010).

Visual Context Sensitive Model (*V-Ret*). This model uses only the provided image for retrieval. First, we find a set of K nearest training images for the given test image based on cosine similarity of the *fc7* vision feature vectors. Then we retrieve those K annotations as our pool of K candidates. Finally, we compute the textual similarity among the questions in the pool according to a Smoothed-BLEU (Lin and Och, 2004) similarity score, then emit the sentence that has the highest similarity to the rest of the pool.

Visual & Textual Context Sensitive Model (*V&T-Ret*). This model uses a linear combination of *fc7* and word2vec feature vectors for retrieving similar training instances.

6 Evaluation Setup

We provide both human (Table 5) and automatic (Table 6) evaluations for our question and response generation tasks on the IGC_{Crowd} test set. We crowdsourced our human evaluation on an AMT-like crowdsourcing system, asking seven crowd workers to each rate the quality of candidate questions or responses on a three-point Likert-like scale, ranging from 1 to 3 (the highest). To ensure a calibrated rating, we showed the human judges all system hypotheses for a particular test case at the same time. System outputs were randomly ordered to prevent judges from guessing which systems were which on the basis of position. After collecting judgments, we averaged the scores throughout the test set for each model. We discarded any annotators whose ratings varied from the mean by more than 2 standard deviations.

Although human evaluation is to be preferred, and currently essential in open-domain generation tasks involving intrinsically diverse outputs, it is useful to have an automatic metric for day-to-day

evaluation. For ease of replicability, we use the standard Machine Translation metric, BLEU (Papineni et al., 2002), which captures n-gram overlap between hypotheses and multiple references. Results reported in Table 6 employ BLEU with equal weights up to 4-grams at corpus-level on the multi-reference IGC_{Crowd} test set. Although Liu et al. (2016) suggest that BLEU fails to correlate with human judgment at the sentence level, correlation increases when BLEU is applied at the document or corpus level (Galley et al., 2015; Przybocki et al., 2008).

7 Experimental Results

We experimented with all the models presented in Section 5. For question generation, we used a visual & textual sensitive model that uses bag-of-words (*V&T.BOW-Gen*) to represent the textual context, which achieved better results. Earlier vision & language work such as VQA (Antol et al., 2015) has shown that a bag-of-words baseline outperforms LSTM-based models for representing textual input when visual features are available (Zhou et al., 2015). In response generation, which needs to account for textual input consisting of two turns, we used the *V&T.RNN-Gen* model as the visual & textual-sensitive model for the response rows of tables 5 and 6. Since generating a response solely from visual context is unlikely to be successful, we did not use the *V-Gen* model in response generation. All models are trained on $IGC_{Twitter}$ dataset, except for VQG, which shares the same architecture as with the (*V-Gen*) model, but is trained on 7,500 questions from the VQG dataset (Mostafazadeh et al., 2016b) as a point of reference. We also include the gold human references from the IGC_{Crowd} dataset in the human evaluation to set a bound on human performance.

Table 4 presents example generations by our best performing systems. In human evaluation shown in Tables 5, the model that encodes both visual and textual context outperforms others. We note that human judges preferred the top generation in the n-best list over the reranked best, likely owing to the tradeoff between a safe and generic utterance and a riskier but contentful one. The human gold references are consistently favored throughout the table. We take this as evidence that IGC_{Crowd} test set provides a robust and challenging test set for benchmarking progress.

As shown in Table 6, BLEU scores are low, as is characteristic for language tasks with intrin-

	Human Gold	Generation (Greedy)			Generation (Beam, best)				Generation (Reranked, best)			Retrieval	
		Textual	Visual	V & T	Textual	Visual	V & T	VQG	Textual	Visual	V & T	Visual	V & T
Question	<u>2.68</u>	1.46	1.58	1.86	1.07	1.86	2.28	2.24	1.03	2.06	2.13	1.59	1.54
Response	<u>2.75</u>	1.24	–	1.40	1.12	–	1.49	–	1.04	–	1.44	–	1.48

Table 5: Human judgment results on the IGC_{Crowd} test set. The maximum score is 3. Per model, the human score is computed by averaging across multiple images. The boldfaced numbers show the highest score among the systems. The overall highest scores (underlined) are the human gold standards.

	Textual	Generation			Retrieval	
		Visual	V & T	VQG	Visual	V & T
Question	1.71	3.23	4.41	8.61	0.76	1.16
Response	1.34	–	1.57	–	–	0.66

Table 6: Results of evaluating using multi-reference BLEU.

sically diverse outputs (Li et al., 2016b,a). On BLEU, the multimodal V&T model outperforms all the other models across test sets, except for the VQG model which does significantly better. We attribute this to two issues: (1) the VQG training dataset contains event-centric images similar to the IGC_{Crowd} test set, (2) Training on a high-quality crowd-sourced dataset with controlled parameters can, to a significant extent, produce better results on similarly crowd-sourced test data than training on data found "in the wild" such as Twitter. However, crowd-sourcing multi-turn conversations between paired workers at large scale is prohibitively expensive, a factor that favors the use of readily available naturally-occurring but noisier data.

Overall, in both automatic and human evaluation, the question generation models are more successful than response generation. This disparity might be overcome by (1) implementation of more sophisticated systems for richer modeling of long contexts across multiple conversational turns, (2) training on larger, higher-quality datasets.

8 Conclusions

We have introduced a new task of multimodal image-grounded conversation, in which, given an image and a natural language text, the system must generate meaningful conversational turns, the second turn being a question. We are releasing to the research community a crowd-sourced dataset of 4,222 high-quality, multiple-turn, multiple-reference conversations about eventful images. Inasmuch as this dataset is not tied to the characteristics of any specific social media resource, e.g., Twitter or Reddit, we expect it to remain sta-

ble over time, as it is less susceptible to attrition in the form of deleted posts or accounts.

Our experiments provide evidence that capturing multimodal context improves the quality of question and response generation. Nonetheless, the performance gap between our best models and humans opens opportunities further research in the continuum from casual chit-chat conversation to more topic-oriented dialog. We expect that addition of other forms of grounding, such as temporal and geolocation information, often embedded in images, will further improve performance.

In this paper, we illustrated the application of this dataset using simple models trained on conversations on Twitter. In the future, we expect that more complex models and richer datasets will permit emergence of intelligent human-like agent behavior that can engage in implicit commonsense reasoning around images and proactively drive the interaction forward.

Acknowledgments

We are grateful to Piali Choudhury, Rebecca Hanson, Ece Kamar, and Andrew Mao for their assistance with crowd-sourcing. We would also like to thank our reviewers for their helpful comments.

Abstract

This study addresses the problem of identifying the meaning of unknown words or entities in a discourse with respect to the word embedding approaches used in neural language models. We proposed a method for on-the-fly construction and exploitation of word embeddings in both the input and output layers of a neural model by tracking contexts. This extends the dynamic entity representation used in Kobayashi et al. (2016) and incorporates a copy mechanism proposed independently by Gu et al. (2016) and Gulcehre et al. (2016). In addition, we construct a new task and dataset called *Anonymized Language Modeling* for evaluating the ability to capture word meanings while reading. Experiments conducted using our novel dataset show that the proposed variant of RNN language model outperformed the baseline model. Furthermore, the experiments also demonstrate that dynamic updates of an output layer help a model predict reappearing entities, whereas those of an input layer are effective to predict words following reappearing entities.

1 Introduction

Language models that use probability distributions over sequences of words are found in many natural language processing applications, including speech recognition, machine translation, text summarization, and dialogue utterance generation. Recent studies have demonstrated that language models trained using neural network (Bengio et al., 2003; Mikolov et al., 2010) such as recurrent neural network (RNN) (Jozefowicz et al., 2016) and convolutional neural network (Dauphin

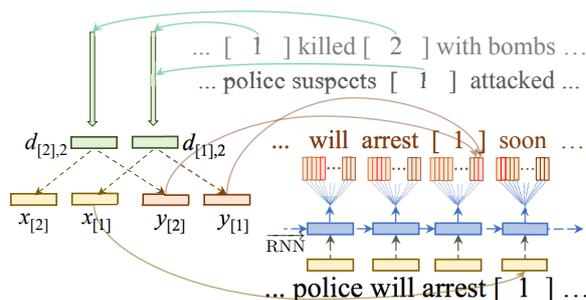

Figure 1: Dynamic Neural Text Modeling: the embeddings of unknown words, denoted by coreference indexes “[k]” are dynamically computed and used in both the input and output layers ($x_{[k]}$ and $y_{[k]}$) of a RNN language model. These are constructed from contextual information ($d_{[k],i}$) preceding the current ($i + 1$)-th sentence.

et al., 2016) achieve the best performance across a range of corpora (Mikolov et al., 2010; Chelba et al., 2014; Merity et al., 2017; Grave et al., 2017).

However, current neural language models have a major drawback: the language model works only when applied to a closed vocabulary of fixed size (usually comprising high-frequency words from the given training corpus). All occurrences of out-of-vocabulary words are replaced with a single dummy token “<unk>”, showing that the word is unknown. For example, the word sequence, *Pikotaro sings PPAP on YouTube* is treated as <unk> sings <unk> on <unk> assuming that the words *Pikotaro*, *PPAP*, and *YouTube* are out of the vocabulary. The model therefore assumes that these words have the same meaning, which is clearly incorrect. The derivation of *meanings of unknown words* remains a persistent and nontrivial challenge when using word embeddings.

In addition, existing language models further assume that the meaning of a word is the same and universal across different documents. Neural

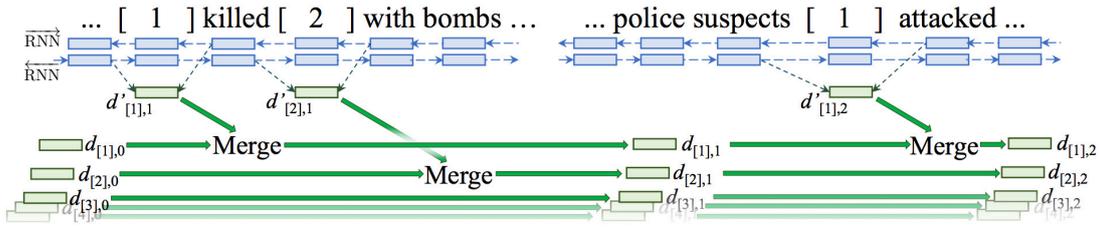

Figure 2: Dynamic Neural Text Modeling: the meaning representation of each unknown word, denoted by a coreference index “[k]”, is inferred from the local contexts in which it occurs.

language models also make this assumption and represent all occurrences of a word with a single word vector across all documents. However, the assumption of a universal meaning is also unlikely correct. For example, the name *John* is likely to refer to different individuals in different documents. In one story, *John* may be a pianist while another *John* denoted in a second story may be an infant. A model that represents all occurrences of *John* with the same vector fails to capture the very different behavior expected from *John* as a pianist and *John* as an infant.

In this study, we address these issues and propose a novel neural language model that can build and dynamically change distributed representations of words based on the multi-sentential discourse. The idea of incorporating dynamic meaning representations into neural networks is not new. In the context of reading comprehension, Kobayashi et al. (2016) proposed a model that dynamically computes the representation of a named entity mention from the local context given by its prior occurrences in the text. In neural machine translation, the *copy mechanism* was proposed as a way of improving the handling of out-of-vocabulary words (e.g., named entities) in a source sentence (Gu et al., 2016; Gulcehre et al., 2016). We use a variant of recurrent neural language model (RNLM), that combines dynamic representation and the copy mechanism. The resulting novel model, *Dynamic Neural Text Model*, uses the dynamic word embeddings that are constructed from the context in the output and input layers of an RNLM, as shown in Figures 1 and 2.

The contributions of this paper are three-fold. First, we propose a novel neural language model, which we named the *Dynamic Neural Text Model*. Second, we introduce a new evaluation task and dataset called *Anonymized Language Modeling*. This dataset can be used to evaluate the ability of

a language model to capture word meanings from contextual information (Figure 3). This task involves a kind of one-shot learning tasks, in which the meanings of entities are inferred from their limited prior occurrences. Third, our experimental results indicate that the proposed model outperforms baseline models that use only global and static word embeddings in the input and/or output layers of an RNLM. Dynamic updates of the output layer helps the RNLM predict reappearing entities, whereas those of the input layer are effective to predict words following reappearing entities. A more detailed analysis showed that the method was able to successfully capture the meanings of words across large contexts, and to accumulate multiple context information.

2 Background

2.1 RNN Language Model

Given a sequence of N tokens of a document $D = (w_1, w_2, \dots, w_N)$, an RNN language model computes the probability $p(D) = \prod_{t=1}^N p(w_t | w_1, \dots, w_{t-1})$. The computation of each factorized probability $p(w_t | w_1, \dots, w_{t-1})$ can also be viewed as the task of predicting a following word w_t from the preceding words (w_1, \dots, w_{t-1}) . Typically, RNNs recurrently compute the probability of the following word w_t by using a hidden state \mathbf{h}_{t-1} at time step $t - 1$,

$$p(w_t | w_1, \dots, w_{t-1}) = \frac{\exp(\vec{\mathbf{h}}_{t-1}^\top \mathbf{y}_{w_t} + b_{w_t})}{\sum_{w \in V} \exp(\vec{\mathbf{h}}_{t-1}^\top \mathbf{y}_w + b_w)}, \quad (1)$$

$$\vec{\mathbf{h}}_t = \overrightarrow{\text{RNN}}(\mathbf{x}_{w_t}, \vec{\mathbf{h}}_{t-1}). \quad (2)$$

Here, \mathbf{x}_{w_t} and \mathbf{y}_{w_t} denote the input and output word embeddings of w_t respectively, V represents the set of words in the vocabulary, and b_w is a bias value applied when predicting the word w . The function $\overrightarrow{\text{RNN}}$ is often replaced with

LSTM (Hochreiter and Schmidhuber, 1997) or GRU (Cho et al., 2014) to improve performance.

2.2 Dynamic Entity Representation

RNN-based models have been reported to achieve better results on the CNN QA reading comprehension dataset (Hermann et al., 2015; Kobayashi et al., 2016). In the CNN QA dataset, every named entity in each document is anonymized. This is done to allow the ability to comprehend a document using neither prior nor external knowledge to be evaluated. To capture the meanings of such anonymized entities, Kobayashi et al. (2016) proposed a new model that they named *dynamic entity representation*. This encodes the local contexts of an entity and uses the resulting context vector as the word embedding of a subsequent occurrence of that entity in the input layer of the RNN. This model: (1) constructs context vectors $\mathbf{d}'_{e,i}$ from the local contexts of an entity e at the i -th sentence; (2) merges multiple contexts of the entity e through max pooling and produces the dynamic representation $\mathbf{d}_{e,i}$; and (3) replaces the embedding of the entity e in the $(i+1)$ -th sentence with the dynamic embedding $\mathbf{x}_{e,i+1}$ produced from $\mathbf{d}_{e,i}$. More formally,

$$\mathbf{x}_{e,i+1} = W_{dc}\mathbf{d}_{e,i} + \mathbf{b}_e, \quad (3)$$

$$\mathbf{d}_{e,i} = \text{maxpooling}(\mathbf{d}'_{e,i}, \mathbf{d}_{e,i-1}), \quad (4)$$

$$\mathbf{d}'_{e,i} = \text{ContextEncoder}(e, i). \quad (5)$$

Here, \mathbf{b}_e denotes a bias vector, maxpooling is a function that yields the largest value from the elementwise inputs, and ContextEncoder is an encoding function. Figure 2 gives an example of the process of encoding and merging contexts from sentences. An arbitrary encoder can be used for ContextEncoder; Kobayashi et al. (2016) used bidirectional RNNs, encoding the words surrounding the entity e of a sentence in both directions. If the entity e fails to appear in the i -th sentence, the embedding is not updated, i.e., $\mathbf{d}_{e,i} = \mathbf{d}_{e,i-1}$.

3 Proposed Method: Dynamic Neural Text Modeling

In this section, we introduce the extension of dynamic entity representation to language modeling. From Equations 1 and 2, RNLM uses a set of word embeddings in the input layer to encode the preceding contextual words, and another set of word embeddings in the output layer to predict a word

from the encoded context. Therefore, we consider incorporating the idea of dynamic representation into the word embeddings in the output layer (\mathbf{y}_w in Equation 1) as well as in the input layer (\mathbf{x}_w in Equation 2; refer to Figure 1). The novel extension of dynamic representation to the output layer affects predictions made for entities that appear repeatedly, whereas that in the input layer is expected to affect the prediction of words that follow the entities.

The procedure for constructing dynamic representations of e , $\mathbf{d}_{e,i}$ is the same as that introduced in Section 2.2. Before reading the $(i+1)$ -th sentence, the model constructs the context vectors $[\mathbf{d}'_{e,1}, \dots, \mathbf{d}'_{e,i}]$ from the local contexts of e in every preceding sentence. Here, $\mathbf{d}'_{e,j}$ denotes the context vector of e in the j -th sentence. ContextEncoder in the model produces a context vector \mathbf{d}'_e for e at the t -th position in a sentence, using a bidirectional RNN¹ as follows:

$$\mathbf{d}'_e = \text{ReLU}(W_{hd}[\vec{\mathbf{h}}_{t-1}, \overleftarrow{\mathbf{h}}_{t+1}] + \mathbf{b}_d), \quad (6)$$

$$\vec{\mathbf{h}}_t = \overrightarrow{\text{RNN}}(\mathbf{x}_{w_t}, \vec{\mathbf{h}}_{t-1}), \quad (7)$$

$$\overleftarrow{\mathbf{h}}_t = \overleftarrow{\text{RNN}}(\mathbf{x}_{w_t}, \overleftarrow{\mathbf{h}}_{t+1}). \quad (8)$$

Here, ReLU denotes the ReLU activation function (Nair and Hinton, 2010), while W_{dc} and W_{hd} correspond to learnable matrices; \mathbf{b}_d is a bias vector. As in the RNN language model, $\vec{\mathbf{h}}_{t-1}$ and $\overleftarrow{\mathbf{h}}_{t+1}$ as well as their composition \mathbf{d}'_e can capture information necessary to predict the features of the target e at the t -th word.

Following context encoding, the model merges the multiple context vectors, $[\mathbf{d}'_{e,1}, \dots, \mathbf{d}'_{e,i}]$, into the dynamic representation $\mathbf{d}_{e,i}$ using a merging function. A range of functions are available for merging multiple vectors, while Kobayashi et al. (2016) used only max pooling (Equation 4). In this study, we explored three further functions: GRU, GRU followed by ReLU ($\mathbf{d}_{e,i} = \text{ReLU}(\text{GRU}(\mathbf{d}'_{e,i}, \mathbf{d}_{e,i-1}))$) and a function that selects only the latest context, i.e., $\mathbf{d}_{e,i} = \mathbf{d}'_{e,i}$. This comparison clarifies the effect of the accumulation of contexts as the experiments proceeded².

¹Equations 2 and 7 are identical but do not share internal parameters.

²Note that merging functions are not restricted to considering two arguments (a new context and a merged past context) recurrently but can consider all vectors over the whole history $[\mathbf{d}'_{e,1}, \dots, \mathbf{d}'_{e,i}]$ (e.g., by using attention mechanism (Bahdanau et al., 2015)). However, for simplicity, this research focuses only on the case of a function with two arguments.

Anonymized Version

the hottest gift [1] could be [2] , but good luck finding one . as [3] reports , many stores have sold out of [2] even ...

Figure 3: An example document for Anonymized Language Modeling. Token “[k]” is an anonymized token that appears k-th in the entities in a document. Language models predict the next word from the preceding words, and calculate probabilities for whole word sequences.

The merging function produces the dynamic representation $\mathbf{d}_{e,i}$ of e . In language modeling, to read the $(i + 1)$ -th sentence, the model uses two dynamic word embeddings of e in the input and output layers. The input embedding \mathbf{x}_e , used to encode contexts (Equation 2), and the output embedding \mathbf{y}_e , used to predict the occurrence of e (Equation 1), are replaced with dynamic versions:

$$\mathbf{x}_e = W_{dx}\mathbf{d}_{e,i} + \mathbf{b}_e^x, \quad (9)$$

$$\mathbf{y}_e = W_{dy}\mathbf{d}_{e,i} + \mathbf{b}_e^y, \quad (10)$$

where W_{dx} and W_{dy} denote learnable matrices, and \mathbf{b}_e^x and \mathbf{b}_e^y denote learnable vectors tied to e . We can observe that a conventional RNN language model is a variant that removes the dynamic terms ($W_{dx}\mathbf{d}_{e,i}$ and $W_{dy}\mathbf{d}_{e,i}$) using only the static terms (\mathbf{b}_e^x and \mathbf{b}_e^y) to represent e . The initial dynamic representation $\mathbf{d}_{e,0}$ is defined as a zero vector, so that the initial word embeddings (\mathbf{x}_e and \mathbf{y}_e) are identical to the static terms (\mathbf{b}_e^x and \mathbf{b}_e^y) until the point at which the first context of the target word e is observed. All parameters in the end-to-end model are learned entirely by backpropagation, maximizing the log-likelihood in the same way as a conventional RNN language model.

We can view the approach in Kobayashi et al. (2016) as a variant on the proposed method, but using the dynamic terms only in the input layer (for \mathbf{x}_e). We can also view the copy mechanism (Gu et al., 2016; Gulcehre et al., 2016) as a variant on the proposed method, in which specific embeddings in the output layer are replaced with special dynamic vectors.

4 Anonymized Language Modeling

This study explores methods for on-the-fly capture and exploitation of the meanings of unknown words or entities in a discourse. To do this, we introduce a novel evaluation task and dataset that we

called *Anonymized Language Modeling*. Figure 3 gives an example from the dataset. Briefly, the dataset anonymizes certain noun phrases, treating them as unknown words and retaining their coreference relations. This allows a language model to track the context of every noun phrase in the discourse. Other words are left unchanged, allowing the language model to preserve the context of the anonymized (unknown) words, and to infer their meanings from the known words. The process was inspired by Hermann et al. (2015), whose approach has been explored by the research on reading comprehension.

More precisely, we used the OntoNotes (Pradhan et al., 2012) corpus, which includes documents with coreferences and named entity tags manually annotated. We assigned an anonymous identifier to every coreference chain in the corpus³ in order of first appearance⁴, and replaced mentions of a coreference chain with its identifier. In our experiments, each coreference chain was given a dynamic representation. Following Mikolov et al. (2010), we limited the vocabulary to 10,000 words appearing frequently in the corpus. Finally, we inserted “<bos>” and “<eos>” tokens to mark the beginning and end of each sentence.

An important difference between this dataset and the one presented in Hermann et al. (2015) is in the way that coreferences are treated. Hermann et al. (2015) used automatic resolution of coreferences, whereas our study made use of the manual annotations in the OntoNotes. Thus, the process of Hermann et al. (2015) introduced (intentional and unintentional) errors into the dataset. Additionally, the dataset did not assign an entity iden-

³We used documents with no more than 50 clusters, which covered more than 97% of the corpus.

⁴Following the study of Luong et al. (2015), we assigned “<unk1>”, “<unk2>”, ... to coreference clusters in order of first appearance.

Split	Train	Valid	Test
# of documents	2725	335	336
Avg. # of sentences	25.7	27.2	26.4
Avg. # of unique entities	15.6	16.8	15.8
Avg. # of unique entities occurring more than once	9.3	9.9	9.5
Avg. # of occurrences of an entity	3.2	3.2	3.1

Table 1: Statistics of Anonymized Language Modeling dataset.

tifier to a pronoun. In contrast, as our dataset has access to the manual annotations of coreferences, we are able to investigate the ability of the language model to capture meanings from contexts.

Dynamic updating could be applied to words in all lexical categories, including verbs, adjectives, and nouns without requiring additional extensions. However, verbs and adjectives were excluded from targets of dynamic updates in the experiments, for two reasons. First, proper nouns and nouns accounted for the majority (70%) of the low-frequency (unknown) words, followed by verbs (10%) and adjectives (9%). Second, we assumed that the meaning of a verb or adjective would shift less over the course of a discourse than that of a noun. When semantic information of unknown verbs and adjectives is required, their embeddings may be extracted from ad-hoc training on a different larger corpus. This, however, was beyond the scope of this study.

5 Experiments

5.1 Setting

An experiment was conducted to investigate the effect of *Dynamic Neural Text Model* on the *Anonymized Language Modeling* dataset. The split of dataset followed that of the original corpus (Pradhan et al., 2012). Table 1 summarizes the statistics of the dataset.

The baseline model was a typical LSTM RNN language model with 512 units. We compared three variants of the proposed model, using different applications of dynamic embedding: in the input layer only (as in Kobayashi et al. (2016)), in the output layer only, and in both the input and output layers. The context encoders were bidirectional LSTMs with 512 units, the parameters of which were not the same as those in the LSTM RNN language models. All models were trained by maximizing the likelihood of correct tokens, to

achieve best perplexity on the validation dataset⁵. Most hyper-parameters were tuned and fixed by the baseline model on the validation dataset⁶.

It is difficult to adequately train the all parts of a model using only the small dataset of Anonymized Language Modeling. We therefore pretrained word embeddings and ContextEncoder (the bi-directional RNNs and matrices in Equations 6–8) on a sentence completion task in which clozes were predicted from the surrounding words in a large corpus (Melamud et al., 2016)⁷. We used the objective function with negative sampling (Mikolov et al., 2013): $\sum_e (\log \sigma(\hat{x}_e^T x_e) + \sum_{v \in Neg} (\log \sigma(-\hat{x}_e^T x_v)))$. Here, \hat{x}_e is a context vector predicted by ContextEncoder, x_e denotes the word embedding of a target word e appearing in the corpus, and Neg represents randomly sampled words. These pretrained parameters of ContextEncoder were fixed when the whole language model was trained on the Anonymized Language Modeling dataset. We implemented models in Python using the Chainer neural network library (Tokui et al., 2015). The code and the constructed dataset are publicly available⁸.

5.2 Results and Analysis

5.2.1 Perplexity

Table 2 shows performance of the baseline model and the three variants of the proposed method in terms of perplexity. The table reports the mean and standard error of three perplexity values after training using three different randomly chosen initializations (we used the same convention

⁵We performed a validation at the end of every half epoch out of five epochs.

⁶Batchsize was 8. Adam (Kingma and Ba, 2015) with learning rate 10^{-3} . Gradients were normalized so that their norm was smaller than 1. Truncation of backpropagation and updating was performed after every 20 sentences and at the end of document.

⁷We pretrained a model on the Gigaword Corpus, excluding sentences with more than 32 tokens. We performed training for 50000 iterations with a batch size of 128 and five negative samples. Only words that occurred no fewer than 500 times are used; other words were treated as unknown tokens. Melamud et al. (2016) used three different sets of word embeddings for the two inputs with respect to the encoders (\vec{RNN} and \overleftarrow{RNN}) and the output (target). However, we forced the sets of word embeddings to share a single set of word embeddings in pretraining. We initialized the word embeddings in both the input layer (x_w) and the output layer (y_w) of the novel models, including the baseline model, with this single set. The word embeddings of all anonymized tokens were initialized as unknown words with the word embedding of “<unk>”.

⁸https://github.com/soskek/dynamic_neural_text_model

With only dynamic output (C)	62.5±0.3	35.9±3.7	129.0±0.7	69.5±0.3
With dynamic input & output (D)	60.7±0.2	34.0±1.3	106.8±0.6	67.6±0.04

Table 2: Perplexities for each token group of models on the test set of Anonymized Language Modeling dataset. All values are averages with standard errors, calculated respectively by three models (trained with different random numbers). Dynamic models used GRU followed by ReLU as the merging function.

throughout this paper). Here, we discuss the proposed method using GRU followed by ReLU as the merging function, as this achieved the best perplexity (see Section 5.2.2 for a comparison of functions). We also show perplexity values when evaluating words of specific categories: (1) all words; (2) reappearing entity words; (3) words following entities; and (4) non-entity words.

All variants of the proposed method outperformed the baseline model. Focusing on the categories (2) and (3) highlights the roles of dynamic updates of the input and output layers. Dynamic updates of the input layer (B) had a larger improvement for predicting words following entities (3) than those of the output layer (C). In contrast, dynamic updates of the output layer (C) were quite effective for predicting reappearing entities (2) whereas those of the input layer (B) were not. These facts confirm that: dynamic updates of the input layer help a model predict words following entities by supplying on-the-fly context information; and those of the output layer are effective to predict entity words appearing multiple times.

In addition, dynamic updates of both the input and output layers (D) further improved the performance from those of either the output (C) or input (B) layer. Thus, the proposed dynamic output was shown to be compatible with dynamic input, and *vice versa*. These results demonstrated the positive effect of capturing and exploiting the context-sensitive meanings of entities.

In order to examine whether dynamic updates of the input and output embeddings capture context-sensitive meanings of entities, we present Figures 4, 5 and 6. Figure 4 depicts the perplexity of words with different positions in a document⁹. The figure confirms that the advantage of the proposed method over the baseline is more evident

⁹It is more difficult to predict tokens appearing latter in a document because the number of new (unknown) tokens increases as a model reads the document.

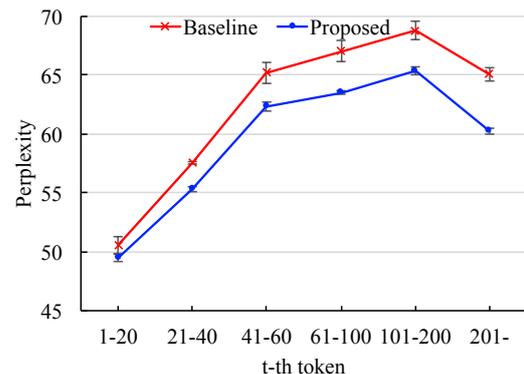

Figure 4: Perplexity of all tokens relative to the time at which they appear in the document.

especially in the latter part of documents, where repeated words are more likely to occur.

Figure 5 shows the perplexity with respect to the frequency of words t within documents. Note that the word embedding at the first occurrence of an entity is static. This figure indicates that entities appearing many times enjoy the benefit of the dynamic language model. Figure 6 visualizes the perplexity of entities with respect to the numbers of their antecedent candidates. It is clear from this figure that the proposed method is better at memorizing the semantic information of entities appearing repeatedly in documents than the baseline. These results also demonstrated the contribution of dynamic updates of word embeddings.

5.2.2 Comparison of Merging functions

Table 3 compares models with different merging functions; GRU-ReLU, GRU, max pooling, and the use of the latest context. The use of the latest context had the worst performance for all variants of the proposed method. Thus, a proper accumulation of multiple contexts is indispensable for dynamic updates of word embeddings. Although Kobayashi et al. (2016) used only max pooling as the merging function, GRU and GRU-ReLU were

Models	Merging function	# of parameters (to be finetuned)	(1) All	(2) Reappearing entities	(3) Following entities	(4) Non-entities
Only dynamic input	GRU-ReLU	18.9M (14.2M)	62.8±0.3	42.4±1.1	109.5±1.4	66.4±0.3
	GRU	18.9M (14.2M)	63.2±0.4	43.3±2.7	111.2±0.7	66.8±0.4

shown to be comparable in performance and superior to max pooling when predicting tokens related to entities (2) and (3).

5.2.3 Predicting Entities by Likelihood of a Sentence

In order to examine contribution of the dynamic language models on a downstream task, we conducted cloze tests for comprehension of a sentence with reappearing entities in a discourse. Given multiple preceding entities $E = \{e^+, e^1, e^2, \dots\}$ followed by a cloze sentence, the models were required to predict the true antecedent e^+ which allowed the cloze to be correctly filled, among the other alternatives $E^- = \{e^1, e^2, \dots\}$.

Language models solve this task by comparing the likelihoods of sentences filled with antecedent candidates in E and returning the entity with the highest likelihood of the sentence. In this experiment, the performance of a model was represented by the *Mean Quantile* (MQ) (Guu et al., 2015).

The MQ computes the mean ratio at which the model predicts a correct antecedent e^+ more likely than negative antecedents in E^- ,

$$MQ = \frac{|\{e^- \in E^- : p(e^-) < p(e^+)\}|}{|E^-|}. \quad (11)$$

Here, $p(e)$ denotes the likelihood of a sentence whose cloze is filled with e . If the correct antecedent e^+ yields highest likelihood, MQ gets 1.

Table 4 reports MQs for the three variants and merging functions. Dynamic updates of the input layer greatly boosted the performance by approximately 10%, while using both dynamic input and output improved it further. In this experiment, the merging functions with GRUs outperform the others. These results demonstrated that Dynamic Neural Text Models can accumulate a new information in word embeddings and contribute to modeling the semantic changes of entities in a discourse.

6 Related Work

An approach to addressing the unknown word problem used in recent studies (Kim et al., 2016; Sennrich et al., 2016; Luong and Manning, 2016; Schuster and Nakajima, 2012) comprises the embeddings of unknown words from character embeddings or subword embeddings. Li and Jurafsky (2015) applied word disambiguation and use a sense embedding to the target word. Choi et al. (2017) captured the context-sensitive meanings of common words using word embeddings, applied through a gating function controlled by history words, in the context of machine translation. In future work, we will explore a wider range of models, to integrate our dynamic text modeling with methods that estimate the meaning of unknown words or entities from their constituents. When addressing well-known entities such as *Obama* and *Trump*, it makes sense to learn their embeddings from external resources, as well as dynamically from the preceding context in a given discourse (as in our Dynamic Neural Text Model). The integration of these two sources of information is an intriguing challenge in language modeling.

A key aspect of our model is its incorporation of the copy mechanism (Gu et al., 2016; Gulcehre et al., 2016), using dynamic word embeddings in the output layer. Independently of this study, several research groups have explored the use of variants of the copy mechanisms in language modeling (Merity et al., 2017; Grave et al., 2017; Peng and Roth, 2016). These studies, however, did not incorporate dynamic representations in the input layer. In contrast, our proposal incorporates the copy mechanism through the use

of dynamic representations in the output layer, integrating them with dynamic mechanisms in both the input and output layers by applying dynamic entity-wise representation. Our experiments have demonstrated the benefits of such integration.

Another related trend in recent studies is the use of neural network to capture the information flow of a discourse. One approach has been to link RNNs across sentences (Wang and Cho, 2016; Serban et al., 2016), while a second approach has exploited a type of memory space to store contextual information (Sukhbaatar et al., 2015; Tran et al., 2016; Merity et al., 2017). Research on reading comprehension (Kobayashi et al., 2016; Henaff et al., 2017) and coreference resolution (Wiseman et al., 2016; Clark and Manning, 2016b,a) has shown the salience of entity-wise context information. Our model could be located within such approaches, but is distinct in being the first model to make use of entity-wise context information in both the input and output layers for sentence generation.

We summarize and compare works for entity-centric neural networks that read a document. Kobayashi et al. (2016) pioneered entity-centric neural models tracking states in a discourse. They proposed *Dynamic Entity Representation*, which encodes contexts of entities and updates the states using entity-wise memories. Wiseman et al. (2016) also proposed a method for managing similar entity-wise features on neural networks and improved a coreference resolution model. Clark and Manning (2016b,a) incorporated such entity-wise representations in mention-ranking coreference models. Our paper follows Kobayashi et al. (2016) and exploits dynamic entity representations in a neural language model, where dynamic representations are used not only in the neural encoder but also in the decoder, applicable to various sequence generation tasks, e.g., machine translation and dialog response generation. Simultaneously with our paper, Ji et al. (2017) use dynamic entity representation in a neural language model for reranking outputs of a coreference resolution system. Yang et al. (2017) experiment language modeling with referring to internal contexts or external data. Henaff et al. (2017) focus on neural networks tracking contexts of entities, achieving the state-of-the-art result in bAbI (Weston et al., 2015), a reading comprehension task. They encode the contexts of each entity by an attention-

like gated RNN instead of using coreference links directly. [Dhingra et al. \(2017\)](#) also try to improve a reading comprehension model using coreference links. Similarly to our dynamic entity representation, [Bahdanau et al. \(2017\)](#) construct on-the-fly word embeddings of rare words from dictionary definitions.

The first key component of dynamic entity representation is a function to merge more than one contexts about an entity into a consistent representation of the entity. Various choices for the function exist, e.g., max or average-pooling ([Kobayashi et al., 2016](#); [Clark and Manning, 2016b](#)), RNN (GRU, LSTM ([Wiseman et al., 2016](#); [Yang et al., 2017](#)) or other gated RNNs ([Henaff et al., 2017](#); [Ji et al., 2017](#))), or using the latest context only (without any merging) ([Yang et al., 2017](#)). This paper is the first work comparing the effects of those choices (see Section 5.2.2).

The second component is a function to encode local contexts from a given text, e.g., bidirectional RNN encoding ([Kobayashi et al., 2016](#)), unidirectional RNN used in a language model ([Ji et al., 2017](#); [Yang et al., 2017](#)), feedforward neural network with a sentence vector and an entity's word vector ([Henaff et al., 2017](#)) or hand-crafted features with word embeddings ([Wiseman et al., 2016](#); [Clark and Manning, 2016b](#)). This study employs bi-RNN analogously to [Kobayashi et al. \(2016\)](#), which can access full context with powerful learnable units.

In the task setting proposed in this study, a model must capture the meaning of a given specific word from a small number of its contexts in a given discourse. The task could also be seen as novel one-shot learning ([Fei-Fei et al., 2006](#)) of word meanings. One-shot learning for NLP like this has been little studied, with the exception of the study by [Vinyals et al. \(2016\)](#), which used a task in which the context of a target word is matched with a different context of the same word.

7 Conclusion

This study addressed the problem of identifying the meaning of unknown words or entities in a discourse with respect to the word embedding approaches used in neural language models. We proposed a method for on-the-fly construction and exploitation of word embeddings in both the input layer and output layer of a neural model by

tracking contexts. This extended the dynamic entity representation presented in [Kobayashi et al. \(2016\)](#), and incorporated a copy mechanism proposed independently by [Gu et al. \(2016\)](#) and [Gulcehre et al. \(2016\)](#). In the course of the study, we also constructed a new task and dataset, called *Anonymized Language Modeling*, for evaluating the ability of a model to capture word meanings while reading. Experiments conducted using our novel dataset demonstrated that the RNN language model variants proposed in this study outperformed the baseline model. More detailed analysis indicated that the proposed method was particularly successful in capturing the meaning of an unknown words from texts containing few instances.

Abstract

Implicit discourse relation recognition is an extremely challenging task due to the lack of indicative connectives. Various neural network architectures have been proposed for this task recently, but most of them suffer from the shortage of labeled data. In this paper, we address this problem by procuring additional training data from parallel corpora: When humans translate a text, they sometimes add connectives (a process known as *explicitation*). We automatically back-translate it into an English connective, and use it to infer a label with high confidence. We show that a training set several times larger than the original training set can be generated this way. With the extra labeled instances, we show that even a simple bidirectional Long Short-Term Memory Network can outperform the current state-of-the-art.

1 Introduction

When humans comprehend language, their interpretation consists of more than just the sum of the content of the sentences. Additional semantic relations (known as coherence relations or discourse relations) are inferred between sentences in the text. Identification of discourse relations is useful for various NLP applications such as question answering (Jansen et al., 2014; Liakata et al., 2013), summarization (Maskey and Hirschberg, 2005; Yoshida et al., 2014; Gerani et al., 2014), machine translation (Guzmán et al., 2014; Meyer et al., 2015) and information extraction (Cimiano et al., 2005). Recently, the task has drawn increasing attention, including two CoNLL shared tasks (Xue et al., 2015, 2016).

Discourse relations are sometimes expressed

with an *explicit* discourse connective (DC), such as “because”, “but”, “if”. Example 1 shows an explicit discourse relation marked by “because”; the text spans between which the relation holds are marked as *Arg1* and *Arg2*. DCs serve as strong cues and allow us to classify discourse relations with high accuracy (Pitler et al., 2008, 2009; Lin et al., 2014).

However, more than half of the discourse relations in a text are not signalled by a connective. See for example 2: a contrastive relation can be inferred between the text spans marked as *Arg1* and *Arg2*. Implicit relation classification is very challenging and represents a bottleneck of the entire discourse parsing system.

1. [The city’s Campaign Finance Board has refused to pay Mr Dinkins \$95,142 in matching funds]_{Arg1} **because** [his campaign records are incomplete.]_{Arg2}

— *Explicit, Contingency.Cause*

2. [They desperately needed somebody who showed they cared for them, who loved them.]_{Arg1} [The last thing they needed was another drag-down blow.]_{Arg2}

— *Implicit, Comparison.Contrast*

In order to classify an implicit discourse relation, it is necessary to represent the semantic content of the relational arguments, which may give a cue to the coherence relation, e.g. “care” – “drag-down blow” in 2. Early methods have focused on designing various features to overcome data sparsity and more effectively identify relevant concepts in the two discourse relational arguments. (Lin et al., 2009; Zhou et al., 2010; Biran and McKeown, 2013; Park and Cardie, 2012; Rutherford and Xue, 2014), while recent efforts use distributed representations with neural network architectures (Zhang et al., 2015; Ji and Eisenstein,

2015; Ji et al., 2016; Chen et al., 2016; Qin et al., 2016, 2017). Both streams of methods suffer from insufficient annotated data (Wang et al., 2015), since the Penn Discourse Treebank (PDTB) (Prasad et al., 2008), which is the discourse annotated resource mostly used by the community, consists of just 12763 implicit instances in the usual training set and 761 relations in the test set. Some second-level relations only have about a dozen instances. It is therefore crucial to obtain extra data for machine learning.

In this paper, we propose a simple approach to automatically extract samples of implicit discourse relations from parallel corpus via back-translation: Our approach is motivated by the fact that humans sometimes omit connectives during translation (*implicitation*), or insert connectives not originally present in the source text (*explicitation*) (Laali and Kosseim, 2014; Koppel and Ordan, 2011; Cartoni et al., 2011; Hoek and Zufferey, 2015; Zufferey, 2016). When explicitating an implicit relation, the human translator is, in other words, disambiguating the source implicit relation with an explicit DC in the target language.

Our contribution is twofold: Firstly, we propose a pipeline to automatically label English implicit discourse relation samples based on explicitation of DCs in human translation, which is the target side of a parallel corpus. Secondly, we show that the extra instances mined by the proposed method improve the performance of a standard neural classifier by a large margin, when evaluated on the PDTB 2.0 benchmark test set as well as by cross-validation (Shi and Demberg, 2017).

2 Related Work

Early works addressing discourse relation parsing were trying to classify unmarked discourse relations by training on explicit discourse relations with the marker been removed (Marcu and Echihiabi, 2002). While this method promised to provide almost unlimited training data, it was shown that explicit relations differ in systematic ways from implicit relations (Asr and Demberg, 2012), so that performance on implicits is very poor when learning on explicits only (Sporleder and Lascarides, 2008).

The release of PDTB (Prasad et al., 2008), the largest available corpus which annotates implicit examples, lead to substantial improvements in classification of implicit relations, and spurred

a variety of approaches to the task, including feature-based methods (Pitler et al., 2009; Lin et al., 2009; Park and Cardie, 2012; Biran and McKeown, 2013; Rutherford and Xue, 2014) and neural network models (Zhang et al., 2015; Ji and Eisenstein, 2015; Ji et al., 2016; Chen et al., 2016; Qin et al., 2016, 2017). However, the limited size of the annotated corpus, in combination with the difficulty of the task of inferring the type of relation between given text spans, presents a problem both in training (Rutherford et al. (2017) find that a simple feed-forward architecture can outperform more complex architectures, and argues that the larger number of parameters can not be estimated adequately on the small amount of training data) and testing (Shi and Demberg (2017) report experiments showing that results on the standard test set are not reliable due to the small set of just 761 relations).

Data extension has therefore been a longstanding goal in discourse relation classification. The main idea has been to select explicit discourse instances that are similar to implicit ones to add to the training set. Wang et al. (2012) proposed to differentiate typical and atypical examples for each discourse relation, and augment training data for implicits only by typical explicits. In a similar vein, Rutherford and Xue (2015) proposed criteria for selecting among explicitly marked relations ones that contain discourse connectives which can be omitted without changing the interpretation of the discourse. These relations are then added to the implicit instances in training.

On the other hand, Lan et al. (2013) presented multi-task learning based systems, which in addition to the main implicit relation classification task, contain the task of predicting previously removed connectives for explicit relations, and profit from shared representations between the tasks. Similarly, HERNAUT et al. (2010) observes features that occur in both implicit and explicit discourse relations, and exploit such feature co-occurrence to extend the features for classifying implicits using explicitly marked relations. Mihăilă and Ananiadou (2014) and Hidey and McKeown (2016) proposed semi-supervised learning and self-learning methods to improve recognition of patterns that typically signal causal discourse relations.

The approach proposed here differs from previous approaches, because we extend our train-

ing data only by originally implicit relations, and obtain the label through the disambiguation that sometimes happens in human translation.

Parallel corpora have been exploited as a resource of discourse relation data in previous work but have mostly been used with goals different from ours: Cartoni et al. (2013) and Meyer et al. (2015) use parallel corpora to label and disambiguate discourse connectives in the target language based on explicitly marked English relations, in order to help machine translation. A second application has been to project discourse annotation from English onto other languages through parallel corpora, in order to construct discourse annotated resources for the target language (Versley, 2010; Zhou et al., 2012; Laali and Kosseim, 2014).

The approach that is in spirit most similar to ours is by Wu et al. (2016), who extracted bilingual-constrained synthetic implicit data from a sentence-aligned English-Chinese corpus and got improvements by incorporating these data via a multi-task neural network on the 4-way classification.

3 Method

Our proposed method aims at sentence pairs in the parallel corpora where an *implicit* discourse relations on the source English side has been translated by human translators into an explicitly marked relation on the target side. The inserted connective hence disambiguates the originally implicit relation, and the discourse relation can be classified with confidence (under the assumption that the same discourse relation holds in the original source text).

The pipeline of our approach is detailed in below steps.

1. The target side of a sentence-aligned parallel corpus, with English as the source text, is back-translated to English using a pre-trained machine translation system.
2. An end-to-end discourse relation parser for English is run on both the source side and the back-translated target side. The parser will output a list of explicit and implicit relations, including the relation sense and argument spans of each relation.
3. Implicit-to-explicit discourse relation alignments are identified according to the output

of the end-to-end parser. Implicit relations in the PDTB are only ever annotated between consecutive sentences. Therefore, we specifically extract pairs of consecutive sentences on the source English side:

- that are identified as the *Arg1* and *Arg2* of an *implicit* discourse relation¹;
- whose corresponding back-translated target sentences are identified as the *Arg1* and *Arg2* of an *explicit* relation;
- that are not part of the *Arg1* or *Arg2* of any other discourse relations².

4. Label the source English implicit relation with the relation class of the explicit relation in back-translated target text. The two consecutive sentences are marked as *Arg1* and *Arg2* respectively.

Figure 1 illustrates the pipeline of our approach, which takes an English-to-French parallel corpus as input and outputs a list of implicit discourse relations, each containing two arguments from the source English text and a relation class according to the back-translated French DC.

We then compare the performance of a neural implicit discourse relation classifier trained with the annotated implicit relation samples in PDTB alone and also with the extra training samples mined from the parallel corpus. The classifier performance is evaluated on the standard PDTB implicit relation test set and by cross-validation.

3.1 Advantages of using back-translation

In the proposed method, we disambiguate implicit relations according to the explicitated translation. Instead of directly classifying the explicit relation in the target language, we back-translate the target text to the source language by machine translation (MT) because:

- Discourse parsers on low-resource languages do not perform well, or are even not available.
- Different languages have different sets of discourse relation classes defined. By the means of back-translation, we can use an English discourse parser on the target text, and thus

¹ Relations signaled by *Alternative Lexicalization* are counted as implicit relations and extracted as samples. However, *NoRel* and *EntRel* are excluded.

² This restriction avoids mis-alignment of relations between source and target texts.

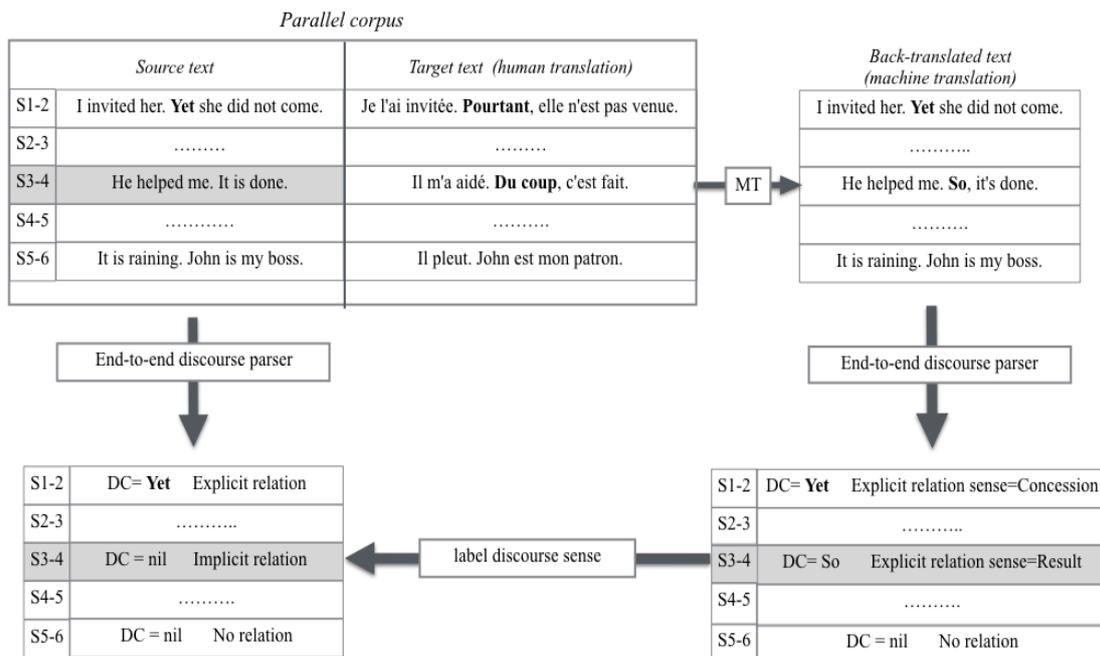

Figure 1: Pipeline showing how an implicit discourse relation sample, sentence pair 3-4, is extracted and labeled using a parallel corpus.

label the implicit relations with the same set of relation labels defined for English.

- The quality of the MT system has limited impact on our approach. Since the DC tokens are powerful features to disambiguate an explicit relation, limited contextual features are required. We just need correct translation of the explicit DC tokens, irrespective of word order and the rest of the translation.

3.2 Inter-sentential and intra-sentential relations

Only inter-sentential implicit relations are annotated in the PDTB, due to time and resource constraints (Prasad et al., 2008). However, this does not mean that implicit relations only hold between consecutive sentences.

We decided to extract intra-sentential relation samples from the parallel corpus based on two motivations: Firstly, we hypothesize that intra-sentential implicit relations share similar features as inter-sentential ones. Including both types may hence increase dataset size. In fact, we will see in the experiment results that intra-sentential training samples largely improve classification of implicit relations, even though the test data from PDTB contains inter-sentential samples only. An analysis on what we learn from the intra-sentential samples is presented in Section 6.1.

Secondly, intra-sentential relations can potentially be identified with higher reliability: Parallel corpora are typically sentence-aligned. This makes it a lot easier to extract sentences that are detected by the end-to-end discourse relation parser as explicit in the (back-)translation target side but not on the original source side, without needing to worry about whether any sentences in the dataset were removed or the order changed during preprocessing (which would be detrimental for detecting intra-sentential relations).

3.3 Argument spans

It is possible but not entirely trivial to determine the argument spans of the discourse relations labeled with the back-translation method. In this paper, we chose a neural network model that concatenates the *Arg1* and *Arg2* representations (see Section 4.4), so that determining exact text spans of *Arg1* and *Arg2* was not necessary. We are not the first one to do like this, in the work by Rönqvist et al. (2017), they modeled the *Arg1-Arg2* pairs as a joint sequence and did not compute intermediate representations of arguments separately, to make it more generally flexible in modeling discourse units and easily extend to additional contexts.

4 Experiment

4.1 Data

Parallel Corpora The corpora used for the extraction of implicit discourse relation samples are publicly available bilingual English-French parallel datasets compiled by Rabinovich et al. (2015).³ They consist of European parliamentary proceedings, literary works and the Hansard corpus – genres that are different from the PDTB, because we want to expand the diversity of discourse relation samples available in the PDTB. These corpora contain a total of ~ 1.9 M sentence pairs with an average of 22.7 words per English sentence. Each corpus contains an originally written part in English (used as target for the MT system) and its corresponding human translation in French (used as source). We use the same corpora to train the French–English MT system (Section 4.2), to back-translate the French side into English and to extract additional discourse training data.

The Penn Discourse Treebank (PDTB) We use the Penn Discourse Treebank 2.0 (Prasad et al., 2008) for the training and testing of the implicit discourse relation classifier. PDTB is the largest available manually annotated corpus of explicit and implicit discourse relations based on one million word tokens from the Wall Street Journal. Each discourse relation is annotated with at most two senses from a three-level hierarchy of discourse relations. The first level roughly categorizes the relations into four major classes, each of which is further categorized into more distinct relation types. Conventionally, discourse relation classifiers are either evaluated by the accuracy of the first-level 4-way classification (Pitler et al., 2009; Rutherford and Xue, 2014; Chen et al., 2016), or the second-level 11-way classification (Lin et al., 2009; Ji and Eisenstein, 2015; Qin et al., 2016, 2017).

4.2 Machine Translation System

We train an MT system to back-translate the target side of the parallel corpus to English. To produce the highest-quality back-translation, we use a neural MT system trained on the same parallel corpus. The system is implemented by Open-source Neural Machine Translation (OpenNMT) (Klein et al., 2017). Source words are first mapped to word vectors and then fed into a recurrent neural network.

³All corpora are available at <http://cl.haifa.ac.il/projects/translationese/>

At each target time step, *attention* is applied over the source RNN and combined with the current hidden state to produce a prediction of the next word, and this prediction would be fed back into the target RNN.

We evaluate the MT system on *newstest2014* and *newsdiscusstest2015*, reaching 24.63 and 22.58 BLEU respectively. The French side of the training data back-translated into English is evaluated against the originally written English source, leading to a BLEU score of 34.17.⁴ The evaluation of the back-translated corpus indicates that the source text is not exactly reproduced. Critically, we assume that the MT system preserves the explicitness of the target DCs, instead of explicating or implicitating DCs as in the human translation.

4.3 End-to-end discourse parser

We employ the PDTB-style End-to-End Discourse Parser (Lin et al., 2014) to identify and classify the explicit instances from the back-translated English sentences. It achieved about 87% F1 score for explicit relations on level-2 types, even higher than human agreement of 84%. The accuracy on explicit DC identification is 96%.

On the source side, the end-to-end parser is applied to pick implicit relations from other types of relations, i.e. explicit relations or *no relation*, in order to extract implicit-to-explicit DC translation from the parallel corpus⁵. On the back-translation, the end-to-end parser is applied to identify only explicitly marked discourse relations.

4.4 Implicit relation classification model

We use a Bidirectional Long Short-Term Memory (LSTM) network as the implicit relation classification model to evaluate the samples extracted by the proposed method. This architecture inspects both left and right contextual information and has been proven effective in relation classification (Zhou et al., 2016; Rönnqvist et al., 2017).

The model is illustrated in Figure 2, where each word from the two discourse relational arguments is represented as a vector, which is found through a look-up word embedding. Given the word representations $[\mathbf{w}_1, \mathbf{w}_2, \dots, \mathbf{w}_n]$ as the input sequence, an

⁴Case sensitive BLEU implemented in *mteval-v13a.pl*. Test sets available at <http://www.statmt.org/wmt15/translation-task.html>

⁵The non-explicit sense classification module of this parser is thus not used in the proposed method.

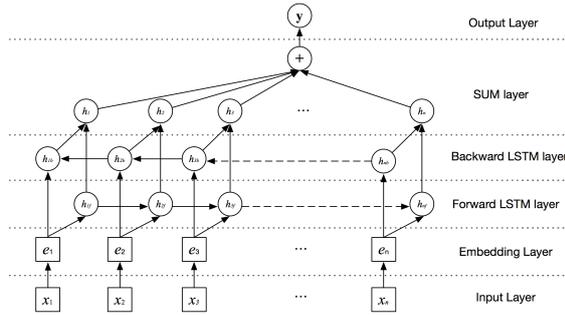

Figure 2: The bidirectional LSTM Network for the task of implicit discourse relation classification.

LSTM computes the state sequence $[\mathbf{h}_1, \mathbf{h}_2, \dots, \mathbf{h}_n]$ with the following equations:

$$\begin{aligned} \mathbf{i}_t &= \sigma(\mathbf{W}_w^i \mathbf{w}_t + \mathbf{W}_h^i \mathbf{h}_{t-1} + \mathbf{W}_c^i \mathbf{w}_{t-1} + \mathbf{b}_i) \\ \mathbf{f}_t &= \sigma(\mathbf{W}_w^f \mathbf{w}_t + \mathbf{W}_h^f \mathbf{h}_{t-1} + \mathbf{W}_c^f \mathbf{w}_{t-1} + \mathbf{b}_f) \\ \mathbf{g}_t &= \tanh(\mathbf{W}_w^c \mathbf{w}_t + \mathbf{W}_h^c \mathbf{h}_{t-1} + \mathbf{b}_c) \\ \mathbf{c}_t &= \mathbf{f}_t \odot \mathbf{c}_{t-1} + \mathbf{i}_t \odot \mathbf{g}_t \\ \mathbf{o}_t &= \sigma(\mathbf{W}_w^o \mathbf{w}_t + \mathbf{W}_h^o \mathbf{h}_{t-1} + \mathbf{b}_o) \\ \mathbf{h}_t &= \tanh(\mathbf{c}_t) \odot \mathbf{o}_t \end{aligned}$$

The forward and backward LSTM layers traverse the sequence \mathbf{e}_i , producing sequences of vectors \mathbf{h}_{if} and \mathbf{h}_{ib} respectively, which are summed together in the coming sum layer.

Following the preprocessing method in (Lin et al., 2009), relations with too few instances (*Contingency.Condition*, *Pragmatic.Condition*; *Comparison.Pragmatic Contrast*, *Pragmatic Concession*; *Expansion.Exception*) are removed during training and evaluation, resulting in 11 types of relations. Among instances annotated with two relation senses, we only use the first sense.

The model is implemented in Keras⁶, which is capable of running on top of Theano. We use word embeddings of 300 dimensions, which are trained on the original English side of the parallel corpora as well as PDTB with the Skip-gram architecture in *Word2Vec* (Mikolov et al., 2013). We initial-

⁶<https://keras.io/>

Relation	intra-	inter-	Total
explicit → explicit	199,047	111,090	310,137
explicit → implicit	101,381	29,964	131,345
implicit → explicit	77,228	25,086	102,314

¹ “→” means from source to target side.

Table 1: Numbers of intra/inter-sentence samples extracted from parallel corpora.

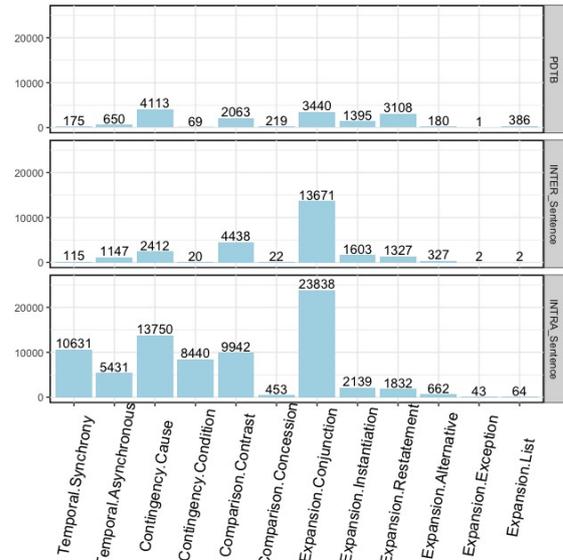

Figure 3: Relation sense distribution of implicit relations in PDTB and the extra intra- and inter-sentence samples

ize the weights with uniform random; use standard cross-entropy as our loss function; employ Adagrad as the optimization algorithm of choice and set dropout layers after the embedding layer and output layer with a drop rate of 0.2 and 0.5 respectively. Each LSTM has a vector dimension of 300, matching the embedding size.

We split the PDTB data and evaluate the classifier in two settings. Firstly, we adopt the standard PDTB splitting convention, where section 2-21, 22, and 23 are used as train, validation and test sets respectively (Lin et al., 2009). Secondly, we conduct 10-fold cross validation on the whole corpus including sections 0-24, as advocated in (Shi and Demberg, 2017). And extra samples are only added into training folds in the CV setting, which means that testing fold consists of instances from PDTB only. Models trained with and without extra samples we extracted, on top of the PDTB data, are compared.

5 Distribution of additional instances

In total, 102,314 implicit discourse relation samples are extracted, of which 25,086 are inter-sentential relations and 77,228 are intra-sentential⁷. Inter-sentential relations are much less abundant because stricter screening strategy is applied (the end of point 3 in Section 3). From Table 1 we can also see that majority of DCs in the

⁷A dataset containing these additional instances will be made available to researchers upon publication of the paper.

Models		PDTB Test Set	Cross Validation
Most common class		25.36	25.59
Lin et al. (2009)		40.20	-
Qin et al. (2016)		43.81	-
Qin et al. (2017)		44.65	-
Rutherford et al. (2017)		39.56	-
Shi and Demberg (2017) (no surface features)		37.68	34.44
Ours	PDTB only	34.32	30.01
	PDTB + inter-sentential samples	42.29	34.14
	PDTB + intra-sentential samples	44.29	35.08
	PDTB + all samples	45.50	37.84

¹ “-” means no result currently.

Table 2: Accuracy of 11-way classification of implicit discourse relations on PDTB test set and by cross validation.

source side have been translated into the target side explicitly.

Figure 3 compares the distribution of relation senses among the annotated implicit relations in the PDTB and our extracted samples. The relation distribution generally corresponds to the distribution in PDTB, but some relations, such as *Temporal* and *Contingency.Condition*, are particularly numerous in the intra-sentential samples.

6 Results

We compare our model with current state-of-the-art models that were evaluated under the same setting (11-way classification, PDTB section 23 as test set) (Qin et al., 2016, 2017; Rutherford et al., 2017), as well as a model based on linguistic features (Lin et al., 2009) that uses this setting for evaluation.

Qin et al. (2017) developed an adversarial model, which consists of two CNNs in which arguments are represented separately, a four-layer Perceptron and a dense layer for classification, to enable an adaptive imitation scheme through competition between the implicit network and a rival feature discriminator. Our model substantially differs from that setup, as it uses a much simpler network architecture and represents the two discourse relation arguments jointly, i.e. without knowledge of the arguments’ spans. We can see that our baseline model performs substantially less well than the state of the art, and also less well than (Shi and Demberg, 2017), who also use an LSTM but represent discourse relational arguments separately. As adding training data can be expected to

be largely orthogonal to the choice of classification model, we are here most interested in seeing whether adding the new instances improves over the baseline model with identical architecture.

Table 2 shows that including the extra inter- and intra-sentential instances leads to very substantial improvements in classification accuracy. Using the additional data, our method not only improves performance by 11%-points on the PDTB test set compared to training on the PDTB implicit relations only, but also outperforms much more complex neural network models (Qin et al., 2016, 2017) on this task.

The evaluation using cross-validation (around 8% point improvement over the baseline) furthermore shows that the obtained improvements do not only hold for the PDTB standard test set but also are stable across the whole PDTB data. These results strongly support the effectiveness of the implicit relation samples mined from parallel texts.

The accuracies reported for our models are based on 10 repeat-runs with different initializations of the network. This allows us to show the amount of variance in results we obtained in Figure 4. We found that results sometimes varied a lot between different runs, and would therefore like to encourage others in the field to also report variability due to initialization or other random factors. For instance, our best run achieved 49.84% accuracy on the PDTB test set trained with all additional instances, while mean performance for that setting is 45.50% accuracy. Variances were substantially smaller for the cross-validation setting, as the number of overall instances going into the

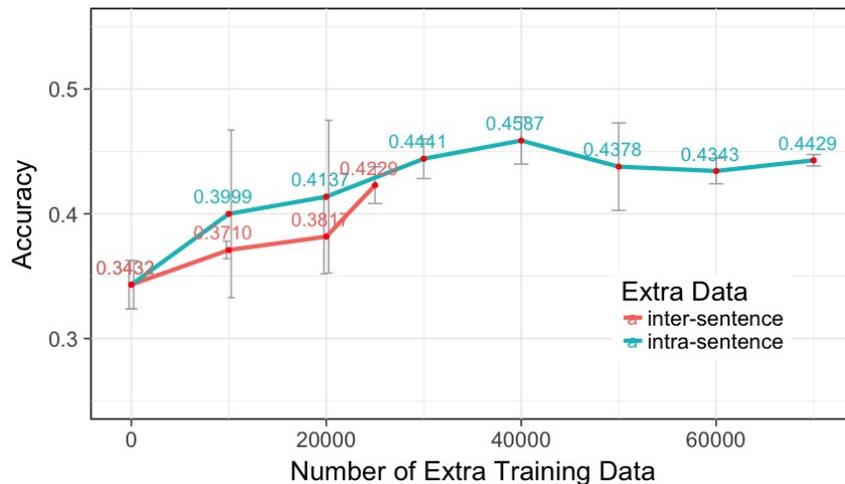

Figure 4: Average and variance of classification accuracy evaluated on the PDTB test set with different sample size.

evaluation is a lot larger in this setting, and hence yields more stable performance estimates.

6.1 Qualitative Analysis

In order to illustrate what kinds of instances our method extracts, we show an instances below. The underlined DC is the explicit DC identified in the back-translated target text; the discourse relation is automatically classified based on the back-translation.

3. *[Justice demands it.]_{Arg1} **but** [The minister refuses.]_{Arg2}*
 — *Comparison.Contrast*

One strength of the proposed method is that it can mine and label discourse relations that are not commonly regarded as discourse relations and hence not annotated in PDTB. Below are some examples where the bold DC was identified in the (back-)translation:

4. *A conservative member was kicked out of his caucus for defending Nova Scotians.*
 — **because**, *Contingency.Cause*
5. *A failure to do so would affect our attitude to their eventual accession.*
 — **if**, *Contingency.Condition*

These extra samples are in fact an invaluable resource of discourse-informative patterns, which are not available to discourse relation parsers that are trained only on the PDTB dataset. These cases provide evidence that our proposed method can not only provide instances that are similar to implicit labelled instances, but detect additional patterns, as attempted in (Mihăilă and Ananiadou,

2014; Hidey and McKeown, 2016) for causal relations, and generalize from the semantic content observed in such relations to actual implicit discourse relations.

For example, as reported in Section 5, numerous *Temporal* relations are mined from the parallel corpus. These include cases where the original text contained a verbal construction which expresses the temporal relation, which through back-translation gets expressed as a discourse relation, or where explicit relations include gerunds in the Arg2, e.g.

- “any plan takes time to have the effect required”* → *“before getting the effect required”*
“how much longer do women have to wait for fairness?” → *“before women have fairness.”*
“having gone over the estimates” → *“after going over the estimates.”*

(source text followed by (back-)translation, where the explicitated DC is underlined).

In this work, we only extracted inter- and intra-sentential discourse relations, but the method can be in principle extended to other discourse relations that are not annotated in the PDTB, such as implicit relation between non-consecutive sentences. Discourse parsers that identify a larger range of relations are more useful in end applications. More importantly, identification of discourse-informative linguistic patterns by the proposed method opens the opportunity to mine extra samples under a monolingual setting and further improve classification performance.

6.2 Quantitative Analysis

In order to get detailed insights on how much extra data is most beneficial to the task, we also trained our classifier with different numbers of additional extracted samples. Figure 4 compares the classification accuracy when training on incremental number of extra instances. We find that the performance increases with samples size, but plateaus after 40,000 intra-sentential samples.

In fact, this sample size produces the highest averaged classification accuracy of 45.87%, which is even higher than our model which includes all extracted samples. A possible reason for not seeing further improvement in adding more intra-sentential examples is the difference in distribution and properties of these extra samples compared to the PDTB data. We also experimented with training on the parallel-text samples only (i.e., without any PDTB training samples), but the result was worse than using PDTB only. Adding more *inter-sentential* samples might further improve the performance, as these instances are closer to the PDTB data.

6.3 Methodological Discussion

Our proposed method uses back-translated target DCs to label implicit relations. The quality of the relation label is intrinsically subject to the translation policy of the parallel corpora and also extrinsically subject to the accuracy of explicit DC classification by the end-to-end parser and the quality of the MT system. For example, a particularly high proportion of *Contingency.Condition* relations is found in the intra-sentential samples. Analyzing these samples, we found numerous instances where the word ‘if’ is wrongly identified as a DC (e.g. *He asked if it was correct.*). It is not surprising to have noisy samples extracted because limited screening strategy is applied in the current method.

As a reference for the quality of the relation label produced, we analysed the intra-sentential relations in the parallel corpus that are explicit on the source side and also in the (back-)translation. We found that 68% of the originally explicit DCs are (back-)translated to the same explicit DCs and 75% to DCs of the same level-2 sense, according to automatic explicit DC classification of the end-to-end parser.

7 Conclusion and Future work

We showed that explicitation during human translation can provide a valuable signal for expanding datasets for implicit discourse relations. As the expansion of training instances is orthogonal to the mechanism of DR classification, this method can be applied to improve any methods of implicit DR classification.

We see plenty of room for further improvement by controlling the sample quality, such as selection based on explicit discourse connective identification confidence, restraining the discourse relation structure, identifying Arg1 and Arg2 such that approaches which use two separate representations for arguments instead of a single concatenated vector become possible, reducing language-specific bias by mining from parallel corpora of other language pairs, and fine-tuning the MT system for discourse connective translation. We leave the exploration of these areas to future work.

Abstract

Identifying implicit discourse relations between text spans is a challenging task because it requires understanding the meaning of the text. To tackle this task, recent studies have tried several deep learning methods but few of them exploited the syntactic information. In this work, we explore the idea of incorporating syntactic parse tree into neural networks. Specifically, we employ the Tree-LSTM model and Tree-GRU model, which are based on the tree structure, to encode the arguments in a relation. Moreover, we further leverage the constituent tags to control the semantic composition process in these tree-structured neural networks. Experimental results show that our method achieves state-of-the-art performance on PDTB corpus.

1 Introduction

It is widely agreed that text units such as clauses or sentences are usually not isolated. Instead, they correlate with each other to form coherent and meaningful discourse together. To analyze how text is organized, discourse parsing has gained much attention from both the linguistic (Weiss and Wodak, 2007; Tannen, 2012) and computational (Marcu, 1997; Soricut and Marcu, 2003) communities, but the current performance is far from satisfactory. The most challenging part is to identify the discourse relations between text spans, especially when the discourse connectives (e.g., “because” and “but”) are not explicitly shown in the text. Due to the absence of such evident linguistic clues, trying to model and understand the meaning of the text becomes the key point in identifying such implicit relations.

Arg1: The index is intended to **measure future economic performance**

Arg2: A figure above 50 indicates **the economy is likely to expand**

(Expansion.Restatement.Specification, wsj_0233)

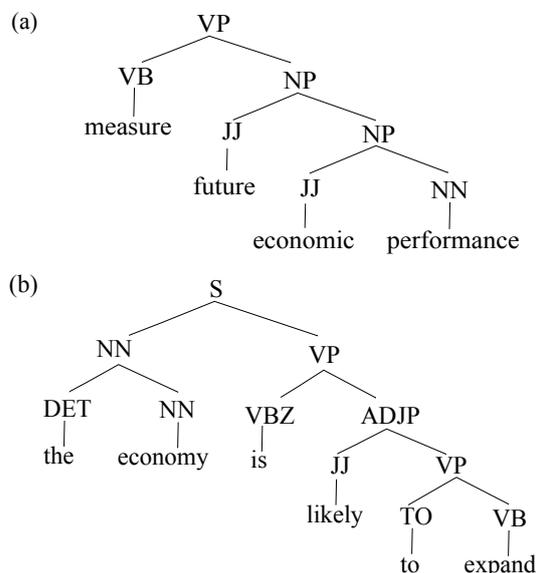

Figure 1: An example of two sentences with their discourse relation as *Expansion.Restatement.Specification*. Subfigure (a) and (b) are partial parse trees of the two important phrases with yellow background.

Previous studies in this field treat the task of recognizing implicit discourse relations as a classification problem and various techniques in semantic modeling have been adopted to encode the arguments in each relation, ranging from traditional feature-based models (Lin et al., 2009; Pitler et al., 2009) to the currently prevailing deep learning methods (Ji and Eisenstein, 2014; Liu and Li, 2016; Qin et al., 2017). Despite of the superior ability of the deep learning models, the syntactic

information, which proves to be helpful for identifying discourse relations in many early studies (Subba and Di Eugenio, 2009; Lin et al., 2009), is seldom employed by recent work. Therefore we are curious to explore whether such missing syntactic information can be leveraged in deep learning methods to further improve the semantic modeling for implicit discourse relation classification.

Tree-structured neural networks, which recursively compose the representation of smaller text units into larger text spans along the syntactic parse tree, can tactfully combine syntactic tree structure with neural network models and recently achieve great success in several semantic modeling tasks (Eriguchi et al., 2016; Kokkinos and Potamianos, 2017; Chen et al., 2017). One useful property of these models is that the representation of phrases can be naturally captured while computing the representations from bottom up. Taking Figure 1 for an example, those highlighted phrases could provide important signals for classifying the discourse relation. Therefore, we will employ two latest tree-structured models, i.e. the Tree-LSTM model (Tai et al., 2015; Zhu et al., 2015) and the Tree-GRU model (Kokkinos and Potamianos, 2017), in our work. Hopefully, these models can learn to preserve or highlight such helpful phrasal information while encoding the arguments.

Another important syntactic signal comes from the constituent tags on the tree nodes (e.g., NP, VP, ADJP). Those tags, derived from the production rules, describe the generative process of text and therefore could indicate which part is more important in each constituent. For example, considering a node tagged with NP, its child node tagged with DT is usually neglectable. Thus we propose to incorporate this tag information into the tree-structured neural networks, where those constituent tags can be used to control the semantic composition process.

Therefore, in this paper, we will approach the discourse relation classification task with two tree-structured neural networks proposed recently (Tree-LSTM and Tree-GRU). To our knowledge, this is the first time these models are applied to discourse relation classification. Moreover, we further enhance these models by leveraging the constituent tags to compute the gates in these models. Experiments on PDTB 2.0 (Prasad et al., 2008) show that the models we propose can achieve state-of-the-art results.

2 Related Work

2.1 Implicit Discourse Relation Classification

Discourse relation identification is an important but difficult sub-component of discourse analysis. One fundamental step forward recently is the release of the large-scale Penn Discourse TreeBank (PDTB) (Prasad et al., 2008), which annotates discourse relations with their two textual arguments over the 1 million word Wall Street Journal corpus. The discourse relations in PDTB are broadly categorized as either “Explicit” or “Implicit” according to whether there are connectives in the original text that can indicate the sense of the relations. In the absence of explicit connectives, identifying the sense of the relations has proved to be much more difficult (Park and Cardie, 2012; Rutherford and Xue, 2014) since the inferring is solely based on the arguments.

Prior work usually tackles this task of implicit discourse relation identification as a classification problem with the classes defined in PDTB corpus. Early attempts use traditional various feature-based methods and the work inspiring us most is Lin et al. (2009), in which they show that the syntactic parse structure can provide useful signals for discourse relation classification. More specifically they employ the production rules with constituent tags (e.g., SBJ) as features and get competitive performance. Recently, with the popularity of deep learning methods, many cutting-edge models are also applied to our task of implicit discourse relation classification. Qin et al. (2016) tries to model the sentences with Convolutional Neural Networks. Liu and Li (2016) encodes the text with Long Short Term Memory model and employ multi-level attention mechanism to capture important signals. Qin et al. (2017) proposes a framework based on adversarial network to incorporate the connective information. To be noted, Ji and Eisenstein (2014) adopts Recursive Neural Network to exploit the representation of sentences and entities, which is the first yet simple tree-structured neural network applied in this task.

2.2 Tree-Structured Neural Networks

Tree-structured neural networks are one of the most widely-used deep learning models in natural language processing. Such neural networks usually recursively computes the representation of larger text spans from its constituent units according to the syntactic parse tree. Thanks to this

compositional nature of text, tree-structured neural network models show superior ability in a variety of semantic modeling tasks, such as sentiment classification (Kokkinos and Potamianos, 2017), natural language inference (Chen et al., 2017) and machine translation (Eriguchi et al., 2016).
