The earliest and simplest tree-structure neural network is the Recursive Neural Network proposed by Socher et al. (2011), in which a global matrix is learned to linearly combine the constituent vectors. This work is further extended by replacing the global matrix with a global tensor to form the Recursive Neural Tensor Network (Socher et al., 2013). Based on them, Qian et al. (2015) first proposes to incorporate tag information, which is very similar as our idea described in Section 3.2, by either choosing a composition function according to the tag of a phrase (Tag-Guided RNN/RNTN) or combining the tag embeddings with word embeddings (Tag-Embedded RNN/RNTN). Our method of incorporating tag information improves from theirs and somewhat combines these two methods by using the tag embedding to dynamically determine the composition function via the gates in LSTM or GRU.

One fatal weakness of vanilla RNN/RNTN is the well-known gradient exploding or vanishing problem due to the multiple computation steps in the vertical direction. Therefore Tai et al. (2015) and Zhu et al. (2015) propose to import the Long Short Term Memory into tree structured neural networks and design a novel network architecture called Tree-LSTM. The adoption of the memory cell enables the Tree-LSTM model to preserve information even though the tree becomes very high. Similar to Tree-LSTM, Kokkinos and Potamianos (2017) introduces the so-called Tree-GRU network, which replace the LSTM unit with Gated Recurrent Unit (GRU). With less parameters to train, Tree-GRU achieves better performance on the sentiment analysis task. In this work, we will experiment with these Tree-LSTM and Tree-GRU models for the semantic modeling in implicit relation classification.

3 Our Method

This section details the models we use for implicit discourse relation classification. Given two textual arguments without explicit connectives, our task is to classify the discourse relation between them. It can be viewed as two parts: 1) modeling the se-

mantics of the two arguments; 2) classifying the relations based on the semantics. Our main contribution concentrates on the semantic modeling part with two types of tree-structured neural networks described in Section 3.1 and we further illustrate how to leverage the constituent tags to enhance these two models in Section 3.2. In Section 3.3, we will shortly introduce the relation classifier and the training procedure of our model. The architecture of our system is illustrated in Figure 2.

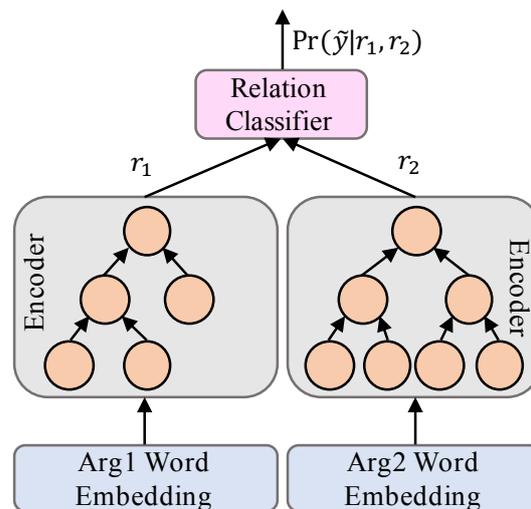

Figure 2: Architecture of our discourse relation classification model. Layers with the same color share the same parameters.

3.1 Modeling the Arguments with Tree-Structured Neural Networks

In a typical tree-structured neural network, given a parse tree of the text, the semantic representations of smaller text units are recursively composed to compute the representation of larger text spans and finally compute the representation for the whole text (e.g., sentence). In this work, we will construct our models based on the constituency parse tree, as is shown in Figure 1. Following previous convention (Eriguchi et al., 2016; Zhao et al., 2017), we convert the general parse tree, where the branching factor may be arbitrary, into a binary tree so that we only need to consider the left and right children at each step. Then the following Tree-LSTM and Tree-GRU models can be used to obtain a vector representation of each argument.

Tree-LSTM Model. In a standard sequential LSTM model, the LSTM unit is repeated at each

step to take the word at current step and previous output as its input, update its memory cell and output a new hidden vector. In the Tree-LSTM model, a similar LSTM unit is applied to each node in the tree in a bottom-up manner. Since each internal node in the binary parse tree has two children, the Tree-LSTM unit has to consider information from two preceding nodes, as opposed to the single preceding node in the sequential LSTM model. Each Tree-LSTM unit (indexed by j) contains an input gate i_j , a forget gate f_j ¹ and an output gate o_j . The computation equations at node j are as follows:

$$i_j = \sigma \left(W^{(i)} x_j + U^{(i)} [h_j^L, h_j^R] \right) \quad (1)$$

$$f_j = \sigma \left(W^{(f)} x_j + U^{(f)} [h_j^L, h_j^R] \right) \quad (2)$$

$$o_j = \sigma \left(W^{(o)} x_j + U^{(o)} [h_j^L, h_j^R] \right) \quad (3)$$

$$u_j = \tanh \left(W^{(u)} x_j + U^{(u)} [h_j^L, h_j^R] \right) \quad (4)$$

$$c_j = i_j \odot u_j + f_j \odot c_j^L + f_j \odot c_j^R \quad (5)$$

$$h_j = o_j \odot \tanh(c_j) \quad (6)$$

where x_j is the embedded word input at current node j , σ denotes the logistic sigmoid function and \odot denotes element-wise multiplication. h_j^L , h_j^R are the output hidden vectors of the left and right children, and c_j^L , c_j^R are the memory cell states from them, respectively. To save space, we leave out all the bias terms in affine transformations and the same is true for other affine transformations in this paper.

Intuitively, u_j can be regarded as a summary of the inputs at current node, which is then filtered by i_j . The memory from left and right children are forgotten by f_j and then we compose them together with the new inputs to form the the new memory c_j . At last, part of the information in memory c_j is exposed by o_j to generate the output vector h_j for current step. Another thing to note is that only leaf nodes in the constituency tree have words as its input, so x_j is set to a zero vector in other cases.

Tree-GRU Model. Similar to Tree-LSTM, the Tree-GRU model extends the sequential GRU model to tree structures. The only difference between Tree-GRU and Tree-LSTM is how they

modulate the flow of information inside the unit. Specifically, Tree-GRU unit removes the separate memory cell and only uses two gates to simulate the reset and update procedure in information gathering. The computation equations in each Tree-GRU unit are the following:

$$r_j = \sigma \left(W^{(r)} x_j + U^{(r)} [h_j^L, h_j^R] \right) \quad (7)$$

$$z_j = \sigma \left(W^{(z)} x_j + U^{(z)} [h_j^L, h_j^R] \right) \quad (8)$$

$$\tilde{h}_j = \tanh \left(W^{(h)} x_j + U^{(h)} [h_j^L \odot r_j, h_j^R \odot r_j] \right) \quad (9)$$

$$h_j = z_j \odot \tilde{h}_j + (1 - z_j) \odot (h_j^L + h_j^R) \quad (10)$$

where r_j is the reset gate and z_j is the update gate. The reset gate allows the network to forget previous computed representations, while the update gate decides the degree of update to the hidden state. There is no memory cell in Tree-GRU, with only h_j^L and h_j^R as the hidden states from the left and right children.

3.2 Controlling the Semantic Composition with Constituent Tags

The constituent tag in a parse tree describes the grammatical role of its corresponding constituent in the context. Bies et al. (1995) defines several types of constituent tags, including clause-level tags (e.g., SBAR, SINV, SQ), phrase-level tags (e.g., NP, VP, PP) and word-level tags (e.g., NN, VP, JJ). These constituent tags greatly interleave with the semantics and in some ways can provide determinant signals for the importance of a constituent. For example, for most of the time, constituents with PP (prepositional phrase) tag are less important than those with VP (verb phrase) tag. Therefore we argue that these tags are worth considering when we compose the semantics in the tree-structured neural networks.

One way to leverage such tags is using tag-specific composition functions but that would lead to large number of parameters and some tags are very sparse so it's very hard to train their corresponding parameters sufficiently. To solve this problem, we propose to use tag embeddings and dynamically control the composition process via the gates in our model.

Gates in Tree-LSTM and Tree-GRU units control the flow of information and thus determine how the semantics from child nodes are composed

¹The original Binary Tree-LSTM in (Tai et al., 2015) contains separate forget gates for different child nodes but we find single forget gate performs better in our task.

to a new representation. Furthermore, these gates are computed dynamically according to the inputs at a certain step. Therefore, it's natural to incorporate the tag embeddings in the computation of these gates. Based on this idea, we propose the Tag-Enhanced Tree-LSTM model, where the input, forget and output gates in each unit are calculated as follows:

$$i_j = \sigma \left(W^{(i)}x_j + M^{(i)}t_j + U^{(i)} [h_j^L, h_j^R] \right) \quad (11)$$

$$f_j = \sigma \left(W^{(f)}x_j + M^{(f)}t_j + U^{(f)} [h_j^L, h_j^R] \right) \quad (12)$$

$$o_j = \sigma \left(W^{(o)}x_j + M^{(o)}t_j + U^{(o)} [h_j^L, h_j^R] \right) \quad (13)$$

Similarly, we can have the Tag-Enhanced Tree-GRU model with new reset and update gates:

$$r_j = \sigma \left(W^{(r)}x_j + M^{(r)}t_j + U^{(r)} [h_j^L, h_j^R] \right) \quad (14)$$

$$z_j = \sigma \left(W^{(z)}x_j + M^{(z)}t_j + U^{(z)} [h_j^L, h_j^R] \right) \quad (15)$$

where t_j is the embedding of the tag at current node (indexed by j).

3.3 Relation Classification and Training

In our work, the two arguments are encoded with the same network in order to reduce the number of parameters. After that we get a vector representation for each argument, which can be denoted as r_1 for argument 1 and r_2 for argument 2. Supposing that there are totally n relation types, the predicted probability distribution $\hat{y} \in \mathbb{R}^n$ is calculated as:

$$\hat{y} = \text{softmax} \left(W^{(\hat{y})} [r_1, r_2] + b^{(\hat{y})} \right) \quad (16)$$

To train our model, the training objective J is dened as the cross-entropy loss with $L2$ regularization:

$$E(\hat{y}, y) = - \sum_{j=1}^n y_j \times \log \hat{y}_j \quad (17)$$

$$J(\theta) = \frac{1}{N} \sum_{k=1}^N E(\hat{y}, y) + \frac{\lambda}{2} \|\theta\|^2 \quad (18)$$

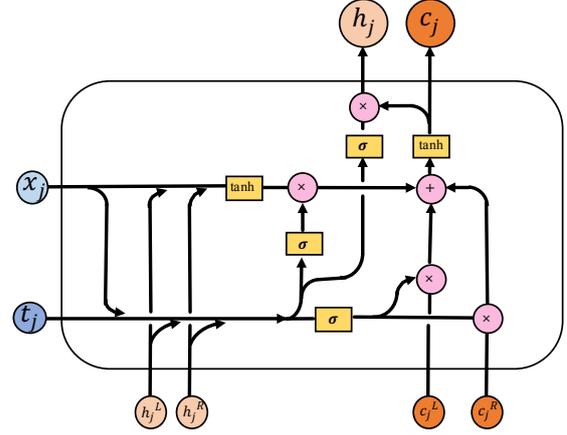

Figure 3: Flow of Information in Tag-Enhanced Tree-LSTM unit.

where \hat{y} is the predicted probability distribution, y is the one-hot representation of the gold label and N is the number of training samples.

4 Experiments

4.1 Experiment Setup

Corpus. We evaluate our method on the Penn Discourse Treebank (PDTB) (Prasad et al., 2008), which provides annotations of discourse relations over the Wall Street Journal corpus. Each relation instance consists of two arguments, typically adjacent pairs of sentences in a text. As is mentioned in Section 2.1, the relations in PDTB are generally categorized into either explicit or implicit and our work focuses on the more challenging implicit relation classification task. Totally, there are 16,224 implicit relation instances in PDTB dataset, with a three-level hierarchy. The first level is defined as 4 major classes of the relation, including: *Tem-*

Models	Level-1 Classification		Level-2 Classification	
	Dev	Test	Dev	Test
Bi-LSTM	55.10	56.88	35.02	42.44
Bi-GRU	55.21	57.01	35.34	42.46
Tree-LSTM	56.04	58.89	35.76	43.02
Tree-GRU	55.36	58.98	36.09	43.78
Tag-Enhanced Tree-LSTM	56.97	59.85	35.92	45.21
Tag-Enhanced Tree-GRU	56.63	59.75	36.93	44.55

Table 1: The accuracy score of multi-class classification

poral, *Contingency*, *Comparison* and *Expansion*. Then for each class, it is further divided into different types, which is supposed to provide finer pragmatic distinctions. This totally yields 16 relation types at the second level. At last, a third level of subtypes is defined for some types according to the semantic contribution of each argument.

Preprocessing. Following the common setup convention (Rutherford and Xue, 2014; Ji and Eisenstein, 2014; Liu and Li, 2016), we split the dataset into training set (Sections 2-20), development set (Sections 0-1), and test set (Section 21-22). For preprocessing, we employ the Stanford CoreNLP toolkit (Manning et al., 2014) to lemmatize all the words and get the constituency parse tree for each sentence. Then we convert the parse tree into binary with right branching and we remove the internal nodes that have only one child so that our binary tree-structured models can be applied. Small portion of the arguments in PDTB are composed of multiple sentences. In such cases, we add a new “Root” node and link the original root nodes of those sentences to this shared “Root” before converting the tree into binary.

Multi-Class Classification There are mainly two ways to set up the classification tasks in previous work. Early studies (Pitler et al., 2009; Park and Cardie, 2012) train and evaluate separate “one-versus-all” classifiers for each discourse relation since the classes are extremely imbalanced in PDTB. However, recent work put more emphasis on the multi-class classification, where the goal is to identify a discourse relation from all possible choices. According to Rutherford and Xue (2014), the multi-class classification setting is more natural and realistic. Moreover, the multi-class classifier can directly serve as one building block of a complete discourse parser (Qin et al., 2017). Therefore, in this work, we will focus on the multi-

class classification task. Moreover, we will experiment on the classification of both the Level-1 classes and the Level-2 types, so that we can compare with most of previous systems and thoroughly analyze the performance of our method.

It should be noted that roughly 2% of the implicit relation instances are annotated with more than one types. Following Ji and Eisenstein (2014), we treat these different types as multiple instances while training our model. During testing, if the classifier hits either of the annotated types, we consider it to be correct. We also follow previous studies (Lin et al., 2009; Ji and Eisenstein, 2014) to remove the instances of 5 very rare relation types in the second level. Therefore we have totally 11 types to classify for Level-2 classification and 4 classes for Level-1 classification.

4.2 Model Settings

We tune the hyper-parameters of our Tag-Enhanced Tree-LSTM model based on the development set and other models share the same set of hyper-parameters. The best-validated hyper-parameters, including the size of the word embeddings ω , the size of the tag embeddings τ , the dimension of the Tree-LSTM or Tree-GRU hidden state d , the learning rate η , the weight of L2 regularization term λ and the batch size b are shown in Table 2.

ω	τ	d	η	λ	b
50	50	250	0.01	0.0001	10

Table 2: Hyper-parameters of our model

The Pre-trained 50-dimensional Glove Vectors (Pennington et al., 2014), which is case-insensitive, are used for initializing the word embeddings and they are tuned together with other parameters in the same learning rate during training.

We adopt the AdaGrad optimizer (Duchi et al., 2011) for training our model and we validate the performance every epoch. It takes around 5 hours (5 epochs) for the Tag-Enhanced Tree-LSTM and 4 hours (6 epochs) for the Tag-Enhanced Tree-GRU model to converge to the best performance, using one INTEL(R) Core(TM) I7 3.4GHz CPU and one NVIDIA GeForce GTX 1080 GPU.

4.3 Results

The evaluation results of our models on both the Level-1 classification and the Level-2 classification are reported in Table 1. Accuracy score is used to measure the overall performance and we present our performance on both the development set and the test set. In addition to the four tree-structured neural networks described in Section 3, we also implement two baseline models: the bi-directional LSTM model and the bi-directional GRU model. The hyper-parameters of these two models are tuned separately from other models. Due to the space limitation, we don't present the details here. Comparison of these sequential models with the tree-structured models are expected to show the effects of tree structures.

From Table 1, we can see that the sequential Bi-LSTM model and Bi-GRU model perform worst for our task, which confirms our hypothesis that the tree-structured neural networks can really capture some important signals that are missing in the sequential models.

Furthermore, if we add the tag information to tree-structured models, both the Tag-Enhanced Tree-LSTM model and the Tag-Enhanced Tree-GRU model provide conspicuous improvement (around 1%) compared with the no-tag version. This demonstrates the usefulness of those constituent tags and the effectiveness of our method to incorporate this important feature. Especially, since both the Tree-LSTM model and Tree-GRU model rely on the gating mechanism to control the flow of information, this double confirms that the tag information can help with the computation of such gates and therefore can be leveraged to control the semantic composition process.

Another discovery from our results is that the GRU models performs similarly as its corresponding variant of LSTM model. This conforms to previous empirical observation in sequential models that LSTM and GRU have comparable capability (Chung et al., 2014). However, the Tree-GRU

model have less parameters to train which could alleviate the problem of overfitting and also cost less training time.

4.4 Comparison with Other Systems

For a comprehensive study, we compare our models with other state-of-the-art systems. The systems that conduct Level-1 classification are reported in Table 3, including:

- Zhang et al. (2015) proposes to use convolutional neural networks to encode the arguments.
- Rutherford and Xue (2014) manually extracts features to represent the arguments and use a maximum entropy classifier for classification. Rutherford and Xue (2015) further exploits discourse connectives to enrich the training data.
- Liu et al. (2016) employs a multi-task framework that can leverage other discourse-related data to help with the training of discourse relation classifier.
- Liu and Li (2016) represents arguments with LSTM and introduces a multi-level attention

Cross-Lingual Sentiment Analysis Without (Good) Translation

Mohamed Abdalla and Graeme Hirst

msa@ and gh@cs.toronto.edu

Department of Computer Science, University of Toronto
Toronto, Canada

Abstract

Current approaches to cross-lingual sentiment analysis try to leverage the wealth of labeled English data using bilingual lexicons, bilingual vector space embeddings, or machine translation systems. Here we show that it is possible to use a single linear transformation, with as few as 2000 word pairs, to capture fine-grained sentiment relationships between words in a cross-lingual setting. We apply these cross-lingual sentiment models to a diverse set of tasks to demonstrate their functionality in a non-English context. By effectively leveraging English sentiment knowledge without the need for accurate translation, we can analyze and extract features from other languages with scarce data at a very low cost, thus making sentiment and related analyses for many languages inexpensive.

1 Introduction

Methods for sentiment analysis and classification have largely been limited to English, making use of large amounts of labeled data to produce sentiment classification. As a consequence, many developed approaches cannot be readily applied to other languages, which usually do not have the wealth of labeled data that is exclusive to English. Therefore many approaches which deal with other languages often: i) experiment with small datasets that are limited in domain or size of training and testing sets (Lee and Renganathan, 2011; Tan and Zhang, 2008), or ii) attempt to elucidate sentiment lexicons for their respective languages (Mohammad et al., 2016).

A growing number of publications attempt to leverage labeled English data to compensate for

the relative lack of training material in the other languages. This is usually done through the use of either bilingual lexicons (Balamurali et al., 2012), machine translation (MT) systems (Salameh et al., 2015; Zhou et al., 2016), or more recently, through the use of bilingual vector space embeddings (Chen et al., 2016).

Unfortunately, in some cases such data is still expensive to obtain. Many languages do not have good, or sometimes any, MT systems, and the cost of producing word alignments or sentence alignments for training bilingual word embeddings (BWE) (Zou et al., 2013; Bengio and Corrado, 2015) or similar techniques (Jain and Batra, 2015) is prohibitive for data-poor languages.

Here we introduce a high-performance, low-cost approach to cross-lingual sentiment classification, which can be used to benchmark more expensive methods. We demonstrate the utility of this approach by highlighting how very limited training data suffices for effective cross-lingual sentiment analysis in various contexts (both at the word and sentence/document level). Our approach relies on the simple vector space translation matrix method (Mikolov et al., 2013a), which computes a matrix to convert from the vector space of one language to that of another. It hinges on the observation that sentiment is highly “preserved” even in the face of poor translation accuracy. We observed that a sentiment classifier trained only with word vectors from English (hereafter referred to as the target language) performs well on unseen words from other unseen languages (referred to as the source languages) that are translated into the English vector space through the simple matrix method, even with very poor translation scores.¹

¹This work involves transfers in both directions between English and other languages. We will take the perspective of the translation matrix (section 3.2) and refer to English as the target language and the others as source languages.

We quantitatively evaluate our methods by training on English and testing on words from Spanish and Chinese. We chose these languages in order to show: i) the robustness of the technique irrespective of the grammar of the source and target languages and, ii) the ability to validate the technique (*i.e.*, as baselines for experiments). We emphasize that, regardless of the source languages used, we treated them as if they had no MT systems. We made use of only 2000, 4500, or 8500 word pairs – a task easily accomplished by a human translator on a data-poor language. We experiment with differing amounts of data during training to show the robustness of our observation. We then apply the fine-grained sentiment regressor to the task of review classification as done by [Chen et al. \(2016\)](#), and show that our naïve algorithm achieves results similar to their benchmark but at a much lower cost.

2 Previous Work

2.1 Cross-Lingual Word Embeddings

Monolingual word embedding algorithms use large unlabeled datasets to learn useful features about the given language ([Pennington et al., 2014](#); [Mikolov et al., 2013b](#)). These algorithms learn vector representations for the words of the language — an encoding that has proven utility in a variety of NLP tasks including sentiment analysis ([Maas et al., 2011](#)) and machine translation ([Mikolov et al., 2013a](#)).

When working with more than one language, we seek to satisfy two objectives: i) monolingually, similar words of the same language have similar embeddings; and ii) cross-lingually, similar words across languages also have similar embeddings. Satisfying these two criteria would allow us to use algorithms trained for the embeddings of a single language (such as English, with a wealth of labeled data) for other languages as well. Below we discuss algorithms to achieve the cross-lingual objective, their costs, performance, and the rationale underlying our algorithm design.

2.1.1 Offline Alignment

The simplest approach to achieving the cross-lingual objective is to train each monolingual objective separately (create a model for each language), and then learn a transformation to enforce the second objective. This approach uses a dictionary of paired words in order to learn a trans-

formation or ‘alignment’ from the vector space of one language to that of another.

First introduced by [Mikolov et al. \(2013a\)](#), and later extended by [Faruqui and Dyer \(2014\)](#), this offline alignment is fast and low cost, but does not achieve a high translation accuracy. A big drawback of these approaches is that using a dictionary ignores the polysemic nature of languages. It is also not clear or proven that a single transformation would be able to capture the relationship between all the words in a cross-lingual setting.

We opt to use offline alignment to show that such a low-cost approach does, in fact, capture a significant part of the relationship between words of different languages when it comes to sentiment. That is, a single transformation (linear in the case of our work) is sufficient to learn a projection which allows one to use labeled English data to aid in sentiment analysis.

2.1.2 Parallel-Only

An alternative approach to offline alignment is the parallel-only approach. Approaches which fall into this group, such as BiCVM ([Hermann and Blunsom, 2013](#)) and bilingual auto-encoder (BAE) ([Sarath Chandar et al., 2014](#)), rely exclusively on sentence-aligned parallel data to train a model with similar representations. Such approaches can be effective, but require extremely expensive data. Another drawback is that these approaches can be affected by the writing style of the parallel text ([Bengio and Corrado, 2015](#)).

2.1.3 Jointly-Trained Model

Combining the offline alignment and parallel-only algorithms is a third class of jointly-trained approaches. These approaches jointly optimize the monolingual objective at the same time as the cross-lingual objective, making use of both monolingual and parallel data. Approaches like those of [Klementiev et al. \(2012\)](#) and [Zou et al. \(2013\)](#) use word-aligned data in order to learn the fine-grained cross-lingual features and tend to be quite slow. Other approaches (including that of [Bengio and Corrado \(2015\)](#)) rely on sentence-aligned data and are faster than those using word-aligned data. While these models are more cost-efficient than parallel-only approaches, it remains expensive and sometimes prohibitive to obtain sentence alignments for many languages (a problem that we seek to avoid).

A lower-cost alternative to these expensive

jointly trained models was proposed by Duong et al. (2016) and later used to project multiple languages in the same vector space (Duong et al., 2017). The model involved creating and making use of translations produced using a bilingual dictionary during training. Using expectation-maximization-inspired training, sentence translations were produced by selecting translations of words based on context to deal with polysemy, and this approach demonstrated improvements on the simple linear transformation method. However, even this model uses a significantly larger amount of data than the methods used in this work, with its smallest dictionary being composed of 35,000 word pairs compared to our approach, which can use as little as 2000 words for both translation and sentiment regression.

2.2 Cross-Lingual Sentiment Analysis

Previous approaches to cross-lingual sentiment analysis can be classified into two main categories: i) those that rely on parallel corpora to train BWE's (*i.e.*, they use pre-trained embeddings) (Chen et al., 2016; Sarath Chandar et al., 2014; Tang and Wan, 2014), and ii) those that use translation systems (Zhou et al., 2015, 2016) in order to obtain aligned inputs to learn to extract features which work on both languages. Both approaches allow the sentiment portion of training and testing data to be in the same vector space. However, many languages have no MT system, and it is extremely expensive to create one on a language-by-language basis.

Our proposed approach is simpler in that it requires only a small word-list to learn both the embedding and the sentiment classification, the duality of which cannot be claimed by previous approaches.

3 Methods and Data

3.1 Data

3.1.1 Vector Space Data

English Vector Space Model For English we used a model pre-trained on part of the Google News dataset (which is composed of approximately 100 billion words).² The words are represented by 300-dimensional vectors.

Spanish Vector Space Model For the Spanish word embeddings we opted to use a model

²<https://code.google.com/archive/p/word2vec/>

pre-trained on the Spanish Billion Word Corpus (Cardellino, 2016). It consists of just under 1.5 billion words compiled from a variety of Spanish resources. As with the English model, the words are represented by 300-dimensional vectors.

Chinese Vector Space Model For Chinese word embeddings we learned our own vector representations using a Wikimedia dump³ composed of around 150 million words from 250,000 articles in both simplified and traditional Chinese. We used OpenCC⁴ to translate the articles in simplified Chinese to traditional. To segment the text into tokens we used Jieba⁵. Finally, to create the actual word embedding model, we used Gensim (Řehůřek and Sojka, 2011) with the minimum count set to 1, using continuous bag of words (CBOW), a window of 8, and vector dimension set to 300.

3.1.2 Word Lists

Translation Word List For the process of learning a translation matrix from one language to the other, a lexicon of approximately 10,000 English words was obtained online by scraping the most commonly used words as determined by n-gram frequency analysis in Google's "Trillion Word Corpus"⁶. The lexicon was then translated using Google Translate⁷ in order to obtain corresponding words in Spanish and Chinese. For alignment lists of smaller sizes during experimentation, a random subset of the larger list was selected. During the randomized selection, we discarded any words which were not in the target language vector space and whose translation was not in the source language(s) vector space(s).

Binary Sentiment Word List For the task of binary sentiment classification we used a list⁸ curated by Hu and Liu (2004) containing both positive and negative English opinion words (or sentiment words). Google Translate was used to translate the list into the other languages to obtain cross-lingual word pairs. During training and testing we made sure to balance the dataset and to discard words that were not in the vector space of the target language or whose translation was not in the vector space of the source language(s).

	Low Stimulus	High Stimulus
Arousal	<i>relaxed</i> (2.39)	<i>infatuation</i> (7.02)
Dominance	<i>victim</i> (2.69)	<i>confident</i> (7.68)
Valence	<i>death</i> (1.61)	<i>beauty</i> (7.82)

Table 1: Examples of words on each end of the spectrum for each of the three dimensions of ANEW. Numeric stimulus value is shown in parentheses.

3.1.3 Fine-Grained Data

For fine-grained sentiment regression, we used Affective Norms for English Words (ANEW) (Bradley and Lang, 1999). The creators of ANEW sought to provide emotional ratings for a large number of words in the English language.

ANEW proposes that all human emotion can be organized in a vector space with three basic underlying dimensions (or axes). The first dimension, *valence*, ranges from *pleasant* to *unpleasant*; the second dimension, *arousal*, ranges from *calm* to *excited*; and the third dimension, *dominance*, ranges from *in-control* to *out-of-control*. Examples are shown in Table 1.

Bradley and Lang (1999) used a nonverbal pictographic measure, the Self-Assessment Manikin (SAM) (Bradley and Lang, 1994), to measure stimuli across these three dimensions. The figures in the SAM consist of bipolar scales depicting different values along each of the three emotional dimensions. For example, when considering valence, SAM ranges from a frowning unhappy figure to a smiling happy figure. Similar ranges are extended across the two other dimensions. Using this test, Bradley and Lang were able to arrive at a numerical value representing a word’s stimulus for each dimension ranging from 1 to 9; where 1 is the low value (*unpleasant, calm, in-control*) and 9 is the high value (*pleasant, excited, out-of-control*).

3.1.4 Review Data

In this subsection, we discuss the data used to replicate the review classification task done by Chen et al. (2016) as a means of validating the utility of our model. This experiment was done using only English and Chinese because there was no Spanish data for this task and the Arabic review data-set that Chen et al. (2016) used was not freely available.

Labeled English Reviews Following Chen et al. (2016), we obtained a balanced dataset of 700,000 reviews of businesses on Yelp from Zhang et al.

(2015) with their sentiment ratings as labels ranging from 1 for very negative to 5 for very positive. **Labeled Chinese Reviews** Here we use a dataset from Lin et al. (2015). Their work provides hotel reviews, with labels ranging from 1 for very negative to 5 for very positive. In order to fairly compare our work with that of Chen et al. (2016), we use 10,000 reviews for model selection, and another unseen 10,000 as our test set.

3.2 Translation Matrix Technique

As described by Mikolov et al. (2013a), the translation matrix technique assumes that we are given a set of word pairs and their associated vector space representations. More specifically, we are given j word pairs, $\{x_i, z_i\}_{i=1}^j$ where $x_i \in \mathbb{R}^n$ is a vector from the source language of word i and $z_i \in \mathbb{R}^m$ is the vector representation of the corresponding translated word in the target language.

We then want to find a transformation matrix W such that Wx_i approximates z_i . We learn this by solving the following optimization problem:

$$\min_W \sum_{i=1}^j \|Wx_i - z_i\|^2$$

Instead of solving with stochastic gradient descent, we instead opt to use the closed-form solution.

To translate a word from source language to target language, we can map it using $z = Wx$, and then find the closest word in that language space using cosine similarity as the measure of distance. The method of testing was Monte Carlo cross-validation run 10 times with a split of 90% training data and 10% test data.

3.3 Models

3.3.1 Binary Sentiment Analysis Model

The sentiment analysis model, Figure 1(a), is a simple linear support vector machine (SVM) classifier. Implemented using Sci-kit Learn’s *SGD-Classifer* function (Pedregosa et al., 2011), this model takes a word represented as a vector with dimension of 300 and outputs a prediction of either -1 or $+1$ (for negative and positive respectively). The classifier itself performs stochastic gradient descent (SGD) with $l2$ regularization to arrive at the best classification.

The training procedure of this model is quite simple and involves only the target language. The model is trained only on word embeddings from

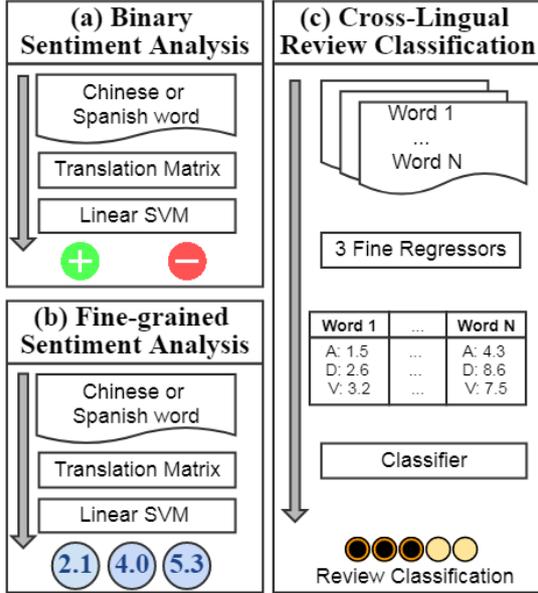

Figure 1: The three models used in the experiments.

the target language but tested on embeddings returned by the translation of words originally from the source language(s). We made sure that the English translation of the test words had not been seen before in training. The training/testing split was changed to 80% and 20% from the previous 90%/10% to account for the smaller number of examples in the dataset (and the fact that we wanted to test on a representative sample of the data).

3.3.2 Fine-Grained Sentiment Analysis Model

The fine-grained sentiment analysis model in Figure 1(b) is a regression model to predict the ANEW values for each of the three dimensions. For this task, we built a regressor for each of the three dimensions whose input is a 300-dimension vector and whose output is a real number from 1 to 9. The regressor used was a Bayesian Ridge regressor, which estimates a probabilistic model of the regression problem. The prior for the parameter w is given by a spherical Gaussian:

$$p(w|\lambda) = \mathcal{N}(w|0, \lambda^{-1}I_p).$$

The model is similar to that of the Ridge regression. The model was implemented using Sci-kit Learn’s with hyperparameters `alpha_1` and `alpha_2` set to 1.

The training procedure of this model is quite simple and similar to that of the previous model.

	1000 WORDS		4500 WORDS		8500 WORDS	
Translation	P@1	P@5	P@1	P@5	P@1	P@5
EN → ES	20.3	34.6	33.42	46.13	34.79	47.79
EN → CN	2.4	11.6	7.60	20.29	8.87	23.01

Table 2: Accuracy of the word translation method. P@1 and P@5 represent Top-1 and Top-5 accuracy respectively.

Again, it only trains on the vector of the target language, and is tested purely on words from the source language whose translation into the target language was not seen in the training of the regressor (so that there may be no chance of skewing the results). The training/testing split here was 75%/25%.

3.3.3 Review Classification Model

For the task of review classification, another model Figure 1(c), was built to make use of the previously described fine-grained sentiment analysis model. The classifier used for this task is a logistic regression classifier. For a given review r_i in the target language, composed of n words, we construct a $1 \times Max_length$ sentiment vector (where Max_length is the number of words of the longest target review). We construct this vector by passing in the word embedding for every word into the sentiment analysis model and placing the resulting values (of 1 to 9) into the constructed array. The array is then padded with 0’s in order to make it of length Max_length .

For reviews in the source language, the process is similar, with the only change being that the words are first translated from their original vector space to that of the target language before being passed into the sentiment classifier. Once the review vector has been constructed, it is passed to the classifier to produce a classification of 1 to 5.

As with the previous classifier, the training procedure is quite simple and involves only the target language (*i.e.*, the classifier is trained only on reviews which are originally from the target language, but it is tested on reviews only from the source language).

4 Results

4.1 Translation Accuracy

We first measure the accuracy of the matrix translation method using the same test described by Mikolov et al. (2013a). The purpose of these tests is two-fold: i) verifying that the data used and implementation of the technique reproduces what is

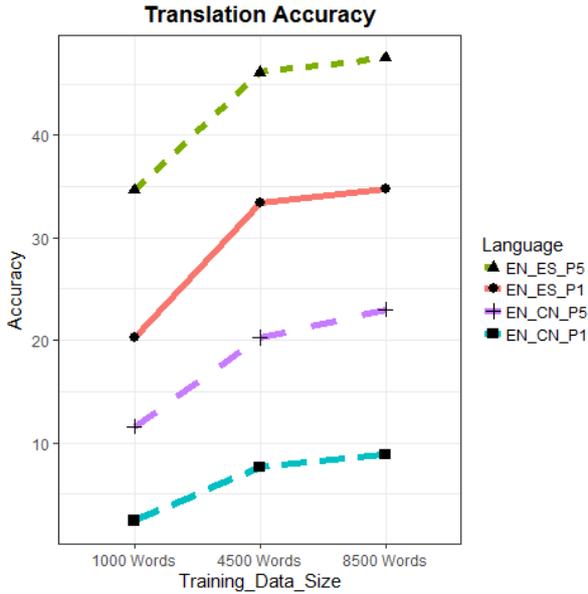

Figure 2: Top-1 and Top-5 accuracy for Spanish and Chinese using various amounts of training data.

expected, and ii) quantifying how much sentiment is preserved with low translation accuracy (by explicitly noting the poor accuracy of the translation). The data used is described in section 2.1. Table 2 shows the effect of training size (number of words) on the accuracy of the translation matrix method. As expected (and previously shown by Mikolov et al. (2013a)), the translation accuracy increases with more training examples, as shown in Figure 2. The data and methods used in this work are further validated as the translation accuracy results closely approximate those of Mikolov et al. (2013a), with English-Spanish translational accuracy achieving 35% and 48% accuracy for P@1 and P@5 respectively when compared to the original 33% and 51%. This concordance is further validation of the method. It is also interesting to note that Chinese, which is less like English than Spanish is, also suffers a lower translation score across both categories. However, we see that this large drop is not represented significantly in later portions.

4.2 Binary Word Sentiment Classification

The second experiment tested the binary cross-lingual sentiment classification capabilities of the matrix translation method, *i.e.*, how well can we differentiate between positive and negative words of a language we have not seen before using a model trained only on English words? Here we

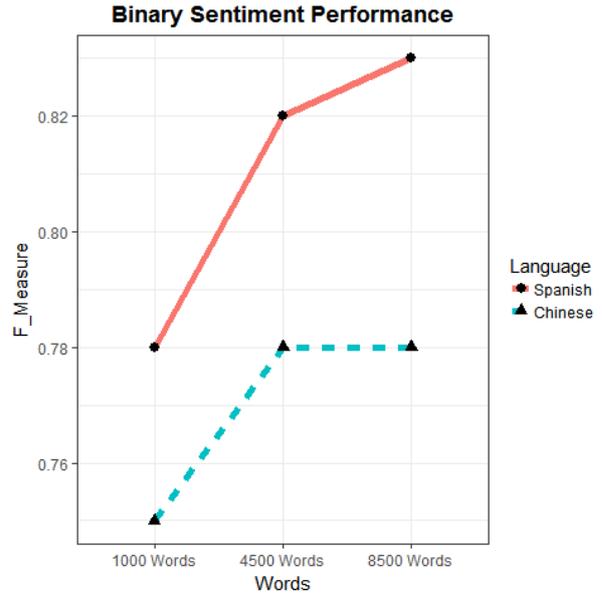

Figure 3: F-measure of binary sentiment classifier with varying amounts of training data for both Spanish and Chinese.

used the binary sentiment word list described in section 2.1.2 in order to assess whether or not the translation matrix would preserve sentiment even with poor translation accuracy scores. Given that the classifier is trained only on the target language vectors, we used the translation matrices produced previously to translate a word from source to target language embedding space.

As we can see in Table 3 and Figure 3, even with low translation accuracy, such as the 1000-word Chinese translation matrix, we are able to achieve good binary sentiment classification. We also noted that a significant drop in translation accuracy results in only a relatively small drop in sentiment classification performance.

4.3 Fine-Grained Sentiment Analysis

In the third experiment, we tested the accuracy of cross-lingual regression when it comes to predicting a word’s value in any of the three ANEW dimensions of *valence*, *arousal*, and *dominance*. We attempted to predict the *valence*, *arousal*, and *dominance* of words in source language, having only trained on target language. As we saw in the last experiment, massive drop-off in translation accuracy need not result in a massive drop-off in sentiment analysis. As this is a regression problem, Table 4 presents both the r^2 and the mean squared error (MSE) as measurements of model performance. The MSE per dimension is visual-

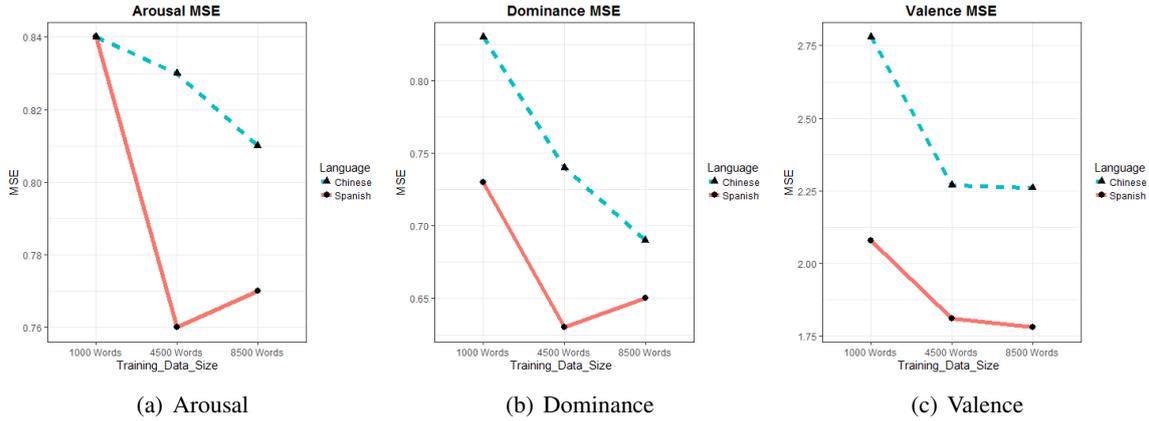

Figure 4: Mean squared error for each regression problem with varying amounts of training data for all three of the ANEW dimensions. (Lower is better).

	Spanish	Chinese		Spanish	Chinese
1000 Words			1000 Words		
Precision	0.77	0.76	Arousal	0.24 (0.84)	0.24 (0.84)
Recall	0.79	0.74	Dominance	0.31 (0.73)	0.23 (0.83)
F-measure	0.78	0.75	Valence	0.48 (2.08)	0.32 (2.78)

Precision	0.82	0.79	Arousal	0.33 (0.76)	0.28 (0.83)
Recall	0.82	0.77	Dominance	0.39 (0.63)	0.28 (0.74)
F-measure	0.82	0.78	Valence	0.54 (1.81)	0.44 (2.27)
8500 Words			8500 Words		
Precision	0.83	0.80	Arousal	0.33 (0.77)	0.29 (0.81)
Recall	0.83	0.77	Dominance	0.38 (0.65)	0.31 (0.69)
F-measure	0.83	0.78	Valence	0.54 (1.78)	0.43 (2.26)

Table 3: Results of the binary sentiment classification task for each language with each translation matrix.

Table 4: Results of the fine-grained sentiment regression task for each language with each translation matrix, in the form of $r^2(MSE)$.

ized in Figure 4. Given the data’s scale from 1 to 9 with an average standard deviation among participants for each word of 2.02, an average mean squared error of approximately 1 shows that our model has high predictive power.

4.4 Sentiment Classification of Reviews

In the fourth experiment, we sought to show that the regressor developed in section 3.3.2 could be used as a feature extractor in performing other tasks. To this end, we replicated the experiment by Chen et al. (2016), who predicted hotel ratings from Chinese reviews using a model trained only on English restaurant reviews.

Chen et al. (2016) had two baseline models which they beat with their new model: i) a lo-

gistic regression classifier (line 1 in Table 5), and ii) a non-adversarial variation of adversarial deep averaging network (ADAN) (line 2), referred to as DAN (deep averaging network), which is one of the state-of-the-art neural models for sentiment classification. These were the only two models which did not make use of either labeled Chinese examples or an MT system, and therefore were chosen to serve as a fair comparison to our method. Both models use bilingual word embeddings as an input representation to map words from both languages into the same vector space. Our own model (line 3 in Table 5) uses logistic regression on sentence arrays created by predicting their ANEW values for each dimension to predict review scores.

Approach	Accuracy
Logistic regression (BWE)	30.58%
Deep averaging network (DAN)	29.11%
Logistic regression (ANEW)	28.05%

Table 5: Model performance on sentiment extracted vectors versus previous approaches. Logistic regression on predicted sentiment (ANEW) values performed similarly to both regression and DAN on BWEs.

Table 5 shows that we were able to closely match the accuracy of the baseline systems implemented by Chen et al. (2016) for Chinese reviews. These results demonstrate that our sentiment regressors encoded enough information into the sentence vectors to achieve similar results to the baseline models which took bilingual word embedding as input, and that the fine-grained sentiment model can be used to extract sentiment-based features for other tasks in languages where aligned data might be expensive to obtain.

5 Discussion and Future Work

We have shown that the matrix translation method can be used to infer and predict cross-lingual sentiment. More notably we observed that: i) sentiment is preserved accurately even with sub-par translations, and ii) this low-cost approach also maintained fine-grained sentiment information between languages.

We further cemented these observations through a variety of experiments. The first experiment performed was testing the translation accuracy of the method presented to verify validity of the algorithm. The second experiment, was binary word classification into either positive and negative for words in Chinese or Spanish, given a model that was trained only with English. With a translation P@5 as low as 11%, our linear classifier was still able to predict with 75% precision and recall the polarity of a word’s sentiment. The third experiment, in which we were able to predict a word’s position on the three-dimensional ANEW 9-point scale with an error margin of 1 (per dimension), lent further credibility to the validity and data-efficiency of our approach. Our fine-grained sentiment analysis with the ANEW scale is notable as it demonstrates how the algorithm works at the word level — useful in building sentiment lexicons in an automated fashion at a very low cost and with little manual effort. Our last experiment, Chinese

review classification, further highlighted the robustness of our model, by showing that vectors created using the regressor encoded enough sentiment information to match the baseline methods of passing in bilingual word embeddings to a trained model. We showed how competitive the proposed approach is when compared to much more expensive methods and that it can directly be applied to sentiment classification tasks for data-poor languages.

Throughout the experiments, we saw the general trend of reduced error and increased accuracy with more training data. However the increase in accuracy starts to diminish with around 8500 words. The root of this leveling of accuracy could be the inherent limitation of either the translation technique used or the classification or regression algorithms used or both.

A surprising finding was how well sentence vectors composed of ANEW values for each word performed when compared to the baselines of Chen et al. (2016), Table 5. Achieving similar results to the previous baseline using the same classification algorithm (logistic regression) means that the sentence vectors composed of ANEW values encode enough (and as much) information as the BWE, or that the classification algorithm used on the BWEs isn’t strong enough to extract more meaningful relationships between the values. The truth is probably a mixture of both reasons.

By choosing the number and type of languages selected we have shown that this observation holds across languages with different roots and different grammar systems, which is further re-affirmed by the fact that we train our models only on English data, but test purely on Chinese and Spanish.

We explore the effect of poor translation on fine-grained sentiment analysis by taking a look at a few concrete examples of poor translations (Table 6). Table 6 presents four different Chinese words with predicted valence of varying accuracy. We can see that even with poor translation (*i.e.*, the closest five words are all completely unrelated, as is the case with *hungry*), sentiment is still accurately predicted. On the other hand we also show that it is possible to have related words but have poor prediction, as is the case with *misery*, because the base sentiment predictor itself is not perfectly accurate. This suggests that the sentiment vector space, a hypothetical space produced by finding the sentiment value of each point in the original

Chinese Word (English)	Computed English Translation	True Valence (Predicted Valence)
飢餓 (Hungry)	Mugabe misrule Boo hoo Quagmire Chikwanine Sylvain Angerlotte	3.58 (2.85)
街 (Incentive)	Circumstances dictate Selfless sacrifices Humility President Obama EquityMarketReport	7.00 (6.17)
善良 (Kindness)	Really hateful lemmings Loving Dad Flowering orchids Dear robin	7.81 (6.84)
苦難 (Misery)	Violence begets violence Indignations Sufferings Sincerely Unconfessed sin	1.93 (3.91)

Table 6: Four poorly translated Chinese words, their accompanying true English translation, the five nearest English words to the translated vector, and the true (English) valence with the accompanying predicted valence of the translated vector.

embedding space, which we term topological sentiment map, has two properties: i) it is maintained through linear transformation, and ii) it is “flat” enough that highly accurate mapping (read: translation) between languages is not required to arrive at usable sentiment classification. This second property allows for the sentiment analysis of languages where a large amount of labeled material is not available at an extremely low cost, and can also be used to aid in many cross-lingual sentiment related tasks.

In the future we hope to extend both the analysis and experiments discussed here to other languages and applications. For example the cross-lingual fine-grained sentiment analysis techniques could possibly be used to study the change in sentiment of words in a single language over time, leading to new insights or re-affirming old ones. Future analysis could compare different transformations and their effect on sentiment analysis. The ability to produce a “stable” topographic sentiment map could also be used to evaluate algorithms which create the vector spaces as well.

Lastly, future work will focus on developing other low-cost approaches, possibly by implementing Duong et al. (2016)’s technique to improve the accuracy and precision of sentiment regression. This would serve to demonstrate the (expected) limits of the linear transformation model’s

in handling polysemy and subsequently its impact on the topological mapping of sentiment in vector space.

Abstract

Target-dependent sentiment analysis investigates the sentiment polarities on given target mentions from input texts. Different from sentence-level sentiment, it offers more fine-grained knowledge on each entity mention. While early work leveraged syntactic information, recent research has used neural representation learning to induce features automatically, thereby avoiding error propagation of syntactic parsers, which are particularly severe on social media texts.

We study a method to leverage syntactic information without explicitly building parser outputs, by training an encoder-decoder structure parser model on standard syntactic treebanks, and then leveraging its hidden encoder layers when analysing tweets. Such hidden vectors do not contain explicit syntactic outputs, yet encode rich syntactic features. We use them to augment the inputs to a baseline state-of-the-art target-dependent sentiment classifier, observing significant improvements on various benchmark datasets. We obtain the best accuracies on two different test sets for targeted sentiment.

1 Introduction

Target-dependent sentiment analysis investigates the problem of assigning sentiment polarity labels to a set of given target mentions in input sentences. Some example are shown in Table 1. For instance, given a sentence “I like [*Twitter*] better than [*Facebook*]”, a target-specific sentiment model is expected to assign a positive (+) sentiment label on

“I like [<i>Twitter</i>] ₊ better than <i>Facebook</i> ”
“I like <i>Twitter</i> better than [<i>Facebook</i>] ₋ ”
[<i>lindsay lohan</i>] ₀ goes on yet another emo rant on her twitter.
Choose [<i>NBT</i>] ₊ for insulation, home energy audits, housing repairing, air sealing, windows and doors, furnaces, air conditioners and en energy efficient appliances.

Table 1: Target-dependent sentiment analysis

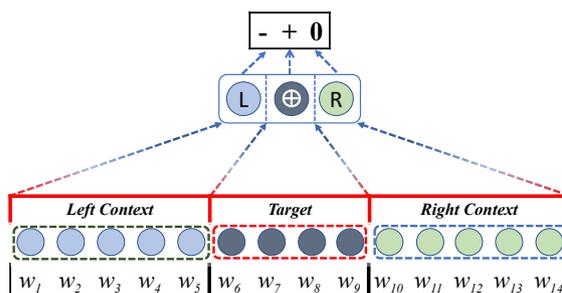

Figure 1: Sentence level context

the target *Twitter* and a negative (−) sentiment label on the target *Facebook*.

The task has been addressed using neural network models, which learn target-specific representations of the input sentence. These representations are then used for predicting target-dependent sentiment polarities. In particular, Dong et al. (2014) derive the syntactic structure of input sentence using a dependency grammar, before transforming the tree structure to a target-centered form. A recursive neural network is used to transform the dependency syntax of a sentence into a target-specific vector for sentiment classification. More recently Vo and Zhang (2015) split the input sentence into three segments, with the target entity mention being in the center, and its left and right contexts surrounding it, as shown in Figure 1.

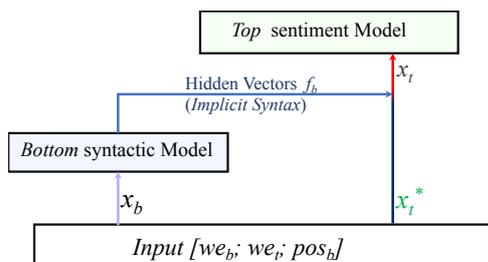

Figure 2: Model structure

Rich word embedding features are extracted from the target entity mention and its contexts, which are then used for classification by a linear SVM model. Without using syntactic information, this model gives better accuracies compared with the method of Dong et al. (2014).

Since syntactic parsing of tweets can be inaccurate due to intrinsic noise in their writing style, most subsequent work followed Vo and Zhang (2015), avoiding the use of syntactic information explicitly. Zhang et al. (2016) applied a bi-directional Gated RNN to learn a dense representation of the input sentence, and then use a three-way gated network structure to integrate target entity mention and its left and right contexts. The final resulting representation is used for softmax classification. Tang et al. (2015) also use a RNN (LSTM) to represent the input sentence, yet directly integrating the target embedding to each hidden state for deriving a target-specific vector, which is used for sentiment classification. Liu and Zhang (2017) extended both Zhang et al. (2016) and Tang et al. (2015) by introducing the attention mechanism, obtaining the best accuracies on both datasets so far.

Intuitively, syntactic information should be useful for sentiment analysis given a target, since target-related semantic information such as predicate-argument structure information is contained in syntactic structures. The main issue of Dong et al. (2014)’s method is that *explicit* syntactic structures are inaccurate and noisy. We try to avoid this issue by using *implicit* syntactic information, by integrating the hidden feature layers of a state-of-the-art neural dependency parsing as features to the state-of-the-art targeted sentiment classification models of Liu and Zhang (2017), using neural stacking (Zhang and Weiss 2016; Chen et al. 2016). The main structure of our model is shown in Figure 2.

We choose the parser of Dozat and Manning

(2016) as our syntactic model, which gives the best results on a WSJ benchmark by using multi-layer LSTMs to encode rich input information. The structure of the model is shown in Figure 4, which first learns a vector form of each input word (**W** and **T**), and then uses a simple bi-affine attention mechanism to find word-word relations. The feature vectors (**A** and **D**) thus contain rich syntactic information about each word, yet do not explicitly specify the syntactic structure of the sentence. Hence, using them as features gives our model more syntactic background of the sentence, yet without suffering from error propagation.

Results on both the dataset of Zhang et al. (2016) and the dataset of Tang et al. (2015) show that syntactic information is highly useful for improving the accuracies of target-dependent sentiment analysis. Our final models give the best reported results on both datasets. The source code is released at <https://github.com/CooDL/TSSSF>.

2 Model

As shown in Figure 2, our neural stacking model consists of two brief components: a bottom level syntactic model for obtaining the syntactic information and a top level sentiment model for target-dependent sentiment classification.

2.1 Input representation

Given an input sentence, we first obtain its word representations. In particular, we train two separate word embedding sets for the bottom level syntactic model and top level sentiment model, respectively, denoted as we_b and we_t , respectively. This is because our syntactic parser is trained on news data, while our sentiment classification is trained on Twitter data.

In addition, for the bottom syntactic model, we also use optionally part-of-speech tag embeddings pos_b , which are randomly initialised and learned during the training of the model. Formally, given a word w , the representation for the bottom level model is:

$$x_b = we_b \oplus pos_b,$$

and the input form of the top level model is

$$x_t = x_t^* \oplus f_b = we_t \oplus Bottom(x_b)$$

Here we use $Bottom(x_b)$ indicate the bottom level syntax model.

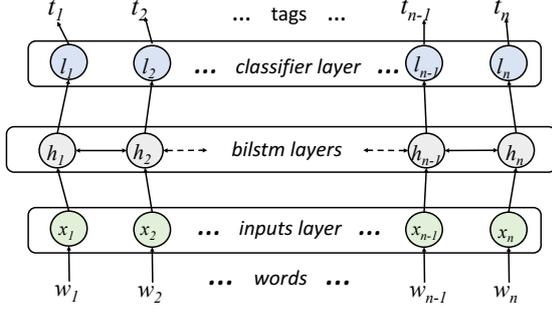

Figure 3: POS-tagging model

2.2 Syntactic Sub Models

The twitter data suffer poor accuracies by syntax parsers in contrast with news data such as PTB. Directly using explicit twitter syntax features has an error propagation problem. We use a pre-trained syntax model to turn raw word embeddings into implicit syntactic features. Both a POS model and a dependency model are used to utilize syntax features.

2.2.1 POS Model

We employ a simplified bi-directional LSTM (BiLSTM) POS-tagging model (see Figure 3), trained on PTB3 (Toutanova et al. 2003; Labeau et al. 2015). As for every sentence sequence w_1, w_2, \dots, w_n , its corresponding word embedding sequence x_1, x_2, \dots, x_n , we integrate its word embedding into a k_1 -layer BiLSTM:

$$\begin{aligned} S' &= [h_1, h_2, \dots, h_n] \\ &= \text{BiLSTM}([x_1, x_2, \dots, x_n])^{k_1}, \end{aligned} \quad (1)$$

where S' is the k_1 -layer BiLSTM hidden state output. A classifier is then used to weight the hidden state of each word in S' and derive the label. Here W_1 is the weight matrix and b is the bias:

$$\text{Labels} = \text{Classifier}(W_1 S' + b), \quad (2)$$

The BiLSTM hidden layer h_1, h_2, \dots, h_n and the result of $W_1 S' + b$ (the labels' logits) will act as our implicit syntactic features.

2.2.2 Dependency Model

In this model, we use a dependency parser to replace the POS-tagging model in Section 2.2.1. In particular, the model of Dozat and Manning (2016) is used, which fuses several BiLSTM layers to encode the input sentence before doing

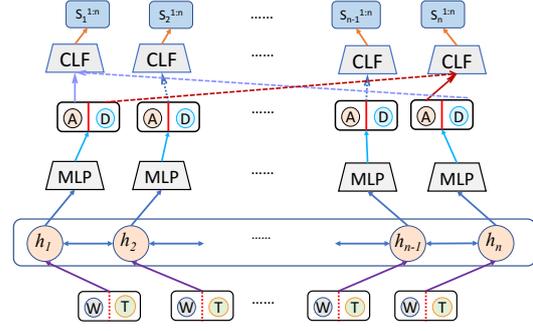

Figure 4: Dependency parsing model

bi-affine attention to learn dependency arcs between different words.

Two different dependency models are trained: one being a $\text{POS} \oplus$ dependency with bottom input $w_e \oplus \text{pos}_b$, one being no-POS dependency model with just word embedding w_e . , given a sentence sequence w_1, w_2, \dots, w_n , it integrates the word embedding $w_e(\mathbf{W})$ and POS-tag embedding $\text{pos}_b(\mathbf{T})$ into a k_2 -layer BiLSTM and generate the LSTM states S' of the words in sentence S , here $x_i = w_e^i \oplus \text{pos}_b^i$, $h_i = \overleftarrow{h}_i \oplus \overrightarrow{h}_i$,

$$\begin{aligned} S' &= [h_1, h_2, \dots, h_n] \\ &= \text{BiLSTM}([x_1, x_2, \dots, x_n])^{k_2}, \end{aligned} \quad (3)$$

MLP (Multilayer Perceptron) layers are used to reduce the dimension size and build features from the BiLSTM state output S' . Here it gives four kind features: head_{arc} , head_{dep} , rel_{arc} , rel_{dep} :

$$\begin{aligned} \text{head}_{arc}, \text{head}_{dep}, \text{rel}_{arc}, \text{rel}_{dep} \\ &= \text{MLP}([h_1, h_2, \dots, h_n])^{k_3}, \end{aligned} \quad (4)$$

Based on the features, a bi-affine classifier gives every word in the sentence S a corresponding dependency head using the feature $\text{head}_{arc}(\mathbf{A})$ and $\text{head}_{dep}(\mathbf{D})$. We obtain the head relation set $S'_{\text{head}} = \{\text{head}_i^j, i, j \in [1, n]\}$:

$$\text{head}_i^j = \text{Classifier}(\text{head}_{arc}^i, \text{head}_{dep}^j) \quad (5)$$

Another bi-affine classifier is used to classify the dependency relation based on the feature $\text{head}_{arc}(\mathbf{A})$, $\text{head}_{dep}(\mathbf{D})$ and head_i^j , and we obtain the rel relation label set $S'_{\text{rel}} = \{\text{rel}_i^j, i, j \in [1, n]\}$:

$$\text{rel}_i^j = \text{Classifier}(\text{head}_{arc}^i, \text{head}_{dep}^j, \text{head}_i^j), \quad (6)$$

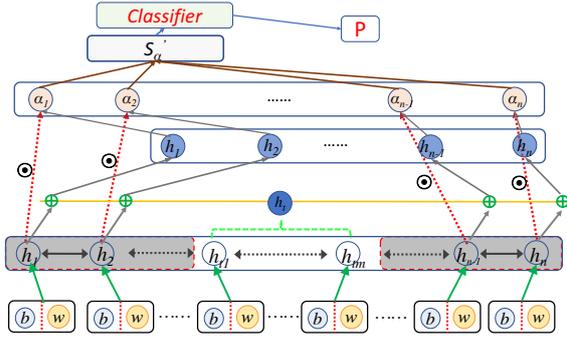

Figure 5: Target-dependent sentiment analysis with attention, shadow parts donate the attention part in a sentence

Using the two classifiers, we obtain the dependency root and relation between every two words in the sentence S . We pre-train the dependency parser model with 4 bi-directional LSTM layers and 2 layers of MLP, and use its intermediate output (the MLP output vector) as implicit syntactic feature inputs to the top sentiment model.

The normal dependency syntax model shares the same network frame with the no-POS dependency model. They have slight differences in the classifier. Both models are end-to-end dependency parsers with different initial inputs. We choose the same output (Bi-LSTM hidden vector and MLP vector) of the two models as implicit syntactic features.

2.3 Target-dependent Sentiment Model

We use the attention-based model of Liu and Zhang (2017) as our top level model. The overall structure is shown in Figure 5. Given a sentence, it first uses several BiLSTM layers to learn its syntactic features, and then an attention layer is used to select the relative weights of the words according to the target entity over the untargeted words in the whole sentence (Bahdanau et al. 2014; Yang et al. 2016). In particular, for a target word, it applies the target word hidden vector to find a weight for every word (except the target words) in the sentence (see Figure 5). The model also uses a BiLSTM to represent the feature layer from bottom syntactic model $f_b(\mathbf{b})$ and the word embedding $we_t(\mathbf{w})$ of a word sequence w_1, w_2, \dots, w_n as the hidden vector of each word.

$$[h_1, h_2, \dots, h_n] = \text{BiLSTM}([r_1, r_2, \dots, r_n])^{k_4}, \quad (7)$$

where $r_i = f_b^i \oplus we_t^i$ and k_4 is the BiLSTM

layer number.

The target phrase words $h_{t_1}, h_{t_2}, \dots, h_{t_m}$ are represented as one vector h_t ($h_t \notin [h_1, h_n]$). It is the average of the target phrase words hidden vectors, $h_t = \frac{1}{m} \sum_{i=1}^m h_{t_i}$.

We build a vanilla attention model by calculating a weight value α_i for each word in the sentence. The sentence S then can be represented as follows:

$$\begin{aligned} S'_\alpha &= \text{Attention}([h_1, h_2, \dots, h_n], h_t) \\ &= \sum_{i=1}^n \alpha_i h_i, \end{aligned} \quad (8)$$

where $\alpha_i = \exp(\beta_i) / \sum_{j=1}^n \exp(\beta_j)$.

The weight scores β_i are calculated by using target representation h_t and each word hidden vector representation in the sentence,

$$\beta_i = U^T \tanh(W_2 \cdot [h_i : h_t] + b_1), \quad (9)$$

The sentence representation S'_α is used to predict the probability vector P sentiment labels on target by:

$$P = \text{Classifier}(W_3 \cdot S'_\alpha + b_2), \quad (10)$$

2.4 Training

Our training procedure consists of two steps, one being to pre-train the bottom syntactic models, the other being to apply the pre-trained bottom syntactic model and train the top sentiment analysis model.

All models are trained by minimizing the sum of cross-entropy loss and a L_2 regularization loss of all trainable weights ΔW .

$$\text{loss} = \frac{1}{n} \sum_i \sigma(y_i, y'_i) + \frac{\lambda}{2} \|\Delta W\|^2, \quad (11)$$

The model feature inputs (word embeddings, POS-tag embeddings) are the sum of a trainable embedding and a pre-trained (or learned) embedding. All the weight matrix will be initialized with an orthogonal loss less than $1e^{-6}$.

We choose different intermediate outputs of different bottom level syntax models. For POS-tagging model, we use the BiLSTM hidden output (lm_{pos}) and POS-tags vector before softmax (lt_{pos}). For the dependency sub model, we utilize

3 Experiments

We evaluate the performances of our model and compare them with state-of-the-art results using two standard datasets for target-dependent sentiment (Zhang et al., 2016; Tang et al., 2015). The PTB3 dataset is used to pre-train our bottom level syntax models.

3.1 Data

We conduct experiments on two datasets, one being the training/dev/test dataset of Zhang et al. (2016) (Z-Set), which consists of the MPQA corpus¹ and Mitchell et al. (2013)’s corpus², the other being the dataset of the benchmark training/test dataset of ? (T-Set), we label these datasets’ POS-tags with the open parser tools ZPar (Zhang and Clark, 2011). Two sets of word embedding are used in this experiment: The GloVe³ (Pennington et al., 2014) twitter embedding (100 dimensions) for the bottom model, and the GloVe twit-

	Dev	1036	255	272	509
	Test	1170	294	295	581

Table 3: Sentiment Distribution

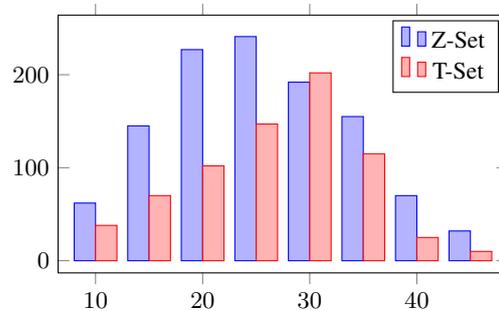

Figure 6: Test-set length distribution

ter word embedding (200 dimensions) for the top target-dependent sentiment analysis model. Also, due to lack of syntactically labelled twitter data, we used the PTB3 dataset to pre-train our bottom models. We follow the standard splits of PTB3, using 2-21 as the bottom model training data, section 22 for the development set and 23 as the test set.

We calculate statistics on sentiment polarities and lengths for both datasets. Table 3 shows the same percentage of three sentiment labels and Figure 6 shows length distribution on the test sets.

3.2 Training Settings

First, we use the PTB3 dataset with the standard split method pre-train the POS syntax model and dependency syntax model with the hyper-parameters listed in Table 2. A best model on the devset is saved for the neural stacking bottom syntax model.

Once obtaining the pre-trained bottom syntax model, we build the top sentiment model based on intermediate output syntax model features f_b and top word embedding we_t .

3.3 Hyper-parameters

Embedding Size: Our embedding is a superposition of a trainable and a pre-trained word embedding. We fixed the word embedding dimension of we_b and we_t to 100 and 200, respectively to match two pre-trained GloVe word embeddings set from Pennington et al. (2014).

Models	Acc.(%)	F1(%)	UAS	LAS
POS-tagging	92.4	91.6	/	/
Normal Dep.	/	/	95.6	93.8
No-POS Dep.	/	/	94.3	92.7

Table 4: Results for Syntactic Sub Model on PTB3 development set.

Dropout Rate: Dropout wrappers are applied to both the bottom level syntax model and top level sentiment model to avoid overfitting and learn better features. For the bottom syntax model, we use the PTB3 dataset to pre-train and tune hyper-parameters. A dropout rate of $\xi = 0.6$ for the BiLSTM layer and a softmax classifier layer to classify the learned features from hidden BiLSTM vector are used, respectively. Dropout rates of $\xi = 0.6$ and $\xi = 0.67$ are applied to every second BiLSTM layer and MLP layer, respectively, in the dependency model. We gain the best results (see Table 4) of different bottom syntax models on the PTB3 dataset.

For the top sentiment model, we use the model with only top word embedding inputs as our baseline. Here, the bottom syntactic features f_b are pre-processed with a dropout wrapper of $\phi = 0.5$ before being concatenated to the top model word embedding we_t , which is also wrapped with a dropout of $\varphi = 0.8$ for training models.

Training: We tune the hyper-parameters of the bottom syntax model on the PTB3 development set and top sentiment on the Z-Set development set. Words that occur less than a minimum amount of 3 times are treated as unknown words. Standard SGD with a decaying learning rate ($2e^{-2}$) is used for optimization, where the decay rate (0.75) is used to reduce the learning rate after each training iteration step ($lr_{distance}$).

$$lr_{new} = lr \cdot (lr_{speed})^{total_steps/lr_{distance}}, \quad (12)$$

There are several hyper-parameters in our models. We tune all the model hyper-parameters on the dev set with grid-search. With a learning rate of $\varphi = 2e^{-2}$, we did a large parameter iteration on learning rate decay steps $lr_{distance}$, decay rate lr_{speed} , batch size ($b_b \& b_t$) and dropout. The batch size ($b_b \& b_t$) has a great impact on model weights gradient and training speeds, and we choose a balanced point of 200 and 1000 for top and bottom model respectively. The decaying learning rate can also help in avoiding early overfitting and

Models	Acc.(%)
Baseline	73.24
+ lm_{pos}	73.53
+ lt_{pos}	73.34
+ $lm_{pos} \& lt_{pos}$	73.81
+ mlp_{dep}	74.23
+ lm_{dep}	73.96
+ $lm_{dep} \& mlp_{dep}$	74.59

Table 5: Dev set accuracies for sentiment sub model

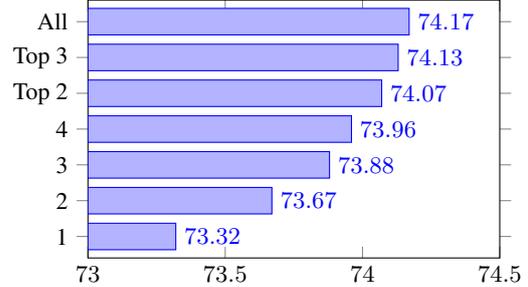

Table 6: Dev Results on BiLSTM feature layers

large weights optimization. The details of other hyper-parameters are listed in Table 2.

3.4 Development Experiments

Syntactic features: We measure the efficiency of different syntax features; the results are listed in Table 5. Within syntactic features, the baseline system (our implementation of Liu and Zhang (2017)) gives an accuracy of 73.24%. With only POS features, the accuracies can reach 74.23%, which is significantly ($p < 0.01$ by T-test) higher. With dependency information, the accuracy further rises to 74.59%, which is significant improved by 1.4 points to the baseline. This shows that syntactic information is indeed useful for target-dependent sentiment classification.

BiLSTM Layers: We also concatenate the hidden BiLSTM vector from different layers to construct a fast forward feature network to build feature from the dependency model.

$$lm_{dep} = \text{MLP}(\text{CONCAT}(lm_{dep}[1 : n])), \quad (13)$$

here, MLP is used to reduce the concatenated lm_{dep} dimensions and ($1 \leq n \leq 4$). A dropout wrapper of $\phi = 0.6$ is applied for the concatenated LSTM vectors $lm_{dep}[1 : n]$.

The results of fast forwards features from different LSTM layer are shown in Tabel 6. Here

Table 7: Test set results with different syntactic features, the features with * means they are built from the no-POS dependency syntax model

we refer to the *first* BiLSTM layer as 1, and the *last* BiLSTM layer as 4. *Top 2* indicates the *layer3* & *layer4*. Without fast forward connections, the results are 73.24%. With setting 1 to 4, the accuracies increase from 73.24% to 73.32%, 73.67%, 73.88% and 73.96%, respectively. Finally, the best results are obtained with 74.17%. We thus use the settings *layer4* for final tests, for a nice balance of efficiency and accuracy.

3.5 Results

We conduct final tests on the test set of Z-Set and T-Set, respectively investigating two questions. First, we verify whether this kind implicit features enhance the accuracy of twitter target-dependent sentiment analysis. Second, we measure how syntax affect target-dependent sentiment analysis results.

First, we compare the effects of different features on target target-dependent sentiment analysis. We take the top model with only word embedding inputs as our baseline system. The results are listed in Table 7. We can see that the syntactic features contribute to enhancing the accuracy of target-dependent sentiment analysis. Compared with our baseline on both test-set, we obtain an increase of Acc. by 1.3 points ($p < 0.01$) on Z-Set and 1 point ($p < 0.05$) on T-Set. For the POS-tagging model, the lm_{pos} feature provides more information than the lt_{pos} feature, and the lt_{pos} has

		Pos	Neg	Neu
Z-Set	Baseline	61.64	69.83	78.67
	$POS_{[c]}$	61.43	70.17	78.97
	$DEP_{[f]}$	61.14	71.14	79.63
T-Set	Baseline	62.57	69.36	75.70
	$POS_{[c]}$	61.84	69.41	77.62
	$DEP_{[f]}$	62.74	70.31	78.42

Table 8: F1 values(%) of each polarity on test set of Z-Set, T-Set, the $POS_{[c]}$ and $DEP_{[f]}$ indicate the features listed in Table 7

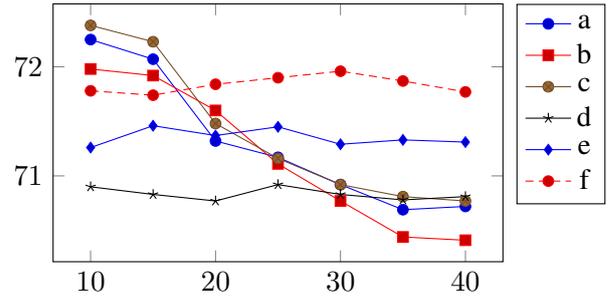

Figure 7: Test-set Accuracy against sentence length (Z-Set), a,b,c,d,e,f indicate the features listed in Table 7, respectively

little impact in their combination case.

The dependency model features work better than the POS-tag features. lm_{dep} is weaker than the mlp_{dep} feature, since mlp_{dep} feature contains more learned and special features, which provide the model with sentence level dependency structure.

Second, we separately test the effect of features made with respect to different sentence lengths and sentiment polarities. As two datasets have different max sentence lengths (Z-set 84 words, T-set 44 words), we focus on the length range [10,40] and treat the sentence with length 10- and 40+ as 10 and 40, respectively. The results are listed in Table 8, Figure 7 (Here we use the test set of Zhang et al. (2016)). The POS-tags features (a,b,c in Table 7) have advantages in short sentence (10-15 words), it gains a significant higher than the dependency features. In contrast, the dependency features (d,e,f in Table 7) show larger contribution on longer sentence (30-40 words).

Finally, our model gives a F1 score of 71.8% and 71.4% on both test sets, respectively, which are the best reported results so far.

3.6 Analysis

The results show that features have different contributions to enhance the accuracy of targeted sentiment classification. The bottom syntax model output contains different syntactic information. Using them as features do contribution to the top model gain the information about sentence structure or word interrelation.

The POS-tagging model features perform well on short sentences. We believe that a POS-tagging model feature vector contains relation between a present word and its POS context words. This matches its adjacent words, helping model gain local phrase-level structure information. For example, if a word has a VB tag and its adjacent words are RB and NN, a tighter relation will be generated between VB and NN.

Phrase-level structure contributes to short sentences, but can be ambiguous for long sentence. Even though a RNN can learn some sentence-level information, with the increasing of the sentence length, this local benefit can decrease gradually. This can be the reason of the result in Figure 7 where the F1 value of the POS-tagging model drops as the sentence length increase.

The stable performance of the dependency model in Figure 7 suggests that the overall sentence structure and local phrase-level structure can be both provided by the dependency model features. The more nonlocal sentence structure can help the model grasp the sentence sentiment easier. It has a slightly weakened in the overall structures of longer sentence.

The benefits from semantic features is structural and non-sentiment related. Though POS-tag information can generate dependency relations, we use the PTB3 data to pre-train the bottom level models, where noise may weaken the advantages. In contrast, the dependency model contains more detailed information, and is useful for PTB-like formal data. The effect can be discounted on twitter data. The results from Table 8 show that the F1 values show no significant variation on different sentiment polarities.

3.7 Attention values

We compared both types of features with the baseline on the attention values and structural relation between words (Figure 8). The relation is computed by the top model LSTM hidden vector under feature $[f]$ in Table 7. The grey level cor-

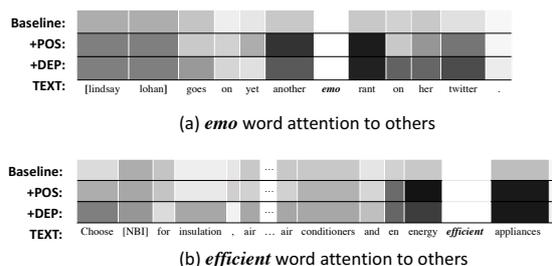

Figure 8: Word attention under implicit syntactic features, darker grayscale means closer attention

responds to their attention values. Darker colors mean closer attention. Here the baseline is the top model with only word embedding inputs. Figure 8(a) is a short sentence (12 words). We can see that the different features do not affect the sentence structure significantly. The POS-tagging model features focus on its adjacent and related words, such as the word ‘emo’, which has a tight relation with the adjacent word ‘rant’ and its adjunct word ‘another’. When the sentence length increases, the difference between POS and DEP becomes obvious. In Figure 8(b), the DEP has more related darker grey words attention compared to a normal word in the sentence (20+ words, we here hide some words due to limited space). For the phrase ‘en engery efficient appliances’, for example, the POS features give shallow local relations, but deep remote semantic relations are given by the DEP features, such as the nominal modifier word ‘Choose’ and its paralleling structure word ‘insulation’.

4 Conclusion

We investigated the use of implicit syntactic features for improving target-dependent sentiment analysis, by using hidden word representations of a state-of-the-art parsing to augment the input of a state-of-the-art target-dependent sentiment classifier. Neural stacking is used, where the parser is first trained using news article data, and then fine-tuned during the training of the sentiment classification system. In this way, our method leverages syntactic information, which is intuitively useful for target-dependent sentiment analysis, yet does not suffer from error propagations of using explicit syntactic parsing output features. Results on two target-dependent sentiment datasets show that our use of syntax can significantly enhance

the accuracies of the baseline model, and our final model outperforms existing methods that use explicit syntactic features and without syntactic features, giving the best accuracies on both datasets.

Abstract

The *sentiment aggregation problem* accounts for analyzing the sentiment of a user towards various aspects/features of a product, and meaningfully assimilating the pragmatic significance of these features/aspects from an opinionated text. The current paper addresses the sentiment aggregation problem, by assigning weights to each aspect appearing in the user-generated content, that are proportionate to the strategic importance of the aspect in the pragmatic domain. The novelty of this paper is in computing the pragmatic significance (weight) of each aspect, using graph centrality measures (applied on domain specific ontology-graphs extracted from *ConceptNet*), and deeply ingraining these weights while aggregating the sentiments from opinionated text. We experiment over multiple real-life product review data. Our system consistently outperforms the state of the art - by as much as a F-score of 20.39% in one case.

1 Introduction

User-generated content accounts for a large fraction of the online content that is available today. The advent of web-platforms such as on online social networks (e.g., *Facebook*, *Twitter* etc.), blogs, discussion forums and product portals (e.g., *Amazon*) has resulted in creation of a plethora of user-generated opinionated-content. The task of sentiment analysis focuses on analyzing such text, and deciphering user sentiment towards given products or their features, often referred to as *aspects*.

The task of sentiment aggregation builds upon sentiment analysis processes in general. While sentiment analysis (SA) aims to classify an

opinion into positive or negative or neutral categories (in case of coarse-grained SA) or into more intricate categories (in case of fine-grained/dimensional SA), often enough, it considers the opinion in its entirety, and is agnostic of the aspect-specific sentiments expressed. However, in practical settings, opinions expressed by users (such as product reviews) often tend to focus on multiple aspects, not just one. The diversity of the aspects, does not allow the aspect-specific sentiment-polarity values to be just naively summed up for the purpose of obtaining an overall aggregated sentiment of a given user towards a given product.

As an example, let us consider the following text regarding a software application: *This app has a beautiful interface. It is not bug free though.* The first sentence here is a positive feel to it from the *interface* feature (aspect). The second sentence has a negative feel to it from the *accuracy (bug)* feature (aspect). Thus, a simple linear aggregation (sum of the individual polarities) of the features, will yield a overall neutral review polarity score. This is not necessarily accurate. While an interface is a necessary enabler for users to use a software, it is of imperative necessity that the software runs accurately, without posing problems of bugs. Perhaps, a reasonable interface with an error-free running platform, is more necessary for an application software, than to just have a beautiful interface and erroneous execution. So the overall polarity of this review should be negative.

Let us flip the above example to the following: *This app has a bad and unfriendly interface. The software is, however, stellar in terms of execution.* This time, the first sentence shows a negative intent, while the second shows positive. Again, clearly, the overall sentiment can be deemed positive, although a simple-minded sum of the individual aspects would yield a neutral value.

While in the previous examples the words such as *however* and *though* could potentially appear to act as discourse markers, such discourse markers will not appear in most of the cases. For instance, consider the following review example: *I hated the little hints they gave us hardcore NDers on the Dare to Play message board. I had extremely high hopes for this game—I adored Last Train to Blue Moon Canyon and waited AGES for this game. Now, besides the absurd level of difficulty in this game [it was seemingly VERY hard in my eyes—I could not make it the first time through without the assistance of a walkthrough], I LOVED it.* Clearly, while there are both positive and negative aspects in the review, the aggregate sentiment of the review is overall positive. And there is no discourse marker to simplify detecting the aggregated sentiment.

Assigning an overall review polarity requires a deeper aggregation of the sentiment polarity of each aspect. This involves not only understanding the sentiment purely from a natural language processing (NLP) standpoint, but also needs to account for the domain, and the pragmatic significance of the feature in the given domain.

Multiple works in the literature, such as (Hatzivassiloglou and Wiebe, 2000), (Turney, 2002), (Wu et al., 2009) and (Chen and Yao, 2010) have attempted to perform sentiment aggregation. One promising line of work explores usage of *domain ontologies* in order to factor for the *pragmatic value* of each aspect of the product. A recent work by (Mukherjee and Joshi, 2013) attempted to use *ConceptNet* (Liu and Singh, 2004), to learn the product attribute-hierarchy over *attributes*, *synonyms*, *essential components* and *functionalities*, and create a domain-specific ontology tree, using *ConceptNet* relationships across concepts. They subsequently map the sentiments associated with each feature of each given product to this ontology tree, and determine the overall aggregated sentiment as a weighted sum of these features, where the weights are computed as a function of proximity of the concept to the root node of the ontology.

Our work also uses domain ontologies for sentiment aggregation; however, we do not use the concept of ontology trees that has been used in the literature (Mukherjee and Joshi, 2013). We propose a novel approach, that extracts ontology-graphs from *ConceptNet*, around given themes, *e.g.*, *software*. The extracted concepts are assigned weights

using a measure of their *centrality* to the theme under consideration (*e.g.*, the centrality of *bug* given the theme *software*). Akin to Mukherjee and Joshi (2013), these weights are combined with the associated feature sentiments, and a weighted aggregation is carried out to obtain the final sentiment aggregation scores for each user review.

For experiments, we use the same datasets as used by (Mukherjee and Joshi, 2013). Our system is more effective compared to the rest of the literature: it outperforms the state of the art for all the domains, including a large F-score margin of 20.39% in one case. Amongst the four datasets we experiment with, *closeness centrality* often outperforms the other graph centrality measures we use, namely *betweenness centrality* and *PageRank*; however, *betweenness centrality* outperforms the rest in a few cases. These centrality measures are explained in Section 3.1.

Overall, we provide a novel graph-driven baseline over domain ontologies, for deeply ingraining pragmatic information of various aspects of product reviews. Experiments indicate that the performance of our system is consistent across datasets, and also it consistently outperforms the state of the art. The system is expected to provide insights to organizations in understanding overall user sentiments towards products, by analyzing user-generated natural language text content.

2 Related Work

Sentiment analysis (SA) has been an area of long-standing area of research. A seminal work was carried out by Hatzivassiloglou and McKeown (1997), attempting to identify the sentiment polarity orientation of adjectives, using conjunction constraints, using a four-step supervised learning algorithm. One school of research has conducted significant exploration towards SA from user generated content, and a large fraction of these works look at the social media such as Twitter. This includes works by Agarwal et al. (2011), Barbosa and Feng (2010) and Kouloumpis et al. (2011), and Opinion Finder at University of Pittsburgh (Wilson et al., 2005). Many recent works, such as Khan et al. (2015), Kolchyna et al. (2015), Le and Nguyen (2015), Severyn and Moschitti (2015), and Zimbra et al. (2016), have also investigated the sentiment analysis problem on user generated content. Recent systems are based on variants of deep neural network built on top of embed-

dings. A few representative works in this direction for sentiment analysis are based on Convolutional Neural Networks (CNNs) (dos Santos and Gatti, 2014; Kim, 2014; Tang et al., 2014), Recurrent Neural Networks (RNNs) (Dong et al., 2014; Liu et al., 2015) and combined architecture (Wang et al., 2016). A few works exist on using deep neural networks for sarcasm detection, such as by Ghosh and Veale (2016) that uses a combination of RNNs and CNNs.

Sentiment analysis for product reviews has been investigated since a long time, in the literature. An early work attempting to classify reviews into positive vs. negative was conducted by Tong (2001), generating sentiment timelines. This was followed by several works, that attempted to replace the bag-of-words based early models by more sophisticated feature driven models (such as lexical, syntactic and semantic features). Some noteworthy works in this space include Hatzivassiloglou and Wiebe (2000), Kamps et al. (2001), Turney (2002) and Turney and Littman (2003). However, neither did these works consider domain-specific information, nor did they account for users' views on the different aspects (features) of a given product - all of which are central to comprehend the overall aggregate sentiment of a user towards a product.

Subsequent works attempted to incorporate user sentiments towards specific product aspects (product features); few of these incorporated deeper NLP techniques, such as dependency parsing (Wu et al., 2009; Chen and Yao, 2010; Mukherjee and Bhattacharyya, 2012) and joint sentiment topic models using LDA (Lin and He, 2009). These works, however, do not provide methodical or robust approaches to combine the feature-specific sentiments, to form the aggregate review polarity of a given user towards a given product.

Mukherjee and Joshi (2013), which happens to be the work closest to ours, attempt to overcome this shortcoming, extending over Wei and Gulla (2010) and Sureka et al. (2010). Wei and Gulla (2010) propose a hierarchical learning method for labeling product attributes and the associated sentiments in product reviews, using a Sentiment Ontology Tree (HL SOT) with a supervised learning technique. However, the work requires feature-specific labeling, which is not practicable in real-life applications, as well as, falls short of proposing any elegant aggregation mechanism for integrating feature-specific sentiments. Sureka et al.

(2010) were among the first ones to use ConceptNet (Liu and Singh, 2004) in sentiment analysis. Mukherjee and Joshi (2013) borrow from the concept of sentiment ontology tree, extract feature-specific ontology using ConceptNet, and finally present an Expected Sentiment Weight based combination of the feature-specific polarities, relying upon (a) the feature-specific sentiment polarity and strength, and (b) the weight of the sentiment derived as a function of the distance of the concept phrase (feature) from the root of the ontology tree. Their system also accounts for noisy and one-to-many relations in ConceptNet, and topic drift.

We notice that, there is scope in research, to fully exploit the intricate inter-relationship of the non-independent concepts that are practically bound to arise in a real-life setting. For example, in a world of *camera*, the concepts of *lens* and *flash* cannot be completely independent. And yet, in the ontology-tree based approach, such interdependencies go uncaptured. Such examples are clearly seen in Figure 1 in Mukherjee and Joshi (2013). This motivates the need to better capture the intricate interdependencies of such concepts, in terms of interdependencies as well as the significance of such dependencies. We hence propose a graph-based approach, where graph vertex properties, including weights, derived from the connectivity structures, can accommodate for such factors. Our approach is weakly supervised, unlike most of the recent SA systems mentioned above, including the conceptually similar but supervised approach of Socher et al. (2013) who model RNN on sentiment treebank for sentiment aggregation. The system is easy to implement and deploy, and consistently outperforms the literature for all the sentiment aggregation benchmark datasets.

3 Why Graph based Solutions?

As discussed earlier, a sentiment aggregator should leverage an ontology structure to alleviate the lack of awareness of the inter-relationships between aspects. It is, however, essential for ontology-driven sentiment aggregators to be aware of all possible inter-relationships between the aspects appearing in the opinionated text. The problem with the existing method of *transforming the ontology into a tree structure and aggregation of sentiment in a bottom-up manner* (Mukherjee and Joshi, 2013) is that it assumes the relationships between aspects (which are essentially mapped

to concepts present in the ontology) to be hierarchical, thereby straight-away eliminating non-hierarchical relationships (like *metonymy*). As discussed earlier, concepts like “lens” and “flash” in camera domain do not share a parent-child relationship; it is thus impossible to find a connection between these two nodes in the ontology-tree. Moreover, as per Mukherjee and Joshi (2013), the intensity of sentiment expressed are aggregated from the leaf node towards the root. This does not allow sharing of sentiment related information between nodes at same levels (like “lens” and “flash”). Our proposed systems overcomes this problem by using the ontology-graph structure as it is, without performing any lossy transformation, unlike Mukherjee and Joshi (2013). We measure the pragmatic importance of the nodes of the ontology-graph through various centrality measures (discussed in Section 3.1), which helps our system decide how much sentiment-information can be shared across nodes during sentiment aggregation. We believe, a graph-based sentiment aggregation technique like ours offers a more natural way of sentiment aggregation that preserves all possible interrelationships amongst aspects.

3.1 Graph Centrality: Definitions

The centrality measures, the key constituents our approach, are explained below. The definitions are borrowed from the domain of graph theory.

Closeness Centrality: The closeness centrality (Bavelas, 1950) of a vertex in a connected graph indicates how central the vertex is to the overall graph structure. This is defined as the average length of the shortest paths between the given vertex and all other vertices in the given graph. If a given connected graph G comprises n vertices, then, the closeness centrality $C(v)$ of a vertex $v \in G$ is computed as

$$C(v) = \frac{n-1}{\sum_u d(u,v)} \approx \frac{n}{\sum_u d(u,v)}, \text{ if } (n \gg 1)$$

where $d(u, v)$ represents the shortest path distance between the vertices u and v .

Betweenness Centrality: For each pair of vertices in any connected graph, there exists at least one shortest path between the pair of vertices, such that, the number of edges constructing the path is minimized (in case of unweighted graphs), or, the total weight of the edges constructed is minimized (weighted graphs). The betweenness cen-

trality (Freeman, 1977) of a given vertex of a graph is defined as the number of such shortest paths passing through the vertex. For a given vertex v , this is computed as

$$g(v) = \sum_{s \neq v \neq t} \frac{\sigma_{st}(v)}{\sigma_{st}}$$

where σ_{st} is the total number of shortest paths from vertex s to vertex t and $\sigma_{st}(v)$ of these pass through vertex v .

PageRank: The PageRank (Brin and Page, 1998) of a given vertex in a graph denotes the stationary probability of a random walk with restarts to arrive on the given vertex. For a given vertex v_i on a given graph G constituting of n vertices, the PageRank of the vertex $P(v_i)$ is computed as

$$P(v_i) = \alpha \sum_j u_{ji} \frac{v_j}{L_j} + \frac{1-\alpha}{n}$$

where $L_j = \sum_i u_{ji}$ is the number of neighbors of vertex j , and α , the damping factor, represents the probability of the random walk to continue.

4 Our Approach: Sentiment Aggregation using Graph Centrality

Our approach consists of two steps for assigning an overall polarity to a review for a product, based on the polarities expressed for individual aspects.

- The first step computes the *pragmatic significance* score for each aspect of a product, based on the graph centrality metrics obtained from domain specific ontology-graphs constructed from ConceptNet.
- The second step aggregates the polarities of different aspects to get one overall polarity for a review text, based on the scores from the earlier step and the polarities expressed for each aspect.

We provide the details of our approach below.

4.1 Ontology Graph Construction

We first construct the *ontology graph*, for each given concept/domain. Domain ontology captures intricate relationships and dependencies among different aspects of a product. We exploit the domain ontology in constructing a rich graph where nodes represent aspects and edges connecting them represent relationships among them. The

graph representation rightly captures all the dependencies among the aspects as well as the complicated relationships among them.

The graph is constructed as follows. The concept/domain is identified by a *seed word* such as, *camera, automobile, etc.*. A vertex is constructed for the seed word, and is marked as *unexplored* in the set of graph vertices. This is added to \mathcal{V} , the set of vertices in the ontology graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$. For each *unexplored* vertex v in the graph, each concept in ConceptNet that has at least one relationship with v , a vertex u is added to the vertex set \mathcal{V} and is marked as *unexplored*, as well as, an edge (u, v) is added to \mathcal{E} . At this stage, the vertex v is marked as *explored*. The ontology graph creation algorithm completes, when all vertices in \mathcal{V} are marked as *explored*. We provide a maximum graph distance cut-off of n (a given number), where n is number of edges on the minimum-length path to reach from the concept to the seed word in the graph. Algorithm 1 provides the details of the ontology graph creation algorithm.

Hierarchical	LocatedNear, HasA, PartOf, MadeOf, IsA, InheritsFrom
Synonymous	Synonym, ConceptuallyRelatedTo
Functional	UsedFor, CapableOf, DefinedAs, HasProperty

Table 1: Categorization of ConceptNet Relationship Types

Three types of ConceptNet relationships are used to form the edges, shown in Table 1. *Hierarchical* relationships represent parent-child relationships of concepts. *Synonymous* relationships are used to identify related concepts. *Functional* relationships are used to identify the purpose or property of interest of the given concept.

4.2 Graph Centrality Computation

This step computes the centrality of each concept appearing in the domain ontology graph constructed in the earlier step. For computing pragmatic significance score for each aspect, we employ graph centrality measures. Specifically, we propose to use centrality metrics such as closeness centrality, betweenness centrality and page rank, since these centrality measures captures significance of a node from different perspectives. In

Algorithm 1 ONTOLOGY GRAPH CREATION

```

1: function OntologyGraphCreate():
2:  $\mathcal{V} \leftarrow$  domain seed word as vertex  $s$ 
3: REM E.g.: kitchen, automobile, software, camera etc.
4: mark  $s$  as unexplored
5:  $\mathcal{E} \leftarrow \phi$ 
6: while there exists at least one unexplored vertex  $v \in \mathcal{V}$  do
7:   for  $u \in neighbors(v)$  do
8:     (REM neighbors( $e$ ) includes all vertices that have Hierarchical, Synonymous and Functional relationships with vertex  $e$ )
9:     if graph_distance( $s, u$ )  $\leq n$  then
10:       $\mathcal{V} \leftarrow \mathcal{V} \cup u$ 
11:      mark  $u$  as unexplored if not already explored previously
12:       $\mathcal{E} \leftarrow \mathcal{E} \cup (u, v)$ 
13:     end if
14:   mark  $v$  as explored
15:   end for
16: end while
17: Output:  $\mathcal{G} \leftarrow (V, E)$ 

```

computation of the different centrality metrics we do not consider the type of relationship on an edge. An example of a closeness centrality graph, has been provided in Figure 1, for the domain *camera*.

4.3 Feature/Aspect-Specific Sentiment Computation

A user’s opinion (review) could constitute of multiple aspects (features) of a given product, and different sentiment (opinion) polarities with respect to each aspect. The process of overall user sentiment analysis, mandates understanding the user’s sentiment towards each of these aspects. To determine the sentiment polarity expressed by a user towards each aspect (feature), we perform *dependency parsing* of each review, to associate a given aspect of the review, with the opinion of the user towards the given feature, expressed in the text.

Let R be a user review towards a product. Let W be the words constituting the review R . Following the approach of (Mukherjee and Bhattacharyya, 2012), we perform dependency parsing, and obtain D , the set of significant dependency relations in the corpus (*e.g.*, *nsubj*, *amod*, *doj*, *etc.*). For each dependency D_l where $D_l(d_i, d_j) \in D$, a graph $G(W, E)$ is constructed

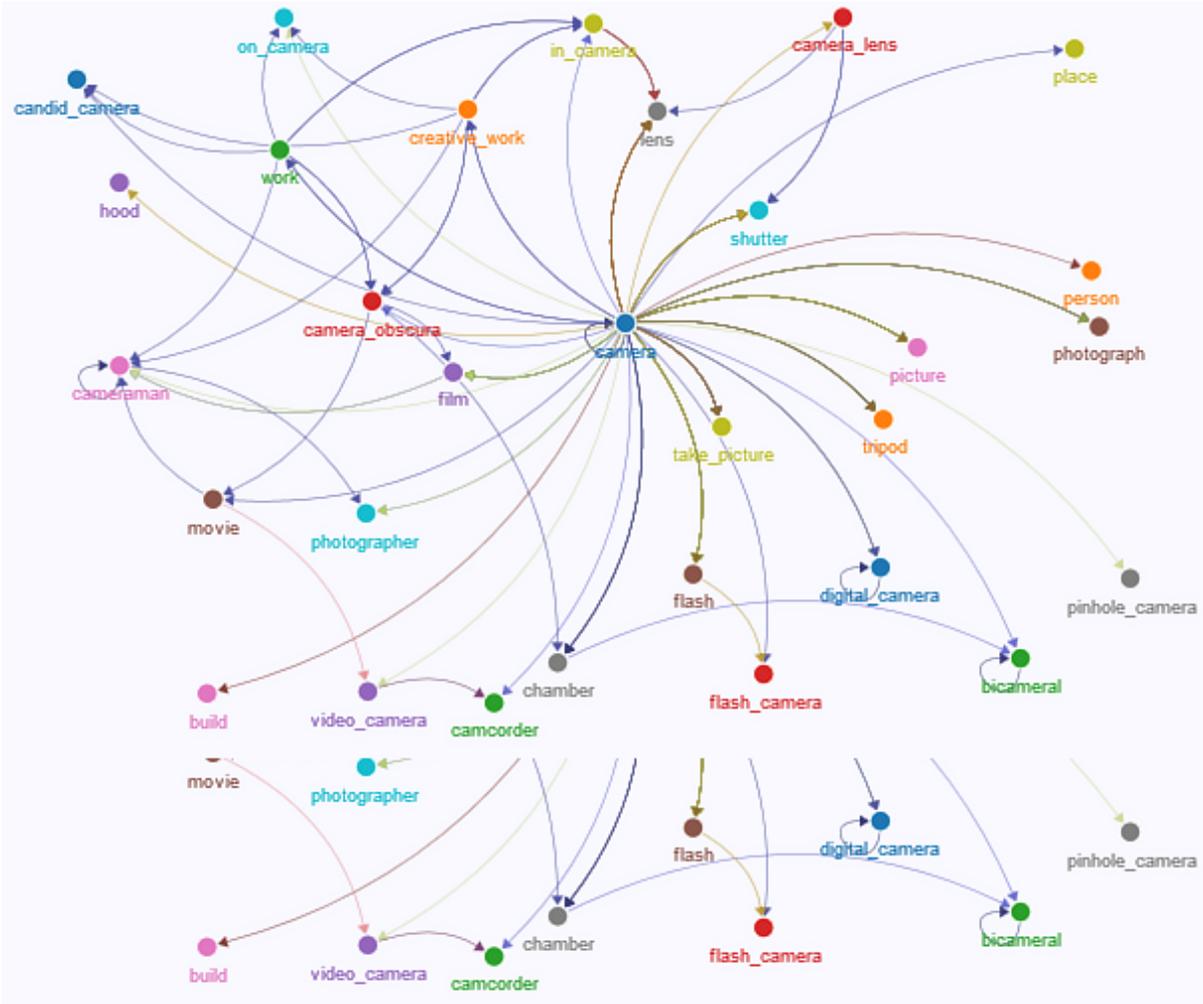

Figure 1: Depiction of closeness centrality measure for Camera Ontology

s.t. all $(w_i, w_j) \in W$ are connected by edge $e_k \in E$.

A PoS tagger is used to extract the entities (nouns). These entities are used as the initial feature (aspect) set $f_i \in F$. For each feature f_i , a cluster C_i is initiated, where f_i acts as the cluster head of C_i . Each word $w \in W$ occurring in review R , is assigned to the cluster having closest cluster head. The “closest” distance is measured, using the number of edges in the shortest path, that connects the word to the closest cluster head. Two clusters are merged, if the distance between the two cluster heads are less than a given threshold.

The set of words W_i belonging to each cluster C_i , are used to determine the user’s opinion about feature f_i . This is attained by conducting a simple *majority voting* of the sentiment values of the individual words $w_i \in W_i$, using sentiment lexicons. A final aspect-specific sentiment score is produced, as -1 for negative, 0 for neutral and $+1$

for positive.

Also note that, we use the simple negation handling framework that was also adopted by (Mukherjee and Joshi, 2013). We reverse the sentiment polarities of all the words appearing within a window of size 5 (Hu and Liu, 2004), starting from any of the negation operators *not*, *nor*, *neither* and *no*.

4.4 Sentiment Polarity Aggregation

In this step, we aggregate polarities across all the aspects, to assign overall polarity to a review text. We define the overall polarity of a text as a weighted sum of (a) the sentiment polarity expressed by the user towards each aspect (feature) of the product the review text, and (b) the pragmatic significance of the aspect in the given domain, reflected in the graph centrality measures. These two factors ensure that the final polarity value for a given review text aggregates polar-

ity values across different aspects, with adequate weightage that the aspect requires.

Let R be a review text, for a product P which has M aspects. Let m_i and m_i^p represent i^{th} aspect, and its sentiment polarity as computed as described earlier. Let c_{m_i} represent the centrality score for an aspect m_i computed using the ontology graph for the domain which P belongs to. The polarity value $p(sum)$ for a review text R is found by computing the polarity value, as the following:

$$p(sum) = \sum_{i=1}^M m_i^p \times c_{m_i}$$

Finally, the aggregated sentiment polarity S is assigned as:

$$\begin{cases} S = Positive & \text{if } p(sum) > 0 \\ S = Negative & \text{if } p(sum) < 0 \\ S = Neutral & \text{if } p(sum) = 0 \end{cases}$$

To find the aggregate sentiment of all users for a given product, we again opt for a *majority-voting* strategy. The overall methodology is presented in Algorithm 2.

5 Datasets and Ontologies

Dataset from four different domains corresponding to *automobile*, *camera*, *kitchen* and *software* are used for experiments. The camera reviews are collected from Mukherjee and Joshi (2013). The automobile, kitchen and software reviews are taken from Blitzer et al. (2007). Table 2 shows the dataset statistics.

	Positive	Negative	Total
Domain	Reviews	Reviews	Reviews
Automobile	584	152	736
Camera	986	210	1196
Kitchen	1001	1000	2001
Software	1000	915	1915

Table 2: Dataset Statistics

Note that, akin to Mukherjee and Joshi (2013), all the words have been lemmatized in the reviews, which ensures that all the terms such as *camera* and *cameras* are treated as the root word *camera*. Further, words such as *hvnt*, *dnt* have been replaced to their original forms.

In the ontology graph construction process, we keep adding *unexplored* vertices to the vertex set,

Domain	Corpus		
	Frequent Features	Ontology Nodes	Ontology Edges
Automobile	132	114	778
Camera	986	979	1280

Table 3: Ontology-graph Statistics

as long as, there is at least one edge between the corresponding concept to an existing vertex in the vertex-set, of one of the types *functional*, *hierarchical* or *synonymous*. However, we restrict to adding vertices such that the maximum distance between the *seed word* and the newly added concept remains less than a given threshold n . We empirically fix $n = 4$, which practically provides a sufficiently large number of concepts that are realistically related to the concept of the seed word. Higher values of n lead to domain concept delusion and topic drift. Table 3 presents statistics of the ontology graphs extracted for four domains.

6 Experiments

6.1 Tools and Resources

We use several well-known tools and resources.

- For PoS tagging, we use Stanford NLP Toolkit¹. PoS tagging is carried out to tag the user reviews, which in turn is used to identify the entities (noun concepts) in the reviews.
- For ontology construction for the domains, we use ConceptNet 5².
- To compute centrality measures of the ontology graphs, we use the graph tool \mathbf{R}^3 .
- For dependency parsing of the user reviews, we use Stanford Dependency Parser⁴.
- For sentiment lexicons, we experiment with SentiWordNet (Baccianella et al., 2010) and Bing Liu sentiment dictionary (Hu and Liu, 2004). Although we report our results only for the Bing Liu sentiment dictionary for the

25: return  $\text{Sentiment\_Dictionary\_Lookup}(w)$  (REM SentiWordNet, Bing Liu etc.)
```

sake of brevity, we observe similar performances using SentiWordNet also.

6.2 Results

We establish the first baseline of our work, using the *lexical classification* based approach of (Taboada et al., 2011). In this approach, a sentiment lexicon is used as a reference, that consists of words having positive and negative sentiment polarities. In a given review, if the total number of positive terms is higher compared to the total number of negative terms, the review is considered positive, and is considered negative if the opposite holds true. The baseline does not incorporate the feature (aspect) specific approach. We modify the approach to associate the lexical terms with the aspects (features), and thus obtain a feature-specific lexical sentiment. We subsequently aggregate these sentiments, to obtain improved baseline results. For sentiment lexicon, we empirically ex-

plore with SentiWordNet and Bing Liu sentiment dictionary.

We further compare our work against the reported approach for the same task by (Mukherjee and Joshi, 2013) which also uses ConceptNet, and has an approach similar to ours. However, as mentioned earlier, they consider ontology as a *tree* while we construct a *graph*. Also, they assign pragmatic weights to each aspect present in the review, using the height (distance) of the aspect from the root (*seed word*) of the ontology tree they construct, while we use graph centrality measures.

Table 4 illustrates the results we obtain with different approaches. The performance of the systems are reported in terms of accuracy (to ensure direct comparison with previous work) and **weighted F1-score** (to tackle class-imbalances). We report the results of the lexical baseline by (Taboada et al., 2011) using Bing Liu sentiment dictionary baseline, the results of Mukherjee and

Models	Automobile		Camera		Kitchen		Software	
	F1	Acc.	F1	Acc.	F1	Acc.	F1	Acc.
Lexical Baseline (Bing Liu)	73.45	64.43	79.74	63.65	66.77	67.11	66.04	69.38
Hierarchical Aggr. (Mukherjee et al., 2013)	71.48	70.23	81.22	70.38	67.28	67.62	70.19	70.28
Aggr. <i>Closeness</i> (Our approach)	75.93	73.85	84.68	74.00	85.66	72.96	70.87	70.52

McNemar Significance Test (p)	< 0.0001		< 0.0001		< 0.0001		< 0.0001	

Table 4: Overall F1 score and accuracy (in %) of all models across all domains. For all domains, the performance improvements obtained using *Closeness* centrality measure over that reported in the literature (Mukherjee et al., 2013) are statistically significant (with $p \ll 0.05$), as confirmed by McNemar test.

Joshi (2013), and our results, using the three different graph centrality measures. As observed, all our proposed centrality based approaches outperform the baseline. The *closeness* centrality measure performs the best, with statistically significant improvement ($p \ll 0.05$) observed over the system reported by Mukherjee and Joshi (2013). Other graph based approaches also show improvement, except for the *software* domain.

7 Conclusion and Future Work

In this paper, we performed sentiment aggregation as a combination of user sentiments, analyzed towards multiple aspects/features of a product, from user-generated content. The novelty of this work was in deeply ingraining the sentiment weight of each entity derived from the user generated content, and pragmatic significance of the entity in the domains that was obtained by using a graph-structured ontology. We observe a consistently high performance of our system across all the keywords that we experiment with. We outperform the state of the art by a F-score of 3.02%, 3.46%, 20.39% and 0.68%, for *automobile*, *camera*, *kitchen* and *software* respectively. Further, the effectiveness of our system often increases by using *closeness centrality* over the other graph centrality measures such as *betweenness centrality* and *PageRank*, although *betweenness centrality* does outperform the rest of the methods in some cases. In future, we would like to improve the current technique to include the intensity of sentiment bearing words appearing in the reviews. Integrating lexico-semantic knowledge acquired through concept-embeddings learned from ontology structures in the aggregation step is also a future work. Our system will have significant real-life impact in helping organizations understand overall user sentiment towards products, on e-commerce sites

(e.g., Amazon) as well as online social networks, discussion forums and blogs.

Sentence Modeling with Deep Neural Architecture using Lexicon and Character Attention Mechanism for Sentiment Classification

Huy Thanh Nguyen and Minh Le Nguyen

Japan Advanced Institute of Science and Technology

{huy.nguyen, nguyenml}@jaist.ac.jp

Abstract

Tweet-level sentiment classification in Twitter social networking has many challenges: exploiting syntax, semantic, sentiment and context in tweets. To address these problems, we propose a novel approach to sentiment analysis that uses lexicon features for building lexicon embeddings (LexW2Vs) and generates character attention vectors (CharAVs) by using a Deep Convolutional Neural Network (DeepCNN). Our approach integrates LexW2Vs and CharAVs with continuous word embeddings (ContinuousW2Vs) and dependency-based word embeddings (DependencyW2Vs) simultaneously in order to increase information for each word into a Bidirectional Contextual Gated Recurrent Neural Network (Bi-CGRNN). We evaluate our model on two Twitter sentiment classification datasets. Experimental results show that our model can improve the classification accuracy of sentence-level sentiment analysis in Twitter social networking.

1 Introduction

Tweet-level sentiment classification is a fundamental task of sentiment analysis in Twitter social networking and is essential to understand user generated contents in social networking. Twitter sentiment classification have intensively researched in recent years (Go et al., 2009) (Nakov et al., 2016). There are many works related to deep learning methods involved learning word representation (Socher et al., 2011). Word representation is central to deep learning and essential feature extractor that encode different features of words in their dimensions. The combination of

word representation and deep learning achieved impressive results because word embeddings enable efficient computation of word similarities through low-dimensional matrix operations (Kim, 2014). In addition, deep learning models achieved remarkable performance. Some researchers use Convolution Neural Network (CNN) for sentiment classification. CNN utilizes convolution filters applied to local features. CNN models has been shown to be effective for NLP. For example, the model of (Dos Santos and Gatti, 2014) used CNN to form a sentence-level representation for sentiment classification. In addition, Bidirectional Gated Recurrent Neural Network (Bi-GRNN) is another deep learning model that has achieved an excellent result for sentiment analysis and other traditional tasks (Chung et al., 2014).

Inspired by the models above, the goal of this research is to build a model for exploiting syntax, semantic, sentiment and context of tweets by constructing four kinds of embeddings: CharAVs, LexW2Vs, ContinuousW2Vs and DependencyW2Vs. On the other hand, we modify Bi-GRNN of (Chung et al., 2014) into Bi-CGRNN to take word embeddings in order to produce a sentence-wide representation from sentence compositions. Our paper makes the following contributions:

- We construct a tweet processor which standardizes tweets by using pre-processing steps and a semantic rule-based approach. We construct four kinds of embeddings: CharAVs, LexW2Vs, ContinuousW2Vs and DependencyW2Vs. A DeepCNN is used for training CharAVs by producing fixed-size feature vectors and attending on the best feature vectors. CharAVs can capture the morphology and shape of a word. The morphological and shape information illustrate how words are

formed, and their relationship to other words.

- We create an integration of CharAVs and LexW2Vs with ContinuousW2Vs and DependencyW2Vs. Such embeddings are advanced continuous word embeddings and advanced dependency-based word embeddings.
- We modify a standard Bi-GRNN to be a Bi-CGRNN by incorporating contextual features (e.g., Syntactic contexts) in order to take both advanced word embeddings. The output of Bi-CGRNN is sentence compositions that are formed into a sentence-wide representation. The purpose of Bi-CGRNN is to connect the information of words in a sequence and maintain the order of words for a sentence-level representation.

The organization of the paper is as follows: Section 2 describes the model architecture which introduces the structure of the model. We explain the basic idea of the model and the way of constructing the model. Section 3 shows results and analysis and Section 4 summarizes this paper.

2 Model architecture

2.1 Basic Idea

Our proposed model consists of a tweet processor and a deep learning module that are treated as two distinct components. The tweet processor standardizes tweets, applies semantic rules and then generates embeddings. The deep learning module is a combination of Bi-CGRNN and DeepCNN. To formulate our challenges in increasing the classification accuracy, we illustrate the basic idea of our model in Figure 1 as follows: Tweets are firstly considered by the tweet processor based on pre-processing steps of (Go et al., 2009) and the semantic rule-based approach from (Appel et al., 2016). Then, we construct four kinds of embeddings in the representation-level step: ContinuousW2Vs, CharAVs, LexW2Vs and DependencyW2Vs, where CharAVs are generated from a DeepCNN. The DeepCNN is constructed from two wide convolutions which can learn to recognize specific n-grams at every position in a word and allow features to be extracted independently of these positions in the word. These features maintain the order and relative positions of characters and are formed at a higher abstract level. In those embeddings, ContinuousW2Vs take the syntax and semantic of words (Mikolov et al., 2013)

while the LexW2Vs can capture the sentiment of words (Shin et al., 2016). DependencyW2Vs derive the syntactic relations of words and exhibit more functional similarity than the original skip-gram embeddings led to form global syntactic contexts of words (Levy and Goldberg, 2014). Twitter sentiment label belongs to global sentence level while traditional word embeddings capture local contexts only. Therefore, DependencyW2Vs are useful in capturing global context of tweets. On the other hand, we create two advanced embeddings by integrating LexW2Vs and CharAVs with ContinuousW2Vs and DependencyW2Vs for Bi-CGRNN. A Bi-CGRNN is enhanced from a standard Bi-GRNN of (Chung et al., 2014) by incorporating contextual features (e.g., dependency-based contexts) into the model. The Bi-CGRNN produces a sentence-level representation from sentence compositions in order to maintain the order of word and capture syntax, semantic, sentiment and context of a sentence based on these embeddings.

2.2 Data Preparation

- *Stanford - Twitter Sentiment Corpus (STS Corpus)*: STS Corpus contains 1,600K training tweets collected by a crawler from (Go et al., 2009). (Go et al., 2009) constructed a test set manually with 177 negative and 182 positive tweets. The Stanford test set is small. However, it has been widely used in different evaluation tasks (Go et al., 2009) (Dos Santos and Gatti, 2014).
- *Health Care Reform (HCR)*: This dataset was constructed by crawling tweets containing the hashtag #hcr (Speriosu et al., 2011). The task of this paper is to predict positive/negative tweets.

2.3 Tweet Processor

We first take the unique properties of Twitter to reduce the feature space such as *Username, Usage of links, None, URLs and Repeated Letters*. We then process *retweets, stop words, links, URLs, mentions, punctuation and accentuation*. For emoticons in the dataset, we consider them as words in order that deep learning classifiers can capture information from emoticons. Because the test set contains emoticons, they do not influence classifiers if emoticons do not contain in its training data. Therefore, the emoticons would be useful

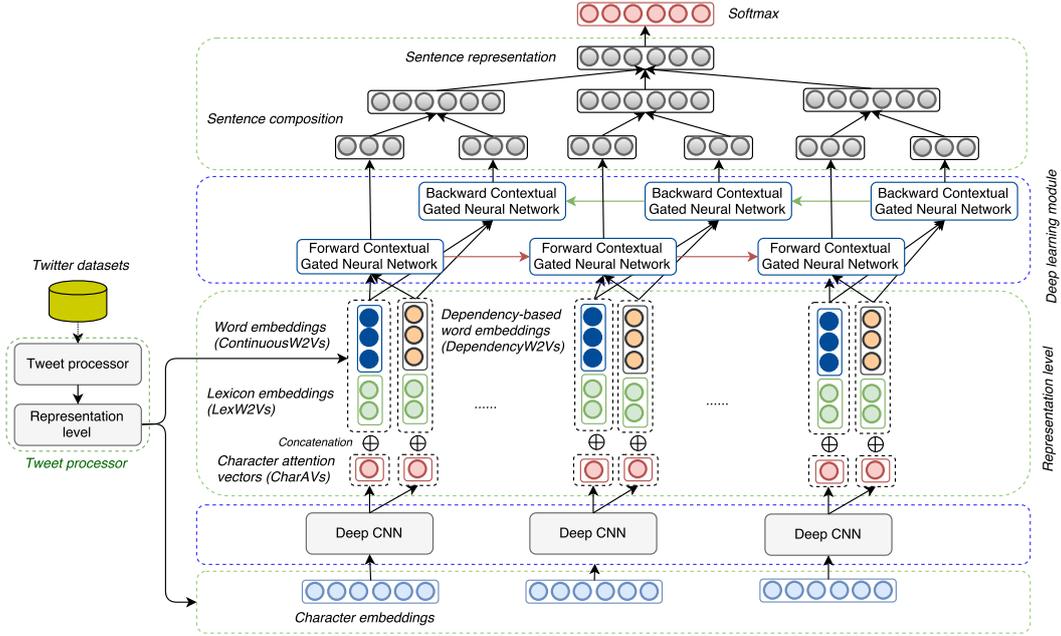

Figure 1: The overview of a deep learning system.

when classifying test data by using deep learning model. However, our preprocessing steps are different from (Go et al., 2009), they remove the emoticons out from their training datasets because they revealed that the training process makes the usage of emoticons as noisy labels and if they consider the emoticons, there is a negative impact on classification accuracy. In addition, traditional classifiers can not focus on non-emoticons (e.g., unigrams and bi-grams) to predict exactly the sentiment of tweets. After the pre-processing steps, we apply the semantic rules based on the idea of (Appel et al., 2016) and use a tweet processor from our previous work (Nguyen and Nguyen, 2017) to remove unnecessary sub-sentences from tweets in order that the deep learning model learns essential features from tweets. The semantic rule-based approach can handles negation and shows advances led to effectively affect the output of classifiers.

2.4 Representation Level

In this section, we describe how the kinds of embeddings are constructed by the representation module. To construct embedding inputs for our model, we use a fixed-sized word vocabulary V^{word} and a fixed-sized character vocabulary V^{char} . Given a word w_i is composed from characters $\{c_1, c_2, \dots, c_M\}$, the character-level embeddings are encoded by column vectors u_i in the embedding matrix $W^{char} \in R^{d^{char} \times |V^{char}|}$, where V^{char} is the size of the character vocabulary. For

continuous word-level embedding r_{word} , we use a pre-trained word-level. We build every word w_i into two advanced word embeddings:

- Advanced continuous word embeddings $v_i = [r_i; e_i; l_i]$ is constructed by three sub-vectors: the pre-trained word-level embedding $r_i \in R^{d^{word}}$, the character attention vector $e_i \in R^l$ of w_i where l is the length of the filter of wide convolutions, the lexicon embedding $l_i \in R^{d^{score}}$ where d^{score} is list of sentiment scores for that word in lexicon datasets.
- Advanced dependency-based word embeddings $d_i = [de_i; e_i; l_i]$ is also built by three sub-vectors: the dependency-based word embedding $de_i \in R^{d^{word}}$, the character attention vector e_i and the lexicon embedding l_i . The advanced dependency-based word embeddings contain syntactic contexts and is increased information from LexW2Vs and CharAVs.

This deals with three main problems: (i) Sentences have any different size; (ii) Important information of characters that can appear at any position in a word are extracted; (iii) The syntax, semantic, sentiment, context and the morphology of words in a sentence are captured by concatenating two advanced embeddings via Bi-CGRNN in order to produce sentence representation.

We have N fixed-size CharAVs corresponding to word-level embeddings in a sentence. In sub-section 2.5, 2.6 and 2.7, we illustrate the methods of constructing LexW2Vs, CharAVs using Deep-CNN and DependencyW2Vs.

2.5 Lexicon Embeddings (LexW2Vs)

The LexW2Vs are constructed by taking scores from various lexicon datasets. In lexicon datasets, each word contains key-value pairs in which the key is a word and the value is a list of sentiment scores for that word. These scores range from -1 to 1, where -1 is most negative and 1 is most positive, respectively.

For each word $w_i \in V^{word}$, where V^{word} is a fixed-sized word vocabulary, a lexicon embedding is constructed by concatenating all of the scores among lexicon datasets with respect to w_i . If w_i does not exist in a certain dataset, 0 value is substituted. The lexicon embedding is a form of a vector $l_i \in R^{d^{score}}$, where d^{score} is the total number of scores across all lexicon datasets. We use seven lexicon datasets for building LexW2Vs:

- Bing Liu Opinion Lexicon (Hu and Liu, 2004).
- NRC Hashtag Sentiment Lexicon (Mohammad et al., 2013).
- Sentiment140 Lexicon (Mohammad et al., 2013).
- NRC Sentiment140 Lexicon (Kiritchenko et al., 2014).
- MaxDiff Twitter Sentiment Lexicon (Kiritchenko et al., 2014).
- National Research Council Canada (NRC) Hashtag Affirmative and Negated Context Sentiment Lexicon (Kiritchenko et al., 2014).
- Large-Scale Twitter-Specific Sentiment Lexicon (Tang et al., 2014).

The purpose of building LexW2Vs is to take the different kinds of words for capturing the different sentiments of words. Table 1 illustrates the type of words for each dataset. We share idea with (Shin et al., 2016). However, our LexW2Vs are distinguished their approaches in the aspect: We cover the colloquial expressions and colloquial emoticons in tweets by using Large-scale Twitter-Specific Sentiment Lexicon.

Lexicon dataset	The type of words
Bing Liu Opinion Lexicon	Sentiment adjective words
NRC Hashtag Sentiment Lexicon	Hashtag emotion words & Hashtag topic words
Sentiment140 Lexicon	Emoticons & Sentiment words
NRC Sentiment140 Lexicon	Affirmative context words & Sentiment140 Negated Context words
MaxDiff Twitter Sentiment Lexicon	Twitter sentiment words
Hashtag Affirmative and Negated Context Sentiment Lexicon	Hashtag affirmative words & Negated contextual words
Large-Scale Twitter-Specific Sentiment Lexicon	Colloquial words & Emoticons

Table 1: The types of words in lexicon dataset.

We call such lexicon-based features as lexicon embeddings because embeddings are a feature input of deep learning model and describe the properties of a word or a phrase. Each word in each lexicon datasets actually has many values that can be built by training a neural network. The deep learning model uses this input for calculating a computational graph (weight matrix) that describe relatedness among words (n-gram order).

2.6 Character Attention Vectors (CharAVs)

Figure 2 describes the way of forming a character attention vector. We use a DeepCNN with two wide convolutions. The first convolution produces a fixed-size character feature vector named m -gram features by extracting local features around each character window of the given word and using a max pooling over vertical character windows. The second convolution retrieves the fixed-size character feature and transforms the representation to yield a character attention vector by performing max pooling on each row of matrix instead of each column. The purpose of this method is to attend on the highest n -gram feature in order to transform these m -gram features at previous level into a representation at a more focused abstract level and produces an attention over only the best feature vector. Character attention vectors has two advantages: One is that this model could adaptively assign an importance score to each piece of word embedding according to its semantic relatedness with characters of each word. Another advantage is that this attention model is differentiable, so that it could be easily trained together with other components in an end-to-end fashion. In the next sub-section, we introduce the

structure of CNN with wide convolution.

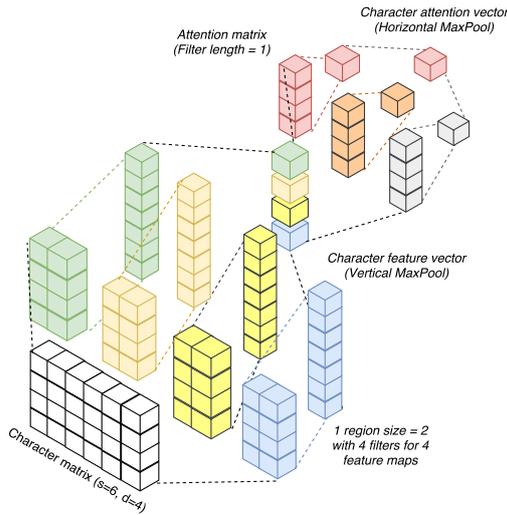

Figure 2: DeepCNN for the sequence of character embeddings of a word. For example with 1 region size is 2 and 4 feature maps in the first convolution and 1 region size is 3 with 3 feature maps in the second convolution. The CharAVs is then created by performing max pooling on each row of the attention matrix.

Convolutional Neural Network: The convolution has a filter vector m and take the dot product of filter m with each m -grams in the sequence of characters $s_i \in R$ of a word in order to obtain a sequence c :

$$c_j = m^T s_{j-m+1:j} \quad (1)$$

Based on Equation 1, we have two types of convolutions that depend on the range of the index j . The narrow type requires that $s \geq m$ and produce a sequence $c \in R^{s-m+1}$. The wide type does not require on s or m and produce a sequence $c \in R^{s+m-1}$. Out-of-range input values s_i where $i < 1$ or $i > s$ are taken to be zero.

Wide Convolution: Given a word w_i composed of M characters $\{c_1, c_2, \dots, c_M\}$, we take a character embedding $u_i \in R^{d^{char}}$ for each character c_i and construct a character matrix $W^{char} \in R^{d^{char}} \times |V^{char}|$. The values of the embeddings u_i are parameters that are optimized during training. The trained weights in the filter m correspond to a feature detector which learns to recognize a specific class of n -grams. The use of a wide convolution has some advantages more than a narrow convolution because a wide convolution ensures that all weights of filter reach the whole characters of

a word at the margins. The resulting matrix has dimension $d \times (s + m - 1)$.

2.7 Dependency-based Word Vectors (DependencyW2Vs)

To construct context embeddings, we use the idea of (Levy and Goldberg, 2014) to derive syntactic contexts based on the syntactic relations of a word. Most previous works on neural word embeddings take the contexts of a word by computing *linear-context* words that precede and follow the target word. However, these contexts can be exploited similar by generalizing the *SKIP-GRAM* model. The model for learning Dependency-based Word Vectors is improved from *SKIP-GRAM* model in which the linear bag of words contexts are replaced with arbitrary word contexts from dependency tree. Syntactic contexts are derived from produced dependency parse-trees. Specifically, the bag-of-words in the *SKIP-GRAM* model yield *broad topical similarities*, while the dependency-based contexts yield more *functional similarities* of a *cohyponym nature*. In the *SKIP-GRAM* model, the contexts of a word are the words surrounding it in the text. However, there is a limitation of *SKIP-GRAM* word embeddings: Contexts need not correspond to all of the words and the number of context-types maybe larger than the number of word-types. Therefore, dependency-based contexts capture more information than bag-of-words contexts. In Figure 3, the contexts are extracted for each word in the sentence and the contexts of a word are derived from syntactic relations of a word in the sentence. For parsing syntactic dependencies, we use a parser from (Goldberg and Nivre, 2013) for Stanford dependencies and the corpus are tagged with parts-of-speech using Stanford parser¹.

After parsing each sentence, we consider word context as Figure 3: For a target word w with modifiers m_1, m_2, \dots, m_n and a head h , we form the contexts as $(m_1, lbl_1), \dots, (m_n, lbl_n), (h, lbl_h^{-1})$, where lbl is the type of the dependency relation between the head and the modifier, lbl^{-1} is used to mark the inverse-relation. The advantages of syntactic dependencies are inclusive and more focused than bag-of-words. In addition, they can capture relations that out-of-reach with small windows and filter out contexts that are not directly related to the target word. For example, *Australian*

¹<https://nlp.stanford.edu/software/lex-parser.shtml>

is not used as the context for *discovers*. Therefore, we have more focused embeddings that capture more functional and less topical similarity.

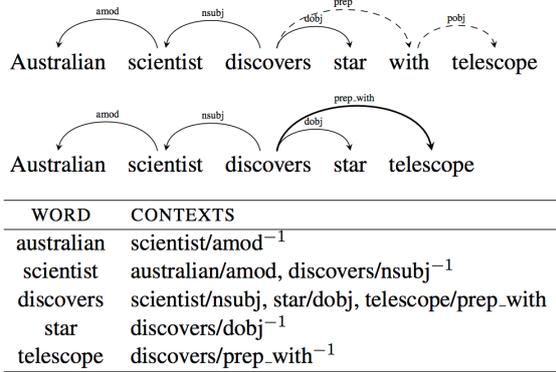

Figure 3: Dependency-based context extraction example (Levy and Goldberg, 2014)

2.8 Contextual Gated Recurrent Neural Network (CGRNN)

Gated Recurrent Neural Network: The Bi-GRNN is a version of (Chung et al., 2014) in which a Gated Recurrent Unit (GRU) has two gates, a reset gate r_t and a update gate z_t . Intuitively, the reset gate determines how to combine the new input with the previous memory, and the update gate defines how much of the previous memory to keep around. We use GRUs for our model because GRUs are quite new and their tradeoffs have not been fully explored yet. On the other hand, GRUs have fewer parameters (U and W are smaller) and thus may train a bit faster or need less data to generalize. The equation 2 illustrates the construction of a GRU cell:

$$\begin{aligned}
 r_t &= \sigma(W_{xr}x_t + W_{hr}h_{t-1} + b_r) \\
 z_t &= \sigma(W_{xz}x_t + W_{hz}h_{t-1} + b_z) \\
 \hat{h}_t &= g(x_tW_{xh} + (r_t \odot h_{t-1})W_{hh} + b_h) \\
 h_t &= (1 - z_t) \odot h_{t-1} + z_t \odot \hat{h}_t.
 \end{aligned} \tag{2}$$

Contextual Gated Recurrent Neural Network: Based on the idea of GRNN model, we build a power of syntactic contexts into a standard Bi-GRNN model which adapt GRNN cell to take both words and syntactic contexts by modifying the equations representing operations of the GRNN cell. A GRNN cell is added dependency-based word vector T to reset gate, update gate and hidden state. In the Equation 3, the term in bold is the modification made to the original GRNN equation.

Based on these equations, adding dependency-based word vector T is corresponding to considering a composite input $[x_i, T]$ to the GRNN cell that concatenates the advanced continuous word embeddings and advanced dependency-based word embeddings.

$$\begin{aligned}
 r_t &= \sigma(W_{xr}x_t + W_{hr}h_{t-1} + \mathbf{W}_{Ti}\mathbf{T} + b_r) \\
 z_t &= \sigma(W_{xz}x_t + W_{hz}h_{t-1} + \mathbf{W}_{Ti}\mathbf{T} + b_z) \\
 \hat{h}_t &= g(x_tW_{xh} + (r_t \odot h_{t-1})W_{hh} + \mathbf{W}_{Ti}\mathbf{T} + b_h) \\
 h_t &= (1 - z_t) \odot h_{t-1} + z_t \odot \hat{h}_t.
 \end{aligned} \tag{3}$$

This approach of concatenating syntactic contexts and word embeddings works better in practice and deal with the context challenge in sentiment analysis.

3 Results and Analysis

3.1 Experimental setups

For the Stanford Twitter Sentiment Corpus (STS Corpus), we use the number of samples as (Dos Santos and Gatti, 2014). The training data is selected 80K tweets for a training data and 16K tweets for the development set randomly from the training data of (Go et al., 2009). We conduct a binary prediction for STS Corpus.

In Health Care Reform Corpus (HCR Corpus), we also select 10% randomly for the development set in a training set and construct as (Da Silva et al., 2014) for comparison. We describe the summary of datasets in Table 2.

Data	Set	N	c	l_w	l_c	$ V_w $	$ V_c $
STS	Train	80K	2	33	110	67083	134
	Dev	16K		28	48		
	Test	359		21	16		
HCR	Train	621	2	25	70	3100	60
	Dev	636		26	16		
	Test	665		20	16		

Table 2: Summary statistics for the datasets after using semantic rules. c : the number of classes. N : The number of tweets. l_w : Maximum sentence length. l_c : Maximum character length. $|V_w|$: Word alphabet size. $|V_c|$: Character alphabet size.

Hyperparameters: For all datasets, the filter window size (h) is 7 with 6 feature maps each for the first wide convolution layer, the second wide convolution layer has a filter window size of 1 with 14 feature maps each. Dropout rate (p) is 0.5, l_2 constraint, learning rate is 0.1 and momentum of 0.9.

Mini-batch size for STS Corpus is 100 and HCR corpus is 4. Training is done through stochastic gradient descent over shuffled mini-batches with Adadelta update rule (Zeiler, 2012).

Pre-trained Word Vectors: We use the publicly available *Word2Vec*² trained from 100 billion words from Google and *TwitterGlove*³ of Stanford is performed on aggregated global word-word co-occurrence statistics from a corpus. *Word2Vec* has dimensionality of 300 and *Twitter Glove* have dimensionality of 200. Words that do not present in the set of pre-train words are initialized randomly.

3.2 Experimental results

Table 3 shows the results of our model for sentiment analysis against other models. The different kinds of models are constructed to evaluate the impacts of embeddings on classification accuracy. We build the Bi-CGRNN enhanced CharAVs and LexW2Vs. In addition, we evaluate separately the effectiveness of CharAVs and LexW2Vs on Twitter datasets by incorporating with standard Bi-GRNN.

We compare our model performance with the approaches of (Go et al., 2009) and (Dos Santos and Gatti, 2014). The model of (Go et al., 2009) displays the good results in the previous time and the model of (Dos Santos and Gatti, 2014) reported the state-of-the-art so far by using a charSCNN. Our model shows the result of 88.57 is the best prediction accuracy for STS Corpus.

For HCR Corpus, we compare the performance with the results of (Da Silva et al., 2014) that used an ensemble of multiple base classifiers (ENS) such as Naive Bayes (NB), Random Forest (RF), SVM and Logistic Regression (LR). The ENS model is combined with bag-of-words (BoW), feature hashing (FH) and lexicons (lex). Our model outperforms the model of (Da Silva et al., 2014) with result of 80 so far.

3.3 Analysis

The model with CharAVs and LexW2Vs built on top of *GoogleW2V* vectors and *DependencyW2Vs* is effective in order to increase classification accuracy. These experiments show that CharAVs and LexW2Vs achieve good performances and contribute in enhancing information for words. However, the experiments indicate that

Bi-CGRNN + CharAVs + LexW2Vs + GloveW2Vs	86.9	80.0
Bi-CGRNN + GoogleW2Vs	85.7	77.74
Bi-GRNN + CharAVs + GoogleW2Vs	86.0	79.09
Bi-GRNN + LexW2Vs + GoogleW2Vs	88.0	78.79

Table 3: Accuracy of different models for binary classification.

CharAVs are more effective in small dataset than LexW2Vs. In addition, the Bi-CGRNN enhanced CharAVs and LexW2Vs have a great impact on Twitter datasets. Table 4 displays the effectiveness of our model in predicting the tweets. In the table 4, the Bi-GRNN using LexW2Vs captures the positive words (green words) and negative words (red words) for computing scores and predicts wrong labels because of the contexts of tweets while the Bi-CGRNN enhanced CharAVs and LexW2Vs recognizes contexts for true prediction. For example, the model using LexW2Vs predicts the last tweet to be positive because 'strong' word has sentiment stronger than 'no' word, however, the context of this tweet is negative. The pre-train word vectors are good, universal feature extractors. The syntactic contexts support in dealing context problems in tweets and the lexicons support word embeddings in dealing the sentiment of tweets. The difference between our model and other approaches is the ability of our model to capture enough features and combine these features at high level. In addition, the usage of DeepCNN for characters can learn a structure of words in higher abstract level. LexW2Vs and syntactic contexts

Model	Input from HCR Corpus	Gold Label	Prediction
Bi-CGRNN + CharAVs + LexW2Vs	@seanbaran74 well that's what's next. after #hcr they'll save the environment, give us CFLs and take	Negative	True

contribute in supporting information for word embeddings. This helps the model not only learns to recognize single n-grams of a word, negation, but also patterns in n-grams led to form a structure significance of a sentence.

4 Conclusions

In the present work, we build a model that solves four challenges in Twitter: syntax, semantic, sentiment and context. Our results show the well-establish evidence that CharAVs, LexW2Vs and DependencyW2Vs are important ingredients for ContinuousW2Vs in increasing classification accuracy for sentiment analysis. Our source and processed data are available at Github⁴.

Abstract

In this paper we propose a lightly-supervised framework to rapidly build text classifiers for contextual advertising. In contextual advertising, advertisers often want to target to a specific class of webpages most relevant to their product, which may not be covered by a pre-trained classifier. Moreover, the advertisers are only interested in the target class. Therefore, it is more suitable to model as a one-class classification problem, in contrast to traditional classification problems where disjoint classes are defined a priori.

We first apply two state-of-the-art lightly-supervised classification models, generalized expectation (GE) criteria (Druck et al., 2008) and multinomial naïve Bayes (MNB) with priors (Settles, 2011) to one-class classification where the user only provides a small list of labeled words for the target class. We fuse the two models together by using MNB to automatically enrich the constraints for GE training. We also explore ensemble method to further improve the accuracy. On a corpus of real-time bidding requests, the proposed model achieves the highest average F_1 of 0.69 and closes half of the gap between previous state-of-the-art lightly-supervised models to a fully-supervised MaxEnt model.

1 Introduction

Contextual advertising (or contextual targeting) is a technique to maximize the relevance of online advertisements by performing page analysis of the webpages. Contextual advertising is closely related to text classification problem, which is well-

known to the NLP community. Underlying, the system classifies webpages into predefined Ads verticals (categories). Based on the classification result, the real-time bidding (RTB) system will decide whether to bid for a particular page to display their Ads. Successful contextual advertising leads to lower advertising cost and higher click-through and conversion rate (Chatterjee et al., 2003; Broder et al., 2007).

Contextual targeting differs from traditional text classification in three ways. Firstly, with thousands of vastly different products coming to market every day, there are large number of categories (usually thousands of categories). Secondly, the advertisers often want to customize an existing category or create new categories to target a set of more relevant webpages. I.e. the classes are not static but evolving. It is therefore unrealistic to ask the advertisers to provide labeled webpages for each new or modified category they want to target. Lastly, while the advertisers can provide prior knowledge for the class they want to target, they cannot accurately specify the irrelevant (or negative) category because it likely covers broad topics in the wild. However, to train a classifier, usually labeled instances for each class are required. Because of these constraints, prominent service providers such as Peer39¹ and Grapeshot² build their contextual targeting systems mainly using hand-crafted keywords instead of learning based approaches.

In this work, we model contextual targeting as lightly-supervised one-class classification problem. The algorithm takes unlabelled documents³ DOC_U and the user provided keywords S_c for the

¹ <https://www.sizmek.com/peer39/>

² <https://www.grapeshot.com/>

³We classify only based on the text in the webpages. Henceforth we use “document” to refer to “webpage”, conforming to the terminology commonly used in NLP.

target class c as input and returns a classifier M_c that can classify documents belonging to class c . It is lightly-supervised because we do not use any document labels, but labeled keywords instead. It is one-class classification because the users need to provide labeled keywords only for the class they want to target, not the negative class.

We apply two state-of-the-art lightly-supervised classification models, generalized expectation (GE) criteria (Druck et al., 2008) and multinomial naïve Bayes (MNB) with priors (Settles, 2011) in the one-class classification setting. Inspired by the relative strength and weakness of the two models, we propose a novel approach to fuse them together where MNB is trained first. The salient words are read off from the posterior class-word distributions and automatically added to form additional constraints for GE. We also employ ensemble method to produce a final classifier that closed more than half of the gap between previous state-of-the-art lightly-supervised models to a fully-supervised MaxEnt model.

The contributions of this paper are:

1. Extended state-of-the-art semi-supervised classifiers for one-class classification problem.
2. Enriched expectation constraints for GE using a MNB model trained using EM algorithm.
3. Successfully employed ensemble method to produce a final classifier that closed more than half of the gap between previous state-of-the-art semi-supervised models to a fully-supervised MaxEnt model.

The paper is organized as follows: Section 2 presents previous works in two related fields: semi-supervised classification and one-class classification. We review the two previous state-of-the-art models we depend heavily on, generalized expectation (GE) criteria and multinomial naïve Bayes (MNB) with priors in Section 3 and 4, followed by applying them to one-class classification problem (Section 5). Section 6 describes two distinct approaches to combine these two models together. In section 7, we present our experimental results. Lastly, we present conclusions and suggest future directions.

2 Related Work

2.1 Semi-Supervised Text Classification

Supervised text classification methods were successfully applied to various tasks, such as sentiment analysis (Pang et al., 2002; Wang and Manning, 2012), information extraction (Jin et al., 2013) and stance recognition (Hasan and Ng, 2014). The main problem of supervised classification technique is that it requires sizeable set of labeled training documents for each predefined class.

Various semi-supervised classification methods have been proposed to address the lack of training documents. We are particularly interested in *lightly-supervised* methods that exploit prior knowledge (usually in the form of labeled words for each class) and eliminate the need of any labeled documents. Two main categories of approaches are often employed to exploit the word labels. The first one is to build an initial weak classifier to obtain soft labels of the documents and then apply expectation maximization (EM) algorithm (Liu et al., 2004; Schapire et al., 2002). More recently, there is growing interest in methods that incorporate labeled word features directly into the classification model, either as constraints in an objective function (Druck et al., 2008; Zhao et al., 2016) or as priors on model parameters (Settles, 2011; Lucas and Downey, 2013).

Liu et al. (2004) proposed to label a set of representative words for each class, which is used to extract a set of documents as the initial training set. EM algorithm was then applied to iteratively refine the labels of the documents and to improve the accuracy of the classifier. Schapire et al. (2002) used hand-crafted rules based on keywords to label documents, and modified AdaBoost to fit both the labeled training data and the soft-labeled data.

The methods above convert domain knowledge into labeled documents. An alternative approach is to use the domain knowledge to provide model constraints. Druck et al. (2008; 2011) proposed generalized expectation (GE) criteria, which use labeled words to constrain the model's predictions on unlabeled data. GE has been successfully applied on different tasks, such as text categorization (Druck et al., 2008), semantic tagging (Druck et al., 2009), information structure analysis of scientific documents (Guo et al., 2015) and language identification in mixed-language documents (King and Abney, 2013). Similarly, Zhao et al. (2016)

made use of word-level statistical constraints to preserve the class distribution on words, so that the classifier will not drift due to the extra (noisy) labels introduced by EM algorithm.

Labeled words can also provide priors for generative models. Settles (2011) extended multinomial naïve Bayes model to allow labels for words by increasing their Dirichlet prior. His method consists of three steps: firstly to estimate the initial parameters using only the priors; secondly to apply the induced classifier on unlabeled documents; lastly to re-estimate the model parameters using both labeled and probabilistically-labeled documents. Using an interactive approach to query document and word labels from the user, the system can achieve 90% of state-of-the-art performance after a few minutes of annotation.

Dermouche et al. (2013) also exploited prior knowledge in a multinomial naïve Bayes model. Instead of modifying the priors, their method artificially modifies the occurrences of the terms in the right and wrong class. This method uses the full set of document labels and a large sentiment lexicon consisting of around eight thousand terms, making it less suitable for the lightly-supervised setting for contextual targeting.

2.2 One-Class Classification

Another area related to our work is one-class classification problem (Moya and Hush, 1996), where no labeled negative instance is available. One-class SVM (Schölkopf et al., 2001) learns only from positive examples. The model classifies new instances as similar or different to the training set. Lee et al. (2003) observed that this approach is highly sensitive to the input representation and it did not perform well for text classification.

We highlight that one-class classification problem is not restricted to using only positive labeled instances. When positive and *unlabelled* data are available, a popular approach is to randomly assign the negative class to unlabelled instances in the beginning and iteratively refine the labels using EM-like algorithms (Yu et al., 2002; Liu et al., 2003; Li et al., 2009).

Our task lies in the intersection of semi-supervised classification and one-class classification, yet it differs from both tasks in principled ways. Aforementioned semi-supervised classification algorithms were applied on corpora with predefined (two or more) classes. When the ir-

relevant (or negative) class refers to “everything else”, we cannot accurately provide prior knowledge for the irrelevant class using expert domain knowledge. On the other hand, previous one-class classification problems assumed the presence of labeled instances of the positive class, without which neither the similarity-based nor the EM-like algorithms can be applied directly.

3 Generalized Expectation (GE) Criteria

Generalized expectation (GE) criteria (Mann and McCallum, 2008) are constraint terms used to train discriminative linear models. GE provides a flexible framework for encoding prior knowledge to provide training signals for parameter estimation. When applied to text classification, constraint functions G_k are expressed as the reference distribution of the feature labels.⁴ For example $puck \rightarrow \{baseball : 0.1, hockey : 0.9\}$ means 90% of documents containing the word “puck” should be labeled the class “hockey”. Each constraint is translated into a term to add to the objective function to encourage parameters that yield predictions conforming to the reference distribution on unlabeled documents. Formally, the combined objective function can be written as:

$$C = - \sum_{k \in K} D(\hat{p}(y|x_k > 0) || \tilde{p}(y|x_k > 0)) - \Delta$$

where $\hat{p}(y|x_k > 0)$ is the reference distribution, $\tilde{p}(y|x_k > 0)$ is the empirical distribution and D is a distance function. Δ is shorthand for a zero-mean σ^2 -variance Gaussian prior on parameters.

GE does not require one-to-one correspondence between constraint functions G_k and model feature functions. The optimization problem for GE is always under-constrained, meaning the number of parameters to be estimated far exceeds the number of constraints the user provides. To make the optimization tractable, the model updates the gradient for an unlabeled feature j based on how often j co-occurs with a labeled feature k .⁵ Hence Druck et al. (2009) commented that GE can also be interpreted as a bootstrapping method that estimates parameters using limited training signals.

⁴The features consist of word unigrams in both Druck et al. (2008) and in this paper.

⁵Please refer to Druck et al. (2008) for the derivation.

4 Multinomial Naïve Bayes (MNB) with Priors

Multinomial Naïve Bayes is a generative classification algorithm making a strong assumption that each word w_k occurs independent of each other when conditioned on the class label c_j . Hence,

$$\hat{y} = \underset{j \in \{1, \dots, J\}}{\operatorname{argmax}} P(c_j) \prod_{k=1}^{n_d} P(w_k | c_j)$$

where $P(c_j)$ is the probability of class c_j and $P(w_k | c_j)$ is the probability of generating word w_k given class c_j . $P(w_k | c_j)$ is estimated using:

$$P(w_k | c_j) = \frac{m_{jk} + \sum_i P(c_j | x^{(i)}) f_k(x^{(i)})}{Z(f_k)}$$

where $f_k(x^{(i)})$ is the count of word w_k in the i th document in the training set and $Z(f_k)$ is a normalization constant summing over all words in the vocabulary. Typically, a uniform Laplacian prior is used (all m_{jk} have the same value 1). To incorporate the word labels, Settles (2011) increased the prior m_{jk} by α if word w_k is labeled with class c_j . To exploit unlabeled documents, Settles (2011) used an initial model estimated with only the priors to probabilistically label the unlabeled documents. The probabilistically labeled documents are combined with the labeled words and documents to estimate the parameters for the final model using a single-iteration EM algorithm.

5 Applying GE and MNB to One-Class Classification

In Druck et al. (2009) and Settles (2011), the authors ran their models using human labeled keywords for each predefined class. Analogous to one-class classification, where the system takes only positive (and unlabelled) documents as input, We now try to train GE and MNB with priors using only *user-provided* positive keywords and unlabelled documents as input.⁶

GE cannot cope with one-class classification by nature. If we only provide labeled words for the “+” class, the “+” label will be “propagated” to all the word features co-occurring with a labeled word. The trained classifier will predict “+” for

⁶We use positive/+ to denote the target class and negative/- to denote the irrelevant class.

all the unseen documents. In contrary, MNB with priors can be trained using only the “+” keywords. When we increase the prior for labeled words in class c_+ , it decreases $P(w'_k | c_+)$ with respect to $P(w'_k | c_-)$ for an unlabeled feature w'_k (the normalization constant Z_+ is greater than Z_- due to the increased priors in the “+” class). This is desirable because if a document only contains random unlabeled words, the model will predict “-”.

5.1 Labeling Words for the Target Class

Liu et al. (2004) observed that it is difficult for the user to come up with a set of representative words for each class independently because they usually can only provide a few words, which are insufficient to train an accurate classifier. Therefore, it is critical that the system can assist the user by suggesting a good set of candidate words to label instead of asking them to come up with all the words by themselves. We use a hybrid candidate word suggestion method that asks the user to input a seed keyword (in most cases, it is merely the class name they want to target) and the system will suggest other words that are closely related to it. We make use of word vectors (Mikolov et al., 2013), pointwise mutual information (PMI) (Church and Hanks, 1990) and Wikipedia.

Word vectors have been widely used to measure word similarities (Tang et al., 2014; Levy et al., 2015). We calculate cosine similarity using pre-trained GloVe word vectors⁷ (Pennington et al., 2014) to find similar words to the seed word. Word vectors can identify linguistically or semantically related words. E.g. “luxurious” and “lavish” are the nearest neighbours of “luxury”.

We use PMI to mine the words that tend to co-occur with the seed word. For example, “resort”, “BMW”, “Gucci” all receive high PMI scores with “luxury” while none of them are near the word “luxury” in the word vector space.

Lastly, we automatically extract the keywords and keyphrases from the Wikipedia page of the seed word (if the page exists). This method is aimed to cover the technical terms that are confident indicators but are rarely observed in the corpus. E.g. “Somniloquy” is a synonym of “sleep-talking” but it is thirty times less frequent than the latter.

We show the top 50 candidate words suggested by each of the three methods to the user, who will

⁷<http://nlp.stanford.edu/projects/glove/>

select relevant words to add to the keyword list. Based on user study reported in Settles (2011), labeling words takes on average 3.2 seconds. This suggests the total time for the user to complete labeling is within 10 minutes.

5.2 Special Treatment for GE

As mentioned above, GE also requires labeled words for the “-” class to train. However, it is impractical and time-consuming to ask the users to label a list of words irrelevant to the target class. We form the keyword list for the “-” class by simply performing a multinomial sampling from the vocabulary, where each word is weighted by its log count in the unlabeled corpus. This assumes that a randomly sampled word is unlikely to be a keyword for the target class. Additionally, we use L_2 -based penalty instead of the default KL divergence because previous work showed that it is more robust to label noises (Druck, 2011).

The labeled words are translated into GE constraints using Schapire-distributions (Schapire et al., 2002). For the user labeled “+” keywords, We assign $P_+ = 0.9$ and $P_- = 0.1$. I.e. if “puck” is a labeled word for the class “hockey”, the corresponding constraint will be $puck \rightarrow \{hockey : 0.9, others : 0.1\}$. For the “-” class, we randomly sample 20 times more keywords than the “+” class but use a more even distribution, where we set $P_+ = 0.25$ and $P_- = 0.75$. This is in the same spirit with *biased sparsity* in Wang et al. (2016), which says the word distribution of the targeted topic only focuses on a small number of representative words and the word distribution of non-targeted topics contain almost all possible words. We do not use too many negative keywords (constraints) because it significantly increases the computational cost to train GE.

We refer to this system as *GE/Random* because it uses randomly sampled “-” keywords.

6 Combining GE and MNB

6.1 Using MNB to Enrich GE Constraints

Settles (2011) observed that MNB outperformed GE when the number of labeled words were between five to 20. When the number of labeled keywords increased (with more prior knowledge), GE usually performed better. This inspired us to fuse the two models together, in which MNB’s role is to bootstrap more labeled words to train a more accurate GE classifier.

We first use the user labeled “+” words and unlabeled documents to train an MNB model. Then we obtain a list of salient words for the “+” class which are not already covered in the user labeled words. We use a simple rule that word w_k will be added to the set S_{MNB} if $\frac{P(w_k|c_+)}{P(w_k|c_-)} > 10$ (w_k appears 10 times more likely given the “+” class than given the “-” class).⁸ In this way, we exploit the strength of a generative model (MNB) to discover latent structure and topics from unlabeled data to augment a discriminative model (GE), which usually achieves higher accuracy for classification tasks.

Algorithm 1 summarizes the training procedure for the combined model GE/MNB. Line 2-4 are the procedure to train a MNB with priors model with EM algorithm. We obtain the list of salient words for the target class in line 5. All the words in S_{user} , S_{MNB} and S_{rand} are translated into GE constraints to train the final GE/MNB model.

Algorithm 1: Train GE/MNB Classifier

```

1 train classifier ( $S_{user}, DOC_U$ );
   Input : User labeled features  $S_{user}$  and unlabeled
          corpus  $DOC_U$ 
   Output: Trained GE/MNB classifier
2  $M_{MNB/Priors} = \text{train}(S_{user})$ ;
3  $DOC_{prob} = M_{MNB/Priors}.\text{classify}(DOC_U)$ ;
4  $M_{MNB/Priors+EM_1} = \text{train}(S_{user}, DOC_{prob})$ ;
5  $S_{MNB} = M_{MNB/Priors+EM_1}.\text{getSalientWords}()$ ;
6  $S_{rand} = \text{randomlySampleWords}()$ ;
7  $M_{GE/MNB} = \text{train}([S_{user}, S_{MNB}, S_{rand}], DOC_U)$ ;
8 return  $M_{GE/MNB}$ ;

```

6.2 Using Ensemble Approach

Another intuitive way to combine GE and MNB is to train the two classifiers independently and use ensemble approach (Dietterich, 2000) to combine the prediction results of the two classifiers. GE and MNB behave quite differently although they make use of the same labeled keywords. The variety they introduce is a critical condition for the success of ensemble approach (Dietterich, 2000).

We first group the aforementioned classifiers into two families based on the algorithm to train their final classifier. The GE family includes GE/Random and GE/MNB. The MNB family includes MNB/Priors and MNB/Priors+EM₁. We used a simple ensemble rule: the classifier ensemble outputs “+” if and only if at least one GE **and**

⁸We also tried to replace the randomly sampled “-” keywords with words that have high $\frac{P(w_k|c_-)}{P(w_k|c_+)}$. However, the result was worse in general.

one MNB classifier output “+”. We denote this classifier ensemble as $GE_1 \wedge MNB_1$. We used this heuristic rule instead of stacking or other more sophisticated techniques because it does not require any labeled documents to train the ensemble.

7 Evaluation

7.1 Baselines and Datasets

We compared the proposed GE/MNB and $GE_1 \wedge MNB_1$ with various baselines. For GE, we experimented with GE/Random, which uses user provided keywords for the target class and randomly sampled negative keywords to train. For MNB with priors, we ran two configurations following Settles (2011), MNB/Priors+EM₁, the full model using EM algorithm and MNB/Priors, the initial model using only user labeled priors. We also compared with a keyword voting baseline and a fully-supervised MaxEnt model trained using labeled documents. The results of the MaxEnt model is for reference purpose, as our goal is not to beat a supervised model, but to improve from previous lightly-supervised models.

We use the GE implementation in the MALLET toolkit⁹ and the implementation of MNB with priors provided by Settles (2011)¹⁰, which also extends from MALLET. All the classifiers share the same standard preprocessing pipeline.

We made use of two datasets for evaluation. The first dataset is sampled from the actual real-time bidding (RTB) requests. The second one is the well-known 20 Newsgroups corpus (Lang, 1995). The results on the first corpus is more relevant and indicative while the results on the 20 Newsgroups allows to benchmark the models beyond the application of RTB.

7.2 Evaluations on RTB Dataset

We created the real-time bidding (RTB) dataset from a database of 30 million historical requests. We used open-source Boilerpipe library (Kohlschütter et al., 2010) to extract the textual content from the webpages and we obtained the category labels for the webpages from a leading Ad Exchange platform (in total 2,200 categories).¹¹

⁹<http://mallet.cs.umass.edu>

¹⁰<https://github.com/burrsettles/dualist>

¹¹The dataset is available at <https://sites.google.com/site/jinyipingnus/research> for future works to reproduce our results.

Class	Docs	+/- Ratio
Cold & Flu	1,363	1:50
Cancer	3,234	1:20
Diabetes	1,394	1:50
Sleep Disorder	2,592	1:25
Nutrition	22,176	1:3
Sampled “-” docs	68,626	

Table 1: Number of documents for each class and relevant/irrelevant class ratio.

We randomly selected five categories in the “Health” domain to carry out evaluation. For each experiment, the documents labeled with one of the selected categories were assigned to be the “+” class. We uniformly sampled from all other categories to use as the “-” class. We hide the document labels during training for all models except for MaxEnt.

Table 1 shows the number of documents for each class and the rounded +/- ratio. We can see that the +/- classes are very imbalanced, which is to be expected in real-world RTB requests. In practice, we cannot simply perform up- or down-sampling without the labels of the documents. Therefore, we did not try to modify the class ratio to make it more balanced. For each set of experiment, we used the same 9:1 split of training and testing set.

One author of this paper composed the labeled keywords with the assistance of the hybrid keyword suggestion method described in Section 5.1. The keywords for each class were composed independently. He was not allowed to add words not suggested by the system so that we can validate the utility of the keyword suggestion method. Table 2 shows the keywords for each category he composed. The labeling stopped when either he finished reviewing all the suggested words or the time reached 10 minutes.

Table 3 shows the P/R/F₁ scores of each classifier for each class. We did not use the accuracy measure because the ratio of +/- classes is strongly imbalanced. We used the same set of user labeled keywords for system 0-5. For GE and MNB with priors, we used the parameter setting proposed in the original papers (GE: Gaussian Prior=1; MNB: $\alpha=50$).

We can make some interesting observations from the result. Firstly, the keyword voting approach lagged behind all of the lightly-supervised models. This shows that learning based approaches improved from a simple rule-based sys-

Table 2: Labeled words for each class

tem using the same prior knowledge.

Secondly, GE/Random and MNB/Priors+EM₁ performed comparably, with GE/Random performing slightly better.

The combined GE/MNB classifier improved recall by 4% from GE/Random. This is mainly due to the additional keywords we obtained from the MNB model. On average, 53 new keywords were added for each classifier, doubling the number of the original user labeled words.

The average precision dropped slightly due to the decreased precision of “ColdFlu” and “Cancer” class. After error analysis, we identified that for these two classes, some common words frequently co-occurring with user labeled keywords were introduced by MNB as new constraints. E.g. for “ColdFlu”: cold, congestion, swine; for “cancer”: breast, prostate. Such words are not real indicators of the target class and likely cause the precision to drop. Table 4 shows the top 10 automatically added keywords for each class.

The performance of the classifier ensemble GE₁∧MNB₁ was impressive, improving a further 4% from GE/MNB and reaching macro average F₁ score of 0.69. The system achieved the highest or close to the highest F₁ for all the classes among the lightly-supervised models. Its F₁ score

is only 3% lower than the fully-supervised MaxEnt model. This is particularly encouraging because the MaxEnt model was trained using many thousands of labeled training documents.

7.3 Evaluations on 20 Newsgroups Corpus

We also applied the systems on the well-known 20 Newsgroups corpus (Lang, 1995) to facilitate future comparisons. The corpus contains 20 different newsgroups having 1,000 documents each. We used the documents with file name ending with “0” for testing (roughly 10% of the corpus) and the rest for training.

Following Druck et al. (2008), we used mutual information of the candidate words with the oracle document labels to mine the keywords for each class. This simulates the scenario where a domain expert can suggest and label relevant keywords. We further removed the keywords that appear in more than two classes. While keywords that appear in many classes can be “balanced out” in multi-class classification setting. We find that including them will usually harm the performance for one-class classification. We used in total 262 keywords (on average 13.1 per class).

We ran 20 experiments using each newsgroup as the target class at a time. We differentiate from Druck et al. (2008) and Settles (2011) mainly in that for each experiment, we only take the keywords for the target class as input, but not the keywords for other classes. We made this decision in order to be consistent with the one-class classification problem. We can think of this experiment as more lightly-supervised than Druck et al. (2008) and Settles (2011). Table 5 shows the performance of various systems.

We were not surprised that GE performed worse than the MNB counterpart given the small list of labeled words. By bootstrapping labeled words using MNB, the GE/MNB model improved recall by 3% at the sacrifice of 2% precision, which is similar to the result on the RTB dataset.

The classifier ensemble GE₁∧MNB₁ still managed to achieve the highest precision and F₁ score (tie with MNB/Priors+EM₁), showing its robustness despite the lackluster performance of individual classifiers.

We also experimented with MaxEnt varying the amount of the training data. MaxEnt (γ=0.1) used 10% of the corpus (2,000 labelled documents) for training. Its average F₁ score is similar to the

System	Cold Flu	Cancer	Diabetes	Sleep Dis.	Nutrition	Macro Avg.
0: keyword voting	.44/.63/.52	.60/.59/.60	.65/.61/.63	.53/.65/.58	.64/.44/.52	.57/.59/.58

2: MNB/Priors+EM ₁	.63/.64/ .63
3: MNB/Priors	.39/ .69 /.50
4: GE/MNB	.60/.53/.56
5: GE ₁ ∧ MNB ₁	.67 /.60/ .63
MaxEnt ($\gamma = 0.1$)	.86/.42/.57
MaxEnt	.88/.72/.79

Table 5: Macro average Precision/Recall/ F_1 scores for each classifier on 20 Newsgroups corpus.

lightly-supervised models. Based on the user experiments in Settles (2011), annotating documents takes 10.8s on average. Therefore the estimated time to annotate the training data for this model is 6 hours, roughly 25 times the time needed to label 262 keywords. The last line shows the result of the MaxEnt model using the full training set. Its average F_1 score is 16% higher than GE₁∧ MNB₁.

The larger gap is likely because the keywords used on the 20 Newsgroups Corpus are automatically extracted from the corpus, while the keywords used on the RTB dataset exploited external resources (pre-trained word vectors and Wikipedia) and they are curated by a human annotator. In the real-world scenario, the keywords will be composed by non-technical users, instead of researchers in NLP who are familiar with the algorithm. Therefore, we cannot make assumptions of the quality of the keywords the user composes. However, this further confirms the importance of a good keyword suggestion method to assist the user to compose high-quality keywords.

8 Conclusions and Future Works

This paper proposed a framework to build lightly-supervised one-class text classifiers by applying generalized expectation (GE) criteria (Druck et al., 2008) and multinomial naïve Bayes (MNB) with priors (Settles, 2011). The classification methods make use of user-labeled words for the target class as the form of supervision and do not require any labeled documents. Motivated by the relative strengths of the two models, we merged them by using MNB to enrich the set of GE constraints.

We further improved the classification accuracy by combining the output of two families of classifiers through ensemble method. This resulted in a classifier ensemble which achieved an

average of 0.69 F_1 score on a dataset of webpages from real-time bidding requests. It is 5% or 6% higher than previous state-of-the-art lightly-supervised models and 3% lower than a supervised MaxEnt model.

The framework has been deployed into an online advertising platform where advertisers can build customized classifiers to target their Ads to the most relevant webpages.

A direction for future work is to further improve the classification accuracy and to match the performance of not just a MaxEnt model, but a more recent fully-supervised deep neural network models such as Lai et al. (2015). This would likely require a more complex non-linear model and a novel method to train such model in a lightly-supervised manner.

In ongoing research, we are exploring to build multi-modal classifiers by exploiting information in the webpages beyond the textual content, such as URLs and images. We are also exploring transfer learning methods which can use the predictions for existing classes to improve the accuracy for new classes.

Abstract

Despite successful applications across a broad range of NLP tasks, conditional random fields (“CRFs”), in particular the linear-chain variant, are only able to model local features. While this has important benefits in terms of inference tractability, it limits the ability of the model to capture long-range dependencies between items. Attempts to extend CRFs to capture long-range dependencies have largely come at the cost of computational complexity and approximate inference. In this work, we propose an extension to CRFs by integrating external memory, taking inspiration from memory networks, thereby allowing CRFs to incorporate information far beyond neighbouring steps. Experiments across two tasks show substantial improvements over strong CRF and LSTM baselines.

1 Introduction

While long-range contextual dependencies are prevalent in natural language, for tractability reasons, most statistical models capture only local features (Finkel et al., 2005). Take the sentence in Figure 1, for example. Here, while it is easy to determine that *Interfax* in the second sentence is a named entity, it is hard to determine its semantic class, as there is little context information. The usage in the first sentence, on the other hand, can be reliably disambiguated due to the post-modifying phrase *news agency*. Ideally we would like to be able to share such contexts across all usages (and variants) of a given named entity for reliable and consistent identification and disambiguation.

A related example is forum thread discourse analysis. Previous work has largely focused on

linear-chain Conditional Random Fields (CRFs) (Wang et al., 2011; Zhang et al., 2017), framing the task as one of sequence tagging. Although CRFs are adept at capturing local structure, the problem does not naturally suit a linear sequential structure, i.e., a post may be a reply to either a neighbouring post or one posted far earlier within the same thread. In both cases, contextual dependencies can be long-range, necessitating the ability to capture dependencies between arbitrarily distant items. Identifying this key limitation, Sutton and McCallum (2004) and Finkel et al. (2005) proposed the use of CRFs with skip connections to incorporate long-range dependencies. In both cases the graph structure must be supplied a priori, rather than learned, and both techniques incur the need for costly approximate inference.

Recurrent neural networks (RNNs) have been proposed as an alternative technique for encoding sequential inputs, however plain RNNs are unable to capture long-range dependencies (Bengio et al., 1994; Hochreiter et al., 2001) and variants such as LSTMs (Hochreiter and Schmidhuber, 1997), although more capable of capturing non-local patterns, still exhibit a significant locality bias in practice (Lai et al., 2015; Linzen et al., 2016).

In this paper, taking inspiration from the work of Weston et al. (2015) on memory networks (MEMNETS), we propose to extend CRFs by integrating external memory mechanisms, thereby enabling the model to look beyond localised features and have access to the entire sequence. This is achieved with attention over every entry in the memory. Experiments on named entity recognition and forum thread parsing, both of which involve long-range contextual dependencies, demonstrate the effectiveness of the proposed model, achieving state-of-the-art performance on the former, and outperforming a number of strong baselines in the case of the latter. A full imple-

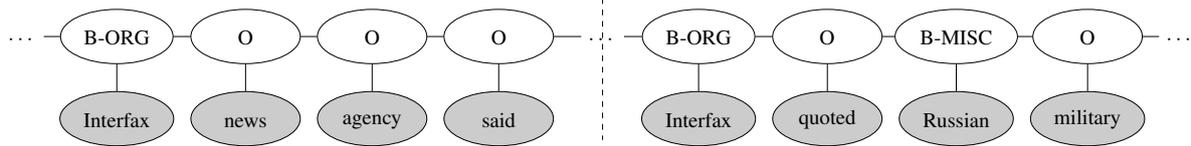

Figure 1: A NER example with long-range contextual dependencies. The vertical dash line indicates a sentence boundary.

mentation of the model is available at: <https://github.com/liufly/mecrf>.

The paper is organised as follows: after reviewing previous studies on capturing long range contextual dependencies and related models in Section 2, we detail the elements of the proposed model in Section 3. Section 4 and 5 present the experimental results on two different datasets: one for thread discourse structure prediction and the other named entity recognition (NER), with analyses and visualisation in their respective sections. Lastly, Section 6 concludes the paper.

2 Related Work

In this section, we review the different families of models that are relevant to this work, in capturing long-range contextual dependencies in different ways.

Conditional Random Fields (CRFs). CRFs (Lafferty et al., 2001), in particular linear-chain CRFs, have been widely adopted and applied to sequence labelling tasks in NLP, but have the critical limitation that they only capture local structure (Sutton and McCallum, 2004; Finkel et al., 2005), despite non-local structure being common in structured language classification tasks. In the context of named entity recognition (“NER”), Sutton and McCallum (2004) proposed skip-chain CRFs as a means of alleviating this shortcoming, wherein distant items are connected in a sequence based on a heuristic such as string identity (to achieve label consistency across all instances of the same string). The idea of label consistency and exploiting non-local features has also been explored in the work of Finkel et al. (2005), who take long-range structure into account while maintaining tractable inference with Gibbs sampling (Geman and Geman, 1984), by performing approximate inference over factored probabilistic models. While both of these lines of work report impressive results on information extraction tasks, they come at the price of high computational cost and

incompatibility with exact inference.

Similar ideas have also been explored by Krishnan and Manning (2006) for NER, where they apply two CRFs, the first of which makes predictions based on local information, and the second combines named entities identified by the first CRF in a single cluster, thereby enforcing label consistency and enabling the use of a richer set of features to capture non-local dependencies. Liao and Grishman (2010) make a strong case for going beyond sentence boundaries and leveraging document-level information for event extraction.

While we take inspiration from these earlier studies, we do not enforce label consistency as a hard constraint, and additionally do not sacrifice inference tractability: our model is capable of incorporating non-local features, and is compatible with exact inference methods.

Recurrent Neural Networks (RNNs). Recently, the broad adoption of deep learning methods in NLP has given rise to the prevalent use of RNNs. Long short-term memories (“LSTMs”: Hochreiter and Schmidhuber (1997)), a particular variant of RNN, have become particularly popular, and been successfully applied to a large number of tasks: speech recognition (Graves et al., 2013), sequence tagging (Huang et al., 2015), document categorisation (Yang et al., 2016), and machine translation (Cho et al., 2014; Bahdanau et al., 2014). However, as pointed out by Lai et al. (2015) and Linzen et al. (2016), RNNs — including LSTMs — are biased towards immediately preceding (or neighbouring, in the case of bi-directional RNNs) items, and perform poorly in contexts which involve long-range contextual dependencies, despite the inclusion of memory cells. This is further evidenced by the work of Cho et al. (2014), who show that the performance of a basic encoder–decoder deteriorates as the length of the input sentence increases.

Memory networks (MEMNETs). More recently, Weston et al. (2015) proposed memory

networks and showed that the augmentation of memory is crucial to performing inference requiring long-range dependencies, especially when document-level reasoning between multiple supporting facts is required. Of particular interest to our work are so-called “memory hops” in memory networks, which are guided by an attention mechanism based on the relevance between a question and each supporting context sentence in the memory hop. Governed by the attention mechanism, the ability to access the entire sequence is similar to the soft alignment idea proposed by Bahdanau et al. (2014) for neural machine translation. In this work, we borrow the concept of memory hops and integrate it into CRFs, thereby enabling the model to look beyond localised features and have access to the whole sequence via an attention mechanism.

3 Methodology

In the context of sequential tagging, we assume the input is in the form of sequence pairs: $\mathcal{D} = \{\mathbf{x}^{(n)}, \mathbf{y}^{(n)}\}_{n=1}^N$ where $\mathbf{x}^{(n)}$ is the input of the n -th example in dataset \mathcal{D} and consists of a sequence: $\{x_1^{(n)}, x_2^{(n)}, \dots, x_T^{(n)}\}$. Similarly, $\mathbf{y}^{(n)}$ is of the same length as $\mathbf{x}^{(n)}$ and consists of the corresponding labels $\{y_1^{(n)}, y_2^{(n)}, \dots, y_T^{(n)}\}$. For notational convenience, hereinafter we omit the superscript denoting the n -th example.

In the case of NER, each x_t is a word in a sentence with y_t being the corresponding NER label. For forum thread discourse analysis, x_t represents the text of an entire post whereas y_t is the dialogue act label for the t -th post.

The proposed model extends CRFs by integrating external memory and is therefore named a **Memory-Enhanced Conditional Random Field** (“ME-CRF”). We take inspiration from Memory Networks (“MEMNETs”: Weston et al. (2015)) and incorporate so-called memory hops into CRFs, thereby allowing the model to have unrestricted access to the whole sequence rather than localised features as in RNNs (Lai et al., 2015; Linzen et al., 2016).

As illustrated in Figure 2, ME-CRF can be divided into two major parts: (1) the memory layer; and (2) the CRF layer. The memory layer can be further broken down into three main components: (a) the input memory $\mathbf{m}_{1:t}$; (b) the output memory $\mathbf{c}_{1:t}$; and (c) the current input \mathbf{u}_t , which represents the current step (also known as the “question” in the context of MEMNET). The input and

output memory representations are connected via an attention mechanism whose weights are determined by measuring the similarity between the input memory and the current input. The CRF layer, on the other hand, takes the output of the memory layer as input. In the remainder of this section, we detail the elements of ME-CRF.

3.1 Memory Layer

3.1.1 Input memory

Every element (word/post) in a sequence \mathbf{x} is encoded with $\mathbf{x}_t = \Phi(x_t)$, where $\Phi(\cdot)$ can be any encoding function mapping the input x_t into a vector $\mathbf{x}_t \in \mathbb{R}^d$. This results in the sequence $\{\mathbf{x}_1, \dots, \mathbf{x}_T\}$. While this new sequence can be seen as the memory in the context of MEMNETs, one major drawback of this approach, as pointed out by Seo et al. (2017), is the insensitivity to temporal information between memory cells. We therefore follow Xiong et al. (2016) in injecting temporal signal into the memory using a bi-directional GRU encoding (Cho et al., 2014):

$$\vec{\mathbf{m}}_t = \overrightarrow{\text{GRU}}(\mathbf{x}_t, \vec{\mathbf{m}}_{t-1}) \quad (1)$$

$$\overleftarrow{\mathbf{m}}_t = \overleftarrow{\text{GRU}}(\mathbf{x}_t, \overleftarrow{\mathbf{m}}_{t+1}) \quad (2)$$

$$\mathbf{m}_t = \tanh(\overrightarrow{\mathbf{W}}_m \vec{\mathbf{m}}_t + \overleftarrow{\mathbf{W}}_m \overleftarrow{\mathbf{m}}_t + \mathbf{b}_m) \quad (3)$$

where $\overrightarrow{\mathbf{W}}_m$, $\overleftarrow{\mathbf{W}}_m$ and \mathbf{b}_m are learnable parameters.

3.1.2 Current input

This is used to represent the current step x_t , be it a word or a post. As in MEMNETs, we want to enforce the current input to be in the same space as the input memory so that we can determine the attention weight of each element in the memory by measuring the relevance between the two. We denote the current input by $\mathbf{u}_t = \mathbf{m}_t$.

3.1.3 Attention

To determine the attention value of each element in the memory, we measure the relevance between the current step \mathbf{u}_t and \mathbf{m}_i for $i \in [1, t]$ with a softmax function:

$$p_{t,i} = \text{softmax}(\mathbf{u}_t^\top \mathbf{m}_i) \quad (4)$$

where $\text{softmax}(a_i) = \frac{e^{a_i}}{\sum_j e^{a_j}}$.

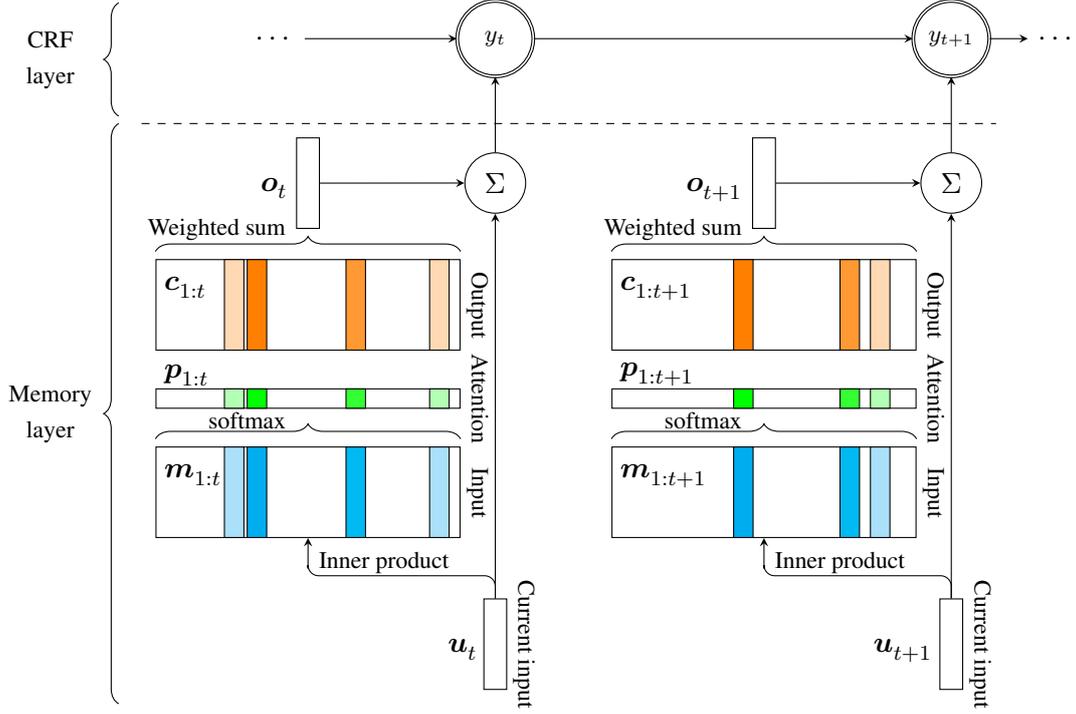

Figure 2: Illustration of ME-CRFs with a single memory hop, showing the network architecture at time step t and $t + 1$.

3.1.4 Output memory

Similar to m_t , c_t is the output memory, and is calculated analogously but with a different set of parameters in the GRUs and tanh layers of Equations (1), (2) and (3). The output memory is used to generate the final output of the memory layer and fed as input to the CRF layer.

3.1.5 Memory layer output

Once the attention weights have been computed, the memory access controller receives the response o in the form of a weighted sum over the output memory representations:

$$o_t = \sum_i p_{t,i} c_i \quad (5)$$

This allows the model to have unrestricted access to elements in previous steps as opposed to a single vector h_t in RNNs, thereby enabling ME-CRFs to detect and effectively incorporate long-range dependencies.

3.1.6 Extension

For more challenging tasks requiring complex reasoning capabilities with multiple supporting facts from the memory, the model can be further extended by stacking multiple memory hops, in

which case the output of the k -th hop is taken as input to the $(k + 1)$ -th hop:

$$u_t^{k+1} = o_t^k + u_t^k \quad (6)$$

where u_t^{k+1} encodes not only information at the current step (u_t^k) but also relevant knowledge from the memory (o_t^k). In the scope of this work, we limit the number of hops to 1.

3.2 CRF Layer

Once the representation of the current step u_t^{K+1} is computed — incorporating relevant information from the memory (assuming the total number of memory hops is K) — it is then fed into a CRF layer:

$$s(\mathbf{x}, \mathbf{y}) = \sum_{t=0}^T \mathbf{A}_{y_t, y_{t+1}} + \sum_{t=1}^T \mathbf{P}_{t, y_t} \quad (7)$$

where $\mathbf{A} \in \mathbb{R}^{|\mathcal{Y}| \times |\mathcal{Y}|}$ is the CRF transition matrix, $|\mathcal{Y}|$ is the size of the label set, and $\mathbf{P} \in \mathbb{R}^{T \times |\mathcal{Y}|}$ is a linearly transformed matrix from u_t^{K+1} such that $\mathbf{P}_{t,:}^\top = \mathbf{W}_s u_t^{K+1}$ where $\mathbf{W}_s \in \mathbb{R}^{|\mathcal{Y}| \times h}$ with h being the size of m_t . Here, $A_{i,j}$ represents the score of the transition from the i -th tag to the j -th tag whereas $P_{i,j}$ is the score of the j -th tag at time i .

Using the scoring function in Equation (7), we calculate the score of the sequence \mathbf{y} normalised by the sum of scores of all possible sequences $\tilde{\mathbf{y}}$, and this becomes the probability of the true sequence:

$$p(\mathbf{y}|\mathbf{x}) = \frac{\exp(s(\mathbf{x}, \mathbf{y}))}{\sum_{\tilde{\mathbf{y}} \in \mathbf{Y}_{\mathbf{x}}} \exp(s(\mathbf{x}, \tilde{\mathbf{y}}))} \quad (8)$$

We train the model to maximise the probability of the gold label sequence with the following loss function:

$$\mathcal{L} = \sum_{n=1}^N \log p(\mathbf{y}^{(n)}|\mathbf{x}^{(n)}) \quad (9)$$

where $p(\mathbf{y}^{(n)}|\mathbf{x}^{(n)})$ is calculated using the forward-backward algorithm. Note that the model is fully end-to-end differentiable.

At test time, the model predicts the output sequence with maximum a posteriori probability:

$$\mathbf{y}^* = \arg \max_{\tilde{\mathbf{y}} \in \mathbf{Y}_{\mathbf{x}}} p(\tilde{\mathbf{y}}|\mathbf{x}) \quad (10)$$

Since we are only modelling bigram interactions, we adopt the Viterbi algorithm for decoding.

4 Thread Discourse Structure Prediction

In this section, we describe how ME-CRFs can be applied to the task of thread discourse structure prediction, wherein we attempt to predict which post(s) a given post directly responds to, and in what way(s) (as captured by dialogue acts). This is a novel approach to this problem and capable of natively handling both tasks within the same network architecture.

4.1 Dataset and Task

In this work, we adopt the dataset of Kim et al. (2010),¹ which consists of 315 threads and 1,332 posts, collected from the Operating System, Software, Hardware and Web Development subforums of CNET.² Every post has been manually linked to preceding post(s) in the thread that it is a direct response to (in the form of “links”), and the nature of the response for each link (in the form of “dialogue acts”, or “DAs”). In this dataset, it is not uncommon to see messages respond to posts which occur much earlier in the thread (based on the chronological ordering of posts). In fact, 18%

¹<http://people.eng.unimelb.edu.au/tbaldwin/resources/con112010-thread/>

²<http://forums.cnet.com/>

of the posts link to posts other than their immediately preceding post.

The task is defined as follows: given a list of preceding posts x_1, \dots, x_{t-1} and the current post x_t , to classify which posts it links to (l_t) and the dialogue act (y_t) of each such link. In the scope of this work, ME-CRFs are capable of modelling both tasks natively, and therefore a natural fit for this problem.

4.2 Experimental Setup

In this dataset, in addition to the body of text, each post is also associated with a title. We therefore use two encoders, $\Phi_{title}(\cdot)$ and $\Phi_{text}(\cdot)$, to process them separately and then concatenate $\mathbf{x}_t = [\Phi_{title}(x_t); \Phi_{text}(x_t)]^\top$. Here, $\Phi_{title}(\cdot)$ and $\Phi_{text}(\cdot)$ take word embeddings as input, processing each post at the word level, as opposed to the post-level bi-directional GRU in Equations (1) and (2), and the representation of a post \mathbf{x}_t (either title or text) is obtained by transforming the last and first hidden states of the forward and backward word-level GRU, similar to Equation (3). Note that $\Phi_{title}(\cdot)$ and $\Phi_{text}(\cdot)$ do not share parameters. As in Tang et al. (2016), we further restrict $\mathbf{m}_i^k = \mathbf{c}_i^k$ to curb overfitting.

In keeping with Wang (2014), we complement the textual representations with hand-crafted structural features $\Phi_s(x_t) \in \mathbb{R}^2$:

- initiator: a binary feature indicating whether the author of the current post is the same as the initiator of the thread,
- position: the relative position of the current post, as a ratio over the total number of posts in the thread;

Also drawing on Wang (2014), we incorporate punctuation-based features $\Phi_p(x_t) \in \mathbb{R}^3$: the number of question marks, exclamation marks and URLs in the current post. The resultant feature vectors are projected into an embedding space by \mathbf{W}_s and \mathbf{W}_p and concatenated with \mathbf{x}_i , resulting in the new \mathbf{x}'_i . Subsequently, \mathbf{x}'_i is fed into the bi-directional GRUs to obtain \mathbf{m}_i .

For link prediction, we generate a supervision signal from the annotated links, guiding the attention to focus on the correct memory position:

$$\mathcal{L}_{\text{LNK}} = \sum_{n=1}^N \sum_{t=1}^T \text{CrossEntropy}(\mathbf{l}_t^{(n)}, \mathbf{p}_t^{(n)}) \quad (11)$$

where $\mathbf{l}_t^{(n)}$ is a one-hot vector indicating where the link points to for the t -th post in the n -th thread,

and $\mathbf{p}_t^{(n)} = \{p_{t,1}, \dots, p_{t,t}\}$ is the predicted distribution of attention over the t posts in the memory. To accommodate the first post in a thread, as it points to a virtual “head” post, we set a dummy post, $\mathbf{m}_0 = \mathbf{0}$, of the same size as \mathbf{m}_i . While the dataset contains multi-headed posts (posts with more than one outgoing link), following Wang (2014), we only include the most recent linked post during training, but evaluate over the full set of labelled links.

For this task, ME-CRF is jointly trained to predict both the link and dialogue act with the following loss function:

$$\mathcal{L}' = \alpha \mathcal{L}_{\text{DA}} + (1 - \alpha) \mathcal{L}_{\text{LNK}} \quad (12)$$

where \mathcal{L}_{DA} is the CRF likelihood defined in Equation (9), and α is a hyper-parameter for balancing the emphasis between the two tasks.

Training is carried out with Adam (Kingma and Ba, 2015) over 50 epochs with a batch size of 32. We use the following hyper-parameter settings: word embedding size of 20, $\mathbf{W}_p \in \mathbb{R}^{100 \times 3}$, $\mathbf{W}_s \in \mathbb{R}^{50 \times 2}$, $\alpha = 0.5$, hidden size of Φ_{title} and Φ_{text} is 20, hidden size of GRU and GRU is 50. Dropout is applied to all GRU recurrent units on the input and output connections with a keep rate of 0.7.

Lastly, we also explore the idea of curriculum learning (Bengio et al., 2009), by fixing the CRF transition matrix $\mathbf{A} = \mathbf{0}$ for the first $e = 20$ epochs, after which we train the parameters for the remainder of the run. This allows the ME-CRF to learn a good strategy for DA and link prediction, as independent “maxent” type classifier, before attempting to learn sequence dynamics. We refer to this variant as “ME-CRF+”.

4.3 Evaluation

Following Wang (2014), we evaluate based on post-level micro-averaged F-score. All experiments were carried out with 10-fold cross validation, stratifying at the thread level.

We benchmark against the following previous work: the feature-rich CRF-based approach of Kim et al. (2010), where the authors trained independent models for each of link and DA classification (“CRF_{KIM}”); the feature-rich CRF-based approach of Wang (2014), where the author further extended the feature set of Kim et al. (2010) and jointly trained a CRF over the link and DA prediction tasks (“CRF_{WANG}”); and the dependency

Model	Link	DA	Joint
CRF _{KIM}	86.3	75.1	—
CRF _{WANG}	82.3	73.4	66.5
DEPPARSER	85.0	75.7	70.6
MEMNET	85.8	76.0	69.5
ME-CRF	86.4	77.5	70.9
ME-CRF+	86.3	77.4	71.2

Table 1: Post-level Link and DA F-scores. Performance for ME-CRF and ME-CRF+ is macro-averaged over 5 runs.

parser-based approach of Wang (2014), where the author treated the discourse structure prediction task as a constrained dependency parsing problem, with posts as nodes in the dependency graph, and the constraint that links must connect to preceding posts in the thread (“DEPPARSER”).³ In addition to the CRF/parser-based systems, we also build a MEMNET-based baseline (named MEMNET) where MEMNET shares the architecture of the memory layer in ME-CRF but excludes the use of the CRF layer. Instead, MEMNET, following the work of Sukhbaatar et al. (2015), predicts the final answer by:

$$\hat{\mathbf{y}} = \text{softmax}(\mathbf{W}_{\text{DA}}(\mathbf{u}^{K+1})) \quad (13)$$

where $\hat{\mathbf{y}}$ is the predicted DA distribution, $\mathbf{W}_{\text{DA}} \in \mathbb{R}^{|\mathcal{Y}| \times d}$ is a parameter matrix for the model to learn, and $K = 1$ is the total number of hops. This is equivalent to classifying link and DA independently at each time step t without taking transitions between DA labels into account.

4.4 Results

The experimental results are presented in Table 1, wherein the first three rows are the three baseline systems.

State-of-the-art post-level results. ME-CRFs achieve state of the art results in terms of joint post-level F-score, substantially better than the baselines. While ME-CRF slightly outperforms the current state-of-the-art (DEPPARSER), ME-CRF+ improves the performance and achieves a further 0.3% absolute gain.

³Note that a mistake was found in the results in the original paper (Wang et al., 2011), and we use the corrected results from Wang (2014).

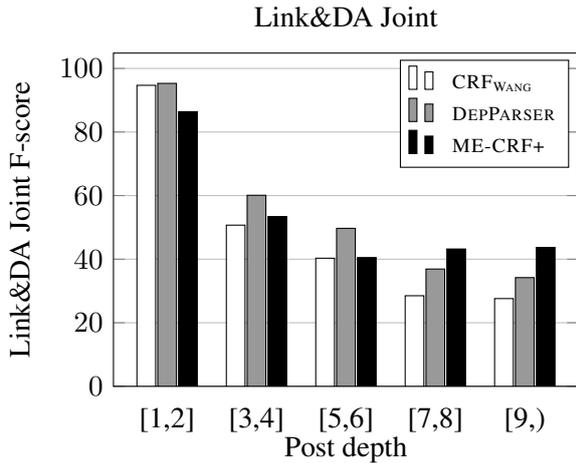

Figure 3: Breakdown of post-level Joint F-scores by post depth, where e.g. “[1, 2]” is the joint F-score over posts of depth 1–2, i.e. the first or second post in the thread. Note that we take the reported performance of CRF_{WANG} and DEPPARSER from Wang (2014).

Curriculum learning improves joint prediction.

Despite the slight performance drop on the DA and link prediction tasks, ME-CRF+, with the CRF transition matrix frozen for the first 20 epochs, achieves a $\sim 0.3\%$ absolute gain in joint F-score over ME-CRF. This suggests that the sequence dynamics between posts, while difficult to capture, are beneficial to the overall task (resulting in more coherent DA and link predictions) if trained with proper initialisation.

MEMNET vs. ME-CRFs. We see consistent gains across all three tasks when the CRF layer is added. Although not presented in Table 1, the difference is most notable at the thread-level (i.e. a thread is correct iff all posts are tagged correctly), highlighting the importance of sequential transitional information between posts.

CRF vs. ME-CRFs. Note that CRF_{KIM} is not trained jointly on the two component tasks, but individually on each task. Without additional data, jointly training on the two tasks generates results that are comparable or substantially better over the individual tasks. This highlights the effectiveness of ME-CRF, especially with the link prediction performance comparable to that of a single-task model CRF, and surpassing it in the case of DA.

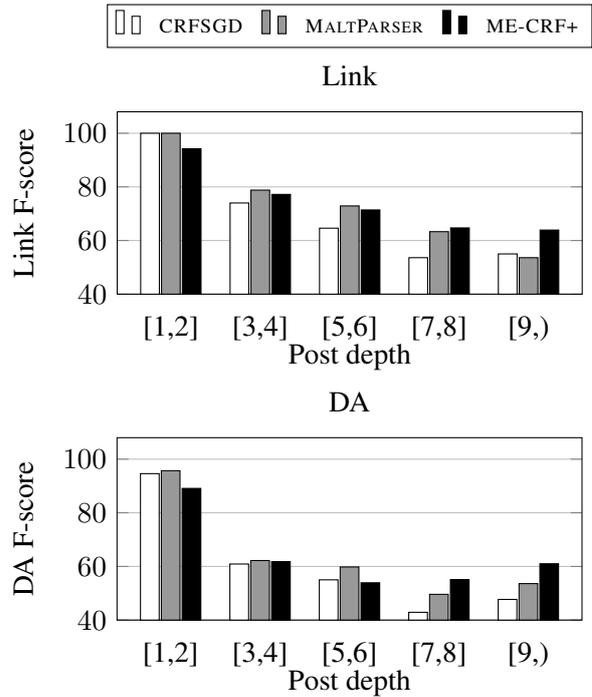

Figure 4: Breakdown of post-level Link and DA F-scores by post depth.

4.5 Analysis

We break the performance down by the depth of each post in a given thread, and present the results in Figure 3. Although below the baselines for the interval [1, 2], ME-CRF+ consistently outperforms CRF_{WANG} from depth 3 onwards, and is superior to DEPPARSER for depths [7,). Breaking down the performance further to the individual tasks of Link and DA prediction, as displayed in Figure 4, we observe a similar trend. In line with the findings in the work of Wang (2014), this confirms that prediction becomes progressively more difficult as threads grow longer, which is largely due to the increased variability in discourse structure. Despite the escalated difficulty, ME-CRF+ is substantially superior to the baselines when classifying deeper posts.

Between the CRF-based models, it is worth noting that despite the lower performance for [1, 2], ME-CRF+ benefits from having global access to the entire sequence, and consistently outperforms CRF_{WANG} for depths [3,), highlighting the effectiveness of the memory mechanism. Overall, these results validate our hypothesis that having unrestricted access to the whole sequence is beneficial, especially for long-range dependencies, offering further evidence of the power of

ME-CRFs.

5 Named Entity Recognition

In this section, we present experiments in a second setting: named entity recognition, over the CoNLL 2003 English NER shared task dataset (Tjong Kim Sang and De Meulder, 2003). Our interest here is in evaluating the ability of ME-CRF to capture document context, to aid in the identification and disambiguation of NEs.

5.1 Dataset and Task

The CoNLL 2003 NER shared task dataset consists of 14,041/3,250/3,453 sentences in the training/development/test set, resp., extracted from 946/216/231 Reuters news articles from the period 1996–97. The goal is to identify individual token occurrences of NEs, and tag each with its class (e.g. LOCATION or ORGANISATION). Here, we use the IOB tagging scheme. In terms of tagging schemes, while some have shown improvements with a more expressive IOBES marginally (Ratinov and Roth, 2009; Dai et al., 2015), we stick to the BIO scheme for simplicity and the observation of little improvement between these schemes by Lample et al. (2016).

5.2 Experimental Setup

We choose $\Phi(x_t)$ to be a lookup function, returning the corresponding embedding x_t of the word x_t . In addition to the word features, we employ a subset of the lexical features described in Huang et al. (2015), based on whether the word:

- starts with a capital letter;
- is composed of all capital letters;
- is composed of all lower case letters;
- contains non initial capital letters;
- contains both letters and digits;
- contains punctuation.

These features are all binary and referred to as $\Phi_l(x_t)$. Similar to the thread structure prediction experiments, we concatenate $\Phi_l(x_t)$ with x_t to generate the new input x' to the bi-directional GRUs in Equations (1) and (2).

In order to incorporate information in the document beyond sentence boundaries, we encode every word sequentially in a document with $\overrightarrow{\Phi}$ and $\overleftarrow{\text{GRU}}$, and store them in the memory m_i and c_i for $i \in [1, t']$, where t' is the index of the current word t in the document.

Training is carried out with Adam, over 100 epochs with a batch size of 32. We use the following hyper-parameter settings: word embedding size = 50; hidden size of $\overrightarrow{\text{GRU}}$ and $\overleftarrow{\text{GRU}}$ = 50; \overrightarrow{W}_m and $\overleftarrow{W}_m \in \mathbb{R}^{50 \times 50}$; and $b_m \in \mathbb{R}^{50}$. Dropout is applied to all GRU recurrent units on the input and output connections, with a keep rate of 0.8. We initialise ME-CRF with pre-trained word embeddings and keep them fixed during training. While we report results only on the test set, we use early stopping based on the development set.

5.3 Evaluation

Evaluation is based on span-level NE F-score, based on the official CoNLL evaluation script.⁴

We compare against the following baselines:

1. a CRF over hand-tuned lexical features (“CRF”: Huang et al. (2015))
2. an LSTM and bi-directional LSTM (“LSTM” and “BI-LSTM”, resp.: Huang et al. (2015))
3. a CRF taking features from a convolutional neural network as input (“CONV-CRF”: Collobert et al. (2011))
4. a CRF over the output of either a simple LSTM or bidirectional LSTM (“LSTM-CRF” and “BI-LSTM-CRF”, resp.: Huang et al. (2015))

Note that for our word embeddings, while we observe better performance with GLOVE (Pennington et al., 2014), for fair comparison purposes, we adopt the same SENNA embeddings (Collobert et al., 2011) as are used in the baseline methods.⁵

5.4 Results

The experimental results are presented in Table 2. Results for the baseline methods are based on the published results of Huang et al. (2015) and Collobert et al. (2011). Note that none of the systems in Table 2 use external gazetteers, to make the comparison fair. As can be observed, ME-CRF achieves the best performance, beating all the baselines.

To gain a better understanding of what the model has learned, Table 3 presents two examples

⁴<http://www.cnts.ua.ac.be/conll2000/chunking/conlleval.txt>

⁵Lample et al. (2016) report a higher result of 90.9 using a BI-LSTM-CRF architecture, but augmented with skip n -grams (Ling et al., 2015) and character embeddings. Due to the differing underlying representation, we exclude it from the comparison.

Model	F-score
CRF	86.1
LSTM	83.7
Bi-LSTM	85.2
CONV-CRF	88.7
LSTM-CRF	88.4
Bi-LSTM-CRF	88.8
ME-CRF	89.5

Table 2: NER performance on the CoNLL 2003 English NER shared task dataset.

where ME-CRF focuses on words beyond the current sentence boundaries. In the example on the left, where the target word is *Juventus* (an Italian soccer team), ME-CRF directs the attention mainly to the occurrence of the same word in a previous sentence and a small fraction to *Manchester* (a UK soccer team, in this context). Note that it does not attend to the other NE (*Europe*) in that sentence, which is of a different NE class. In the example on the right, on the other hand, ME-CRF allocates attention to the same words as the target word in the current sentence. Note that the second occurrence of *Interfax* in the memory is the same occurrence as the first word in the current sentence. While more weight is placed on the second *Interfax*, close to one third of the attention is also assigned to the first occurrence. Given that the memory, m_i and c_i , is encoded with bi-directional GRUs, the first *Interfax* should, to some degree, capture the succeeding neighbouring elements: *news agency*.

This is reminiscent of label consistency in the works of Sutton and McCallum (2004) and Finkel et al. (2005), but differs in that the consistency constraint is soft as opposed to hard in previous studies, and automatically learned without the use of heuristics.

6 Conclusion

In this paper, we have presented ME-CRF, a model extending linear-chain CRFs by including external memory. This allows the model to look beyond neighbouring items and access long-range context. Experimental results demonstrate the effectiveness of the proposed method over two tasks: forum thread discourse analysis, and named entity recognition.

IBM Research Australia

hung.tran@monash.edu, admackin@au1.ibm.com, ayepes@au1.ibm.com

Abstract

Recurrent Neural Network models are the state-of-the-art for Named Entity Recognition (NER). We present two innovations to improve the performance of these models. The first innovation is the introduction of residual connections between the Stacked Recurrent Neural Network model to address the degradation problem of deep neural networks. The second innovation is a bias decoding mechanism that allows the trained system to adapt to non-differentiable and externally computed objectives, such as the entity-based F-measure. Our work improves the state-of-the-art results for both Spanish and English languages on the standard train/development/test split of the CoNLL 2003 Shared Task NER dataset.

1 Introduction

In Natural Language Processing, the term “Named Entity” refers to special information units such as people, organizations, location names, numerical expression (Nadeau and Sekine, 2007). Identifying the references to these special entities in text is a crucial step toward Language Understanding. Thus, there have been many works on these areas.

Some of the early systems employed hand-crafted rules (Rau, 1991; Sekine and Nobata, 2004), however, the vast majority of current systems rely on machine learning models (Nadeau and Sekine, 2007) such as Conditional Random Field (CRF) (McCallum and Li, 2003), Hidden Markov Model (HMM) (Bikel et al., 1997) and Support Vector Machine (SVM) (Asahara and Matsumoto, 2003). Although the traditional machine learning models do not rely on manual rules, they require a manual feature engineering process,

which is rather expensive and dependent on the domain and language.

In recent years, Recurrent Neural Network (RNN) models such as Long-Short-Term-Memory (LSTM) (Hochreiter and Schmidhuber, 1997) and Gated Recurrent Unit (GRU) (Chung et al., 2014) have been very successful in sequence modeling tasks, for example, Language Modeling (Mikolov et al., 2010; Sundermeyer et al., 2012), Machine Translation (Bahdanau et al., 2014) and Dialog Act Classification (Kalchbrenner and Blunsom, 2013; Tran et al., 2017). RNN models can learn from basic components of text (i.e. words and characters). This generalization capability facilitates the construction of Language Independent NER models (Ma and Hovy, 2016; Lample et al., 2016) that rely on unsupervised feature learning and a small annotated corpus.

One simple way of adding representational power to a neural network is layer stacking. A traditional feed forward neural network usually has three fully connected layers: an input layer, a hidden layer, and an output layer. For a Convolutional Neural Network (CNN) or Recurrent Neural Network, the number of stacked layers might be much larger (Amodei et al., 2016). One problem with this stacking scenario is the degraded representation problem (He et al., 2016). The proposed solution for this problem is the residual-identity connection (He et al., 2016). With the information from the lower-level inputs, the upper neural network layers can learn to compensate for the representation errors of lower layers. We adopt this idea for Stacking RNN, however, with a different implementation.

Most of the RNN-based models for NER and machine translation are trained with some form of maximum log-likelihood loss. However, it is often desirable to optimize task-specific metrics (Xu et al., 2016), for example, F-measure

in NER, but optimizing the F-measure directly is not trivial (Busa-Fekete et al., 2015), especially in the case of complex Deep Neural Network models. It is even more difficult considering the way the F-measure is calculated in Named Entity Recognition in the CoNLL-2003 shared task¹, where it depends on the actual/predicted entities and *not* on each token-prediction for which the system is trained for. Inspired by the idea of trainable decoding recently proposed in machine translation (Gu et al., 2017), we introduce a trainable *percentage bias decoding* system that manipulates the outputs of a base system trained with normal loss to adapt to a new objective. Our trainable bias decoding system also bears similarity to the thresholding technique (Lipton et al., 2014), traditionally used to maximize F-measures given a classifier. The proposed decoding system is trained directly on the externally computed F-measures (which relies on the the CoNLL evaluation script) using finite different gradient.

In the next sections, we describe the proposed innovations with detailed motivations and discussions. Results show that our proposed innovations improve the NER state-of-the-art for the English and Spanish languages in the CoNLL-2003 shared task data set.

2 Models

We describe first our RNN-CRF base architecture and then we describe our two modelling innovations: the Stack Residual RNN and the bias decoding.

2.1 The base RNN-CRF architecture

Our system is built upon the RNN-CRF architecture for Named Entity Recognition. Let us denote the input sequence of words as w_0, \dots, w_n . In general, the RNN component encodes the words into a sequence of hidden vectors h_0, \dots, h_n . This sequence of hidden vectors is then treated as features for a linear-chain CRF layer. The training objective will then be the log-likelihood of the correct sequence.

Following Lample et al. (2016); Ma and Hovy (2016); Yang et al. (2016), we employ the character level information and word-embeddings as features in NER. Similar to Lample et al. (2016), in our system, character information is encoded us-

¹[https://www.aclweb.org/aclwiki/index.php?title=CoNLL-2003_\(State_of_the_art\)](https://www.aclweb.org/aclwiki/index.php?title=CoNLL-2003_(State_of_the_art))

ing a bi-directional RNN (biRNN) over characters. Given a word $w_k \in w_0, \dots, w_n$ with m characters, let us denote the character-embedding sequence of this word as $\mathbf{c}_0, \dots, \mathbf{c}_m$, the biRNN function as ρ and the concat function as ψ . The character embedding representation \mathbf{h}_k^c of word w_k is calculated using a biRNN as in Equation 1, in which $\mathbf{f}_0, \dots, \mathbf{f}_m$ and $\mathbf{b}_0, \dots, \mathbf{b}_m$ denote the hidden units in the forward and backward RNNs respectively.

$$\begin{aligned} \mathbf{f}_0, \dots, \mathbf{f}_m &= \rho(\mathbf{c}_0, \dots, \mathbf{c}_m) \\ \mathbf{b}_0, \dots, \mathbf{b}_m &= \rho(\mathbf{c}_m, \dots, \mathbf{c}_0) \\ \mathbf{h}_k^c &= \psi([\mathbf{f}_m, \mathbf{b}_m]) \end{aligned} \quad (1)$$

The feature vector \mathbf{x}_k of word w_k is then the concatenation of \mathbf{h}_k^c and the traditional word-embedding \mathbf{e}_k as shown in Equation 2. Figure 1 shows the feature extraction procedures. All the parameters of the biRNN as well as the embedding tables are jointly trained with other component of the model. The word embedding table is initialized with a pre-trained embedding table.

$$\mathbf{x}_k = \psi([\mathbf{h}_k^c, \mathbf{e}_k]) \quad (2)$$

The most simple architecture would be a one-directional RNN over the word features: $h_0, \dots, h_n = RNN(x_0, \dots, x_n)$. However, it has been shown to be beneficial to have a bidirectional RNN over the input layer, as a bidirectional RNN captures both the left and the right context of a word: $h_0, \dots, h_n = \rho(x_0, \dots, x_n)$.

The final sequence of hidden vectors $\mathbf{h}_0, \dots, \mathbf{h}_n$ is treated as the features for a linear-chained CRF layer. Similar to Lample et al. (2016), the observation scores λ are calculated with a linear transformation from the hidden vectors, as show in Equation 3, where λ_i is the vector observation scores for all the labels in i th time-step, \mathbf{W}_p is an $l \times d$ weight matrix, and \mathbf{b}_p is a bias vector of size l (with d is the size of vector \mathbf{h}_i), and l is the size of the label set \mathbb{Y} (including the special sequence begin and end labels).

$$\lambda_i = \mathbf{W}_p \mathbf{h}_i + \mathbf{b}_p \quad (3)$$

Given a sequence of input words $S = w_0, \dots, w_n$, the score of a particular sequence of labels $Y = Y[0], \dots, Y[n]$ is calculated using the observation scores λ and the transition scores δ as in Equation 4, where δ is a square matrix of dimension $l \times l$, $\delta(Y[j], Y[j+1])$ denotes the transition

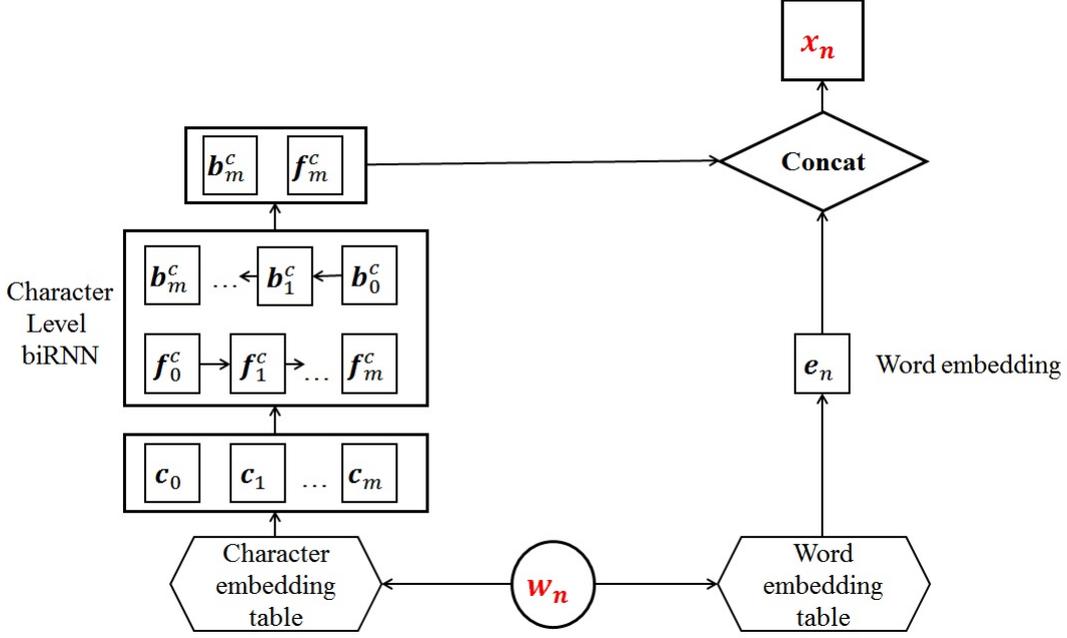

Figure 1: Extracting word features with word embeddings and character level biRNN

score between the label in position j and the label in position $j + 1$ in sequence Y , and $\lambda_i(Y[i])$ is the observation score of i -th label $Y[i]$.

$$\zeta(Y, S) = \sum_{i:[0..n]} \lambda_i(Y[i]) + \sum_{j:[0..n-1]} \delta(Y[j], Y[j + 1]) \quad (4)$$

The probability of a sequence Y is calculated using a softmax over all the possible sequences \mathbb{Y} (Equation 5).

$$Pr(Y|S) = \frac{e^{\zeta(Y,S)}}{\sum_{\tilde{Y} \in \mathbb{Y}} e^{\zeta(\tilde{Y},S)}} \quad (5)$$

During training, we maximize the log-likelihood of the correct sequence Y_c . The loss function \mathbb{L} is defined in Equation 6. Because we employ a linear-chain CRF, the term $\log(\sum_{\tilde{Y} \in \mathbb{Y}} e^{\zeta(\tilde{Y},S)})$ in Equation 6 can be efficiently calculated with dynamic programming.

$$\mathbb{L}(Y_c) = \zeta(Y_c, S) - \log\left(\sum_{\tilde{Y} \in \mathbb{Y}} e^{\zeta(\tilde{Y},S)}\right) \quad (6)$$

During decoding, the best sequence can be found using the Viterbi algorithm. The original Viterbi decoding algorithm builds an $l \times n$ score

table ξ in which l is the size of the label set (including the beginning and end labels) and n is the length of the sequence. $\xi_j(y_i)$ denotes the score of the most probable partial path (up to position j) with position j having the label y_i . $\xi_j(y_i)$ is calculated using dynamic programming as in Equation 7.

$$\xi_j(y_i) = \sum_{y_k \in \mathbb{Y}} (\xi_{j-1}(y_k) + \delta(y_k, y_i)) + \lambda_j(y_i) \quad (7)$$

At the end of the decoding process, sequence \hat{Y} is predicted by selecting the best score at the end of the sequence $j = n$ and then completing the sequence with a backward pointer (Equation 8). Figure 3 depicts the whole RNN-CRF architecture

$$\hat{Y}[n] = \arg \max_{y_i} \xi_n(y_i) \\ \hat{Y}[n-1] = \arg \max_{y_k} (\xi_{j-1}(y_k) + \delta(y_k, \hat{Y}[n])) \quad (8)$$

2.2 Stacked Residual RNN

A traditional way of adding more representational power to a neural network is layer stacking. RNN stacking has been successfully used in a lot of works (Amodei et al., 2016). However, stacking

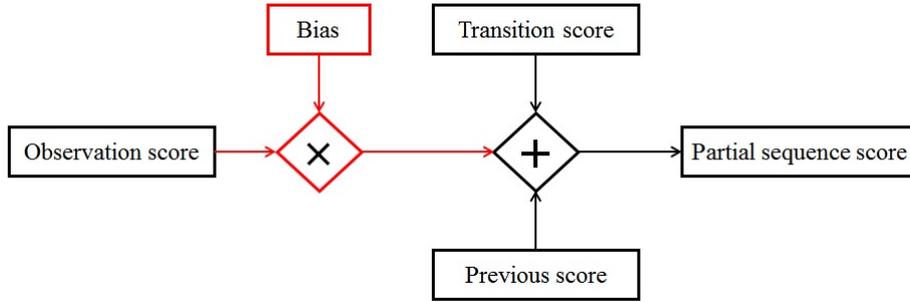

Figure 2: The application of percentage bias to Viterbi decoding

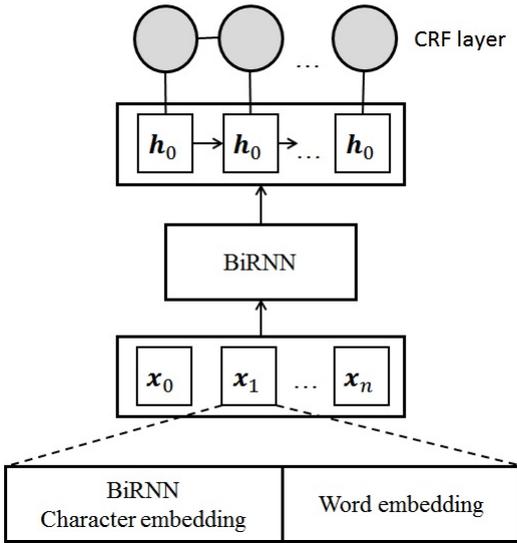

Figure 3: The RNN-CRF architecture

layers of neural networks suffers from the *degradation problem* (He et al., 2016). This is due to the difficulty in training a lot of stacked layers and fit these layers to desired underlying mappings, which leads to representational degradation.

The solution proposed to this problem, the *residual connection* (He et al., 2016; Prakash et al., 2016) tries to create shortcuts between non-consecutive layers. However, the original additional residual connection (adding the input vector to the hidden representation) adds several constraints on the dimensionality of the hidden and input layers, which might require vector clipping (Prakash et al., 2016), and it might lead to a loss of information.

In the original residual connection proposed for image recognition, the residual information is summed to the output of the upper layers ($\mathbb{F}(x) + x$). In our proposal, we want the upper layer of a neural network to have direct access to the original input, thus, the original input is now appended to the output of the lower layers instead of being

summed. With this formulation, there is no dimensionality restriction, and furthermore, we argue that our proposed residual connection can be used to mix feature learners of different complexity (Figure 4). For example, when equipped with our proposed residual connection, the top neural network layer can act like a shallow one-layer feature learner. The two top layers can act like a deeper two-layer feature learner. Equation set 9 shows the exact formulation of our proposed residual connection within the Stack RNN. Similar to the Equation 1, we denote the biRNN function as ρ and the concat function as ψ . This modelling procedure is depicted in Figure 4.

$$\begin{aligned}
 \mathbf{h}_0^0, \dots, \mathbf{h}_n^0 &= \rho(\mathbf{x}_0, \dots, \mathbf{x}_n) \\
 \hat{\mathbf{h}}_0^0, \dots, \hat{\mathbf{h}}_n^0 &= \psi([\mathbf{x}_0, \mathbf{h}_0^0]), \dots, \psi([\mathbf{h}_n^0, \mathbf{x}_n]) \\
 \mathbf{h}_0^1, \dots, \mathbf{h}_n^1 &= \rho(\hat{\mathbf{h}}_0^0, \dots, \hat{\mathbf{h}}_n^0) \\
 \mathbf{h}_0^M, \dots, \mathbf{h}_n^M &= \rho(\hat{\mathbf{h}}_0^{M-1}, \dots, \hat{\mathbf{h}}_n^{M-1})
 \end{aligned} \tag{9}$$

2.3 The bias decoding

Usually NER systems are evaluated with some form of F-measure. For example, for the CoNLL 2013 Shared Task NER dataset, the evaluation is performed by an external script using entity-based F1-measure. Although it has been noted that training on the evaluation metric is beneficial (Xu et al., 2016), most of the deep models for NER are trained with log-likelihood. The main reason for this discrepancy is the difficulty in training with F-measures. Instead of trying to train on F-measure directly, we look into a hybrid solution where we train a model on log-likelihood first, and then use a simpler “adaptation model” to manipulate the output of the base model to fit it to the F-measure.

Inspired by Machine Translation research on decoding with trainable noise (Gu et al., 2017), we

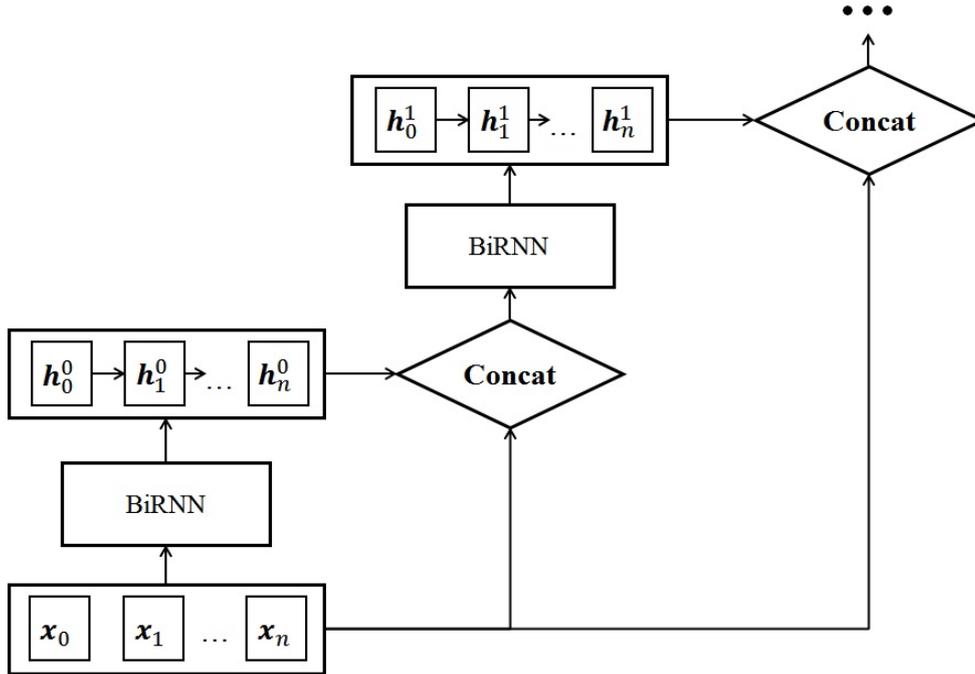

Figure 4: Feature learner mixture with residual connection

explore the possibility of adding trainable noise to the Viterbi decoding process. Analogously to the traditional threshold technique for maximizing the F1 score in binary classification, we introduce a simple *percentage noise* to the decoding process. That is, during the construction of the score table ξ (Equation 7), a label-specific percentage bias is added to the calculation as in Equation 10. Figure 2 shows the application of this bias to the Viterbi decoding.

$$\xi_j(y_i) = \sum_{y_k \in \mathbb{Y}} (\xi_{j-1}(y_k) + \delta(y_k, y_i)) + b_y \lambda_j(y_i) \quad (10)$$

To test this new percentage bias idea, we perform a quick experiment, where we limit the use of bias to the most numerous class in the CoNLL tag set, class O (words that do not belong to any entity). We search for the best bias b_O from the range of $[0.5, 1.5]$ using a value loop with step of 0.1. For each value of b_O , we calculate the F1-measure on the validation set, and choose the value with the highest F1. We use our trained model based on the Stack Residual architecture above as the base probabilistic model. We find that the best b_O value is 1.1 (a value of 1.0 means without any bias). Using this b_O bias for the test data yields

the F1-measures of 91.22 compared to the original score of 91.07 in the test set. This experiment supports our claim that the base model trained with log-likelihood might not optimize well on a different performance measure, and adding this percentage bias noise is really beneficial.

We extended this idea treating the biases as parameters. Thus the trainable bias decoding system has the number of parameters equal to the number of classes. Training with gradient descent with CoNLL’s entity-based F1 loss is rather difficult, as it is hard to calculate the exact gradient. This is solved using the numerical gradient methods as an approximation, which is shown in Equation 11.

$$f'_b \sim \frac{f(b + \epsilon) - f(b - \epsilon)}{2\epsilon} \quad (11)$$

The training procedure is then very similar to stochastic gradient descent. Details on the choice of hyper parameters and other experimental settings are presented in the Experiment section.

3 Experiments

3.1 Dataset and Experimental settings

We have prepared and evaluated the proposed methods on the English and Spanish sets of the CoNLL 2003 NER data

set² (Tjong Kim Sang and De Meulder, 2003).

We have reused the training, development and test set configuration of the CoNLL-2003 Shared Task in our study.

The training set has been used to train the system using several hyperparameter configurations, the development set has been used to select the best configuration and the reported performance of the final system is based on the test set. The Spanish dataset has 8323/1915/1517 sentences in train/dev/test sets respectively. The English dataset is almost twice as large with 14041/3250/3453 sentences in train/dev/test set. For all of our models, the word-embedding size is set to 100 for English and 64 for Spanish. The hidden vector size is 100 for both English and Spanish sets without the LM embeddings. With the LM embeddings, the hidden vector size is changed to 300 for English. We trained the model with Stochastic Gradient Descent (SGD) with momentum, using the learning rate of 0.005. For the bias decoding, the ϵ hyperparameter for each update is randomly chosen from a range of [0.01, ..., 0.1] with step-size of 0.01. Because the base model trained with sequence level log-likelihood fits very well on the training set, the gradient calculated with Equation 11 might be very small, thus we opt to calculate the finite difference with respect to the loss: $\log_2(1 - F1/100)$ instead of the $F1$ to boost the gradient information in the points where $F1$ is very close to 100 (perfect classification). The learning rate for bias training is also set to 0.005. Statistical significance has been determined using a randomization version of the paired sample t-test (Cohen, 1996).

We first conduct several series of experiments to confirm the effectiveness of our two proposed ideas: the Stack Residual RNN and the bias decoding, and the new Language Model embedding in sub-section 3.2. The second sub-section: 3.4 compares our method with state-of-the-art results.

3.2 Component Analysis

Adding stack Residual RNN

Due to computational complexity, there is a practical limit on how many RNN layers we can stack. In this series of experiment, we tested our model without Stacked Residual RNN, and with 2, 3 and 4 Stacked layers. The word embeddings are initialized using the pre-trained word vectors de-

scribed below. The result of this series of experiments is presented in Table 1.

From the result, we can see that the performance seems to increase as we add more stacked layers, and peak at three before dropping. We continue to analyze other components using 3 Stacked Residual Layers of CRF-RNN as the base model, we call this model 3 *Res-RNN* for short.

For English, the 3 and 4 stacked layer improvements are significant ($p < 0.025$) compared to the baseline model and between the stacked layer models, the improvement between 2 and 3 layers is significant ($p < 0.035$).

For Spanish, the 3 stacked layer improvement is significant ($p < 0.03$), with respect to the baseline model. Improvement between the 3 stacked layer and the 4 stacked layer models is significant ($p < 0.03$).

Adding Language Model Embedding

Pre-trained word embeddings have shown useful in Natural Language Processing tasks, but provide information about the word but not about its context. Previous work has explored using language models in addition to word embeddings (Peters et al., 2017) with positive results. We have evaluated our system using pre-trained language models using the 3 Stacked Residual Layer configuration. First, we test the models with forward-only LM embeddings (foreLM), then we test the model with both forward and backLM (backLM). The result of this series of experiments is presented in Table 2.

The gain from the LM embedding is not consistent. It seems to work very well with English, where it improves performance substantially even though this improvement is not specially significant. However, the LM does not improve the performance at all in Spanish. Adding the foreLM and backLM significantly decreases performance.

Adding Bias Decoding

We test the bias decoding on models with and without LM embeddings, with results shown in Table 3. The bias-decoding increases the performance across the board, however the performance increases are not consistent. The increases are notable on some cases (3 Res-RNN + bias on both English and Spanish, 3 Res-RNN + foreLM + backLM + bias for Spanish), while in some cases the increases are minimal (3 Res-RNN + foreLM + bias on both English and Spanish, 3 Res-RNN + foreLM + backLM + bias on English).

²<http://www.cnts.ua.ac.be/conll2003/ner>

System	F1 English	F1 Spanish
CRF-RNN no Stack Residual	90.43	85.41
CRF-RNN 2 Stack Residual	90.72	85.88
CRF-RNN 3 Stack Residual	91.07 *	86.24 *
CRF-RNN 4 Stack Residual	91.02 *	85.51

Table 1: Analysis of the Stack Residual Component. * indicates significance ($p < 0.05$) versus CRF-RNN no Stack Residual.

System	F1 English	F1 Spanish
3 Res-RNN	91.07 *	86.24 *
3 Res-RNN+foreLM	91.43 *	86.13 *
3 Res-RNN+foreLM +backLM	91.66 *	85.83

Table 2: Analysis of the Language Model Embedding. * indicates significance ($p < 0.05$) versus CRF-RNN no Stack Residual in Table 1.

For English, adding bias to the 3 Res-RNN without LM yields a significant improvement ($p < 0.013$), while for Spanish, the boost from adding bias to the 3 Res-RNN + foreLM + backLM model is significant ($p < 0.011$).

3.3 External Knowledge Learning

3.3.1 Word embedding

English word embedding was obtained from Word2vec-api³. The embedding dimension is 100 and it was trained using GloVe with AdaGrad. For the generation of Spanish word embeddings we followed Lample et al. (2016), using Spanish Gigaword Third Edition⁴ as corpus with an embedding dimension of 64, a minimum word frequency cutoff of 4 and a window size of 8.

3.3.2 Language Modeling

In some experiments, we used both forward and backward language models. The English forward language model was obtained from TensorFlow⁵ using the One Billion Word Benchmark⁶ (Chelba et al., 2013) and has a perplexity of 30. As the code generating this pre-trained model is not available, we made use of a substitute which produces a higher perplexity language model. For the backward English language model and the Spanish forward and backward ones, they were generated using an LSTM based baseline⁷ (Jozefowicz

et al., 2016). This code estimates a forward language model and was adapted to estimate a backward language model. Language models were estimated using the One Billion Word benchmark. The vocabulary for the backward English model is the same as the pre-generated forward model. The perplexity for estimated backward English language model is 46; despite the discrepancy in perplexity with the forward language model the performance using this language model still improves the named entity recognition task. The vocabulary for the Spanish language models was generated using tokens with frequency > 2 . The perplexity for the forward and backward Spanish language models are 56 and 57 respectively.

3.4 Comparative performance

Table 4 shows the performance of our best systems compared to the state-of-the-art results on ConLL dataset. We focus our comparison to the systems with the same experimental setups (standard train/val/test split, without the use of external label data). The best previous systems (Ma and Hovy, 2016; Lample et al., 2016) are based upon a similar architecture (CRF-RNN) to ours. Lample et al. (2016) employed LSTM for character-based embedding, while Ma and Hovy (2016) employed CNN for character-based embedding⁸. Overall, we achieve state-of-the-art results on both English and Spanish.

Table 4: Compare our model with systems with comparable experimental settings

4 Discussion

Overall, our model achieves the state-of-the-arts for both English and Spanish Named Entity Recognition. For Spanish, our base model with three layers of Stacked Residual RNN already outperforms the current state-of-the-art.

From the results above, we can see that our innovations, the Stacked Residual connection and bias decoding consistently improve the performance across both data sets. However, the improvements from bias decoding is somewhat small in some models. The numerical gradient for training is noisy, and sometimes the SGD process might take several epochs to find an improvement on the development set. This happens especially on the English dataset because the base model trained with sequence level log-likelihood fits very well on the training set. Even with the boosting trick presented during the Experiments section, the training is still very slow. At first, we expected that the biases might give us some ideas about the trade-off between precision and recall similar to the thresholding technique for binary classification, i.e. the based log-likelihood model might favors precision or recall. However, from the analysis of the biases, we found no obvious trends favoring precision or recall.

Interestingly, the Language Model embeddings seem to have opposite effects on Spanish and English. While it is very helpful in English, it only degrades the performance for Spanish. The English LMs also improve convergence rate, while it is the opposite for Spanish. We attribute this difference in the quality of the Language Model involved. For English, the LMs are arguably better, with much lower perplexities than the LMs for Spanish. The Spanish models also have less data to train with, and it might affect the performance.

5 Conclusions and Future Work

We have explored two innovations over the baseline CRF-RNN model for sequence classification: the Stacked Residual Connection, and bias decoding. With these two improvements, it is possible to achieve state-of-the-art performance in Named Entity Recognition for both English and Spanish.

As future work, we will further investigate trainable bias decoding, and try to solve the problems presented. As the methods presented are general and language/domain independent, we plan to apply it to other domains such as health-care and expand the applications beyond NER.

Abstract

The problem of blend formation in generative linguistics is interesting in the context of neologism, their quick adoption in modern life and the creative generative process guiding their formation. Blend quality depends on multitude of factors with high degrees of uncertainty. In this work, we investigate if the modern neural network models can sufficiently capture and recognize the creative blend composition process. We propose recurrent neural network sequence-to-sequence models, that are evaluated on multiple blend datasets available in the literature. We propose an ensemble neural and hybrid model that outperforms most of the baselines and heuristic models upon evaluation on test data.

1 Introduction

Blending is the formation and intentional coinage of new words from existing two or more words (Gries, 2004). These are called neologisms. Neologisms effectively trace changing cultures and addition of new technologies. Blending is one way to create a neologism. A lexical blend is formed by combining parts of two or more words. Predicting a high quality lexical blend is often unpredictable due to the uncertainty in the formal structure of blends (Beliaeva, 2014). Merging source words *digital* and *camera*, the common expectation is the blend *digamera*, although, in practice, *digicam* is more common (Beliaeva, 2014). There are multiple unknown factors such as phonology, semantics, familiarity, recognizability and lexical creativity that contribute to blend formation. Some downstream applications that can leverage such

Word ₁	Word ₂	Blend	Structure	Category	Coverage
aviation	electronics	avionics	avi-onics	Prefix + Suffix	16.74%

Table 1: Sample blends in our dataset along with the type and coverage. There are other types of rare blends that is beyond the scope of this work.

blending systems include generating names of products, brands, businesses and advertisements to name a few especially if coupled with contextual information about the business or sector.

1.1 Related Work

Blends are compositional words consisting of whole word and a splinter (part of morpheme) or two splinters (Lehrer, 2007). The creative neologism of blend formation has been studied by linguists in an attempt to recognize patterns in the process that model human lexical creativity or to identify source words and blend meaning, context and influence. With the popularity of deep neural networks (DNN)s (LeCun et al., 2015), we are interested in the question if neural network models of learning can be leveraged in a generative capacity, that can sufficiently explore or formalize the process of blend formation. Blends can be formed in several closely related morphologically productive ways as shown in Table 1. Our work targets blends that are ordered combinations of prefixes of first word and suffixes of the second word. Examples include, *avionics* (prefix + suffix), *vaporware* (word + suffix), *robocop* (prefix + word), *carmageddon* (overlap). Several theories have been forwarded as to the structure and mechanism of blending (Gries, 2012), without much consensus (Shaw et al., 2014). Most

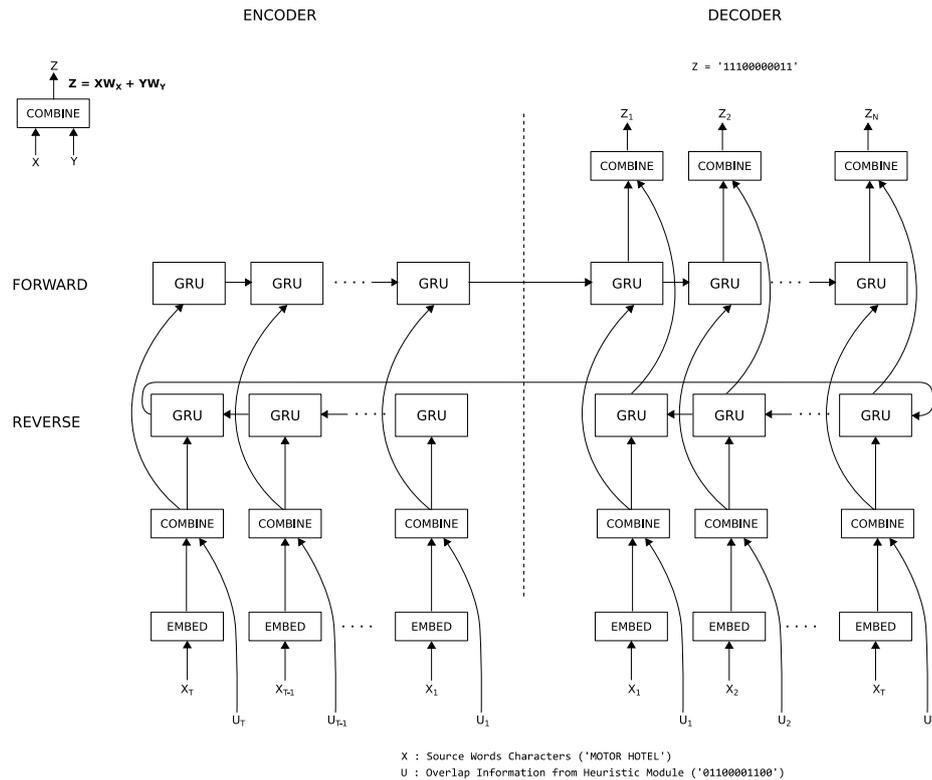

Figure 1: Architectural diagram of the bidirectional hybrid encoder decoder model.

implementation work in blenders and generators is quite sparse in the literature and mainly concern explicit blending of vector embeddings.

Naive implementations of generators exist on the internet¹²³, that are simply lists of all possible blend combinations. Some other work is based on greedy heuristics for better results⁴⁵. Andrew et. Al (2014) built a statistical word blender as a part of a password generator. Ozbal (2012) uses a combination of edit distances and phonetic metrics and Pilichowski (2013) also uses a similar technique. Our work empirically captures some of these mechanisms from blend datasets used in the literature using neural networks. Numerous studies on deterministic rules for blend formation (Kelly, 1998; Gries, 2004, 2006, 2012; Bauer, 2012) do not find consensus on the blending process mainly due to the 'human factor' involved in

designing rules.

The closest work of using novel multitape Finite State Transducers (FST) for blend creation is in work by Deri et. al. (2015). Our model is a neural model, different from the multitape FST model. The multitape FST model is similar to our baseline heuristic model with which we compare our neural model proposed in this paper. The primary benefit of our model is that it attempts to arrive at a consensus among various neural experts in the generative process of new blend creation.

1.2 Contributions

We summarize the main contributions of our work as follows:

1. We propose an ensemble neural network model to learn the compositional lexical blends from two given source words.
2. We generalize the problem of lexical blending by leveraging the character based sequence-to-sequence hybrid bidirectional models in order to predict the blends.
3. We release a blending dataset and demo of our neural blend generator along with open

2 Neural Lexical Blending Model

2.1 Sequence-to-sequence Models

Sequence-to-Sequence (Seq2Seq) neural network models (Sutskever et al., 2014), are a generalization of the recurrent neural network (RNN) sequence learning (Cho et al., 2014) paradigm, where a source sequence x_1, \dots, x_n is mapped to a fixed sized vector using a RNN often serving as the encoder, and another RNN is used to map the vector to the target sequence y_1, \dots, y_n , functioning as the decoder. However, RNNs struggle to train on long term dependencies sufficiently; and therefore, Long Short Term Memory Models (LSTM) and Gated Recurrent Units (GRUs)(Cho et al., 2014) are more common for such sequence to sequence learning.

2.2 Bidirectional Seq2Seq Model

We propose a bidirectional forward and reverse GRU encoder-decoder model for our lexical blends. To this end, both the encoder and the decoder are bidirectional, i.e. they see the ordered input source words both in the forward direction and the backward direction. The motivation here is that in order to sufficiently capture the splinter point, there should be dependency on the neighbouring characters in both directions. Figure 1 shows the bidirectional Seq2Seq model that we propose. Since we have two source words for every blend, that is a sequence of characters, the input to our model has the source words concatenated with a space and padding to align to the longest concatenated example. For example in Figure 1, the source words `work` and `alcoholic` are concatenated as `cilohocla krow` and `work alcoholic` for the encoder and decoder respectively, which subsequently gets reversed to `work alcoholic` and `cilohocla krow` for the reverse encoder and decoder units. The representation of a sequence of characters in the input pair of source words is the concatenation of the fixed dimensional character to vector representations. The model’s prediction corresponding to the two source words in the input, is the order preserving binary output $\{\hat{y}_t = \{0, 1\} | x_t \in y_t\}$ for model prediction \hat{y} , ground truth target y and concatenated source input pair $x = (x_1, \dots, x_T)$. For example, if x is `work alcoholic` with-

out padding, the prediction on the blended word is `11110000111111` for the target `workoholic`. The order is enforced implicitly in the concatenated inputs. The indices that are predicted 1 are for the characters in the concatenated input that are included in the blend.

The forward and reverse hidden states h_t^f and h_t^r of the encoder at time t is given by:

$$h_t^f = GRU_{enc}^f(h_{t-1}^f, x_{t_r}) \quad (1)$$

$$h_t^r = GRU_{enc}^r(h_{t+1}^r, x_{t_r}) \quad (2)$$

where GRU_{enc}^f and GRU_{enc}^r stand for forward and reverse GRU encoder units described by (Cho et al., 2014) and $t_r = T - t + 1$. Similarly, the forward y^f and reverse y^r intermediate outputs of the decoder are given by:

$$y_t^f = GRU_{dec}^f(y_{t-1}^f, x_t) \quad (3)$$

$$y_t^r = GRU_{dec}^r(y_{t+1}^r, x_t) \quad (4)$$

where $y_0^f = h_T^f$ and $y_{T+1}^r = h_1^r$. The final decoder output is the result of applying smooth non-linear sigmoid transformation to the GRU outputs

$$z_t^j = \sigma(W_f y_t^f + U_r y_t^r) \quad (5)$$

z is character wise probability of inclusion in the blend. We apply sigmoid loss on z for training.

2.3 Ensemble Hybrid Bidirectional Seq2Seq Model

We propose an ensemble model of our vanilla bidirectional encoder decoder model discussed in Section 2.2 in order to capture different representations of the source word, hidden state and a variety of blends. Blends can be inherently varying in structure of the blend formation resulting in multiple possible blend candidates. Each member or an expert in our ensemble model has the same underlying architecture as described in Section 2.2 and in Figure 1. However, the experts in the ensemble do not share the model parameters, the motivation being able to capture a wider range of parameter values thus tackling the variations and multiplicity in the blending process adequately. Further, there is a subjective and qualitative nature of the blend formation process that leads to naturally consider ensemble predictions with the notion that

Dataset	No. of Examples	No. of Overlaps
Wiktionary	2854	1379
Train	2140 (75%)	
Validation	428 (15%)	
Test	286 (10%)	
Test + Validation with overlaps	319	319
Test + Validation no overlaps	395	0
Cook	230	90
Thurner	482	320
Believa	335	168

Table 2: Datasets for experiments. Blends need not be overlapping even if the source words share common substrings. E.g. puny + unicode = punycode.

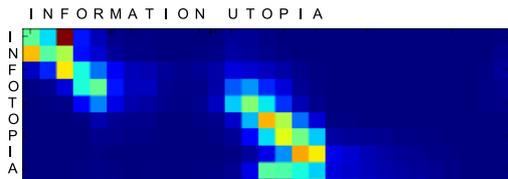

Figure 2: Attention Mask while predicting in attention baseline model.

the collective consensus should be more smooth than capturing individual preferences or specialization in the experts where each expert predicts differently. Each expert is independently initialized and parameterized by a GRU based encoder decoder neural network and trained end-to-end simultaneously.

The model makes the final prediction by using a method of combining the expert predictions known as *confidence measure*. Each expert predicts the blended target $z_t^i = [0, 1]$ using Equation 5, for the i th expert such that $i \in K$, where there are K experts. *Confidence* of each expert i with respect to a pre-defined threshold γ is given by:

$$Cf^i = \frac{\sum_{t=1}^n |z_t^i - \gamma|}{n} \quad (6)$$

For the purposes of evaluating the quality of the ensemble model prediction, we perform a confidence weighted voting on the blended words (at a word level instead of character level) predicted by the individual expert and report the top voted blend predictions by the ensemble by selecting the prediction of the expert(s) that has the highest weighted confidence. The accuracy with respect to the ground truth is then evaluated on the test set and reported in the Section on experiments.

We would like to introduce the two baseline models here, as they naturally lead to the hy-

Table 3: Single instance model results on the Wiktionary Test set. Accuracies are reported at the character and word level. To show fine grained performances the models are additionally tested on two mutually exclusive datasets, one with overlapping blends and the other without. We have run paired t-tests with the baseline heuristic model with p-value of 0.012.

brid aspect of our model which we discuss later. The conditional baseline model builds a conditional probability distribution of the splice points from source word lengths, i.e. $P(i_1|l_1)$ and $P(i_2|l_2)$, where i_1, i_2 are the splice indices and l_1, l_2 are the lengths of source word 1 and 2 respectively. The model predicts using argmax from the distributions and combines the prefix and suffix. The heuristic model greedily looks for common substrings in the two source words and joins them with the overlap e.g. group + coupon = groupon and group + coupon = gron. Then from the set of combinations, it picks the one that has the longest overlap. If no common substring is found, it reverts to plain conditional model.

The bidirectional binary encoder-decoder that we discussed before does poorly on overlapping blends because it struggles to determine the blends with overlaps. We propose a further enhancement to the ensemble model whereby we introduce extra information about the overlap and common substrings between the source words. This is a hybrid between the heuristic and neural model. Consider the overlap type blend group + coupon = groupon. A mapping is induced from the source words that indicates to the neural network that oup is the overlapping segment. This mapping is provided to the hybrid model as additional information in the form of a binary sequence indicating overlaps between the 2 source words so group + coupon gets mapped to 001110011100 and is fed into the encoder just after the embedding layer as

shown in Figure 1. The motivation is that the extra information should take the burden off the model in finding common overlaps.

Effect of dominance To study the effect of dominance of either of the source words we add binary tags to the characters of each source word proportional to the portion of source word in the blend. If the proportion is greater than or equal to 50 percent, then the dominance is set to 1 else 0. Note that both words can have dominance set to 1. Additionally, we set dominance of both the words to 1 if the proportions differ by less than 0.1 percent.

3 Experiments

3.1 Dataset Details

We use modern collection of english blend words curated by Wiktionary⁶ with a total of 3250 blends. Each example consists of two source words and a target blend word. We restrict the dataset to only prefixes of first source word and suffixes of second source word leading to a total of 2854 blends. As held out datasets we use the dataset created by Cook et al. (Cook and Stevenson, 2010) from wordspy.com, and collected in 2008. It has 179 samples distinct from our training set and 230 unique blends in total with a good balance among different types of blends.

⁷ The Thurner dataset that we use has 482 unique blends which are a subset of the full Thurner dictionary (1993) of around 2300 words collected from 85 sources. The structure of the blends is skewed towards overlapping blends constituting roughly about 66 percentage of all the blends. The Believa dataset (2014) has 235 unique blends collected from multiple sources from year 2000 until recent. The dataset has upto 4 source words but we pick only ones with 2. The blends are well balanced with distributions very similar to Cook (2010).

3.2 Network and Training Details

In this section, we discuss the network structure and training details. All the code is written using Tensorflow (Abadi et al., 2016).

Network Layout: As discussed before we use GRU RNN network as our encoder decoder

Table 5: Results of the ensemble models (top-2 accuracy) on various datasets along with the heuristic model.

Seq2Seq model. Our proposed model has single layer GRU units with 128 neurons. The character vocabulary has a size of 40. Our dataset contains blends with numbers, hyphens and also capitals. Larger, multiple layers or more number of experts in the ensemble networks did not improve performance drastically.

Training The ensemble model of experts is trained end-to-end on mini-batches using Adam Optimization (Kinga and Adam, 2015) over the Wiktionary dataset. The mini batch size is 100 and maximum length of the concatenated source word pair is 29. The learning rate is initialized to 0.006. The fixed sized vector embedding representation of the inputs to our model is set at 128 as well. We allow a dropout rate of 0.25 to prevent over-fitting. The parameters of the model are randomly initialized from a normal distribution with zero mean and standard deviation of 0.1. Training is run for 16 epochs. We tuned hyper-parameters based on our models performance over a range on the validation sets.

3.3 Baseline Heuristic, Neural and Hybrid Models

We compare the performance of our proposed model with other models. The baselines are the conditional probability distribution based model and the heuristic model described previously.

We also compared our model with several types of Seq2Seq models. These include the vanilla char-to-char where the encoder takes source words concatenated and the decoder outputs target blend as characters, Attention char-to-char with added attention mechanism (Bahdanau et al., 2014) to the vanilla char-to-char and Split encoder where two encoders each takes one source word and the decoder takes concatenated encoder states as input. Index based target prediction models that we compared against are the Pointer feedforward model that has an encoder like the vanilla Seq2Seq but the decoder is replaced with feed forward network that outputs a distribution over two indices or pointers that indicate splice points. Pointer decoder is another variant where the decoder is unrolled for two time steps always, each providing a distribution over indices of the concatenated source words. Binary target prediction models including our proposed ensemble model outputs a probability of including the character from the source concatenation at each time step. Attention mechanisms were attempted for the other models but showed no meaningful improvement in performance; the attention mask results were blurred in most cases. We suspect this is due to the mismatch in the encoder and decoder representations (characters versus binary or indices).

3.4 Results and Analysis

The demo of our model is available online⁸. Dataset and source code⁹ is also provided. In all the results reported, character level accuracy indicates the generalized accuracy over number of characters that were predicted correctly in the blend word. Word level accuracy indicates the generalized accuracy over the number of correct blend word predictions over all the source word pair instances.

Table 3 shows the results of all our single instance models as discussed in the previous section. The heuristic conditional model achieves high accuracy in correctly predicting overlapping blends. Its outperforms all the other models in the overlapping blends subset dataset. Overlapping blends account to about fifty percent of the total blends in general. The heuristic conditional model however does poorly in the non overlapping blends as it defaults to a greedy search in order to find the sin-

⁸<https://neuroblender.herokuapp.com>

⁹<https://github.com/FreeEnergy/neuramanteau>

gle character overlaps, such that its performance is worse than the plain conditional model in this subset.

In the char-to-char models, the attention based model performs best as it is able to observe the input words in their entirety at every time step. Figure 2 shows the attention mask for this model while predicting the blend *infotopia*. We can clearly see where it jumps to the second word. The two other char-to-char models perform poorly as they have to additionally track the current character to output. The index based models perform slightly better as the problem is now about predicting the correct splice points. Their performance is relatively unaffected by the blend types - overlapping or non-overlapping. The char-to-binary models outperforms the rest as the solution space is restricted to predicting the binary vector indicating the characters that are present in the blend. The bidirectional model is further able to improve its performance due to its ability to scan the character sequence in both directions for exploiting neighbourhood structure. It can make a better decision on the splinters with this extra information. The vanilla binary model is able to perform better on the overlapping blends data than the bidirectional model but loses out on the non-overlapping case. The bidirectional model essentially is able to generalize to both overlapping and non-overlapping subsets. Finally the hybrid model between heuristic and neural performs the best by including extra information on the overlaps when available. Although it is unable to beat the heuristic model in the overlapping blends subset, it does better overall.

In Tables 4 and 5, we report the performance of our proposed bidirectional ensemble model. The ensemble models are able to bring in significant gains as compared to the single instance models. The hybrid model is able to get the best of both world: heuristic and neural models to get the best overall accuracy. However, its performance is skewed towards the overlapping blends resulting in lower performance on the no overlap data subset in comparison to the plain bidirectional model. The heuristic model performs well on the Thurner (1993) dataset due to the majority of the words in the Thurner data comprising overlapping blends. The Cook (2010) and Believa datasets (2014) are more balanced in which the hybrid model outperforms the rest. The Mix-

Table 6: Comparison of predictions from heuristic and ensemble hybrid models on sample inputs.

ture of Experts (MoE) ensemble causes experts to specialize individually to the examples early on, most often converging to a subset of experts. This led to reduced accuracies for MoE throughout. It was difficult to train the model as it preferred to converge (specialize) to a few experts even when enforcing a variance loss to encourage diversity. In contrast, the bidirectional ensemble model did not specialize as each expert is trained separately. That independence helps the ensemble to generalize in capturing the wider variations in the blends. In Table 6, we compare the predictions from the hybrid ensemble model and the heuristic single instance models. On observing the failure modes, due to the qualitative and subjective nature of blends, we find that some of the predicted blends are still quite plausible. We would hazard to say that some of these predictions actually look more natural than the dataset values.

Figure 3 shows the performance plot of the

Model	Top-1 Word Accuracy					
	Test	OL	No OL	Cook	Turner	Believa
Bidirectional Binary with Dominance(K=15)	0.491	0.505	0.491	0.517	0.378	0.415
Hybrid Bidirectional Binary with Dominance (K=15)	0.572	0.721	0.453	0.643	0.525	0.487

Table 7: Results of dominance based models. K indicates number of experts. OL indicates overlaps.

bombay	hollywood	bombaywood	bollywood	bombwood
republican	democrat	republicrat	repumocrat	repubocrat

Table 8: Sample predictions from hybrid ensemble with variation in dominance.

validation accuracy of any expert predicting correctly in comparison to the weighted voting prediction. The weaker metric of evaluating the accuracy based on any expert, outperforms the weighted voting prediction over the training duration. Tables 8 and 7 shows some sample predictions and accuracy by the dominance enhanced hybrid model on sample inputs. With the famous `brunch` blend, our model predicts that the blend would have been `breaklunch` if `breakfast` had been given more importance by the coiner. Similarly our model predicts `phone` and `tablet` gives `phonlet` when dominance of the source words are same. But when the word `tablet` is set to be dominant the model predicts `phablet`, the form of the blend which is in popular use now. We can hypothesize that the creator of this blend perhaps wanted more emphasis on tablets when marketing `phablet` form factor mobile devices.

Comparison with Deri et al. (2015) The main working example in their published paper: `stay + vacation` predicted `stacation` on their demo website, instead of `staycation` as claimed, whereas our model demo predicted `staycation`. Further, on their dataset (with common words with the Wiktionary dataset that we used removed), our baseline heuristic beat their model with accuracy of 47.7% in comparison to their models 45.3%, while our primary model achieved 48.3%. Their dataset consists of 400 examples in contrast to our dataset of 2854 examples. Their system is unable to generalize to non-overlapping blends like `staycation`, `workholic` correctly which our system can.

4 Future Work and Conclusions

In this work, we show that neural networks are well suited to modelling uncertainties in the blending process. The ensemble RNN neural and ensemble RNN neural-hybrid encoder-decoder systems that we propose generalized very well to

overlapping and non-overlapping blended English words from two source words. They outperform statistical, heuristic, neural single instance and mixture of experts ensemble models over multiple datasets. However, these ensemble models are unable to capture the stringent rules and restrictions that disallow certain character combinations like *bxy*, *ii*, *gls*. An attempt to tag inputs with phonetic or articulatory information failed to correct these mistakes. One possibility is to use reinforcement learning (Sutton and Barto, 1998) to apply specific rules of word formation. Other types of errors are recognizability errors which causes loss of recognition of one or both source words and overrepresentation errors which adds extra (and unnecessary) characters from the source words. Some of these examples are provided in the Appendix. We believe these errors occur due to the sparsity in the training data.

Abstract

We explore techniques to maximize the effectiveness of discourse information in the task of authorship attribution. We present a novel method to embed discourse features in a Convolutional Neural Network text classifier, which achieves a state-of-the-art result by a significant margin. We empirically investigate several featurization methods to understand the conditions under which discourse features contribute non-trivial performance gains, and analyze discourse embeddings.¹

1 Introduction

Authorship attribution (AA) is the task of identifying the author of a text, given a set of author-labeled training texts. This task typically makes use of stylometric cues at the surface lexical and syntactic level (Stamatatos et al., 2015), although Feng and Hirst (2014) and Feng (2015) go beyond the sentence level, showing that discourse information can help. However, they achieve limited performance gains and lack an in-depth analysis of discourse featurization techniques. More recently, convolutional neural networks (CNNs) have demonstrated considerable success on AA relying only on character-level n -grams (Ruder et al., 2016; Shrestha et al., 2017). The strength of these models is evidenced by findings that traditional stylometric features such as word n -grams and POS-tags do not improve, and can sometimes even hurt performance (Ruder et al., 2016; Sari et al., 2017). However, none of these CNN models make use of discourse.

Our work builds upon these prior studies by exploring an effective method to (i) featurize the discourse information, and (ii) integrate discourse features into the best text classifier (i.e., CNN-based models), in the expectation of achieving state-of-the-art results in AA.

Feng and Hirst (2014) (henceforth F&H14) made the first comprehensive attempt at using discourse information for AA. They employ an entity-grid model, an approach introduced by Barzilay and Lapata (2008) for the task of ordering sentences. This model tracks how the grammatical relations of salient entities (e.g., *subj*, *obj*, etc.) change between pairs of sentences in a document, thus capturing a form of discourse coherence. The grid is summarized into a vector of transition probabilities. However, because the model only records the transition between two consecutive sentences at a time, the coherence is *local*. Feng (2015) (henceforth F15) further extends the entity-grid model by replacing grammatical relations with discourse relations from Rhetorical Structure Theory (Mann and Thompson, 1988, RST). Their study uses a linear-kernel SVM to perform pairwise author classifications, where a non-discourse model captures lexical and syntactic features. They find that adding the entity-grid with grammatical relations enhances the non-discourse model by almost 1% in accuracy, and using RST relations provides an improvement of 3%. The study, however, works with only one small dataset and their models produce overall unremarkable performance ($\sim 85\%$). Ji and Smith (2017) propose an advanced Recursive Neural Network (RecNN) architecture to work with RST in the more general area of text categorization and present impressive results. However, we suspect that the massive number of parameters of RecNNs would likely cause overfitting when working with smaller datasets, as is often the case in AA tasks.

*The first two authors contributed equally to this work.

Table 2: The probability vector for the excerpt in Table 1 capturing transition probabilities of length 2.

In our paper, we opt for a state-of-the-art character-bigram CNN classifier (Shrestha et al., 2017). We choose to use the entity-grid model because we find it helps avoid overfitting² (adding typical stylistic features such as word *n*-grams and POS tags results in overfitting) and further captures coreference chains, which we show are critical to improving performance on this task (see Section 5). We investigate various ways in which the discourse information can be featurized and integrated into the CNN. Specifically,

- *Featurization.* We attempt to capture a more *global* discourse coherence by modeling the entire sequence of relations in a document for every salient entity, instead of only the relations between pairs of sentences.
- *Feature integration.* Using a neural network architecture allows us to explore embedding the relations from the entity-grid model,³ rather than only exploiting a vector of relation probabilities.

We explore these questions using two approaches to represent salient entities: grammatical relations, and RST discourse relations. We apply these models to datasets of varying sizes and genres, and find that adding any discourse information improves AA consistently on longer documents,

²Primarily compared to previous work where discourse trees are modeled with Recursive Neural Nets (Ji and Smith, 2017).

³Tien Nguyen and Joty (2017) are the first to propose applying embeddings in modeling local coherence (for the coherence judgment task). Our methods roughly subsume theirs, which correspond to our GR CNN2-DE (global) model (Section 3). This scheme did not come out on top in our AA tasks.

but has mixed results on shorter documents. Further, embedding the discourse features in a parallel CNN at the input end yields better performance than concatenating them to the output layer as a feature vector (Section 3). The global featurization is more effective than the local one. We also show that SVMs, which can only use discourse probability vectors, neither produce a competitive performance (even with fine-tuning), nor generalize in using the discourse information effectively.

2 Background

Entity-grid model. Typical lexical features for AA are relatively superficial and restricted to within the same sentence. F&H14 hypothesize that discourse features beyond the sentence level also help authorship attribution. In particular, they propose an author has a particular style for representing entities across a discourse. Their work is based on the entity-grid model of Barzilay and Lapata (2008) (henceforth B&L).

The entity-grid model tracks the grammatical relation (*subj*, *obj*, etc.) that salient entities take on throughout a document as a way to capture local coherence. A salient entity is defined as a noun phrase that co-occurs at least twice in a document. Extensive literature has shown that subject and object relations are a strong signal for salience and it follows from Centering Theory that you want to avoid rough shifts in the center (Grosz et al., 1995; Strube and Hahn, 1999). B&L thus focus on whether a salient entity is a subject (*s*), object (*o*), other (*x*), or is not present (-) in a given sentence, as illustrated in Table 1. Every sentence in a document is encoded with the grammatical relation of all the salient entities, resulting in a grid

similar to Table 3.

	father	mother
(1)	s	-
(2)	o	s
(3)	x	s

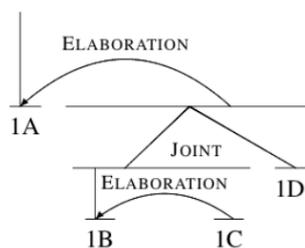

Table 3: The entity grid for the excerpt in Table 1, where columns are salient entities and rows are sentences. Each cell contains the grammatical relation of the given entity for the given sentence (subject *s*, object *o*, another grammatical relation *x*, or not present *-*). If an entity occurs multiple times in a sentence, only the highest-ranking relation is recorded.

The local coherence of a document is then defined on the basis of local entity transitions. A local entity transition is the sequence of grammatical relations that an entity can assume across n consecutive sentences, resulting in $\{s,o,x,-\}^n$ possible transitions. Following B&L, F&H14 consider sequences of length $n=2$, that is, transitions between two consecutive sentences, resulting in $4^2=16$ possible transitions. The probability for each transition is then calculated as the frequency of the transition divided by the total number of transitions. This step results in a single probability vector for every document, as illustrated in Table 2.

B&L apply this model to a sentence ordering task, where the more coherent option, as evidenced by its transition probabilities, was chosen. In authorship attribution, texts are however assumed to already be coherent. F&H14 instead hypothesize that an author unconsciously employs the same methods for describing entities as the discourse unfolds, resulting in discernible transition probability patterns across multiple of their texts. Indeed, F&H14 find that adding the B&L vectors increases the accuracy of AA by almost 1% over a baseline lexico-syntactic model.

RST discourse relations. F15 extends the notion of tracking salient entities to RST. Instead of using grammatical relations in the grid, RST discourse relations are specified. An RST discourse relation defines the relationship between two or more elementary discourse units (EDUs), which are spans of text that typically correspond to syntactic clauses. In a relation, an EDU can function as a nucleus (e.g., *result.N*) or as a satellite (e.g., *summary.S*). All the relations in a document then form a tree as in Figure 1.⁴

⁴For reasons of space, only the first sentence of the excerpt is illustrated.

[My father was a clergyman of the north of England,]^{1A} [who was deservedly respected by all]^{1B} [who knew him;]^{1C} [and, in his younger days, lived pretty comfortably on a joint of a small incumbency and a snug little property of his own.]^{1D}

Figure 1: RST tree for the first sentence of the excerpt in Table 1.

F15 finds that RST relations are more effective for AA than grammatical relations. In our paper, we populate the entity-grid in the same way as F15’s “Shallow RST-style” encoding, but use fine-grained instead of coarse-grained RST relations, and do not distinguish between intra-sentential and multi-sentential RST relations, or salient and non-salient entities. We explore various featurization techniques using the coding scheme.

CNN model. Shrestha et al. (2017) propose a convolutional neural network formulation for AA tasks (detailed in Section 3). They report state-of-the-art performance on a corpus of Twitter data (Schwartz et al., 2013), and compare their models with alternative architectures proposed in the literature: (i) SCH: an SVM that also uses character n -grams, among other stylistic features (Schwartz et al., 2013); (ii) LSTM-2: an LSTM trained on bigrams (Tai et al., 2015); (iii) CHAR: a *Logistic Regression* model that takes character n -grams (Stamatatos, 2009); (iv) CNN-W: a CNN trained on word embeddings (Kalchbrenner et al., 2014). The authors show that the model CNN2⁵ produces the best performance overall. Ruder et al. (2016) apply character n -gram CNNs to a wide range of datasets, providing strong empirical evidence that the architecture generalizes well. Further, they find that including word n -grams in addition to character n -grams reduces performance, which is in agreement with Sari et al. (2017)’s findings.

⁵Shrestha et al. (2017) test two variants of CNN models: CNN1/CNN2 for unigram/bigram character CNNs respectively.

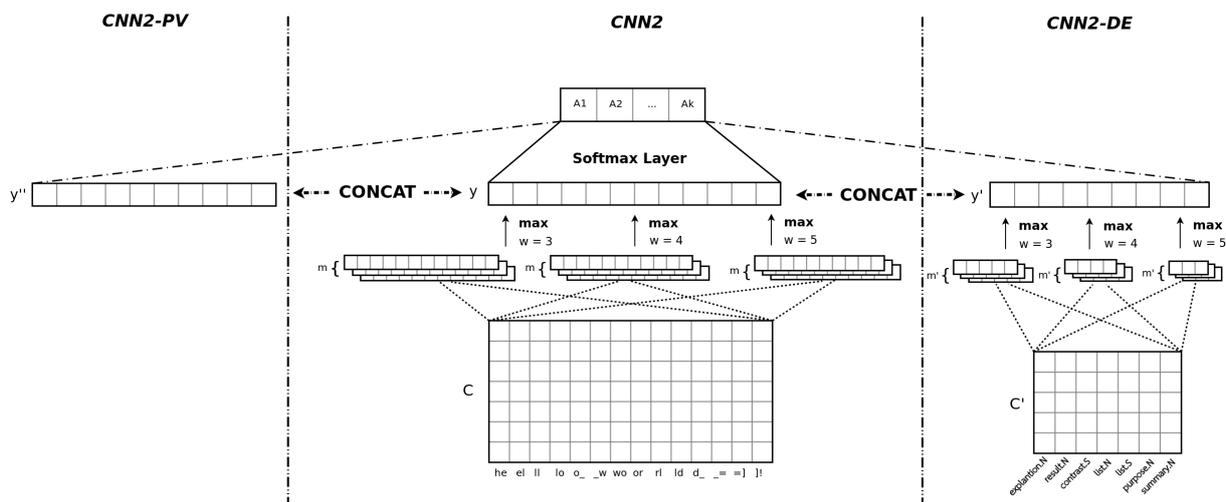

Figure 2: The bigram character CNN models

3 Models

Building on Shrestha et al. (2017)’s work, we employ their character-bigram CNN (CNN2)⁶, and propose two extensions which utilize discourse information: (i) CNN2 enhanced with relation *probability vectors* (CNN2-PV), and (ii) CNN2 enhanced with *discourse embeddings* (CNN2-DE). The CNN2-PV allows us to conduct a comparison with F&H14 and F15, which also use relation probability vectors.

CNN2. CNN2 is the baseline model with no discourse features. Illustrated in Figure 2 (center), it consists of (i) an embedding layer, (ii) a convolution layer, (iii) a max-pooling layer, and (iv) a softmax layer. We briefly sketch the processing procedure and refer the reader to (Shrestha et al., 2017, Section 2) for mathematical details.

The network takes a sequence of character bigrams $\mathbf{x} = \langle x_1, \dots, x_l \rangle$ as input, and outputs a multinomial ϕ over class labels as the prediction. The model first looks up the embedding matrix to produce a sequence of embeddings for \mathbf{x} (i.e., the matrix C), then pushes the embedding sequence through convolutional filters of three bigram-window sizes $w = 3, 4, 5$, each yielding m feature maps. We then apply the *max-over-time* pooling (Collobert et al., 2011) to the feature maps from each filter, and concatenate the resulting vectors to obtain a single vector \mathbf{y} , which then goes through the softmax layer to produce predictions.

CNN2-PV. This model (Figure 2, left+center) fea-

turizes discourse information into a probability vector (PV). The discourse features come in two flavors: (i) grammatical relations (GR), and (ii) RST discourse relations (RST)⁷. For both types of discourse features, an entity grid is first constructed to identify salient entities⁸. Recall each row in the grid is a sentence, and each column is a salient entity. The values of each cell in the grid are then populated differently, depending on which flavor of discourse feature is used.

For GR features, the entity grid is populated with the grammatical relation of each entity in each sentence. The entity grid is then collapsed into a single probability vector as shown in Table 2. The GR feature vector thus consists of a sequence of *grammatical relation transitions* derived from the entity grid, e.g., $\langle sx, xs, ss, \dots \rangle$. The vector is a distribution over all the grammatical role transitions, i.e., $\langle p(sx), p(xs), p(ss), \dots \rangle$.

For RST features, the entity grid is populated with the RST relation and nuclearity of the entity, and additionally the relations and nuclearity of the main EDUs in the current and previous sentence (as in Feng (2015)). We do not encode the entire RST tree since prior work has shown better performance with underspecified trees (Ji and Smith, 2017; Hogenboom et al., 2015). The RST features are represented as *RST discourse relations* with their nuclearity, e.g., $\langle \text{definition.N}, \text{attribution.S}, \dots \rangle$. The probability vector is a distribution

⁶Our preliminary experiments found that using character n -gram orders higher than 2 performed worse, likely due to the increased number of features and overfitting.

⁷Using RST Parser from Ji and Eisenstein (2014).

⁸Using neural coreference resolver, dependency parser in Stanford Core NLP (Clark and Manning, 2016).

Dataset	# authors	mean words/auth	range words/auth
NOVEL-9	9	376,242	124K-1M
NOVEL-50	50	709,880	184K-2.1M
IMDB62	62	349,004	9.8K-75K

Table 4: Statistics for datasets.

over all the RST discourse relations, i.e., $\langle p(\text{definition.N}), p(\text{attribution.S}), \dots \rangle$

Denoting the discourse feature vector with \mathbf{y}'' , we construct the pooling vector \mathbf{y} for the char-bigrams, and concatenate \mathbf{y}'' to \mathbf{y} before feeding the resulting vector to the softmax layer.

CNN2-DE. In this model (Figure 2, center+right), we embed discourse features in high-dimensional space (similar to char-bigram embeddings). Let $\mathbf{z} = \langle z_1, \dots, z_{l'} \rangle$ be a sequence of discourse features⁹, we treat it in a similar fashion to the char-bigram sequence \mathbf{x} , i.e. feeding it through a “parallel” convolutional net (Figure 2 right). We set the embedding size to the average number of relations, then either pad or truncate. The operation results in a pooling vector \mathbf{y}' . We concatenate \mathbf{y}' to the pooling vector \mathbf{y} (which is constructed from \mathbf{x}) then feed $[\mathbf{y}; \mathbf{y}']$ to the softmax layer for the final prediction.

4 Experiments and Results

We begin by introducing the datasets (Section 4.1), followed by detailing the featurization methods (Section 4.2), the experiments (Section 4.3), and finally reporting results (Section 4.4).

4.1 Datasets

The statistics for the three datasets used in the experiments are summarized in Table 4.

novel-9. This dataset was compiled by F&H14: a collection of 19 novels by 9 nineteenth century British and American authors in the Project Gutenberg. To compare to F&H14, we apply the same resampling method (F&H14, Section 4.2) to correct the imbalance in authors by oversampling the texts of less-represented authors.

novel-50. This dataset extends novel-9, compiling the works of 50 randomly selected authors of the

⁹The sequence comes in two variants, depending on the featurization technique, see Section 4.2.

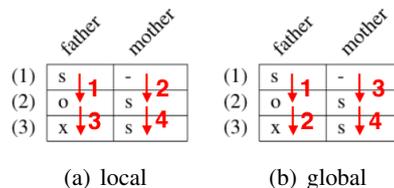

Figure 3: Two variants for creating sequences of grammatical relation transitions in an entity grid.

same period. For each author, we randomly select 5 novels for a total 250 novels.

IMDB62. IMDB62 consists of 62K movie reviews from 62 users (1,000 each) from the Internet Movie dataset, compiled by Seroussi et al. (2011). Unlike the novel datasets, the reviews are considerably shorter, with a mean of 349 words per text.

4.2 Featurization

As described in Section 2, in both the GR and RST variants, from each input entry we start by obtaining an entity grid.

CNN2-PV. We collect the probabilities of entity role transitions (in GR) or discourse relations (in RST) for the entries. Each entry corresponds to a probability distribution vector.

CNN2-DE. We employ two schemes for creating discourse feature sequences from an entity grid. While we always read the grid by column (by a salient entity), we vary whether we track the entity across a number of sentences (n rows at a time) or across the entire document (one entire column at a time), denoted as *local* and *global* readings respectively.

For the GR discourse features, in the case of local reading, we process the entity roles one sentence pair at a time (Figure 3, left). For example, in processing the pair (s_1, s_2) , we find the first non-empty role r_{11} for entity $E1$ in s_1 . If $E1$ also has a non-empty role r_{21} in the s_2 , we collect the entity role transition $r_{11}r_{21}$. We then proceed to the following entity $E2$, until we process all the entities in the grid and move to the next sentence pair. For the global reading, we instead read the entity roles by traversing one column of the entire document at a time (Figure 3, right). The entity roles in all the sentences are read for one entity: we collect transitions for all the non-empty roles (e.g., s_o , but not s_-).

For the RST discourse features, we process non-empty discourse relations also through either local or global reading. In the local reading, we read all the discourse relations in a sentence (a row) then

move on to the next sentence.¹⁰ In the global reading, we read in discourse relations for one entity at a time. This results in sequences of discourse relations for the input entries.

4.3 Experiments

Baseline-dataset experiments. All the baseline-dataset experiments are evaluated on novel-9. As a comparison to previous work (F15), we evaluate our models using a pairwise classification task with GR discourse features. In her model, each novel is partitioned into 1000-word chunks, and the model is evaluated with accuracy.¹¹ Surpassing F15’s SVM model by a large margin, we then further evaluate the more difficult multi-class task, i.e., all-class prediction simultaneously, with both GR and RST discourse features and the more robust F1 evaluation. In this multi-class task, we implement two SVMs to extend F15’s SVM models: (i) SVM2: a linear-kernel SVM which takes char-bigrams as input, as our CNNs, and (ii) SVM2-PV: an updated SVM2 which takes also probability vector features.

Further, we are interested in finding a performance threshold on the minimally-required input text length for discourse information to “kick in”. To this end, we chunk each novel into different sizes: 200-2000 words, at 200-word intervals, and evaluate our CNNs in the multi-class condition.

Generalization-dataset experiments. To confirm that our models generalize, we pick the best models from the baseline-dataset experiments and evaluate on the novel-50 and IMDB62 datasets. For novel-50, the chunking size applied is 2000-word as per the baseline-dataset experiment results, and for IMDB62, texts are not chunked (i.e., we feed the models with the original reviews directly). For model comparison, we also run the SVMs (i.e., SVM2 and SVM2-PV) used in the baseline-dataset experiment. All the experiments conducted here are multi-class classification with macro-averaged F1 evaluation.

Model configurations. Following F15, we perform 5-fold cross-validation. The embedding sizes are tuned on novel-9 (multi-class condition): 50 for char-bigrams; 20 for discourse features. The learning rate is 0.001 using the Adam Optimizer

¹⁰We do not check the next sentences as in GR, because the discourse relations in one cell of the entity grid typically already capture relations beyond the sentence level.

¹¹Averaged over all the author-author pair experiments.

MODEL	AVG. ACCURACY
Baseline	49.8
SVM (LexSyn)	85.5
SVM (LexSyn-PV)	86.4
CNN2	99.5
CNN2-PV	99.8

Table 5: Accuracy for pairwise author classification on the novel-9 dataset, using either a dumb baseline, an SVM with and without discourse to replicate F15, or a bigram-character CNN (CNN2) with and without discourse.

DISC. TYPE	MODEL	F1
None	SVM2	84.9
	CNN2	95.9
GR	SVM2-PV	85.7
	CNN2-PV	96.1
	CNN2-DE (local)	97.0
	CNN2-DE (global)	96.9
RST	SVM2-PV	85.9
	CNN2-PV	96.3
	CNN2-DE (local)	97.4
	CNN2-DE (global)	98.5

Table 6: Macro-averaged F1 score for multi-class author classification on the novel-9 dataset, using either no discourse (None), grammatical relations (GR), or RST relations (RST). These experiments additionally include the Discourse Embedding (DE) models for GR and RST.

(Kingma and Ba, 2014). For all models, we apply dropout regularization of 0.75 (Srivastava et al., 2014), and run 50 epochs (batch size 32). The SVMs in the baseline-dataset experiments use default settings, following F15. For the SVMs in the generalization-dataset experiments, we tuned the hyperparameters on novel-9 with a grid search, and found the optimal setting as: stopping condition `tol` is 1e-5, at a max-iteration of 1,500.

4.4 Results

Baseline-dataset experiments. The results of the baseline-dataset experiments are reported in Table 5, 6 and Figure 4. In Table 5, Baseline denotes the dumb baseline model which always predicts the more-represented author of the pair. Both SVMs are from F15, and we report her results. SVM (LexSyn) takes character and word bi/trigrams and POS tags. SVM (LexSyn-PV) additionally includes probability vectors, similar to our CNN2-PV. In this part of the experiment, while the CNNs clear a large margin over SVMs (all differences

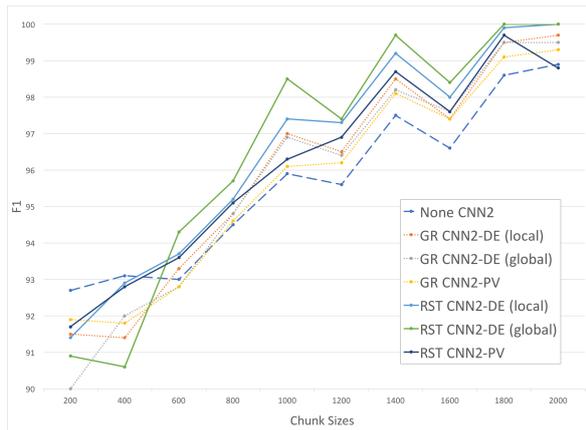

Figure 4: Macro-averaged F1 score for multi-class author classification on the novel-9 dataset in varied chunk sizes.

are statistically significant at $p < 0.005$), adding discourse in CNN2-PV brings only a small performance gain.

Table 6 reports the results from the multi-class classification task, the more difficult task. Here, probability vector features (i.e., PV) again fail to contribute much. The discourse embedding features, on the other hand, manage to increase the F1 score by a noticeable amount, with the maximal improvement seen in the CNN2-DE (global) model with RST features (by 2.6 points). In contrast, the discourse-enhanced SVM2-PVs increase F1 by about 1 point, with overall much lower scores in comparison to the CNNs. In general, RST features work better than GR features.

The results of the varying-sizes experiments are plotted in Figure 4. Again, we observe the overall pattern that discourse features improve the F1 score, and RST features procure superior performance. Crucially, however, we note there is no performance boost below the chunk size of 1000 for GR features, and below 600 for RST features. Where discourse features do help, the GR-based models achieve, on average, 1 extra point on F1, and the RST-based models around 2.

Generalization-dataset experiments. Table 7 summarizes the results of the generalization-dataset experiments. All reported statistical tests are t-test with a significance level of 0.05. First, we note that CNNs show a clear advantage over SVMs for all model variants on both datasets (confirmed significant for SVM2 vs. CNN2 with no discourse, SVM2-PV vs. CNN2-DE with GR and RST). On novel-50, most discourse-enhanced models significantly improve the performance of the baseline non-discourse CNN2 to varying de-

DISC. TYPE	MODEL	NOVEL-50	IMDB62
None	SVM2	92.9	90.4
	CNN2	95.3	91.5
GR	SVM2-PV	93.3	90.4
	CNN2-PV	95.1	90.5
	CNN2-DE (local)	96.9	90.8
	CNN2-DE (global)	97.5	90.9
RST	SVM2-PV	93.8	90.9
	CNN2-PV	95.5	90.7
	CNN2-DE (local)	97.7	91.4
	CNN2-DE (global)	98.8	92.0

Table 7: Macro-averaged F1 score for multi-class author classification on the large datasets, using either no discourse (None), grammatical relations (GR), or RST relations (RST).

grees (significant for CNN2 with no discourse vs. CNN2-DE with GR and RST). The clear pattern again emerges that RST features work better, with the best F1 score evidenced in the CNN2-DE (global) model (3.5 improvement in F1) (significant for CNN2-DE with GR vs. CNN2-DE with RST). On IMDB62, as expected with short text inputs (mean=349 words/review), the discourse features in general do not add further contribution. Even the best model, CNN2-DE, brings only marginal improvement (not statistically significant), confirming our findings from varying the chunk size on novel-9, where discourse features did not help at this input size. However, the difference between the GR and RST variants for the IMDB CNN models are statistically significant. For the SVM models on both datasets, we note discourse features do not make noticeable improvements. On novel-50, SVM2-PV performs slightly better than the no-discourse SVM2 (by 0.4 with GR, 0.9 with RST features). On IMDB62, the same pattern persists with no gains for GR and 0.5 for RST features.

5 Analysis

General analysis. Overall, we have shown that discourse information can improve authorship attribution, but only when properly encoded. This result is critical in demonstrating the particular value of discourse information, because typical stylistometric features such as word n -grams and POS tags do *not* add additional performance improvements (Ruder et al., 2016; Sari et al., 2017).

In addition, the type of discourse information and the way in which it is featurized are crucial to this performance improvement: RST features provide overall stronger improvement, and the global

TARGET EMBEDDING	TOP NEIGHBORS

consequence.N	result.N, list.N, result.S, comment.N, summary.N

Table 8: Nearest neighbors of example embeddings with t-SNE clustering (top 5)

reading scheme for discourse embedding works better than the local one. The discourse embedding proves to be a superior featurization technique, as evidenced by the generally higher performance of CNN2-DE models over CNN2-PV models. With an SVM, where the option is not available, we are only able to use relation probability vectors to obtain a very modest performance improvement.

Further, we found an input-length threshold for utilizing discourse features is helpful (Section 4.4). Not surprisingly, discourse does not contribute on shorter texts. Many of the feature grids are empty for these shorter texts— either there are no coreference chains or they are not correctly resolved. Currently we only have empirical results on short novel chunks and movie reviews, but believe the finding would generalize to Twitter or blog posts.

Discourse embeddings. It does not come as a surprise that discourse-embedding-based models perform better than their relation-probability-based peers. The former (i) leverages the weight learning of the entire computational graph of the CNN rather than only the softmax layer, as the PV models do, and (ii) provides a more fine-grained featurization of the discourse information. Rather than merely taking a probability over grammatical relation transitions (in GR) or discourse relation types (in RST), in DE-based models we learn the dependency between grammatical relation transitions/discourse relations through the w -sized filter sweeps.

To further study the information encoded in the discourse embeddings, we performed t-SNE clustering (van der Maaten and Hinton, 2008) on them, using the best performing model CNN2-DE (global). We examined the closest neighbors of each embedding, and observed that similar discourse relations tend to go together (e.g., explanation and interpretation;

consequence and result). Some examples are given in Table 8. However, it is unclear how this pattern helps improve classification performance. We intend to investigate this question in future work.

Global vs. Local featurization. As described in Section 4.2, the global reading processes all the discourse features for one entity at a time, while the local approach reads one sentence (or one sentence pair) at a time. In all the relevant experiments, global featurization showed a clear performance advantage (on average 1 point gain in F1). Recall that the creation of the grids (both GR and RST) depend on coreference chains of entities (Section 2), and only the global reading scheme takes advantage of the coreference pattern whereas the local reading breaks the chains. To find out whether coreference pattern is the key to the performance difference, we further ran a probe experiment where we read RST discourse relations in the order in which EDUs are arranged in the RST tree (i.e., left-to-right), and evaluated this model on novel-50 and IMDB62 with the same hyperparameter setting. The F1 scores turned out to be very close to the CNN2-DE (local) model, at 97.5 and 90.9. Based on this finding, we tentatively confirm the importance of the coreference pattern, and intend to further investigate how exactly it matters for the classification performance.

GR vs. RST. RST features in general give higher performance gains than GR features (Table 7). The RST parser produces a tree of discourse relations for the input text, thus introducing a “global view.” The GR features, on the other hand, are more restricted to a “local view” on entities between consecutive sentences. While a deeper empirical investigation is needed, one can intuitively imagine that identifying authorship by focusing on the local transitions between grammatical re-

lations (as in GR) is more difficult than observing how the entire text is organized (as in RST).¹²

Error analysis. We conducted a brief error analysis in an effort to understand why discourse helps. Comparing performance by author, we found the least-represented author (Ambrose Bierce) obtains the biggest improvement from discourse. We speculate that although the document must be a certain length for discourse to “kick in”, these features are effective even with few training examples. On the other hand, inspecting the gradients of the character bigrams for these cases reveals a higher incidence of 0s, suggesting the bigram feature is not as robust in the smaller sample space. We further note that two other authors who gained large improvements from the discourse features wrote a variety of genres (e.g., both supernatural/horror fiction and love stories), which we speculate manifests itself in different vocabularies that don’t generalize well in character bigrams, but do have similar rhetorical styles which the discourse features can exploit.

6 Conclusion

We have conducted an in-depth investigation of techniques that (i) featurize discourse information, and (ii) effectively integrate discourse features into the state-of-the-art character-bigram CNN classifier for AA. Beyond confirming the overall superiority of RST features over GR features in larger and more difficult datasets, we present a discourse embedding technique that is unavailable for previously proposed discourse-enhanced models. The new technique enabled us to push the envelope of the current performance ceiling by a large margin.

Admittedly, in using the RST features with entity-grids, we lose the valuable RST tree structure. In future work, we intend to adopt more sophisticated methods such as RecNN, as per [Ji and Smith \(2017\)](#), to retain more information from the RST trees while reducing the parameter size. Further, we aim to understand how discourse embeddings contribute to AA tasks, and find alternatives to coreference chains for shorter texts.

¹²Note that, however, it is simpler to extract GR features, as we rely solely on a high-performance dependency parser, which is widely available, whereas for RST features, we need gold RST-labeled training data, which incurs higher cost and potentially relatively limited generalizability.

Acknowledgments

We thank Stephen Roller and three anonymous reviewers for their valuable feedback. Thanks to Sebastian Ruder for kindly offering his datasets in the exploratory stage of the project, and to Prasha Shrestha for sharing the code from her paper. The first author was supported by an NSF-GRFP fellowship.

Lightly-Supervised Modeling of Argument Persuasiveness

Isaac Persing and Vincent Ng
Human Language Technology Research Institute
University of Texas at Dallas
Richardson, TX 75083-0688
{persingq, vince}@hlt.utdallas.edu

Abstract

We propose the first lightly-supervised approach to scoring an argument’s persuasiveness. Key to our approach is the novel hypothesis that lightly-supervised persuasiveness scoring is possible by explicitly modeling the major errors that negatively impact persuasiveness. In an evaluation on a new annotated corpus of online debate arguments, our approach rivals its fully-supervised counterparts in performance by four scoring metrics when using only 10% of the available training instances.

1 Introduction

Argumentation mining is a relatively new and active area of research in the natural language processing (NLP) community, focusing on extracting argument components (e.g., claims, premises) and determining the relationships (e.g., support, attack) between them. Recently, researchers have begun work on modeling an intriguing linguistic phenomenon, the *persuasiveness* of arguments.

In this paper, we examine argument persuasiveness in the context of an under-investigated task in argument mining, *argument persuasiveness scoring*. Given a text consisting of an argument written for a particular topic, the goal of argument persuasiveness scoring is to assign a score to the text that indicates how persuasive the argument is. An argument persuasiveness scoring system can be used in a variety of situations. In an online debate, for instance, an author’s primary goal is to convince others of the argument expressed in her comment(s). Similarly, in persuasive essay writing, an author should establish convincing arguments. In both situations, a persuasiveness scoring system could provide useful feedback to these authors on how persuasive their arguments are.

Being a *discourse-level* task, argument persuasiveness scoring is potentially more challenging than many NLP tasks. Oftentimes, argument persuasiveness can only be determined by understanding the discourse, not by the presence or absence of lexical cues. As an example, consider the debate argument shown in Table 1, which is composed of the author’s assertion and her justification of the assertion written in response to a debate motion. It is fairly easy for a human to determine that this argument should be assigned a low persuasiveness score because the argument could be more clear. However, the same is not true for a machine, primarily because it is not possible to determine the persuasiveness of this argument merely by considering the words or phrases appearing in it.

Given the difficulty of the task, it is conceivable that *unsupervised* argument persuasiveness scoring is very challenging. Nevertheless, a solution to unsupervised argument persuasiveness scoring is of practical significance. This is because of the high cost associated with manually creating persuasiveness-annotated data needed to train classifiers in a supervised manner. This contrasts with tasks such as polarity classification and stance classification. In these tasks, large amounts of annotated data can be harvested from the Web, as it is typical for a user to explicitly indicate her polarity/stance while writing her comments in a discussion/debate forum.

We propose a *lightly-supervised* approach to argument persuasiveness scoring. To our knowledge, this is the first lightly-supervised approach to the task: virtually all previous work involving argument persuasiveness has adopted supervised approaches, training models with a large number of surface features that encode lexico-syntactic information. Note that learning from a large number of lexico-syntactic features is difficult, if not im-

Motion	This House would ban teachers from interacting with students via social networking websites.
Assertion	Acting as a warning signal for children at risk.
Justification	It is very difficult for a child to realize that he is being groomed; they are unlikely to know the risk. After all, a teacher is regarded as a trusted adult. But, if the child is aware that private electronic contact between teachers and students is prohibited by law, the child will immediately know the teacher is doing something he is not supposed to if he initiates private electronic contact. This will therefore act as an effective warning sign to the child and might prompt the child to tell a parent or another adult about what is going on.

Table 1: The motion, assertion, and justification text of a debate argument.

possible, when annotated data is scarce. Hence, we explore a different idea, addressing lightly-supervised argument persuasiveness scoring via an *error-modeling* approach. Specifically, guided by theoretical work on persuasiveness, we begin by defining a set of *errors* that could negatively impact an argument’s persuasiveness. The key step, then, is to model an argument’s errors: given an argument, we predict the presence and severity of the errors it possesses in an unsupervised manner by bootstrapping from a set of heuristically labeled seeds. Finally, we learn a persuasiveness predictor for each error-labeled argument from a small amount of persuasiveness-annotated data.

Our contributions are two-fold. First, we propose the first lightly-supervised approach to persuasiveness scoring that rivals its supervised counterparts in performance on a new dataset consisting of 1,208 online debate arguments. Second, we make our annotated dataset publicly available.¹ Given the difficulty of obtaining annotated data for this task, we believe that our dataset will be a valuable resource to the NLP community.

2 Related Work

There have been several recent attempts to address tasks related to argument persuasiveness. [Habernal and Gurevych \(2016a,b\)](#) rank a pair of arguments w.r.t. persuasiveness, but ranking alone cannot tell us *how* persuasive an argument is. [Persing and Ng \(2015\)](#) score a student essay based on whether it makes a (un)convincing argument for its thesis. Using the conversations in the ChangeMyView subreddit, [Tan et al. \(2016\)](#) study factors affecting whether a challenger can successfully persuade a commenter to change the view she expressed in her original post.

While [Wei et al. \(2016\)](#) also predict the persuasiveness of debate posts, their work differs from ours in several aspects. First, many of their de-

¹See <http://www.hlt.utdallas.edu/~persingq/Debate/> for a complete list of our annotations.

bate posts are written in response to a preceding comment in the conversation. Hence, it is not uncommon to see emotional rather than logical arguments or even insults and personal attacks. In addition, it may not always be possible to understand what the argument is and why the author made a particular argument without understanding the (preceding) context. In contrast, the debate comments in our corpus are written in response to a given debate topic. In other words, each comment is written independently of the other comments and therefore can be understood without them.

In a broader sense, our error-modeling approach is related to work on holistically scoring an essay via detecting and totaling up specific errors in it. For details, we refer the reader to [Shermis et al. \(2010\)](#) and [Leacock et al. \(2014\)](#).

3 Corpus and Annotation

We use as our corpus a randomly selected subset of 165 debates obtained from the International Debate Education Association (IDEA) website². These debates cover a wide range of topics including politics, economics, religion, and science. Each debate consists of a *Motion*, which expresses a stance on the debate’s topic, and an average of 7.3 arguments, each of which either agrees or disagrees with the motion’s stance. Each of the 1,208 arguments consists of an *Assertion*, which expresses in one sentence why the author agrees or disagrees with the motion, and a *Justification*, which explains in an average of 6.9 sentences why the author believes her assertion.

We ask two native speakers of English to annotate each of the 1,208 arguments with a persuasiveness score after familiarizing them with the (topic- and domain-independent) scoring rubric (see Table 2). Specifically, we ask our annotators to score each argument’s persuasiveness on a scale of 1–6. The example argument in Table 1 gets a persuasiveness score of 2 because it could be expressed more clearly.

²<http://idebate.org/>

Score	Description of Argument Persuasiveness
6	A very persuasive, clear argument. It would persuade most previously uncommitted readers and is devoid of problems that might detract from its persuasiveness or make it difficult to understand.
5	A persuasive , or only pretty clear argument. It would persuade most previously uncommitted readers, but may contain some minor problems that detract from its persuasiveness or understandability.
4	A decent , or only fairly clear argument. It could persuade some previously uncommitted readers, but problems detract from its persuasiveness or understandability.
3	A poor , or only mostly understandable argument. It might persuade readers who are already inclined to agree with it, but contains severe problems that detract from its persuasiveness or understandability.
2	A very unpersuasive or very unclear argument. It is unclear what the author is trying to argue or the argument is just so riddled with problems as to be completely unpersuasive.
1	The author does not make an argument or it is unclear what the argument is . It could not persuade any readers because there is nothing to be persuaded of.

Table 2: Descriptions of argument persuasiveness scores.

	1	2	3	4	5	6
AP	3	12	20	21	20	24

Table 3: Distribution of error/argument persuasiveness scores as percentages.

Table 3 shows the distribution of scores for argument persuasiveness. To measure inter-annotator agreement, we select a subset of 69 arguments and ask both annotators to score them w.r.t. argument persuasiveness. The average difference between the annotator-assigned scores is 0.899. For the sake of our experiments, when annotators disagree on a score, we average their annotations together, rounding up to the nearest whole number to obtain the gold score.

4 Error Types

Key to our approach to persuasiveness scoring is the unsupervised modeling of the errors that could negatively impact persuasiveness. In this section, we define five such error classes, which are motivated by theoretical work on persuasiveness.³

Grammar Error (GE) Connor and Lauer (1985) note that grammar and/or mechanical errors can interrupt the flow of discourse in persuasive essays, so we give arguments a GE score of 1 if they contain GEs severe enough to make the argument hard to understand, and 0 otherwise. The argument in Table 1 gets a GE score of 0 because it contains no severe GEs.

Lack of Objectivity (LO) Oktavia et al. (2014) consider the use of personal opinions as evidence in argumentative writing a fallacy, so we give arguments a LO score of 1 if they display an in-

³We also annotated the 1,208 arguments in our corpus with these five errors even though they were not used in the experiments in this paper. See Persing and Ng (2017) for details on the error annotations.

appropriate lack of objectivity, and 0 otherwise.⁴ The argument in Table 1 receives a LO score of 1 because the author weaves a scenario in which she repeatedly speculates on what a child thinks or will do.

Inadequate Support (IS) Petty and Cacioppo (1984) find that arguments with more support are more persuasive, so we give arguments an IS score of 0 if they offer adequate support to justify their assertion, 1 if they do not offer enough support, or 2 if they offer almost no support. The example argument gets an IS score of 2 because the author’s scenario is completely unsupported.

Unclear Assertion (UA) In Connor’s (1990) criteria for judging assertions in persuasive writing, the lowest score is assigned to essays which did not clearly assert the problem they address. So we give an argument an UA score of 1 if it is not clear how the assertion is related to the motion without reading the justification, or 2 if the assertion is incomprehensible without reading the justification. It receives a score of 0 otherwise. The example argument gets a UA score of 1 because it is not clear how the assertion is related to the motion.

Unclear Justification (UJ) Because a smooth flow of ideas throughout an argument is important to its persuasiveness, Connor (1990) also evaluates persuasive essays’ coherence. Since it is not clear what an incoherent argument is arguing for, we give an argument an UJ score of 2 if the justification appears unrelated to the assertion, 1 if it does not concisely justify the assertion, or 0 if the justification is clear. The example argument gets

⁴Note, however, that other forums may try to craft emotional debates on purpose for their effectiveness. For instance, Lukin et al. (2017) show that emotional arguments can indeed be very persuasive and that they resonate with different audiences due to audience/reader preset biases and their own personality traits.

an UJ score of 0 as it is easy to understand the author’s point in the justification.

5 Approach

In this section, we present our approach to persuasiveness scoring. Broadly, it first predicts the *presence* and *severity* of the aforementioned errors (Section 5.1), then uses these predictions to assign persuasiveness scores (Section 5.2).

5.1 Prediction of Error Types

Our process for predicting error types consists of two steps. First, for each error type, we heuristically apply error severity values to a set of training arguments that can be confidently error-labeled (Section 5.1.1). Using these error-labeled arguments as seeds, we then apply the expectation maximization (EM) algorithm (Dempster et al., 1977) to predict the error severity values of the remaining training arguments (Section 5.1.2).

5.1.1 Heuristics

In this subsection, we describe our heuristics.

Grammar Error (GE) To detect GEs, we use the LanguageTool proofreading program⁵ to detect all GEs (e.g., redundant phrases and typos) in all training set justifications. We then calculate the frequency with which GEs occur per sentence in each justification, clustering these values using k-means clustering⁶. Finally, we label the training set arguments in the highest cluster with a GEs value of 1, and training set arguments in the lowest cluster with a GEs value of 0. This makes intuitive sense because GEs can hinder persuasiveness if they occur very frequently, and cannot hinder persuasiveness if they never occur.

Lack of Objectivity (LO) We count how frequently the word “morally” appears in justifications per token. We employ k-means clustering on these frequencies to help us identify which justifications use it most. The justifications falling in the highest cluster’s arguments are heuristically labeled with a LO severity of 1. We do the same with the word “certain”. Finally, if an author uses less than five definite articles in her justification, we heuristically label her argument with a severity of 1. These rules make sense because arguments that are too concerned with the author’s morality or in which the author seems too certain, or in which

the author is rarely specific are likely to display a LO.⁷

To find arguments not displaying a LO (severity = 0), we count and k-means cluster the frequency of first person plural pronouns in the justifications. Arguments whose justifications are in the lowest cluster are labeled with a LO severity of 0. This makes sense because justifications that lack objectivity often rely on stories about the writer’s personal experiences. We use plural pronouns to capture this rather than singular ones because thesis statements (which are not inherently subjective) often begin with “I believe” or “I think”.⁸

Inadequate Support (IS) To assign IS severities, we first need to know how many sources an argument cites.⁹ An argument that cites no references is assigned an IS severity of 2. If the argument cites only one reference, it gets a score of 1. Finally, we cluster arguments by the number of sources they cite. Arguments in the highest cluster are assigned an IS severity of 0. These rules make sense because arguments that cite a lot of sources are probably adequately supported.

Unclear Assertion (UA) UAs typically consist of very short sentence fragments (e.g. “Europe”). For this reason, we heuristically assign an argument an unclear assertion severity of 2 if they are less than four words long.

To identify arguments with an UA severity of 1, we first identify all content lemmas (nouns, pronouns, verbs, adjectives, adverbs) in the assertion. If none of these lemmas are mentioned in the justification, the argument gets a severity of 1. Since this heuristic necessarily conflicts with the previous one, when applying UA heuristics, rules with greater severity take precedence.

Finally, we k-means cluster the counts of assertion content lemmas appearing in the justification and assertion lengths.¹⁰ If an argument is not in the lowest cluster in either of these, it gets labeled

⁷We note that these lexical features are potentially specific to this particular domain. There have been a number of works examining objectivity and subjectivity that go beyond lexical features and use syntactic structures (Riloff and Wiebe, 2003; Wilson et al., 2005) and emotional and factual arguments (Oraby et al., 2015).

⁸Since more than one heuristic might apply to a given argument, we leave an argument unlabeled if the heuristics tell us to apply inconsistent labels to it. This is also how we handle contradictory heuristics for the remaining errors.

⁹We develop heuristics for extracting references from the justification. See the Appendix for these heuristics.

¹⁰We use $k = 6$ for assertion length clustering because assertions vary greatly in length.

⁵<https://languagetool.org/>

⁶Unless otherwise noted, $k = 4$ in k-means clustering.

1	# of grammar errors per sentence in justification (GE)
2	# of times the word “morally” appears in justification (LO)
3	# of times the word “certain” appears in justification (LO)
4	# of definite articles in justification (LO)
5	# of first person plural pronouns in justification (LO)
6	# of references cited in justification (IS)
7	# of words in assertion (UA)
8	# of content lemmas in assertion that also appear in justification (UA)
9	# of sentences in justification (UJ)
10	# of times words that lemmatically match the assertion’s subject appear in the first argument of a contingency-cause discourse relation in justification (UJ)

Table 4: Features used by the generative model. The error type for which each feature is originally developed is shown in parentheses.

with an UA severity of 0.

Unclear Justification (UJ) As with UAs, UJs are often very short. For this reason, we k-means cluster the sentence counts in our training set justifications, and label arguments whose justifications fall into the lowest cluster with an UJ severity of 2. As in the previous error, this rule takes precedence over other rules.

To identify arguments with UJ severities of 1 or 0, we first dependency and discourse parse our assertions and justifications using Stanford CoreNLP (Manning et al., 2014) and Lin et al.’s (2014) PDTB-style discourse parser, respectively. Using the dependency parse, we identify the assertion’s main subject, which we assume is the first word that is a child in an nsubj or nsubjpass relationship. Next, we count the number of times words that lemmatically match the subject appear in the first argument of a contingency-cause discourse relation in the justification. Finally, we k-means cluster these counts, assigning arguments with justifications in the highest cluster an UJ severity of 0, and those in the lowest cluster a severity of 1. These rules make sense because a justification that discusses its assertion’s topic’s effects frequently is likely to be very topically coherent, thus having a clear justification.

5.1.2 Bootstrapping using EM

Recall that for each error type t , our heuristics only label a subset of the training arguments with error severity values for t .¹¹ To label the remain-

¹¹The heuristics for GE, LO, IS, UA, and UJ can label 39%, 66%, 86%, 50%, and 87% of the training arguments,

ing training arguments, we apply EM to bootstrap from the heuristically labeled seeds for t .

Specifically, we initialize the model parameters using only the seeds for t . After that, we iterate the E-step and the M-step until convergence. In the E-step, we probabilistically (re)label each unlabeled training argument with its error severity value for t using the current model parameter values. Then, in the M-step, we re-estimate the model parameters using both the seeds and the training arguments probabilistically (re)labeled in the E-step.

To understand what the model parameters are, we need to specify the generative model. In our experiments, we employ Naive Bayes as the underlying generative model, effectively assuming that each feature value is conditionally independent of other feature values given the class value (which in this case is the severity value for t).

To fully specify the model parameters, we need to specify the features used to represent each argument. Specifically, we employ the 10 features used in the heuristics described in the previous subsection. For the sake of clarity, we list them again in Table 4. Note that all of them have numerical values. Hence, to reduce data sparseness, we k-means cluster the values, and use the 10 k-valued features in the EM-based bootstrapping process.

Regardless of which error type we train the model for, the same set of 10 k-valued features will be used. In other words, the generative models for the five error classes differ only w.r.t. the set of seeds used to initialize the model parameters. After learning, we employ the model learned for each error type to error-label the test arguments.

5.2 Persuasiveness Prediction

Like many other unsupervised and weakly-supervised models, we make a modeling assumption in our approach in order to facilitate learning in an environment where annotated data is scarce. Specifically, we assume that the persuasiveness score of an argument inversely correlates with the sum of its severity scores over all errors.¹² This assumption intuitively makes sense: as the number and severity of the errors increase, the corresponding argument becomes less persuasive.

Given this assumption, we train a lightly supervised persuasiveness predictor as follows. First, we cluster the training arguments by the sum of

respectively.

¹²For instance, if an argument has an IS severity of 2 and a LO severity of 1, the sum of its severity scores will be 3.

severity scores over all errors.¹³ Then, we randomly select n arguments from each cluster c (where $1 \leq n \leq 12$ in most of our experiments), and manually label them with their persuasiveness scores. Finally, we assign to each c a persuasiveness score that is the average of the persuasiveness scores of the n manually labeled arguments in c .

During testing, we compute the sum of severity scores over all errors for each test argument, assign it to the corresponding cluster, and predict its persuasiveness score as the score of the cluster it is assigned to. Since our system assigns the Average persuasiveness of training arguments having the same Error Severity count, we call it ASE.

6 Evaluation

In this section, we evaluate our approach to persuasiveness prediction. Since there is an element of randomness in our algorithm and the baselines (in which arguments get labeled), we report results using 5 repetitions of 5-fold cross validation.

6.1 Scoring Metrics

We employ four evaluation metrics for persuasiveness scoring, namely E , ME , MSE , and PC .

The simplest metric, E , measures the frequency at which a system predicts the wrong score. ME and MSE measure the mean error and mean squared error of our persuasiveness predictions, respectively. The formulas below illustrate how we calculate E , ME , and MSE , respectively:

$$\frac{1}{N} \sum_{A_j \neq E'_j} 1, \quad \frac{1}{N} \sum_{j=1}^N |A_j - E_j|, \quad \frac{1}{N} \sum_{j=1}^N (A_j - E_j)^2$$

where A_j , E_j , and E'_j are the annotator assigned, system predicted, and rounded system predicted persuasiveness scores¹⁴ respectively for argument j , and N is the number of arguments.

The last metric, PC , computes Pearson's correlation coefficient between a system's predicted

¹³While the highest possible error severity count is 8, there is no argument in our corpus for which we predict that count. Hence, we only end up with 8 clusters, one for each error severity count (0–7).

¹⁴Since a regressor assigns each argument a real value rather than an actual valid score, it would be difficult to obtain a reasonable E score without rounding the system estimated score to one of the possible values. For that reason, we round the estimated score to the nearest valid persuasiveness score (1–6 at one-point increments) when calculating E . For other scoring metrics, we round the predictions to 1.0 or 6.0 if they fall outside the 1.0–6.0 range.

scores and the annotator-assigned scores. A positive (negative) PC implies that the two sets of predictions are positively (negatively) correlated.

Note that E , ME , and MSE are *error* metrics, so lower scores on them imply better performance. In contrast, PC is a *correlation* metric, so higher correlation implies better performance.

6.2 Baseline Systems

We employ six baseline systems. All baselines are support vector regressors (Drucker et al., 1997) trained using LibSVM (Chang and Lin, 2001) with default parameters, differing only in terms of the features used by the learner.

Bag of words (BOW) In the first baseline, we use as features the bag of words extracted from the argument's assertion and justification.

Word n-grams (WNG) The second baseline uses word n-grams ($n=1,2,3$) extracted from the argument's assertion and justification as features.

Bag of part-of-speech tags (BOPOS) Our third baseline employs as features the bag of POS tags in the argument's assertion and justification.

Style Our fourth baseline captures aspects of an argument's style. Specifically, it employs four types of features that are motivated by Tan et al.'s (2016) Style baseline, namely:

Length-based features: As longer arguments can be more detailed, we encode as a feature the length in tokens and sentences of an argument's assertion and justification.

Word category-based features: For each of the following categories of words/tokens, we employ as features the absolute count and frequency per token in an argument's justification: (1) definite and indefinite articles and first and second person pronouns, both of which we learned in Section 5.1 can be useful for detecting lack of objectivity; (2) question marks and quotations, which indicate how an argument is structured; (3) positive and negative sentiment words as determined by Mohammad and Yang (2011) since excessive emotion can also signal a lack of objectivity; (4) URLs, since these may be another way of citing evidence; (5) hedge words¹⁵, which can be used to express argument uncertainty; and (6) phrases that indicate the author is giving an example ("e.g.", "for instance", "for example").

¹⁵The hedge words are taken from <http://english-language-skills.com/item/177writing-skills-hedge-words.html>.

Word complexity features: These features capture the justification’s complexity of word choice, namely the justification’s word entropy, type-token ratio, and grade level (Kincaid et al., 1975).

Word score-based features: Warriner et al. (2013) and Brysbaert et al. (2014) associate each word in a lexicon with four real-valued numbers describing how abstract, intensely emotional, pleasant, and vulnerability-evoking the word is. We extract as features the average value of the words in an argument for each of these qualities.

Duplicated Tan et al. (Tan) As our fifth baseline, we employ our re-implementation of Tan et al.’s (2016) system. Their feature set comprises all the features described in the *Style*, *BOW*, and *BOPOS* baselines, as well as a set of word score-based features exactly like those described above, except that they involve first quartering the justification, then calculating the word scores on each quarter of the text. These are useful because, for example, successful arguments begin by using calmer words.

Persing and Ng (P&N) The sixth baseline is the system we previously designed and implemented for scoring argument persuasiveness in student essays (Persing and Ng, 2015). This system employs five types of features: (1) POS unigrams, bigrams and trigrams, which capture the syntactic generalizations of an argument’s justification; (2) frame-semantic features, which capture the semantic generalizations of the justification; (3) features computed based on the frequency of occurrence of transitional phrases in the justification, which encode its degree of coherence; (4) topic relevance features, which capture the relevance of the justification to its motion based on the number of overlapping entities; and (5) argument label features, which are n-grams of sentence-based argument labels (e.g., CLAIM, SUPPORT) derived from the justification.

6.3 Results and Discussion

Five-fold cross-validation results of the six baselines when trained on 100% of the training data (966 arguments) are shown in the first six rows of Table 5. While BOW and WNG serve as strong baselines for many NLP tasks, the same is not true for persuasiveness scoring: they are among the worst baselines. This is perhaps not surprising given the discussion in the introduction: since persuasiveness scoring is a discourse-level task, in

System	<i>E</i>	<i>ME</i>	<i>MSE</i>	<i>PC</i>
BOW	0.786	1.218	2.087	0.073
WNG	0.786	1.218	2.088	0.063
BOPOS	0.786	1.217	2.084	0.089
Style	0.748	1.102	1.776	0.408
Tan	0.744	1.109	1.799	0.398
P&N	0.785	1.198	2.045	0.252
ASE	0.744	1.097	1.753	0.422

Table 5: Five-fold cross-validation results for persuasiveness scoring. Each baseline is trained on 100% of the training data (966 arguments), while ASE is trained on 96 arguments (10% of the available training data).

many cases an argument’s persuasiveness cannot be determined solely from its words and phrases. The best baselines are *Style* and *Tan*, a system that builds upon *Style*. These systems offer considerably better performance than BOW, WNG, BOPOS, and P&N w.r.t. all four scoring metrics.

Results of our system, ASE, are shown in the last row of Table 5. These results are obtained when n is set to 12. Recall that n is a parameter of ASE that specifies the number of persuasiveness-labeled training arguments used to compute each cluster’s persuasiveness score. Since we have eight clusters, these results are obtained when ASE is trained on 96 persuasiveness-labeled arguments (10% of the training data). Although ASE is lightly-supervised, it outperforms all the baseline systems by all four metrics. The improvements it yields are highly significant w.r.t. three of the four scoring metrics.¹⁶ These results provide suggestive evidence for the efficacy of our error-modeling approach to persuasiveness scoring.

6.4 Additional Experiments

To gain additional insights into ASE, we perform additional experiments.

Lightly-supervised baselines. To be fair in our comparison with the baselines, we retrain them on 10% of the arguments randomly sampled from the training data and compare their performances against ASE. Results are shown in Table 6. In comparison to the results in Table 5, almost all baselines suffer from performance deterioration, particularly w.r.t. *ME*, *MSE*, and *PC*. ASE continues to significantly outperform all baselines

¹⁶Unless otherwise stated, boldfaced results are highly significant compared to the best baseline ($p < .01$, paired t -test).

System	E	ME	MSE	PC

Table 7: Results for persuasiveness scoring when one feature is removed from ASE’s generative model. F # indicates which feature is being referred to (as indexed in Table 4).

w.r.t. these three scoring metrics.

Feature ablation. In order to determine each feature’s contribution to ASE’s generative model, we perform ablation experiments wherein we re-train the model using all but one of the features. Table 7 shows how ASE performs after each feature is removed.¹⁷

From these results, we gather that no feature makes a negative contribution to the model, as no feature’s removal significantly improves performance on any metric. Occurrences of “morally”, first person plural pronouns, the number of content lemmas appearing in both the assertion and the justification, and justification length (features 2, 5, 8 and 9) make significant contributions to performance according to at least one metric.

Error ablation. Recall that ASE predicts persuasiveness based on a summation of the predicted severity scores over all errors. To determine the

¹⁷Unless otherwise stated, results that are significantly worse than that of the original model ($p < .01$, paired t -test) are marked with a dagger.

Table 9: Learning curve results.

importance of each error’s contribution, we perform five ablation experiments wherein we exclude each one of the errors from this summation.

Table 8 shows that the IS, UA, and UJ errors make the most important contributions to persuasiveness scoring since removing them from consideration significantly harms performance compared to ASE. Removing GE and LO, by contrast, harms performance the least since these are likely the two least frequent errors and therefore have less impact on performance.

Learning curve. Table 9 shows how our ASE system performs when n increases from 1 to 10. As we can see, the scores for all metrics with the exception of E follow the expected trajectory of a learning curve, with worse scores for $n = 1$ progressively becoming better as n approaches 10.

Fully-supervised results. Can ASE perform better given more training data? Table 10 shows the results of ASE when it is trained on 10% (ASE(10)) and 100% (ASE(100)) of the training data. As we can see, the answer is yes: ASE(100) significantly outperforms ASE(10) w.r.t. all but the E metric. While it is not surprising to see diminishing returns, what is perhaps surprising is the relative small performance gap between ASE(10)

System	E	ME	MSE	PC
ASE(10)	0.744	1.097	1.753	0.422
ASE(100)	0.745	1.078	1.678	0.441

Table 10: Results for persuasiveness scoring when ASE is trained on 10% (row 1) and 100% (row 2) of the training data.

Train data	E	ME	MSE	PC
10%	0.739	1.110	1.901	0.408
100%	0.731	1.053	1.724	0.454

Table 11: Results for persuasiveness scoring when ASE predicts persuasiveness by means of a support vector regressor that is trained on 10% (row 1) and 100% (row 2) of the training data using only the error severity values as features.

and ASE(100): it suggests that ASE learns very fast from a small amount of labeled data.

Training a persuasiveness predictor with errors as features. Recall that ASE predicts persuasiveness based on the sum of severity scores. Can we instead predict persuasiveness by training a regressor using only the errors as features? To answer this question, we train a support vector regressor using the 13 binary features that correspond to the 13 severity values of the five errors. The value of a feature is 1 if and only if the argument is assigned the corresponding severity value.

Results of the regressor are shown in Table 11. When the regressor is trained on 10% of the training data, its results are worse than the ASE(10) results in Table 10 w.r.t. all but the E metric. However, when it is trained on 100% of the training data, its results are slightly better than the ASE(100) results in Table 10 w.r.t. all but the MSE metric. We speculate that being discriminatively trained, the support vector regressor can yield better results than the simplistic modeling assumption made by ASE only when training data is plentiful. Additional experiments are needed to determine the reason, however.

Correlation. Recall that ASE assumes that the persuasiveness score of an argument correlates with the sum of its severity scores over all errors. To better understand the extent to which this assumption is true, we cluster *all* 1,208 arguments by the sum of severity scores. For each of the eight resulting clusters, we average the gold persuasiveness scores of the arguments in the cluster.

Results are shown in Table 12. As we can see,

SS	Average	SD	SS	Average	SD
0	5.138	1.050	4	3.111	1.331
1	4.886	1.190	5	3.245	1.392
2	4.194	1.338	6	2.909	1.446
3	3.763	1.306	7	3.000	0.000

Table 12: Average persuasiveness score and its standard deviation (SD) against the sum of severity score (SS).

the data satisfies our assumption: average persuasiveness decreases as the sum of severity scores increases. The only exception occurs when $SS=7$, presumably due to the small sample size.

6.5 Error Analysis

Next, we conduct a qualitative error analysis.

While there is a definite correlation between error severity count and persuasiveness, error severity count is likely not the only factor that impacts persuasiveness. An examination of some essays whose persuasiveness scores are far from their ASE predicted scores shows that factors that are harder to analyze such as logical soundness and the presence of claims that seem to contradict the assertion also play a role in persuasiveness.

In other arguments, persuasiveness prediction error can be attributed to our system’s misprediction of the presence/absence/severity of an error. Error annotated data might help address this problem by allowing us to tune our error severity heuristics.

Finally, our error severity scales are pretty coarse-grained. It is reasonable to expect, for example, that a real argument could have an unclear justification error whose severity is halfway between 2 and 1, but our EM algorithm for predicting error severities does not allow this. The introduction of a regression system into our algorithm might address this problem.

7 Conclusion

We proposed a lightly-supervised approach to the under-studied problem of predicting argument persuasiveness scores on debate arguments. Experimental results on 1,208 arguments demonstrated that our approach significantly outperformed six fully-supervised baselines by three out of four scoring metrics when using only 10% of the training data. To stimulate research on this task, we make our annotated data publicly available.

Appendix: Reference Extraction and Internal Citation Cleanup

Given an argument, we employ the following steps to extract references and clean up internal citations.

1. We identify digits and locations in the justification that appear to refer to references. Particularly, we identify each digit in the text that satisfies all the following conditions: (a) it appears next to a punctuation (because the digits usually occur right before or after a sentence’s end punctuation); (b) it does not appear next to another digit (because these are short arguments, a digit next to another digit is probably not a citation); (c) if we take the string consisting of the digit, the punctuation, the character next to the digit other than the punctuation, and the character on the other side of the punctuation, this string is not parsable as a floating point number (if it is part of a floating point number, it is probably not a citation); (d) a ‘\$’ does not appear before it; (e) a ‘%’ does not appear after it; (f)

a ‘/’ does not appear before it; and (g) a ‘/’ does not appear after it.

2. We make a list of all digits identified in step 1 that occur at least twice in the text. (A digit needs to occur twice in order to be a citation because the first time it occurs in the justification text and the last time it occurs right before the reference.)
3. We sort the digits from step 2 in numerical order. We remove 0 from the list if it is present. If there are any gaps in the list (e.g., if ‘1’, ‘2’, and ‘4’ appear in the list), we discard any digits after the gap. (People do not use 0 to make references. And if there are gaps, it usually means that whatever number appears after the gap was erroneously identified as a citation because people do not skip digits when numbering their references.)
4. We sequentially scan the list from step 3. If, at any point in the list, the last location (in the justification) of the digit we are examining occurs before the last location (in the justification) of the previous digit in the list, we discard the digit and all the digits after it in the list. (We expect references to begin with the last occurrences of their corresponding numbers. If one of the digits’ last occurrences seems out of order, that means there is a problem with the list so we cannot rely on it beyond this point.)
5. We split the text according to the locations in the justification of the digits that remain in the list from step 4. The first text segment is the justification’s text, and all the remaining segments are individual references.
6. Finally, we do some cleanup of the text. We remove all the digits identified in step 1 occurring in the justification’s text. (This should help with parsing because the digits make sentences grammatically incorrect.) We also remove all occurrences of ‘[’ or ‘]’ in the text (because some people surround their citation digits with them). Finally we replace any urls (starting with “http:”) with “url”.

Multi-Task Learning for Speaker-Role Adaptation in Neural Conversation Models

Abstract

Building a persona-based conversation agent is challenging owing to the lack of large amounts of speaker-specific conversation data for model training. This paper addresses the problem by proposing a multi-task learning approach to training neural conversation models that leverages both conversation data across speakers and other types of data pertaining to the speaker and speaker roles to be modeled. Experiments show that our approach leads to significant improvements over baseline model quality, generating responses that capture more precisely speakers' traits and speaking styles. The model offers the benefits of being algorithmically simple and easy to implement, and not relying on large quantities of data representing specific individual speakers.

1 Introduction

Conversational engines are key components of intelligent “personal assistants” such as Apple’s Siri and Amazon’s Alexa. These assistants can perform simple tasks, answer questions, provide recommendations, and even engage in chit-chats (De Mori et al., 2008; Chen et al., 2015, 2016). The emergence of these agents has been paralleled by burgeoning interest in training natural-sounding dialog systems from conversational exchanges between humans (Ritter et al., 2011; Sordani et al., 2015; Luan et al., 2014, 2015; Vinyals and Le, 2015). A major challenge for data-driven systems is how to generate output that corresponds to specific traits that the agent needs to adopt, as they tend to generate “consensus” re-

User input: *I am getting a loop back to login page.*

Baseline model: Ah, ok. Thanks for the info.

Our model: I'm sorry to hear that. Have you tried clearing your cache and cookies?

Figure 1: Existing neural conversational models (baseline) tend to produce generic responses. The system presented in this paper better represents the speaker role (support person), domain of expertise (technical), and speaking style (courteous).

sponses that are often commonplace and uninteresting (Li et al., 2016a; Shao et al., 2017).

This is illustrated in Fig. 1, where the output of a standard Sequence-to-Sequence conversation model is contrasted with that of the best system presented in this work. The baseline system generates a desultory answer that offers no useful information and is unlikely to inspire user confidence. The output of the second system, however, strongly reflects the agent’s role in providing technical support. It not only evidences domain knowledge, but also manifests the professional politeness associated with a speaker in that role.

The challenge for neural conversation systems, then, is that an agent needs to exhibit identifiable role-specific characteristics (a ‘persona’). In practice, however, the conversational data needed to train such systems may be scarce or unavailable in many domains. This may make it difficult to train a system represent a doctor or nurse, or a travel agent. Meanwhile, appropriate non-conversational data (e.g., blog and micro-blog posts, diaries, and email) are often abundant and may contain much richer information about the characteristics of a speaker, including expressive style and the role they play. Yet such data is difficult to exploit directly, since, not being in conversational format, it does not mesh easily with existing source-target conversational models.

* This work was performed at Microsoft.

In this paper we address the joint problems of blandness and data scarcity with multi-task learning (Caruana, 1998; Liu et al., 2015; Luan et al., 2016a). This is a technique that has seen success in machine translation, where large monolingual data sets have been used to improve translation models (Sennrich et al., 2016). The intuition is that if two tasks are related, then joint training and parameter sharing can enable one task to benefit the other. In our case, this sharing is between two models: On one hand, a standard Sequence-to-Sequence conversational models is trained to predict the current response given the previous context. On the other hand, using the non-conversational data, we introduce an autoencoder multi-task learning strategy that predicts the response given the same sequence, but with the target parameters tied with the general conversational model.

Our experiments with 4M conversation triples show that multi-task adaptation is effective in that the generated responses capture speaker-role characteristics more precisely than the baseline. Experiments on a corpus of Twitter conversations demonstrate that multi-task learning can boost performance up to 46.2% in BLEU score and 23.0% in perplexity, with a commensurate consistency gains in human evaluation.

2 Related Work

2.1 Conversational Models

In contrast with much earlier work in dialog, our approach to conversation is wholly data-driven and end-to-end. In this respect, it follows a line of investigation begun by (Ritter et al., 2011), who present a statistical machine translation based conversation system. End-to-end conversation models have been explored within the framework of neural networks (Sordoni et al., 2015; Vinyals and Le, 2015; Li et al., 2016a,b; Luan et al., 2017). The flexibility of these Sequence-to-Sequence (SEQ2SEQ) encoder-decoder neural models opens the possibility of integrating different kinds of information beyond the single previous turn of the conversation. For example, (Sordoni et al., 2015) integrate additional contextual information via feed-forward neural networks. (Li et al., 2016a) use Maximum Mutual Information (MMI) as the objective function in order to produce more diverse and interesting responses. (Mei et al., 2017) introduce an attention mechanism into an encoder-decoder network for a conversa-

tion model.

(Wen et al., 2015) introduced a Dialog-Act component into the LSTM cell to guide generated content. (Luan et al., 2016b) use a multiplicative matrix on word embeddings to bias the word distribution of different speaker roles. That work, however, assumes only two roles (questioner and answerer) and is less generalizable than the model proposed here.

Most relevant to the present work, (Li et al., 2016b) propose employing speaker embeddings to encode persona information and allow conversation data of similar users on social media to be shared for model training. That work focused on individuals, rather than classes of people. The approach, moreover, is crucially dependent on the availability of large-scale conversational corpora that closely match the persona being modeled—data that, as we have already observed, may not be readily available in many domains. In this work, we circumvent these limitations by bringing non-conversation corpora (analogous to the use of monolingual data in machine translation) to bear on a general model of conversation. Doing so allows us to benefit in terms of representing both the role of the agent and domain content.

2.2 Multi-Task Learning

Multi-task learning has been successfully used to improve performance in various tasks, including machine translation (Sennrich et al., 2016) and image captioning (Luong et al., 2016). (Sennrich et al., 2016) report methods of exploiting monolingual data—usually available in much larger quantities—to improve the performance of machine translation, including multi-task learning of a language model for the decoder. Autoencoders are widely used to initialize neural networks (Dai and Le, 2015). (Luong et al., 2016) show that an autoencoder of monolingual data can help improve the performance of bilingual machine translation in the form of multi-task learning. In our models, we share the decoder parameters of a SEQ2SEQ model and autoencoder to incorporate textual information through multi-task learning.

3 Background

3.1 Task definition

The task of response generation is to generate a response given a context. In this paper, following (Sordoni et al., 2015), each data sample is

represented as a $(context, message, response)$ triple, where context is the response of the previous turn, and the message is the input string of the current turn. The response, then, is the sequence to be predicted given these two strings of information. In addition to the triple, large-scale non-conversational data from the responder is provided as side information.

3.2 Sequence-to-Sequence Conversational Models

Given a sequence of inputs $X = \{x_1, x_2, \dots, x_{n_X}\}$ and the corresponding output $Y = \{y_1, y_2, \dots, y_{n_Y}\}$, Sequence-to-Sequence (SEQ2SEQ) models use a Long Short-Term Memories (LSTM) (Hochreiter and Schmidhuber, 1997) to encode the input sequence, taking the last hidden state of encoder h_{n_X} to represent output sequence. The decoder is initialized by h_{n_X} , and predict output y_t given h_{n_X} and y_{t-1} .

Our input is context followed by message, delimited by an *EOS* token. The LSTM cell includes an input gate, a memory gate and an output gate, respectively denoted as i_t , f_t and o_t .

3.3 Persona-based conversational model

The persona-based conversational model is a variant of standard SEQ2SEQ models, with user information encoded at decoder. As in standard SEQ2SEQ models, the persona-based conversational model presented in (Li et al., 2016b) first encodes the source message into a vector representation using the source LSTM. Then, for each element in the target side, hidden units are obtained by combining the representation produced by the target LSTM at the previous time step h_{t-1} , the word representations e_t at the current time step, and the embedding s_i for user i .

$$\begin{bmatrix} i_t \\ f_t \\ o_t \\ l_t \end{bmatrix} = \begin{bmatrix} \sigma \\ \sigma \\ \sigma \\ \tanh \end{bmatrix} W \cdot \begin{bmatrix} h_{t-1} \\ e_t \\ s_i \end{bmatrix} \quad (1)$$

$$c_t = f_t \cdot c_{t-1} + i_t \cdot l_t \quad (2)$$

$$h_t = o_t \cdot \tanh(c_t) \quad (3)$$

where $W \in \mathbb{R}^{4K \times 3K}$. This model assigns one K dimensional vector representation to each of the speakers in the corpus. It thus relies on the availability of sufficient conversational training data

of each speaker to learn meaningful speaker embeddings. Since this type of data is usually hard to obtain in real application scenarios, we need a method that can leverage easier-to-obtain non-conversational personal data in order to incorporate richer personal information into conversational models.

4 A Multi-task Learning Approach

Given the limitations of previous methods, we propose the following multi-task learning approach in order to simultaneously leverage conversational data across many users on the one hand, and personal but non-conversation data (written text) of a specific user on the other. We define the following two tasks:

- A **SEQ2SEQ** task that learns conversational models described in Section 3 using conversation data of a large general population of speakers.
- An **AUTOENCODER** task that utilizes large volumes of non-conversational personal data from target speakers.

AUTOENCODER: An AUTOENCODER is an unsupervised method of obtaining sequence embeddings based on the SEQ2SEQ framework. Like a SEQ2SEQ model, it comprises encoding and decoding components built by an LSTM sequential model as in Section 3.2. Instead of mapping source to target as in a SEQ2SEQ model, the AUTOENCODER predicts the input sequence itself.

Parameter sharing: Given the same context, we want to generate a response that can mimic a particular target speaker. Therefore, we share only the decoder parameters of SEQ2SEQ and AUTOENCODER while performing multi-task learning, so that the language model for generation can be adapted to the target-speaker. Since the context is not constrained and can be from any speaker, the encoder parameters are not tied and are learned separately by each task. (See Fig. 2.)

Training Procedure The training procedure is shown in Fig. 3. In each iteration, the gradient of each task is calculated according to the task-specific objective. The training process finishes when perplexity performance converges in dev set and the best model is selected according to SEQ2SEQ perplexity performance.

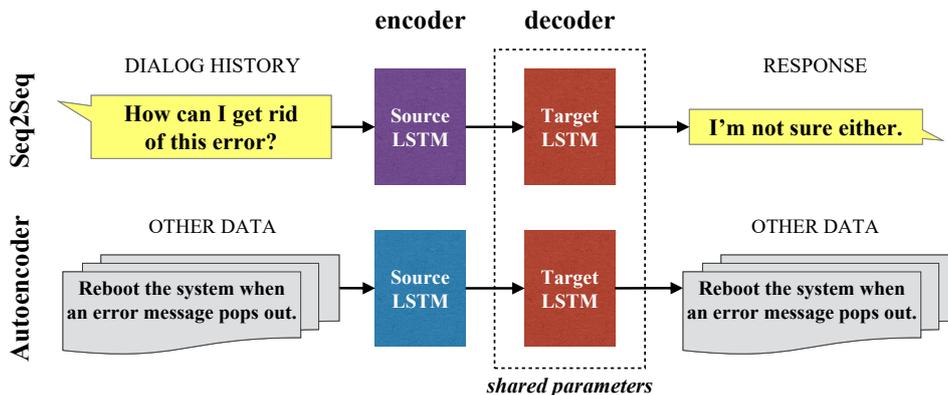

Figure 2: Framework of Multi-task learning. The parameters of decoder are shared across the two tasks.

Training procedure of Multi-task learning:

1. Randomly initialize SEQ2SEQ and AUTOENCODER encoder parameters.
2. Train SEQ2SEQ model until dev set performance converges in perplexity.
3. **While** not dev set performance converged in perplexity **do**:
 - (a) Randomly pick a batch of samples from general conversational data.
 - (b) Compute loss and gradient for SEQ2SEQ task and update parameters.
 - (c) Randomly pick a batch of samples from non-conversational data of the target user.
 - (d) Compute loss and gradient for AUTOENCODER task and update parameters.
4. Choose the best model based on SEQ2SEQ perplexity performance on dev set.

Figure 3: Training Procedure

5 Single v.s. Multiple speaker Settings

Two variants of SEQ2SEQ task are explored:

- **MTASK-S** Personalized response generation for a **single** user, which uses the basic SEQ2SEQ conversational model as described in Section 3.2.
- **MTASK-M** Response generation for **multiple** users, which uses the persona-based SEQ2SEQ model described in Section 3.3.

MTASK-S: We train a personalized conversational model for one speaker at a time. For each target user, we need to perform separate multi-task training which results in N models for N users. This is inefficient in both memory and computational cost.

MTASK-M: In order to address the memory and computation issue of MTASK-S, we introduce user embeddings to SEQ2SEQ model as in Eq. 1. We first train a persona-based conversa-

tional model using conversational data for a general population of speakers. This model differs MTASK-S in that it introduces two parameter matrices into the decoder: a speaker embedding s_i and its corresponding weight matrix that can decouple speaker dependent information from general language information. In the multi-task stage, since the target users have never appeared in the training data, we randomly initialize the user embeddings for those users and follow the training procedure as in Figure 3.¹ The embedding of the unseen user is updated by AUTOENCODER training together with the decoder LSTM parameters.

6 Experimental Setup

6.1 Datasets

As training data, we use a collection of 3-turn conversations extracted from the Twitter FireHose. The dataset covers the six-month period beginning January 1, 2012, and was limited to conversations where the responders had engaged in at least 60 3-turn conversational Twitter interactions during the period. In other words, these are people who reasonably frequently engaged in conversation, and might be experienced “conversationalists.”

We selected the top 7k Twitter users who had most conversational data from that period (at least 480 turns, average: 571). This yielded a total of approximately 4M conversational interactions. In addition to these 7k general Twitter users, we also selected the 20 most frequent users, employing all of their conversation data for development and test. Twitter users typically have many more single posts than posts that interact with other people.

¹The model can also be learned without pre-training (omitting step 2), but we found that pre-training usually helps.

We therefore treat single posts as non-conversation data. All single posts of the 20 top users (at least 9k per user, average 10.3k) were extracted for multi-task learning. The 20 users were of diverse backgrounds, including technical support personnel, novelists, and sports fans.

6.2 Evaluation

As in previous work (Sordoni et al., 2015), we use BLEU and human evaluation for evaluation. BLEU (Papineni et al., 2002) has been shown to correlate fairly well with human judgment at a document- and corpus-level, including on the response generation task.² We also report perplexity as an indicator of model capability.

We additionally report degree of diversity by calculating the number of distinct unigrams and bigrams in generated responses. The value is scaled by total number of generated tokens to avoid favoring long sentences (shown as distinct-1 and distinct-2). Finally, we present a human evaluation that validates our main findings.

6.3 Baseline

Our baseline is our implementation of the LSTM-MMI of (Li et al., 2016a). The MMI algorithm reduced the blandness of SEQ2SEQ models by scoring the generated N-best list with a function that linearly combines a length penalty and the log likelihood of source given target:

$$\log p(R|M, v) + \lambda \log p(M|R) + \gamma|R| \quad (4)$$

where $p(R|M, v)$ is the probability of the generated response given message M and the respondents user ID. $|R|$ is the length of the target and γ is the associated penalty weight. We use MERT (Och, 2003) to optimize γ and λ on BLEU using N-best lists of response candidates generated from the development set. To compute $p(M|R)$, we train an inverse SEQ2SEQ model by swapping messages and responses. The reverse SEQ2SEQ models $p(M|R)$ is trained with no user information considered.

6.4 Training and Decoding

We trained two-layer SEQ2SEQ models on the Twitter corpus, using the following settings:

²(Liu et al., 2016) suggest that BLEU doesn't correlate well with human judgment at the sentence level. Other work, however, has shown that correlation increases substantially with larger units of analysis (e.g., document or corpus) (Galley et al., 2015; Przybocki et al., 2009).

	Baseline	MTASK-S	MTASK-M
Perplexity (dev)	56.33	32.27 (-42.7%)	44.96 (-20.2%)
Perplexity (test)	61.17	39.83 (-34.9%)	43.21 (-29.4%)

Table 1: Perplexity for standard SEQ2SEQ and the user model on the Twitter Persona dev set.

	Baseline	MTASK-S	MTASK-M
BLEU (dev)	1.32	1.76 (+33.3%)	2.52 (+90.1%)
BLEU (test)	1.31	1.69 (+29.0%)	2.25 (+71.7%)
distinct-1	1.69%	2.43%	2.44%
distinct-2	6.53%	10.2%	9.79%

Table 2: Performance on the Twitter dataset of 2-layer SEQ2SEQ models and MMI models. Distinct-1 and distinct-2 are respectively the number of distinct unigrams and bigrams divided by total number of generated words.

- 2 layer LSTM models with 500 hidden cells for each layer.
- Batch size is set to 128.
- Optimization method is Adam (Kingma and Ba, 2015).
- Parameters for SEQ2SEQ models are initialized by sampling from uniform distribution $[-0.1, 0.1]$.
- Vocabulary size is limited to 50k.
- Parameters are tuned based on perplexity.

For decoding, the N-best lists are generated with beam size $B = 50$. The maximum length of the generated candidates was set at 20 tokens. At each time step, we first examine all $B \times B$ possible next-word candidates, and add all hypotheses ending with an *EOS* token to the N-best list. We then preserve the top-B unfinished hypotheses and move to the next word position. We then use LSTM-MMI to rerank the N-best list and use the 1-best result of the re-ranked list in all evaluation.

7 Experimental Results

The perplexity and BLEU score results for three models are shown in Tables 1 and 2. Compared with the baseline model LSTM-MMI, we obtain a 34.9% decrease in perplexity for the MTASK-S model and a 29.4% decrease in perplexity for the MTASK-M model. Significant gains are obtained in BLEU score as well: MTASK-S gains

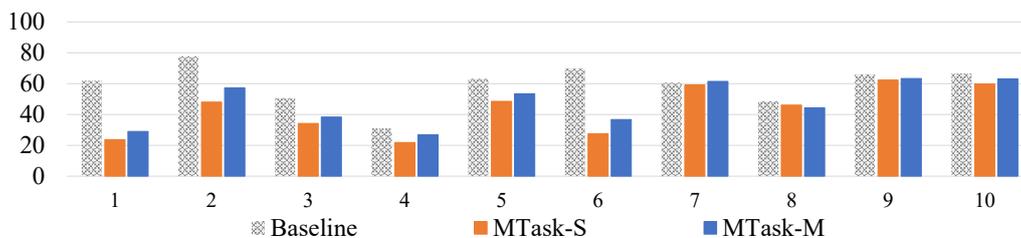

Figure 4: Perplexity scores for the top 10 users with most (non-conversational) training data. Users with obvious speaking styles or stronger user role characteristics (e.g., 1, 2, and 6) show much greater perplexity reduction than the other ones.

29.0% relative increase compared with the baseline and MTASK-M gains 71.7%. MTASK-S performance is better than MTASK-M in perplexity, but worse on BLEU score. Apart from the fact that BLEU does not necessarily correlate with perplexity, this result also indicates that MTASK-S has more parameters (each user has a unique model for MTASK-S) but tends to overfit on development set perplexity. Another possible reason that MTASK-M performs better than MTASK-S is the introduction of user embeddings. The persona-based conversational model can decouple the personalized information from general language patterns and can therefore encode user characteristic better. We further report degree of diversity by calculating the number of distinct unigrams (distinct-1) and bigrams (distinct-2) in generated responses as in Table 2. To avoid biasing toward longer sentences, this value is scaled by the total number of tokens generated. Both MTASK-S and MTASK-M models perform better than baseline in terms of distinct-1 and distinct-2, which we interpret to mean that our approach can help the system generate responses that are more diverse yet better approximate the targeted speaker or speaker type.

Fig. 4 shows the perplexities for the 10 individual users most represented in the non-conversational training data. Our multi-task approaches consistently outperform baseline on perplexity. However, the performance between individual target users can vary substantially.³

After inspecting dev set outputs, we observe that users with obvious speaking styles or stronger user role characteristics show much greater gain than the others. For example, User 1 is a tech-

³We do not report BLEU scores for individual users, as the dev and test set for each specific user tends to be small (less than 500 samples) and BLEU is known to be unreliable when evaluated on small datasets (Graham et al., 2015; Liu et al., 2016).

nical support worker who answers web questions for Twitter users, while User 2 always expresses strong feelings and uses exclamation marks frequently. Conversely, tweets from users that did not show significant gain appear to be more about daily life and chitchat, with no strong role characteristics (e.g., Users 3 and 4). We present example outputs for User 1 and 2 in Section 8.

7.1 Human Evaluation

Human evaluation of the outputs was performed using crowdsourcing.⁴ Evaluation took the form of a preference test in which judges were presented with a random sample of 5 tweets written by the targeted user as example texts, and asked which system output appeared most likely to have been produced by the same person. A 5-point scale that permitted ties was used, and system pairs were presented in random order. A short input message (the input that was used to generate the outputs) was also provided. We used 7 judges for each comparison; those judges whose variances differed by more than two standard deviations from the mean variance were discarded. Table 3 shows the results of pairwise evaluation, along with 95% confidence intervals of the means. MTASK-S and MTASK-M both perform better on average than LSTM-MMI, consistent with the BLEU results. MTASK-M’s gain over the LSTM-MMI baseline is significant at the level of $\alpha = 0.05$ ($p = 0.026$), indicating that judges were better able to associate the output of that model with the target author.

In Table 3 the strength of the trends is obscured by averaging. We therefore converted the scores for each output into the ratio of judges who selected that system for each output (Figs. 5 and 6). To read the charts, bin 7 on the left represents

⁴Two outputs were removed from the datasets owing to offensive content in the examples.

	Baseline	System
MTASK-S	0.491 \pm 0.011	0.504 \pm 0.011
MTASK-M	0.486 \pm 0.012	0.514 \pm 0.012

Table 3: Results of human evaluation, showing relative gain of MTASK-S and MTASK-M systems over the LSTM-MMI baseline in pairwise comparison, together with 95% confidence intervals of the means.

the case where all 7 judges “voted” for the system, bin 6 the case where 6 out of 7 judges “voted” for the system, and so forth.⁵ Bins 3 through 0 are not shown since these are a mirror image of bins 7 through 4. It can be seen that judge support for MTASK-M (Figure 6) tends to be stronger than for MTASK-S (Figure 5).

These differences are statistically significant, but they also suggest that this was a challenging task for crowd workers. In many cases, the 5 random examples may not have been sufficed to distinguish individual styles,⁶ and even when distinctive, similar outputs from arbitrary inputs may not be undesirable—indeed, different individuals may legitimately respond similarly to the same input, particularly when the input itself is bland or commonplace.

8 Discussion

Fig. 7 presents responses generated by baseline and multi-task (MTASK-M) response generation systems. Both systems are presented with a conversation history of up to two dialog turns (context and input message), and this larger context helps produce responses that are more in line with the conversation flow (Sordoni et al., 2015). The first six response examples are generated for the same underlying speaker (a technical support person, User 1 in Fig. 4). The two last multi-task responses are generated for User 2.

We notice striking differences between the baseline and the multi-task model. The six first responses of **Multitask** in Fig. 7 represent a very consistent register in three different aspects. First, it is relatively clear from these responses that the underlying speaker represented by the model is

⁵Partial scores were rounded up. This affects both systems equally.

⁶We limited the number to 5 with the intention of not overwhelming judges with too much information, which may have exacerbated the difficulty.

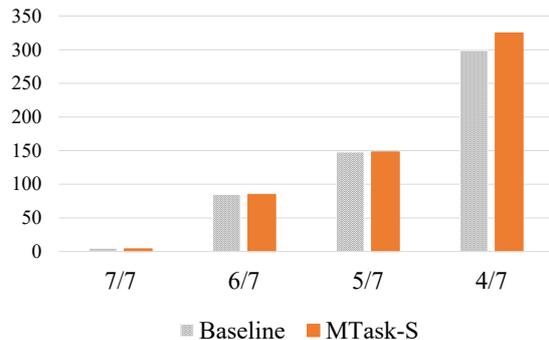

Figure 5: Judge agreement counts for MTASK-S versus Baseline. The difference between the two systems is statistically significant.

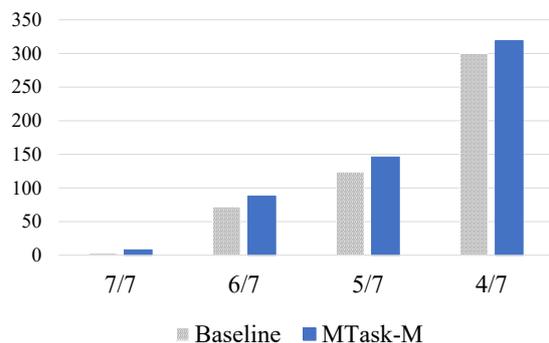

Figure 6: Judge agreement counts for MTASK-M versus Baseline. The difference between the two systems is statistically significant, and the preference for MTASK-M is more evident.

a tech support employee. Interestingly, this employee appears to give help with fitness-related software, and responds that the customer will be “able to run a marathon”. On the other hand, the output of the baseline system is relatively bland and deflective. More crucially the baseline does a relatively poor job producing content words that are relevant to the speaker’s domain of expertise. Finally, the tone of the baseline system is often incongruous, e.g., when it responds “I don’t know what to do with it”, which is unlikely to be a desirable response to offer a customer. In another case, the baseline responds “thanks for the info”. While this kind of response is appropriate for many speaker roles, it is less appropriate here, as the support employee is the one to give information and helpful advice.

The figure also illustrates current limitations of our speaker role model. For example, our response in the fourth example shows that such systems can be deflective (e.g., not giving any suggestion in response to “any idea”), but at least the system

Context: have you tried uninstalling nike+ connec? how about docking it to a different computer?
Input: Tried both of those techniques. But nothing works. I can try the other computer again.
Baseline: Let me know if there's anything else I can help you with. Thanks for the help.
Multitask: Have you tried using a different browser? Let us know if you have any other questions.

Context: What do you see when you have a failed login attempt? Never ending spinner? Loop you back to login page?
Input: I am getting a loop back to login page, windows.
Baseline: Ah, ok. Thanks for the info. I'll check it out. Thanks for the feedback.
Multitask: I'm sorry to hear that. Have you tried clearing your cache and cookies?

Context: To clarify: your first run after resetting your connection will not post to Facebook. Does this help? Let us know.
Input: That's correct. I reset it twice! It still doesn't work.
Baseline: Let me know if there's anything else I can help you with. Thanks for the update.
Multitask: I'm sorry to hear that. Are you receiving any error messages? Let us know.

Context: To link your sensor to your iPod, from home screen go to settings>Nike+ iPod>sensor>link new. Any luck?
Input: not work.. Any idea?
Baseline: I'm not sure, I'll check it out when i get home. Thanks for the update
Multitask: Let me know if you have any other questions. Let us know if the issue persists.

Context: You're welcome. What generation of the iPod Nano are you using?
Input: 5 years old and bought the kit then but my new Nano touch also not detecting sensor maybe receiver broken
Baseline: Ah , I see. I'll have to check it out. Thanks for the update.
Multitask: Ah, I see. I see. Have you been able to try a different network?

Context: Unfortunately you can't transfer your Nike+ training program to your iPod at this time. Let us know if this helps!
Input: Oh! That's a pity I bet I'd be able to run a couple more if this nice voice, told me to speed up in-between
Baseline: That's what I'm hoping for, but I don't know what to do with it.
Multitask: I'm sure you will be able to run a marathon at least once a week or so.

Context: So when are you going to post more n/d stuff?
Input: Soon I guess I have a chapter written, but it's way too short and not good enough to post just yet.
Baseline: Let me know how you get on with it. I don't know what to write.
Multitask: Ah, I see. Well, I'm sure it'll be interesting to see what happens!

Context: Ah, no. Had kind of a crazy day, and I've been writing a lot tonight. I have a new one-shot almost finished!
Input: Alright. I'm sure you'll read it eventually
Baseline: I don't think I'll be able to sleep tonight, but I'm going to sleep.
Multitask: I hope so! I can't wait to read it, hehe.

Figure 7: Responses produced by our baseline and multi-task neural response generation system (Multi-S), given a conversation history (context and input message.) The first 6 examples and last 2 examples correspond respectively to Users 1 (tech support) and 2.

does respond in a customer-support register. In the fifth example, response of the system seems relatively irrelevant, but this kind of natural language comprehension problem seems almost unavoidable. Semantic congruity aside, the response strikes the right tone—it is pragmatically and socially appropriate, which is the primary purpose of this investigation. The final two examples of Fig. 7 show that the model is also able to learn a voice or register for a completely different kind of character. The underlying person is highly assertive—reflected in their use of exclamation marks—and speaks informally (e.g., “hehe”), in a way the tech support person would typically not.

9 Conclusion

This paper introduces a multi-task learning approach to incorporate speaker role character-

istics into conversational models using non-conversational data. Both models presented here are relatively simple to implement, and show significant improvement in perplexity and BLEU score over a baseline system. Overall, MTASK-M is more computationally efficient, and effective in generating speaker-role-specific information, as reflected in human evaluation. Responses generated by these models exhibit a marked ability to capture speaker roles, expressive styles and domain expertise characteristic of the targeted user, without heavy recourse to an individual speaker’s conversational data.

Abstract

Thread disentanglement is a precursor to any high-level analysis of multiparticipant chats. Existing research approaches the problem by calculating the likelihood of two messages belonging in the same thread. Our approach leverages a newly annotated dataset to identify reply relationships. Furthermore, we explore the usage of an RNN, along with large quantities of unlabeled data, to learn semantic relationships between messages. Our proposed pipeline, which utilizes a reply classifier and an RNN to generate a set of disentangled threads, is novel and performs well against previous work.

1 Introduction

The problem of thread disentanglement is a precursor to high-level analysis of multiparticipant chats (Carenini et al., 2011). A typical chat consists of multiple simultaneous and distinct conversations, with Elsner and Charniak (2010) observing an average of 2.75 simultaneous threads of dialogue. Since a conversation does not necessarily entail a contiguous sequence of messages, the interwoven threads must be identified and segmented prior to any high-level analysis of the chat.

To further illustrate the need for thread disentanglement, consider the chat log in *Figure 1*. It should be clear to a reader that there are two independent threads of dialogue occurring within this sequence of messages, the first between John, Jack and Brian and the second between Jenny and Katie. Humans are adept at mentally disentangling conversations and even go as far as to adjust their behavior in order to ease the process of disentanglement which O’Neill and Martin (2003) observed in the form of name mentioning.

John:	i need a new tv show to watch
Jack:	psych/house of cards/breaking bad sound like things you might enjoy
Brian:	oh I should probably renew my Netflix
Katie:	I forgot my laprop at home D:
Jenny:	Katie, that sucks...
Jenny:	Are you going to go back home to get it?
Katie:	laptop*
Brian:	try Black Mirror

Figure 1. An example of a multiparticipant chat with two threads of dialogue.

Our work is novel because it approaches the problem of thread disentanglement by attempting to predict immediate reply relationships between messages. The potential benefits of this idea were discussed by Elsner and Charniak (2010) and Uthus and Aha (2013), but the idea has not yet been explored. Furthermore, Elsner and Charniak (2010) suggest that this approach “might yield more reliable annotations”.

Additionally, we explore the usage of unlabeled data for the purpose of identifying semantic relationships between messages. Previous attempts at semantic modeling by Elsner and Charniak (2010) and Adams and Martel (2010) have not been very effective, however recent accomplishments in next utterance prediction (Lowe et al., 2015) can be leveraged for the purpose of thread disentanglement.

The main contributions of this paper are as follows.

1. We create an annotated dataset¹ which labels direct reply relationships between pairs

¹ The dataset is publicly available and can be found at http://shikib.com/td_annotations.

of messages in a transcript.

2. We create and open-source a tool² for the efficient reply annotation of a dataset.
3. We propose a pipeline for the task of thread disentanglement, consisting of:
 - (a) A classifier, trained on the aforementioned dataset, that predicts reply relationships,
 - (b) A recurrent neural network that models semantic relationships between messages,
 - (c) A thread partitioning algorithm that utilizes a variety of features, including the previous stages of the pipeline, to ultimately partition a transcript into threads.
4. We evaluate our algorithm against all comparable previous approaches and explore potential improvements to the pipeline.

As a preview of the paper, *Section 2* further describes related work. *Section 3* introduces the proposed pipeline, with the subsections detailing the distinct stages of the pipeline. *Section 4* presents the metrics used for evaluating the agreement between a pair of disentanglements. *Section 5* discusses the datasets used by the pipeline, with specific attention to our newly annotated dataset. *Section 6* describes our experiments and presents the results. Finally, *Section 7* discusses our results and suggests potential future improvements upon our work.

2 Related Work

There have been a number of approaches to thread disentanglement, the majority of which contain a clustering/partitioning algorithm using a measure of message relatedness to segment a chat transcript into distinct threads.

Shen et al. (2006) introduce the problem of thread disentanglement, and approach it by using the cosine-similarity of messages to compute the distance between a message and a thread.

Elsner and Charniak (2010) present comprehensive metrics for evaluation along with a corpus to aid with disentanglement. They train a classifier on their corpus, to predict whether two messages belong in the same thread.

² The open-sourced annotation interface can be found at <https://github.com/Shikib/react-chat-reply-annotation>.

Wang and Oard (2003) construct expanded messages using temporal, author and conversational context. By expanding messages using this contextual information, they have more signal to use when assigning a message to a thread.

We build on this work by using our newly annotated dataset to train a classifier which predicts immediate reply relationships. This is a supervised alternative to heuristics used by previous research. Additionally, it is an improvement over the classifier trained by Elsner and Charniak (2010) since the nature of the annotation leads to stronger relationships between message pairs in the training data.

Previous work has explored modeling semantic relationships between messages using a pre-defined list of technical words (Elsner and Charniak, 2010) and applying Latent Dirichlet Allocation (Adams and Martel, 2010). In contrast, we apply the research done by Lowe et al. (2015) by utilizing a Recurrent Neural Network to predict the probability of a message occurring in a given thread.

3 Proposed Pipeline

We propose a novel pipeline to approach the problem of thread disentanglement. This pipeline consists of four stages, as visualized in *Figure 2*.

The first stage, as described in *Section 3.1*, is a classifier to detect reply relationships between pairs of messages.

The second stage is a classifier that predicts whether two messages belong in the same thread. This classifier, described in *Section 3.2*, is similar to the one trained by Elsner and Charniak (2010).

The third stage, described in *Section 3.3*, is a recurrent neural network that uses the content of the messages to predict the probability of a message following a sequence of messages.

The fourth and final stage is a thread partitioning algorithm that uses the information outputted from the previous stages to generate threads. This stage is described in *Section 3.4*.

3.1 Reply Classifier

Given two input messages, the reply classifier outputs the likelihood of the first message being a reply to the second. Given a child and a parent message, a feature vector is generated in order to describe the relationship between the two messages. The features utilized are described in *Table 1*.

Table 1: Description of features utilized for the reply classifier.

Time	The time difference in seconds.
Mention Parent	Whether the child message mentions the author of the parent message.
Mention Child	Whether the parent message mentions the author of the child message.
Same author	Whether the author of the two messages is the same.
Distance	The number of messages separating the two messages.
RNN Output	The probability outputted by the RNN.

These feature vectors are then used to train a random forest (Breiman, 2001) classifier with 250 trees. We performed comparisons to other classifiers, namely a logistic regression classifier, a support vector classifier and a multilayer perceptron classifier, however cross-validation proved random forests to have the highest accuracy. The models were trained and evaluated using scikit-learn (Pedregosa et al., 2011).

The pairs of input messages in the training data were specifically annotated as consisting of a reply relationship. This suggests that each pair of messages is directly related, leading to the classifier learning to identify strong, immediate relationships between messages.

3.2 Same-Thread Classification

Elsner and Charniak (2010) trained a classifier that predicted whether two input messages belonged to the same thread. We implemented a similar classifier through utilization of the features described in Section 3.1 and a dataset that they provided.

Given a pair of messages, the same-thread classifier outputs the probability of the messages belonging to the same thread. The classifier trained was a random forest (Breiman, 2001) with 250 trees, using scikit-learn (Pedregosa et al., 2011).

Unlike the reply classifier, the same-thread classifier was trained on data with weak relationships. Instead of specifically annotated relationships, the pairs of messages used to train the same-thread classifier were labeled as belonging to the same thread. Because the same-thread pairs are a super-

set of the reply pairs, this leads to the classifier learning to identify broader relationships between messages, rather than strictly immediate reply relationships.

As a result of the same-thread classifier being trained on a different set of data than the reply classifier, the learned relationships are different in nature, which suggests that the two classifiers can strongly complement each other.

3.3 RNN for Next Utterance Classification

The third stage of the pipeline attempts to leverage large amounts of unlabeled data for the purpose of modeling semantic relationships between messages. We train a recurrent neural network with LSTM (Hochreiter and Schmidhuber, 1997) hidden units to predict the probability of a message following a sequence of messages (Lowe et al., 2015).

The reasoning behind utilizing an LSTM is for the purposes of identifying dependencies between non-adjacent messages. LSTM units are best able to capture long-term dependencies through the use of a series of gates which control whether an input is remembered, forgotten or used as output. Formally, at every time step an LSTM unit updates the internal state C_t as a function of the observed variable x_t and the previous internal state C_{t-1} and h_{t-1} .

Both the context (the previous sequence of messages) and the message are passed through the LSTM units one word at a time, in the form of learned word embeddings. Let us use c and r to denote the final hidden state representations of the context and reply respectively. We can use these hidden states, along with a learned matrix M , to compute the probability of a reply, as:

$$P(\text{reply} | \text{context}) = \sigma(c^T M r) \quad (1)$$

The model, implemented in PyTorch (A. Paszke, 2017), was trained using hyperparameters recommended by Lowe et al. (2015).

This RNN-based next utterance classification is useful as it supplements the aforementioned classifiers by leveraging unlabeled data to semantically model message relationships.

Additionally, the output of this classifier is added as a feature to the previous two classifiers as well. This allows the reply classifier and the same-thread classifier to use the semantic relatedness of the input messages during classification.

Table 2: Description of the features utilized by the in-thread classifier.

Same-Thread Mean	Mean output of the same-thread classifier.
Same-Thread STD	Standard deviation of the output of the same-thread classifier.
Reply Mean	Mean output of the reply classifier.
Reply STD	Standard deviation of the output of the reply classifier.
Thread Length	Current length of the thread.
Author count	Number of author’s messages already in the thread.
Author total	Number of author’s messages in the chat.
In-thread proportion	Author count divided by Author total.
Author proportion	Author count divided by Thread Length.
Author mentions	Number of times the author’s name was mentioned in the thread.
Time	The time difference between the message and the last message in the thread.
RNN Prediction	The prediction outputted by the RNN.

3.4 Thread Partitioning

Our ultimate goal is to generate a set of disentangled threads, suggesting the usage of a thread partitioning algorithm as the next stage in the pipeline. Using the previously described classifiers, we must identify an optimal segmentation of an input transcript.

3.4.1 In-Thread Classifier

We construct a classifier, referred to as the in-thread classifier, which leverages the output of all previous stages of the pipeline to predict the probability of a message belonging to a thread.

Given a message and a thread, we generate a feature vector using the features described in Table 2.

The model used for classification, built in scikit-

learn (Pedregosa et al., 2011), is a random forest classifier with 300 trees.

3.4.2 Thread Partitioning

Given the in-thread classifier, we can compute the probability that a message belongs in a given thread of conversation. This is used by our thread partitioning algorithm to generate threads.

This algorithm processes the messages in chronological order. For every message, m_i , the algorithm considers every existing thread, t_j , and passed m_i and t_j into the in-thread classifier.

Ultimately m_i is assigned to the thread which maximizes the probability outputted by the classifier, provided that the best probability output is above a threshold. If the best probability is below the threshold, a new thread is created for the message. This threshold was fine-tuned on the validation dataset.

After sequentially iterating over all of the messages in the transcript, the thread partitioning algorithm will output the disentangled threads.

3.5 Pipeline Overview

Figure 2 provides an overview of the proposed pipeline. The thread partitioning algorithm generates a feature vector to represent the relationship between a thread and a message. The features, as listed in Table 2, include the values outputted by the previous stages of the pipeline.

The in-thread classifier, trained on the pilot dataset provided by Elsner and Charniak (2010), uses this generated feature vector to predict the probability of the message belonging to the given thread. Using the outputted probabilities, the thread partitioning algorithm either assigns the message to the most probable existing thread or generates a new thread.

4 Metrics

A number of metrics are used throughout this paper to evaluate the agreement of two disentanglements. It is a non-trivial task to compare two disentanglements which have a different number of threads.

To measure the global similarity between annotations, we utilize **one-to-one accuracy**. This is computed by using optimal bipartite matching to pair up threads between the two annotations and computing the overlap between every pair of matched threads. This metric measures "how well

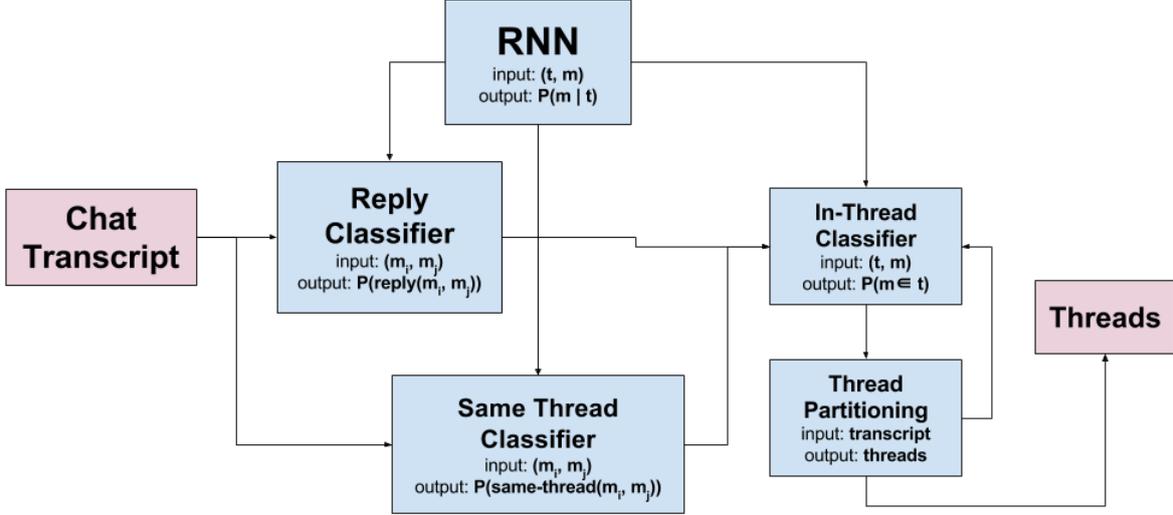

Figure 2. The proposed pipeline for disentangling a chat transcript into threads. Throughout the diagram, t represents a thread and m denotes a message.

we extract whole conversations intact” (Wang and Oard, 2009).

We also use the loc_k score to measure **local agreement**. For a particular message, the previous k messages are either in the **same** or a **different** thread. The loc_k score is computed by considering, for each message, the previous k messages and counting the matches in the same/different thread assignments across annotations.

The third and final metric used to score annotation agreement is the **Shen-F score**, as defined by Shen et al. (2006) which measures how well related messages are grouped. The Shen-F score is defined as:

$$F = \sum_i \frac{n_i}{n} \max_j (F(i, j)) \quad (2)$$

where i is a ground truth thread with a length of n_i , n is the total length of the transcript and $F(i, j)$ is the harmonic mean of the precision and the recall. If the thread overlap is n_{ij} , the length of the gold-standard thread is n_i and the length of the proposed thread is n_j , then $F(i, j)$ is defined as follows:

$$P = \frac{n_{ij}}{n_j} \quad R = \frac{n_{ij}}{n_i} \quad F(i, j) = \frac{2PR}{P + R} \quad (3)$$

The \max_j operation is taken over all detected threads. Since the matching is multiway (i.e., the same j can be chosen for different values of i), the score is not symmetric. When comparing human annotations, this lack of symmetry is addressed by

treating the annotation with higher entropy as the gold standard.

Given a transcript of length n , with thread i having a size of n_i , the entropy of the annotation can be computed as:

$$H(c) = \sum_i \frac{n_i}{n} \log_2 \frac{n}{n_i} \quad (4)$$

These metrics are utilized by both Elsner and Charniak (2010) and Wang and Oard (2009).

To account for differences in annotation specificity, Elsner and Charniak (2010) introduce **many-to-one accuracy**. This metric maps each of the threads of the source annotation to the single thread in the target with which it has the greatest overlap and counts the total percentage of overlap. Similarly to **Shen-F**, the higher entropy annotation is mapped to the lower one.

5 Datasets

We utilize a number of datasets to train various algorithms in our thread disentanglement pipeline. Two of these datasets are external datasets provided by previous research. The reply dataset¹ was annotated as part of this study as described in *Section 5.1*.

Since our classifier aims to learn immediate reply relationships between pairs of messages, there is a need for a newly annotated dataset. This section details the process of data acquisition and provides some preliminary analysis of the data.

Table 3: Single annotation statistics describing three annotations of a 524 message transcript. All of these metrics describe a single annotation. Thread density refers to the number of active threads at any given time.

	Mean	Max	Min
Threads	55.33	62	49
Avg. Thread Length	9.6	10.7	8.5
Avg. Thread Density	1.79	1.82	1.73
Entropy	3.99	4.42	3.64

5.1 Data Acquisition

For the acquisition of our annotated reply dataset a subset of the #linux IRC log data provided by Elsner and Charniak (2010) was used.

An interface was built and open-sourced to allow volunteers to manually annotate the data for the purpose of identifying direct reply relationships between messages. Users were instructed to proceed through the messages in the chat and select the immediate parents for every message.

Three volunteers, familiar with Linux terminology, independently annotated a set of 524 messages from the development dataset provided by Elsner and Charniak (2010). For every message in the dataset, annotators identified the potential immediate parents of the message, where $parent(m)$ is identified as the messages to which m is a direct reply. It is possible for a message to have no parents (e.g., starting a new thread of conversation) and multiple parents (e.g., following up on a multi-participant conversation).

5.2 Data Analysis

On average, we find that a message has 1.22 direct parents and 1.70 direct children. The relatively high number of children suggests that typically a message receives more than one reply. On the other hand, the lower number of direct parents suggests that a message is typically replying to a single parent message.

We can use the reply annotations to retrieve a thread annotation which resembles the structure of the annotated data by Elsner and Charniak (2010). This is done by identifying a disjoint set of messages such that no two messages in different sets share a reply relationship. This allows us to apply the read-based metrics described in Section 4 to evaluate the annotation quality.

As is demonstrated in Table 4, our annotations

Table 4: Pair annotation statistics describing three annotations of a 524 message transcript. These metrics are all computed on a pair of threads and therefore describe inter-annotator agreement.

	Mean	Max	Min
one-to-one	81.49	87.79	74.81
loc_3	90.36	91.81	88.61
many-to-one	97.39	98.28	95.80
Shen F	87.70	100.0	75.00

have high inter-annotator agreement. While our agreement is not directly comparable to that of Elsner and Charniak (2010) due to our annotations being done on a subset of the data, our agreement is evidently much greater. This suggests that a reply-based annotation approach removes ambiguity and by extension removes noise from the data.

5.3 External Datasets

In addition to the aforementioned annotated dataset, we utilized the corpus provided by Elsner and Charniak (2010) to train the same-thread classifier described in Section 3.2. This corpus consists of a pilot set, a development set and a testing set.

We also utilize the Ubuntu Dialogue Corpus (Lowe et al., 2015) to train a recurrent neural network to output the probability of a message occurring after a sequence of messages, as described in Section 3.3.

It is reasonable to utilize both of these datasets, as both are IRC chat logs from channels concerned with Linux related content. The corpora provided by Elsner and Charniak (2010) is from the ##LINUX channel, whereas the Ubuntu Dialogue Corpus (Lowe et al., 2015) consists of data from the ##UBUNTU channel.

6 Experiments and Evaluation Results

6.1 Reply Classifier

We use our annotated data, described in Section 5.1, to generate a set of positive examples (i.e., labeled replies) and a set of negative examples (i.e., the complement of the annotated replies). This data is used to train and validate the reply classifier described in Section 3.1.

The data is very imbalanced, with most pairs being non-replies which naturally leads to a large number of false positives (i.e., non-replies classified as replies). This issue was addressed by ad-

justing the class weights in order to stronger penalize false positives when training the random forest model. Specifically, the class weight of the negative class was set to be $\frac{\text{num_non_replies}}{\text{num_replies}}$ while the class of the positive class was 1.

To further address the problem of imbalanced data, we employ a strategy used by Elsner and Charniak (2010) by only having our classifier consider messages within 129 seconds of each other. This brings the ratio of the two classes much closer and is useful for speeding up inference as well.

Using 10-fold cross-validation, we obtain an average precision of 0.91 and average recall of 0.92. Most message pairs are non-replies and as such these scores are non-representative. For the reply class, we have a precision of 0.83 and a recall of 0.49.

Using Gini feature importance (Breiman, 2001), we find the most important feature to be the probability outputted by the RNN, followed by the time difference and the message distance. This confirms that semantic relatedness is vital for detecting reply relationships. The time difference and message distance are both temporal measurements which represent the fact that new messages are typically a reply to recently sent messages.

6.2 Same-Thread Classifier

The same-thread classifier, described in Section 3.2, was trained on the development set provided by Elsner and Charniak (2010) which was described in Section 5.3. This classifier obtains a precision and recall of 0.7, which is similar to the result obtained by Elsner and Charniak (2010).

The Gini feature importances (Breiman, 2001) indicate that for the same-thread classifier, the most important features are the output of the RNN, the time difference and the 'same author' feature. The relatively high importance of the 'same author' feature can be explained by the fact that an author typically responds numerous times within a conversation. This reaffirms the idea that the two classifiers learn to identify different relationships between messages, and therefore complement each other.

6.3 RNN

The recurrent neural network was trained with the hyperparameters described by Lowe et al. (2015) on the Ubuntu Dialogue corpus, described in Section 5.3. The final model performs within a few percentage points of the result they reported.

6.4 In-Thread Classifier

This classifier was trained and tuned on the pilot dataset provided by Elsner and Charniak (2010) as described in Section 5.3.

To handle the imbalance of the data, we adjust the class weight when training and only consider thread-message pairs within 129 seconds of each other.

With 10-fold cross-validation, we obtain an average precision of 0.91 and an average recall of 0.92. For the positive class, we have a precision of 0.89 and a recall of 0.69.

Using the Gini feature importances (Breiman, 2001), we find that the most important features for the in-thread classifier are the time difference, the proportion of the author's previous messages which belong to the thread, the mean output of the reply classifier and the mean output of the same-thread classifier.

The in-thread proportion of the author's messages is likely a strong feature because high activity within a particular conversation indicates a high likelihood of continued activity.

It is plausible that the output of the RNN is not a strongly used feature because it is already present in the output of the reply and same-thread classifiers.

6.5 Disentanglement Evaluation

We compare the performance of our thread partitioning pipeline to the results reported by Elsner and Charniak (2010) and Wang and Oard (2009). Both of these papers evaluated their disentanglement models on the same dataset, consisting of six annotations of the same transcript of 1000 messages, provided by Elsner and Charniak (2010). The comparison is shown in Table 5, where our approach is shown to outperform the other methods with respect to loc_3 and outperforms Elsner and Charniak (2010) in all metrics.

However, we suspect that the results reported by Wang and Oard (2009) were boosted by the inclusion of *system messages* when computing all of their metrics. In contrast, Elsner and Charniak (2010) only include them for the computation of loc_3 .

System messages are classified into thread -1 by all of the annotators and are extremely easy to classify as they always appear in the form "X joined the room" or "X left the room". We compare the performance of our pipeline, provided

Table 5: The results obtained by our pipeline compared to annotators, Elsner and Charniak (2010) and Wang and Oard (2009).

	Annotators	Elsner & Charniak	Wang & Oard	Proposed Pipeline
Mean one-to-one	52.98	41.23	47.00	44.02
Max one-to-one	63.50	52.12	-	52.75
Min one-to-one	35.63	31.62	-	36.75
Mean loc_3	81.09	72.94	75.13	78.64
Max loc_3	86.53	74.70	-	80.27
Min loc_3	74.75	70.77	-	77.23
Mean Shen F	53.87	43.47	52.79	45.86
Max Shen F	66.08	57.57	-	52.22
Min Shen F	33.43	32.97	-	36.75

Table 6: Our results compared to Wang and Oard (2009), provided we include the system messages when computing the metrics.

	Wang & Oard	Pipeline
Mean one-to-one	47.00	55.22
Mean loc_3	75.13	78.64
Mean Shen F	52.79	56.62

that we include all system messages, to the results obtained by Wang and Oard (2009) in Table 6 where our approach outperforms in all metrics.

6.6 Pipeline Discussion

Our pipeline strongly outperforms previous research, likely due to the fact that we leverage different models and data sources to capture a variety of relationships between messages.

The reply classifier is trained on specifically annotated reply relationships, leading it to excel at identifying strong, local agreements between messages.

The same-thread classifier is trained on pairs of messages that belong to the same thread, resulting in a model which captures broad relationships between messages in the same thread. This is observed in the relatively high importance the model places on the 'same author' feature.

The RNN, trained on a large corpus of unlabeled data, is adept at identifying the strength of semantic relationships between messages. As a result, it is utilized as a feature in every classifier of the pipeline.

Removing the RNN entirely from the pipeline results in a significant quality drop, as shown in Table 7. This drop reaffirms that the pipeline's

Table 7: Demonstration of the significant quality drop observed when removing the RNN.

	Pipeline	Without RNN
Mean one-to-one	44.02	41.06
Mean loc_3	78.64	76.52
Mean Shen F	45.86	43.01

quality stems from its ability to model semantic relationships between messages.

The in-thread classifier is the final model that trains and evaluates on top of the output of the previous models. This model decides how to best utilize the previous models and combines their outputs to ultimately decide whether a message belongs to a thread.

7 Conclusions and Future Work

This work approaches the problem of thread disentanglement from the perspective of identifying reply relationships between messages. A corpus of annotated data for this task is provided, which should allow future research to expand on the work presented in this paper. From our high inter-annotator agreement, it is evident that detecting reply relationships has relatively little noise. We incorporate a combination of features in our disentanglement pipeline, using both meta-data and semantic relationships between messages. We further show that unlabeled data in combination with neural based approaches are effective in aiding with thread disentanglement. The model that we present outperforms all previous work when system messages are included.

In the near future, we plan to expand our reply

annotated corpus, using our open-sourced annotation software, particularly for the purpose of evaluation. We have shown that our reply-based annotation has higher inter-annotator agreement relative to the annotations provided by Elsner and Charniak (2010), therefore supplementing the reply corpus and using it for evaluation may lead to less noisy evaluations.

While we have shown that using an RNN is effective for detecting replies, it may prove useful to perform further experiments to determine if it can be applied more effectively. For example, adding an attention mechanism could be beneficial for the purposes of disentanglement. Additionally, in order to reduce noise in the data and therefore lead the model to converge faster, it is worth experimenting with training the RNN on a disentangled corpus. Other directions for future research could involve exploring these ideas.

Abstract

We present a major step towards the creation of the first high-coverage lexicon of polarity shifters. In this work, we bootstrap a lexicon of verbs by exploiting various linguistic features. Polarity shifters, such as *abandon*, are similar to negations (e.g. *not*) in that they move the polarity of a phrase towards its inverse, as in *abandon all hope*. While there exist lists of negation words, creating comprehensive lists of polarity shifters is far more challenging due to their sheer number. On a sample of manually annotated verbs we examine a variety of linguistic features for this task. Then we build a supervised classifier to increase coverage. We show that this approach drastically reduces the annotation effort while ensuring a high-precision lexicon. We also show that our acquired knowledge of verbal polarity shifters improves phrase-level sentiment analysis.

1 Introduction

We present an approach towards bootstrapping a lexicon of **polarity shifters**. Polarity shifters are content words that have semantic properties similar to negation. For example, the negated statement in (1) involving the negation word *not* can also be expressed by the verbal shifter *fail* in (2).

(1) Peter did **not** pass the exam.

(2) Peter **failed**_{shifter} to pass the exam.

Similarly, shifting is also caused by nouns (e.g. *downfall*) and adjectives (e.g. *devoid*).

Polarity shifters are important for various tasks in NLP, such as relation extraction (Sanchez-Graillet and Poesio, 2007), recognition of textual entailment (Harabagiu et al., 2006) and particularly sentiment analysis (Wiegand et al., 2010).

Similarly to negation words, they may cause the polarity of a statement to shift. Even though (3) contains the positive polar expression *scholarship*, the overall polarity of the sentence is negative. (4) conveys positive polarity despite the presence of the negative polar expression *pain*.

(3) She was [**denied**_{shifter} the [scholarship]⁺]⁻.

(4) The new treatment has [**alleviated**_{shifter} her [pain]⁻]⁺.

Although there has been significant research on polarity shifting in sentiment analysis (Wiegand et al., 2010), this work has focused on the presence of negation words. Negation words (*no*, *not*, *never*, etc.) are typically function words, so only a few exist. Polarity shifters are content words, of which there are a lot more. For instance, WordNet (Miller et al., 1990) contains over 10k verbal, 20K adjectival and 110K nominal lemmas. An exhaustive manual annotation would be far too costly.

To reduce cost, we introduce a bootstrapping approach for the acquisition of polarity shifters. In this work we focus exclusively on verbs. As the main predicates of phrases they tend to have larger scopes than nouns and adjectives, increasing the impact of their polarity shifting. Their vocabulary size is also smaller, allowing us to cover a reasonable share of it in our evaluation.

Existing resources barely cover any verbal shifters at all. Even the most complex negation lexicon for sentiment analysis (Wilson et al., 2005) includes a mere 12 verbal shifters. In contrast, our initial random sample of 2000 verb lemmas contained 300 shifters. The corpora on which negation can be learned, such as the Sentiment Treebank (Socher et al., 2013) or the BioScope corpus (Szarvas et al., 2008), only comprise contiguous sentences of fairly small datasets, so only the most frequently occurring negation words are considered. For example, only 6 verbal shifters are observed on the BioScope corpus (Morante, 2010).

In this work, we address this knowledge gap by bootstrapping a lexicon of polarity shifters. On a sample of manually annotated verbs extracted from WordNet, we first examine a variety of linguistic features for this task. Then we build a supervised classifier to classify the remaining WordNet verbs. Thus we can drastically cut down on the number of verbs to be annotated manually.

Our **contributions** are as follows:

- (i) we present the first high-coverage lexicon of verbal polarity shifters, going substantially beyond what can be extracted from existing phrase-level corpus annotations;
- (ii) we develop methods for high-precision recognition of polarity shifters;
- (iii) in addition to using resource-based generic features, we show that we can boost performance with novel task-specific features, many of which are derived from corpora; and
- (iv) we show that compositional classification based on recognition of polarity shifters significantly outperforms polarity classifiers that lack explicit knowledge of verbal shifters.

The main focus of this paper is to find ways to automatically *extract* verbal shifters. The question of their respective scope is part of future research.¹ While our work focuses on English, the concepts applied are not language-specific. We have made all data that were manually labeled as part of this research **publicly available**.²

2 Data

To obtain a gold standard for verbal shifters, an expert annotator labeled a random sample of 2000 verbs taken from WordNet 3.1 (*see footnote 2*). To measure interannotator agreement, 200 of these were annotated again by one of the authors. The achieved $\kappa = 0.66$ indicates substantial agreement (Landis and Koch, 1977).

Due to the lack of robust word-sense disambiguation, our annotation is on the lemma level. We follow a simple **binary classification**: each verb either can cause polarities to shift or not. In order to qualify as a shifter, the verb must allow polar expressions as dependents and the polarity of the proposition that embeds both the verb and

¹We assume that the scope of a verbal shifter is the set of its dependents (typically its subject or objects).

no shifter	229	81.2	69	94.5	140	74.1

Table 2: Distribution of verbal shifters in the *Subjectivity Lexicon* (Wilson et al., 2005).

polar expression must move towards a polarity that is opposite of the polar expression.

Table 1 shows the distribution of shifters among the set of verbs. At approximately 15%, shifters represent a large enough proportion of verbs to be considered for automatic extraction. Table 2 shows the distribution of shifters among polar verbs. (Polar expressions are identified with the help of the *Subjectivity Lexicon* (Wilson et al., 2005).) While a large number of shifters are themselves negative polar expressions, not all are.

3 Task-Specific Features

In the following we present task-specific features for both verbal shifters (§3.1) and their counterpart, anti-shifters (§3.2). Each feature creates a verb ranking, indicating how likely each verb is to be considered a verbal (anti-)shifter.

Most of our features are corpus-based. As a corpus we use *Amazon Product Review Data* (Jindal and Liu, 2008), comprising over 5.8 million reviews. We chose this dataset for its size and its sentiment-related content. Some features also require knowledge of opinion words and their respective polarity. Such knowledge is obtained from the *Subjectivity Lexicon*. Whenever we use syntactic information (e.g. dependency relations), we obtain it from the Stanford Parser (Chen and Manning, 2014).

3.1 Features for Shifter Detection

As baseline features, we consider all verbs ranked by their frequency in our text corpus (**FREQ**), as well as all negative polar expressions³ ranked by frequency (**NEGATIVE**).

³We consider negative polar expressions since the proportion of shifters is greatest among these expressions (Table 2).

EffectWordNet (EFFECT): This feature uses the idea that events may have beneficial or harmful *effects* on their objects. Wiebe and colleagues (Deng et al., 2013; Choi et al., 2014; Choi and Wiebe, 2014) introduced this idea in the context of annotation and lexical acquisition work for opinion inference.⁴ For example, in (5) the combined facts that *fall* has a negative effect (henceforth referred to as *-effect*) on its theme (i.e. *Chavez*) and that people are happy about Chavez’ fall suggest that people have a negative attitude towards Chavez. As (5) shows, verbs with a *-effect*, such as *fall*, often coincide with verbal shifters. However, *-effect* words do not necessarily shift polarity. For instance, while *abuse* has a *-effect*, it does not shift, as shown by the fact that the verb phrase remains negative in (6).

- (5) I think people are happy because [[Chavez]⁻ has **fallen_{-effect}**]⁺.
 (6) We don’t want the public getting the idea that we [**abuse_{-effect}** our [prisoners]⁻]⁻.

While *-effect* and shifting are not equivalent, their large overlap warrants investigating. We use the related EffectWordNet resource (Choi and Wiebe, 2014), which provides effect labels for synsets. To generalize to lemmas, we label a word as *-effect* if at least one of its synsets has a *-effect* and none have a *+effect*. Analogous to negative polar expressions, we take all *-effect* words and sort them by word frequency (*-EFFECT*).

Distributional Similarity (SIM): As our aim is to identify verbs whose semantics resembles that of negation words, a straightforward method is to extract verbs that are distributionally similar to negation words. Using Word2Vec (Mikolov et al., 2013), we compute word embeddings for our text corpus.⁵ All verbs are ranked by their cosine similarity to a given negation word. The highest ranking verbs are considered verbal shifters. As negation words we consider the intersection of two negation word lists: the *negation* category in the valence shifter lexicon by Wilson et al. (2005) and the negation signals from Morante and Daelemans (2009). The negation words are *neither*, *never*, *no*, *none*, *nor*, *not* and *without*.

⁴Initially, events with positive/negative effects were referred to as *good-for/bad-for* events. We use the terminology Choi and Wiebe (2014) introduced for EffectWordNet.

⁵Following the work of Wiegand and Ruppenhofer (2015) in verb category induction for sentiment roles, a task similar to ours, we use continuous bag-of-words with 500 dimensions.

Polarity Clash (CLASH): Some of our previous examples (e.g. (3)) suggest that shifting is mainly caused by a polar verb (e.g. *lose*⁻, *alleviate*⁺, *deny*⁻) modifying a polar expression with the opposite polarity (e.g. [[*lose_{shifter}*]⁻ [*hope*]⁺]⁻, [[*alleviate_{shifter}*]⁺ [*pain*]⁻]⁺, or [[*deny_{shifter}*]⁻ [*scholarship*]⁺]⁻). We expect that the more often a verb occurs within such constructions, the more likely it is to be a shifter. As we saw in the *Subjectivity Lexicon* that the majority of verbal shifters have negative polarity (Table 2), we look exclusively for negative polar verbs that have a positive polar noun as a direct object. We rank those verbs by the frequency of occurring with positive nouns (CLASH), normalized by the overall frequency of the verb (CLASH_{norm}).

Particle Verbs (PRT): With many particle verbs, the particles signal a particular aspectual property, typically the occurrence of a complete transition to an end state (Brinton, 1985). For instance, *dry (something) out* means *dry (something) completely*. Since shifting normally involves producing a new (negative) end state of some entity, we assume a significant number of shifters among particle verbs ((7) and (8)).

- (7) This [**tore_{down}**]_{shifter} our great [*dream*]⁺]⁻.
 (8) Please [**lay_{aside}**]_{shifter} all your [*worries*]⁻]⁺.

We only consider particles which typically indicate a complete transition to a negative end state: *aside*, *away*, *back*, *down*, *off* and *out*. To produce rankings, we sort the particle verbs by their absolute frequency in our text corpus.

Heuristic using ‘any’ (ANY): Our final shifter feature rests on the linguistic insight that *negative polarity items (NPIs)* (Giannakidou, 2008), such as English *any*, typically appear in the context of a negation, as in (9). Our assumption is that NPIs may similarly occur in the context of a verbal shifter, as in (10), since it similarly conveys a negation. The concept of NPIs is not specific to the English language and can be found in many other languages (Krifka, 1991).

- (9) They did [**not** give us any [*help_{dobj}*]⁺]⁻.
 (10) They [**denied_{shifter}** us any [*help_{dobj}*]⁺]⁻.

The feature we design collects all verbs that take a direct object that is modified by the NPI *any*, as in (10). We sort the verbs by their frequency of co-occurrence with this particular textual pattern (ANY). We normalize that pattern frequency by the frequency of the respective verb

(ANY_{norm}). As a further constraint we demand that the direct object represents a polar expression ($ANY_{norm+polar}$). This constraint is fulfilled in (10) since *help* is a positive polar expression.

3.2 Anti-Shifter Feature (ANTI)

We also introduce a feature for automatically retrieving verbs that – semantically speaking – are the exact opposite of what shifters convey. This is, therefore, a negative feature indicating the absence of a shifter. Our anti-shifter feature determines verbs co-occurring with a very small set of specific adverbials. Using the log-likelihood collocation measure of *Sketch Engine*⁶ we select adverbials that showed attraction to verbs of creation on the one hand, and being repelled by verbs of destruction on the other. Verbs of creation are expected to be anti-shifters, since they typically entail a positive end state (i.e. something is created), while verbs of destruction typically entail a negative end state (i.e. something is destroyed) We identified four different adverbials: *exclusively*, *first*, *newly* and *specially*. Some typical examples are given in (11)–(14). In order to produce a ranking for this feature, we sort the anti-shifter candidate verbs according to their frequency of co-occurrence with either of the respective adverbs, normalized by the respective verb frequency (ANTI).

- (11) In winter, black bears exclusively **live**_{antiShifter} on fish.
- (12) Full keyboards on cellphones were first **introduced**_{antiShifter} in 1997.
- (13) These buildings have been newly **constructed**_{antiShifter}.
- (14) They specially **prepared**_{antiShifter} vegan dishes for me.

4 Generic Features

In addition to the task-specific features presented in §3 we examine some generic features derived from common lexical resources. Unlike the features in §3, the generic features do not produce a ranking. Therefore, we will only be able to evaluate them in the context of a supervised classifier.

WordNet (WN): WordNet is the largest English ontology. It is organized in synsets. However, we want to assign categories to words, rather than senses. Due to the lack of robust word-sense disambiguation, we represent a word as the union of synsets containing it.

A common way to harness WordNet for lexicon induction tasks in sentiment analysis is by using its **glosses** (Esuli and Sebastiani, 2005; Gyamfi et al.,

⁶<http://www.sketchengine.co.uk/>

2009; Choi and Wiebe, 2014; Kang et al., 2014). We assume that the explanatory texts of glosses are similar among shifters. We treat glosses as a bag-of-words feature.

We also use WordNet to assign semantic types. Our intuition is that verbal shifters share the same semantic types. We consider two types of information that have been previously found effective for sentiment analysis in general, namely the **hyponyms** of verbs (Breck et al., 2007) and their **supersenses** (Flekova and Gurevych, 2016).

FrameNet (FN): FrameNet (Baker et al., 1998) is a semantic resource used for various sentiment related tasks, such as opinion holder and target extraction (Kim and Hovy, 2006), stance classification (Hasan and Ng, 2013) or opinion spam analysis (Kim et al., 2015). It provides over 1200 semantic frames that comprise words with similar semantic behavior. We use the frame-memberships of a verb as its features, expecting that verbal shifters are grouped in the same frames. For instance, the frame AVOIDING exclusively comprises verbal shifters (e.g. *desist*, *dodge*, *evade*, *shun*, *shirk* etc.).

The latest version of FrameNet (v1.6) covers only 31.4% of verbs from our gold standard. To **extend coverage**, we use the semantic-parser *SemaFor* (Das et al., 2010), which can infer frames for verbs missing from FrameNet (Das and Smith, 2011). For each missing verb, we have *SemaFor* label 100 sentences from our corpus and use the frame most frequently assigned. In our exploratory experiments with supervised classification, this expansion caused a significant increase of 6% in F-score (paired t-test, $p < 0.05$).

5 Experiments

We will now experimentally evaluate the features introduced in §3 and §4. In §5.1 we analyse the high-precision potential of individual task-specific features (§3). In §5.2 we run a recall-oriented evaluation of our entire gold standard with classifiers using both task-specific and generic features. Using the best classifier from this evaluation, we bootstrap the remaining WordNet verbs into a larger list of shifters in §5.3. Finally, we evaluate the impact of verbal shifter knowledge on phrase-level sentiment analysis in §5.4.

Feature	Retr.	Prec@n			
		20	50	100	250
FREQ	2000	10.0	18.0	22.0	22.0
NEGATIVE	189	30.0	30.0	29.0	N/A
–EFFECT	175	45.0	44.0	46.0	N/A
SIM _{nor}	1901	15.0	24.0	16.0	18.4
SIM _{neither}	1901	20.0	18.0	18.0	21.6
SIM _{none}	1901	25.0	24.0	22.0	21.6
SIM _{not}	1901	25.0	24.0	23.0	23.2

Feature	Retrieved	Prec@n			
		20	50	100	250
FREQ	2000	90.0	82.0	78.0	78.0
POSITIVE	73	90.0	94.0	N/A	N/A
+EFFECT	95	90.0	92.0	N/A	N/A
ANTI	725	95.0	96.0	93.0	87.4

Table 4: Analysis of anti-shifter feature (§3.2).

5.1 Analysis of Task-Specific Features

In Table 3 we analyze how useful the task-specific shifter features from §3.1 are as high-precision candidate lists. Each feature produces a ranking, which we evaluate in terms of precision at a certain rank (*Prec@n*). We also state the number of retrieved verbs. Embedding-based methods (e.g. SIM) could theoretically rank all verbs. However, the default configuration of Word2Vec discards every word which occurs less than 5 times, which is why only 1901 verbs are retrieved.

Table 3 shows that filtering verbs by effect (–EFFECT) brings improvements over the FREQ and NEGATIVE baselines. Regarding distributional similarity to negation words (SIM), most negation words perform no better than the baselines. The only notable exception is *without*, which provides gains at high ranks. We also examined a combination of all negation words by merging them in a centroid vector (SIM_{centroid}) but got mixed results. Polarity clashes (CLASH) show good performance. Particles (PRT) are the second best feature while ANY is the best feature. Normalization and polarity restriction are effective.

We try to further improve the best ranking

Classifier	Acc	Prec	Rec	F1
Baseline _{majority}	84.8	42.4	50.0	45.9
kNN _{noAntiShifter}	67.6*	54.9	56.4	55.6*
kNN	71.5*	58.3	59.6	58.9*
LP _{noAntiShifter}	79.1*	63.0	56.6	59.6*
LP	80.7*	68.6	56.7	62.0*
SVM _{task-spec. features (§3)}	79.9*	65.5	69.7	67.5*
SVM _{generic features (§4)}	89.0*	79.6	74.4	76.9*
SVM _{all features}	89.7*	80.7	77.6	79.1*

*: better than previous feature (paired t-test with $p < 0.05$)

(i.e. ANY_{norm+polar}) by applying **personalized PageRank** (Haveliwala, 2002; Agirre and Soroa, 2009). In traditional *PageRank* a ranking of nodes in a graph is produced where the highest ranked nodes are the ones most highly connected. In *personalized PageRank* prior information is added. A biased graph is constructed in which attention is drawn towards particular regions of interest (i.e. sets of nodes). This is achieved by assigning specific re-entrance weights to the individual nodes.⁷ In our case, we build a word-similarity graph where our verbs are nodes and edges encode similarities between them. The similarities are computed in the same fashion as our distributional similarity features (SIM) (§3). As prior information, we set the nodes representing the verbs returned by ANY_{norm+polar} with a uniform re-entrance weight probability while all other nodes receive a weight of 0. We consider a standard setting of $\alpha = 0.1$ (Manning et al., 2008, ch. 21.2). The resulting ranking indeed improves performance.

In Table 4 we analyze our anti-shifter feature (§3.2). As baseline we again consider all verbs ranked by frequency (FREQ). Complementary to NEGATIVE and –EFFECT from Table 3, we consider positive polar expressions (POSITIVE) and +effects (+EFFECT). Our anti-shifter feature (ANTI) clearly outperforms the other approaches.

5.2 Classifier Evaluation

In preparation to our bootstrapping task, we perform a recall-oriented evaluation to consider the classification of *all* verbs from our gold standard as opposed to the n-best rankings used in §5.1. We consider two types of classifiers (as well as a simple majority-class baseline): **graph-based classifiers** and **supervised classifiers**. As graph-based

⁷A non-uniform distribution causes some preferred nodes of interest to be visited more often during the random walk.

Conf. Rank	1-250	251-500	501-750	751-1043 [†]
Precision	92.8	73.2	62.4	33.2

[†]: final interval covers all remaining predicted *shifters*

Table 6: Classification of WordNet verbs that were *not* part of gold standard (§2); verbs are ranked by confidence-score of classifier and evaluated at intervals by precision of *shifter* label.

classifiers, we use one based on label propagation (LP), as well as a k-nearest neighbor classifier (kNN). **LP and kNN do not employ any manually labeled training data.** We use seeds produced by our best task-specific features (§3.1 and §3.2). Then labels are propagated with the help of a word-similarity graph. We use the graph we already employed for our PageRank experiments in §5.1. As shifter seeds we use the top 250 items from ANY_{norm+polar+pageR}. We use twice as many seeds for anti-shifters⁸ (using ANTI from §3.2) to reflect the general bias towards non-shifter verbs (Table 1). In order to examine whether anti-shifters are actually necessary to get negative seeds of sufficient quality, we also run an alternative setting (*noAntiShifter*) in which the same number of negative seeds is simply extracted from the ranking of frequent verbs. The reasoning behind this is that the proportion of frequent verbs not being shifters is already fairly high, as shown by *FREQ* in Table 4. For LP, we considered the Adsorption label propagation algorithm as implemented in *junto* (Talukdar et al., 2008). For kNN, we set $k = 10$.

Apart from the graph-based classifiers, we also consider a **supervised classifier**, namely Support Vector Machines (SVM) as implemented in SVM^{light} (Joachims, 1999). This classifier uses manually labeled training data, but, unlike LP and kNN, we may combine arbitrary feature sets. We perform 10-fold cross validation and report on accuracy and macro-average precision, recall and F-score. For the task-specific features (§3) we use their most complex configurations from Table 3 (e.g. SIM_{centroid} rather than SIM_{nor} or SIM_{without}).

Table 5 shows that among the graph-based classifiers, LP is notably better than kNN. Both classifiers benefit from anti-shifter seeds. Supervised classification outperforms graph-based classification, so using labeled training data is beneficial.

⁸This value is a first estimate and could be improved by fine tuning on a development set.

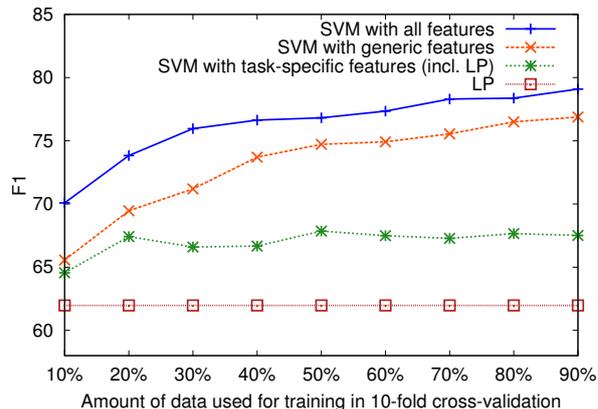

Figure 1: Learning curve on gold standard.

It also means that the *full* set of task-specific shifter features (§3.1) is more effective than just the strongest feature (which is used as seeds for graph-based classification). While the generic features outperform the task-specific features (in supervised classification), combining them results in another significant improvement, demonstrating the importance of the task-specific features.

Figure 1 displays the learning curve of the major feature sets using SVM. While the task-specific features on their own are always worse than the generic features, a classifier combining those feature groups always outperforms the classifier solely trained on the generic features. This improvement is particularly large when few labeled training data are available, which is a typical setting for lexicon bootstrapping tasks. Figure 1 also shows that the SVM classifier has reached roughly the point of saturation when using all features and the maximal amount of labeled training data. This amount should be sufficient for bootstrapping our gold standard lexicon on further unlabeled verbs (as will be shown in §5.3).

5.3 Bootstrapping the Lexicon

We now bootstrap a larger list of shifters from the remaining unlabeled 8581 WordNet verbs not included in our gold standard (§2). On this verb set we run an SVM trained on the gold standard (2000 verbs) with the best performing feature set (Table 5). The classifier predicts 1043 verbs as shifters. The remaining 7538 instances predicted as non-shifters will not be considered further. As our classifier reached a precision of 93.1% on non-shifters on our gold standard data, we are confident that the predicted non-shifters include few actual shifters. As our precision for shifters is lower, i.e.

Information	Example	Label
Sentence	Norah Jones' smooth voice could soothe any savage beast.	
Verb	soothe	
Polar Noun	beast	negative
Verb Phrase	soothe any savage beast	positive

Table 7: Annotation example for the contextual sentiment analysis task. The polarities of the polar noun and the verb phrase are annotated based on context given by the sentence.

68.3%, we manually check the predicted shifter instances. Using our classifier to pre-filter the data (Choi and Wiebe, 2014) reduced the amount to be annotated by 87.8% from 8581 to just 1043 instances. This is an enormous reduction in annotation effort. Table 6 shows the precision on different intervals ranked by confidence score of the SVM on the predicted 1043 shifters. Since the top 250 instances reach a very high precision, with hindsight, a manual annotation of at least these instances would not even have been necessary either.

Among the 1043 predicted shifters, manual annotation confirmed 676 actual shifters. In total we produced a novel list of 980 shifters (304 gold standard + 676 bootstrapping) in this paper (*all included in our public dataset (see footnote 2)*).

5.4 Impact on Sentiment Analysis

We now investigate whether knowledge of verbal shifters can be useful for the identification of contextual **phrase-level sentiment**. Apart from being an intermediate step in compositional sentence-level classification, phrase-level classification is also independently needed for applications such as knowledge base population (Mitchell, 2013), question answering (Dang, 2009) and summarization (Stoyanov and Cardie, 2011). For that reason and because we specifically study compositionality between verbs and their object, we exclusively consider polarity classification for verb phrases.

The experiment is treated as a binary classification task, where the polarity of a noun has either shifted in the context of a verb phrase (VP) or not. For example in (15), the VP *lack her usual passion* contains the positive polarity noun *passion* which is shifted by *lack*.

(15) The book seemed to [lack_v [her usual passion_n⁺]_{NP}]_{VP}⁻.

We compiled sentences from our text corpus (*Amazon Product Review Data*, §2) that contain

Shifting Label	Noun Polarity \Rightarrow VP Polarity		
shifted	+ \Rightarrow -	- \Rightarrow +	\sim \Rightarrow +
	+ \Rightarrow \sim	- \Rightarrow \sim	\sim \Rightarrow -
not shifted	+ \Rightarrow +	- \Rightarrow -	\sim \Rightarrow \sim

Table 8: How the shifting label is derived from the polarities of the polar noun and the verb phrase (positive (+); negative (-); neutral (\sim)).

	Classifier	Acc	Prec	Rec	F1
Baseline	Majority	79.9	39.9	50.0	44.4
	RNTN	59.0	50.8	51.2	51.0
Proposed	LEX _{LP}	84.3	77.7	67.4	72.2
	LEX _{SVM}	87.1	80.0	79.4	79.7
	LEX _{gold}	90.8	88.9	81.2	84.8

Table 9: Evaluation of polarity classification.

a VP headed by a verb that has a polar noun⁹ as a dependent. We annotated 400 randomly sampled sentences in which the verb is a verbal shifter. We then annotated 2231 sentences with non-shifters to match the ratio of shifters and non-shifters in the gold standard (Table 1) (*see footnote 2*).

To cover a variety of different verbs, rather than just the most frequent ones, each verbal shifter occurs only once. For each sentence, an annotator labeled the polarity of the polar noun and the polarity of the VP as either *positive*, *negative* or *neutral*. The annotator was also given the full sentence to establish context and the verb that is the head of the VP to avoid misunderstandings. Table 7 shows an example of the information provided, as well as the annotator’s decision to label *beast* as negative and *soothe any savage beast* as positive.

Depending on whether the VP and its dependent noun have the same polarity or not, the polarity is considered to have *shifted* or *not shifted*, as detailed in Table 8. These are the class labels onto which the output of the systems (and the annotation) will be mapped. The quantitative evaluation happens on these labels. There is currently no consensus as to how shifting is to be modeled in terms of resulting polarities. For example, the shifting of *excellent* in (16) could either be interpreted as the resulting phrase *wasn’t excellent* carrying negative or neutral polarity. The first interpretation simply flips the polarity (Choi and Cardie, 2008), while the second interpretation is driven by the fact that the negation of *excellent* is not synonymous with its antonym *atrocious* (Taboada et al., 2011; Kiritchenko and Mohammad, 2016). The polar in-

⁹Noun polarity is provided by the *Subjectivity Lexicon*.

tensity of *wasn't excellent* is certainly weaker than that of *atrocious* but it is a matter of interpretation whether to classify it as negative or neutral. To accommodate both legitimate interpretations, we count either of these behaviors as shifting (Table 8). We do this since our evaluation is concerned with whether shifting occurs, not with the exact polarities (or polar intensities) involved. Our own approach does not profit from this, as it is based on the knowledge of shifters, not polarities.

(16) Let's say, the movie [wasn't [excellent]⁺]^{-/~}.

As baselines, we consider a majority class classifier (**Majority**) and the Recursive Neural Tensor Network tagger (**RNTN**) by Socher et al. (2013), which is considered the state-of-the-art for handling negation on the phrase level. RNTN is a compositional sentence-level polarity classifier providing polarity values for each tree node in the constituency parse of a sentence. This output allows us to extract polarity predictions for VPs and polar nouns in our data. Apart from achieving best performance on polarity classification datasets, a major highlight of RNTN is its capability of learning shifting directly from labeled training data without explicit knowledge of shifters and shifting rules. However, RNTN depends on manually labeled training data, i.e. sentences in which each node of the parse tree is labeled with polarity information. Such fine-grained manual annotation is currently only provided by the *Stanford Sentiment Treebank (SST)* (Socher et al., 2013). Resources like SST are not suitable for either training or testing a polarity classifier with respect to verbal shifters, since they do not contain each shifter with sufficient frequency. For example, SST contains instances for 16.9% of our verbal shifters, with less than half of these occurring more than once. We expect that RNTN, which has been trained on SST, may only be able to model shifting caused by frequently occurring negation words, but, unlike our own approach, will fail to account for shifting involving any but the most frequent verbal shifters.

Our own approach (**LEX**) is based on inferring the polarity of each VP from the polarity of the noun and whether the verb is a shifter. A VP with a shifter has a polarity moving to the opposite of the noun, a VP without shifter has the same polarity. We evaluate the shifter lexicons generated by our best graph-based classifier (**LEX_{LP}**) and best supervised classifier (**LEX_{SVM}**) from §5.2. Our

human annotated list of 980 shifters (§5.3) establishes an upper bound (**LEX_{gold}**).

Results in Table 9 show that all lexicons exceed the baselines. Even automatically induced shifter lexicons clearly outperform the prediction of existing sentiment analysis systems. Errors in **LEX_{gold}** are mostly due to verbs that exhibit shifter behavior in some of their word senses, but not the one present in the phrase. In (17) *bring down* means *remove* and causes shifting, but in (18) its meaning of *inflict* does not cause shifting. The high scores produced by **LEX_{gold}** also suggest that working on the lemma level instead of the sense level only means a moderate loss in performance.

(17) The revolution [[brought down]_v the tyrant]_N⁺.

(18) She [[brought down]_v a curse]_N⁻ on the village.

6 Related Work

Negation modeling is a central research issue in sentiment analysis, but only few works consider more than typical negation words. We refer the reader to the survey of Wiegand et al. (2010) for more information on negation modeling.

Approaches to learning negation from labeled corpora have been examined in the review domain (Ikeda et al., 2008; Kessler and Schütze, 2012; Socher et al., 2013; Yu et al., 2016), the biomedical domain (Huang and Lowe, 2007; Morante and Daelemans, 2009; Zou et al., 2013) and across domains (Fancellu et al., 2016). However, as outlined in §1, due to their small size the labeled datasets include few different verbal shifters. Moreover, these works mostly focus on scope detection rather than the identification of shifters.

The work most closely related to ours is Danescu-Niculescu-Mizil et al. (2009) who propose using NPIs for shifter extraction.¹⁰ However, our work substantially extends that previous work. We show how the usage of NPIs can be further refined to improve the recognition of shifters (i.e. require the direct object to be a polar noun and subsequently apply PageRank). Moreover, we successfully combine this information with other features. Unlike Danescu-Niculescu-Mizil et al. (2009), we also carry out a recall-oriented evaluation and examine the impact of explicit knowledge of verbal shifters on contextual sentiment analysis.

¹⁰Shifters are referred to as *downward entailing operators*.

7 Conclusion

We took a major step toward producing a comprehensive lexicon of polarity shifters by bootstrapping a large list of verbal polarity shifters. Using a sample of 2000 manually annotated verbs extracted from WordNet, we built a supervised classifier to classify the remaining WordNet verbs. This reduced the number of verbs to be annotated manually by a large amount. We examined a variety of linguistic features and found that in addition to features derived from WordNet and FrameNet, the co-occurrence of the negative polarity item *any* with verbal shifters is particularly effective. We also showed that automatically learned knowledge of shifters improves the prediction of phrase-level sentiment.

Our approach should be largely transferable to other languages. This also applies to the features based on particular constructions such as the NPI *any*. The German NPI *jediglich*, Catalan *cap*, Japanese *dono mo* etc. can be expected to exhibit a very similar behavior (cf. [Haspelmath \(1997\)](#)).

Our goal is to build a complete lexicon of polarity shifters; to this end, future work will aim to add nouns and adjectives to our shifter lexicon.

Acknowledgements

The authors would like to thank Stephanie Köser for annotating the verb lexicon presented in this paper. For proofreading the paper, the authors would also like to thank Anna Schmidt, Meaghan Fowlie, Annemarie Friedrich, Andrea Fischer, David M. Howcroft, Clayton Greenberg, Ines Rehbein and Katja Markert. The authors were partially supported by the German Research Foundation (DFG) under grants RU 1873/2-1 and WI 4204/2-1.

Abstract

Document-level sentiment classification aims to assign the user reviews a sentiment polarity. Previous methods either just utilized the document content without consideration of user and product information, or did not comprehensively consider what roles the three kinds of information play in text modeling. In this paper, to reasonably use all the information, we present the idea that user, product and their combination can all influence the generation of attention to words and sentences, when judging the sentiment of a document. With this idea, we propose a cascading multiway attention (CMA) model, where multiple ways of using user and product information are cascaded to influence the generation of attention on the word and sentence layers. Then, sentences and documents are well modeled by multiple representation vectors, which provide rich information for sentiment classification. Experiments on IMDB and Yelp datasets demonstrate the effectiveness of our model.

1 Introduction

Document-level sentiment classification aims to predict an overall sentiment polarity (e.g., 1-5 stars or 1-10 stars) for a user review document. This task recently draws increasing research concerns and is helpful to many downstream applications, such as user and product recommendation.

Early work focuses on traditional machine learning associated with handcraft text features for sentiment classification (Pang et al., 2002; Ding et al., 2008; Taboada et al., 2011). With the development of deep learning techniques, some researchers design neural networks to automati-

cally learn features from document content and achieve comparable performance (Glorot et al., 2011; Kalchbrenner et al., 2014; Yang et al., 2016), though they ignore the use of user and product information. Almost at the same time, deep learning techniques exhibit another advantage that product and user information can be flexibly modeled with document content for sentiment classification (Tang et al., 2015a; Chen et al., 2016). Tang et al. (2015a) design user and product preference matrices to tune word representations, based on which convolutional neural networks (CNNs) are used to model the whole document. To avoid the high-cost preference matrix, Chen et al. (2016) develop the two-layer (i.e., word and sentence layers) model, where the combination of user and product information is used to generate attention to words and sentences respectively on each layer.

Though previous studies achieve improvements in synthesizing text, user and product for sentiment classification, they are somewhat limited to either of the following two aspects. First, when considering user and product information, previous work mostly models their combination which may cause adverse effects on sentiment classification. As we can see, user and product information also have their own influence on sentence and document representations. For example, a lenient user tends to focus on the good aspects, while a picky user is always concerned about unsatisfactory clues, no matter which product is reviewed. In another view, different products have their own concerns. For example, a car is closely related with fuel consumption while a hotel with bed or food, which are relatively independent of users. Second, in previous hierarchical modeling method, different layers are usually treated with similar means. In our opinion, different linguistic units (e.g., words and sentences) should be given

different treatment to achieve good performance. As we can see, words are closely related with each other and sentences are relatively independent in reflecting their sentimental polarity. Take a restaurant review for example, the review *“Its dinner environment is good. But the pizza is not worth the money!”* is comprised of two sentences. For this review, a user who values environment may mark 5 stars, while a user who thinks highly of food may mark 1 star. Thus, we can not simply combine the two sentences together in judging its sentiment polarity. It is better to model each sentence independently before knowing the users’ or products’ attention.

To address the two issues above, we propose to comprehensively make use of the information of user, product, and their combination to generate attention on the word and sentence layers, and further cascade the multiple ways of attention on the generation of sentence and document representations. Here, we name our proposed model the cascading multiway attention (CMA) model. Specifically, each sentence is first represented with multiple representation vectors through using different ways of attention to focus on the important part. Next, the similar multiple ways of generating attention are applied on the sentence level and used to tune the generation of document representations. In such a case, document representation is not simply treated as a sequence of sentences, but considers more about the influence of user and product information. Finally, we can get a well modeled document representation for sentiment classification. Experiments on three real-world datasets demonstrate that CMA achieves state-of-the-art performance and fully considers the contributions from user and product information.

2 Cascading Multiway Attention Model for Sentiment Classification

In this section, we first give an overview of the cascading multiway attention (CMA) model for sentiment classification. Then, we focus on introducing how to design multiway attention for modeling sentences and documents through using user and product information. Next, we show the training details of CMA.

2.1 Model Overview

Figure 1(a) shows the overall architecture of our CMA model, which is mainly composed of four

levels including word level, sentence level, document level, classification level. With word embeddings as input, we can employ convolutional neural networks or recurrent neural networks to obtain deeper semantic of words on the word level. On the sentence level, we design the multiway attention networks to generate attention to words from three different views and get three representation vectors to represent a sentence. On the document level, we keep generating multiple kinds of attention to sentences and get the document representation, which is fed into a softmax function for classification.

Specifically, let us first formalize the notation. We suppose that a document contains m sentences $\{S_1, S_2, \dots, S_m\}$ whose lengths are set n_1, n_2, \dots, n_m respectively. For Sentence $S_t (1 \leq t \leq m)$, it is composed of a sequence of words $w_t^1, w_t^2, \dots, w_t^{n_t}$ where w_t^j denotes a specific word. To represent a word, we embed each word into a low dimensional real-value vector, called word embedding (Bengio et al., 2003).

Then, we can get $w_t^j \in R^d$ from $M^{v \times d}$, where t is the sentence index in a document, j denotes the word index in sentence t , d means the embedding dimension and v gives the vocabulary size. Word embeddings can be regarded as parameters of neural networks or pre-trained from proper corpus via language model (Collobert and Weston, 2008; Mnih and Hinton, 2007; Mikolov et al., 2010; Huang et al., 2012). In our model, we choose the second strategy.

Next, deeper word semantics representations can be learned by using the neural network models, such as convolutional neural networks (CNN) or recurrent neural networks (RNN). In this paper, the LSTM model is employed to obtain the word representation, since it has the good performance of learning the long-term dependencies and can well model the dependence between words. Formally, for sentence S_t , we input its word embeddings $w_t^1, w_t^2, \dots, w_t^{n_t}$ to the LSTM networks and get the final word representations $r_t^1, r_t^2, \dots, r_t^{n_t}$.

With deeper word representations as input, we adopt the attention mechanism to model sentences. As Section 1 stated, we consider the influence from three views: user (δ^u), product (δ^p), and combination of user and product (δ^{up}), which can generate three kinds of attention to words. Then, we impose the three attention vectors on word representations respectively and get three represen-

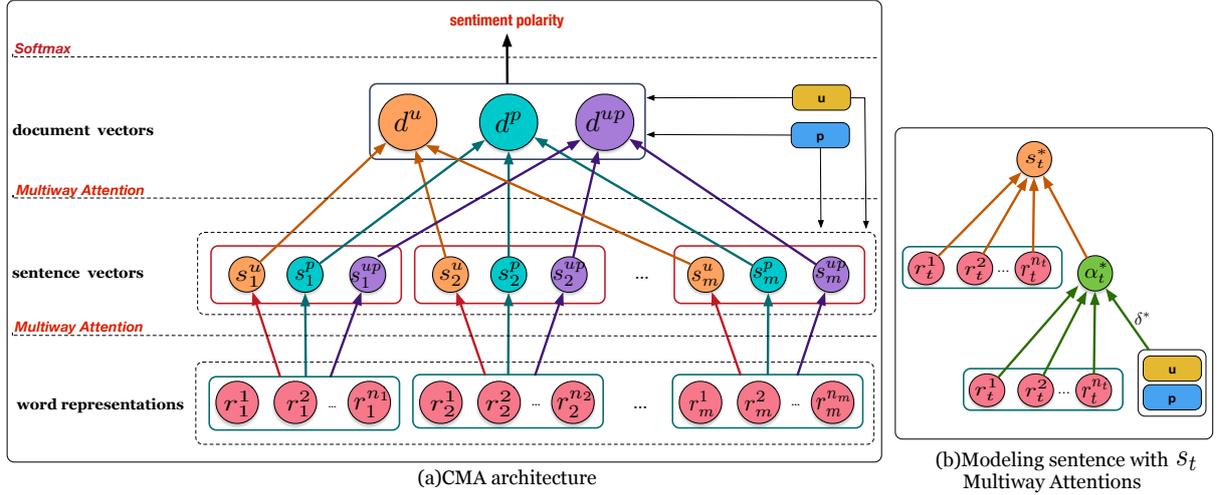

Figure 1: Overall Architecture of CMA.

tation vectors for each sentence. Formally, sentence S_t is represented by the concatenation of three vectors s_t^u, s_t^p, s_t^{up} . On the document level, we still use δ^u, δ^p and δ^{up} respectively to generate attention to sentences and get three vectors $\mathbf{d}^u, \mathbf{d}^p, \mathbf{d}^{up}$ for representing the document. The concrete design is introduced in the next subsection.

Finally, the three vectors $\mathbf{d}^u, \mathbf{d}^p, \mathbf{d}^{up}$ are concatenated to a vector \mathbf{d} for a classifier. Here, we use a non-linear layer to project \mathbf{d} into the space of the targeted C classes. That is,

$$x = \tanh(W_l \cdot \mathbf{d} + b_l) \quad (1)$$

where W_l and b_l are the weight matrix and bias respectively. The probability of labeling document with sentiment polarity $i (i \in [1, C])$ is computed by:

$$y_i = \frac{\exp(x_i)}{\sum_{i=1}^C \exp(x_i)} \quad (2)$$

The label with highest probability is set as the final result.

2.2 Cascading Multiway Attention

Now, we detail how to model user and product information and cascade their influence on representing sentences and documents.

As stated in Section 1, the meaning of a sentence has different interpretations from different views including user, product and their combination, under which words may be paid different attention on. With consideration of each view, only some specific parts are focused on. And different views have their own focuses which contribute

to sentiment classification. Thus, we propose the multiway attention mechanism to capture sentence focuses with respect to different views.

Specifically, in our model, we represent each user and each product with a representation vector which is learned from the model, notated with \mathbf{u} and \mathbf{p} here. To consider the influence from user and product, we formalize user view, product view and their combination view respectively as:

$$\delta^u = W_u \cdot \mathbf{u} \quad (3)$$

$$\delta^p = W_p \cdot \mathbf{p} \quad (4)$$

$$\delta^{up} = W_{u'} \cdot \mathbf{u} + W_{p'} \cdot \mathbf{p} \quad (5)$$

where $W_u, W_p, W_{u'},$ and $W_{p'}$ are weight matrices for tuning the influence of \mathbf{u} and \mathbf{p} .

We take sentence S_t for example to describe the sentence modeling process, as shown in Figure 1(b). With word representations $r_t^1, r_t^2, \dots, r_t^{nt}$, we can generate three attention vectors using δ^u, δ^p and δ^{up} respectively. For convenience we use δ^* to denote δ^u, δ^p or δ^{up} . Then, the attention mechanism generates the attention vector α_t^* with respect to δ^* . The j^{th} dimension $[\alpha_t^*]^j$ denotes the attention weight of the j^{th} word r_t^j .

$$[\alpha_t^*]^j = \frac{\exp(\gamma(r_t^j, \delta^*))}{\sum_{j=1}^{nt} \exp(\gamma(r_t^j, \delta^*))} \quad (6)$$

where γ is a score function that measures the importance of r_t^j in the sentence. The score function γ is defined as:

$$\gamma(r_t^j, \delta^*) = \tanh(W_H \cdot r_t^j + \delta^* + b_s) \cdot v^T \quad (7)$$

where W_H and b_s are weight matrix and bias respectively, and v^T is the transpose of the weight vector v .

After computing the word attention weights, we can get sentence representations \mathbf{s}_t^* using different attention weights:

$$\mathbf{s}_t^* = \sum_{j=1}^{n_t} [\alpha_t^*]^j r_t^j. \quad (8)$$

Then, we get a multi-vector sentence representation: $[\mathbf{s}_t^u, \mathbf{s}_t^p, \mathbf{s}_t^{up}]$ for sentence S_t from three views.

On the sentence level, we apply the similar multiway attention strategy to get the document representation. Unlike the word level, each sentence is relatively independent of other sentences and takes its own part in determining the document sentiment. Thus, we ignore modeling the dependence between sentences and directly use the sentence representations derived from the word level. As we see, from different views each sentence plays a different role, and from a specific view all the sentences should be paid different attention, in document-level sentiment classification. Here, we still consider the influence from user, product and their combination, and get the corresponding document representation $\mathbf{d}^u, \mathbf{d}^p, \mathbf{d}^{up}$, where \mathbf{d}^* ($* \in \{u, p, up\}$) is computed as follows:

$$\mathbf{d}^* = \sum_{t=1}^m \beta_t^* \mathbf{s}_t^* \quad (9)$$

$$\beta_t^* = \frac{\exp(\gamma(\mathbf{s}_t^*, \delta^*))}{\sum_{t=1}^m \exp(\gamma(\mathbf{s}_t^*, \delta^*))} \quad (10)$$

where \mathbf{s}_t^* is the sentence representation of sentence S_t with respect to δ^* . β_t^* denotes the corresponding attention weight of S_t on the view of δ^* , and the γ function is the same as in Eq. (7).

2.3 Model Training

In CMA, we need to optimize all the parameters notated as Θ which are from all the user and product embedding vectors, LSTM networks, two multiway attention layers and the softmax layer.

We use cross entropy with L_2 regularization as the loss function, which is defined as:

$$J = - \sum_{i=1}^C g_i \log(y_i) + \lambda_r \left(\sum_{\theta \in \Theta} \theta^2 \right) \quad (11)$$

where $g_i \in R^C$ denotes the ground truth, represented by one-hot vector. $y_i \in R^C$ is the estimated

probability for each class, computed as in Eq. (2). λ_r is the coefficient for L_2 regularization.

After learning Θ , we test the instances by feeding their text with user and product information into CMA, and the label with the highest probability stands for the predicted sentiment polarity.

3 Experiments

In this section, we first introduce the datasets and metrics used in our experiments. Then, we show the hyperparameter setting of our model. Next, we present the results of our model and compare our model with other state-of-the-art methods. Finally, we use a case study to examine the experimental results of CMA.

Datasets

To validate the effectiveness of our model, we use three real-world datasets: IMDB, Yelp 2013 and Yelp 2014 collected by Tang et al. (2015b). For these data, we preprocess the text including using Stanford CoreNLP (Manning et al., 2014) to split the review documents into sentences and tokenizing all words. Table 1 shows the details of the three datasets including number of documents (#docs), average number of documents per user posts(#docs/user) etc. It is also noted that IMDB is rated with 10 sentiment labels (i.e., 1-10 stars) while Yelp has 5 labels (i.e., 1-5 stars). We also adopt the same data partition used in (Tang et al., 2015b) and (Chen et al., 2016) for training, developing and test.

Evaluation Metrics

To evaluate the performance of sentiment classification, we adopt the metrics of *Accuracy* and *RMSE*. *Accuracy* measures the overall performance. Given the number of correctly predicted samples T and the total number of samples N , *Accuracy* is defined as:

$$Acc = \frac{T}{N}. \quad (12)$$

RMSE evaluates the divergence between predicted labels and ground truth labels and is defined as:

$$RMSE = \sqrt{\frac{\sum_{k=1}^N (l_k - l'_k)^2}{N}} \quad (13)$$

where l_k and l'_k denote the ground truth and predicted label of sample k respectively. Generally, a good system has a high accuracy and a low RMSE.

Dataset	#docs	#users	#products	#docs/user	#docs/product	#sents/doc	#words/doc	#labels
IMDB	84919	1310	1635	64.82	51.94	16.08	24.54	10
Yelp2013	78966	1631	1633	48.42	48.36	10.89	17.38	5
Yelp2014	231163	4818	4194	47.97	55.11	11.41	17.26	5

Table 1: Data Statistics of IMDB, Yelp2013 and Yelp 2014.

Hyperparameter Setting

Following (Chen et al., 2016) and (Tang et al., 2015b), we set the dimensions of word, user and product embeddings as 200 in our experiments. We train the word embeddings through using the training and developing sets of each dataset with word2vec tool (Mikolov et al., 2013). The user and product embeddings are initialized randomly. All the weight matrices are initialized by uniform distribution, and all biases are assigned as zero. We also set the dimensions of the LSTM hidden states and attention vectors as 200.

To train our model, we utilize AdaDelta (Zeiler, 2012), which adopts a self-adaptive learning rate, to optimize the parameters. The coefficient of penalty in the objective function is set to 10^{-5} .

3.1 Method Comparison

To comprehensively evaluate the performance of CMA, we list some baseline methods for comparison. The baselines are introduced as follows.

- **Majority** assigns the largest sentiment polarity occurred in the training set to each sample in the test set.
- **Trigram** uses the unigrams, bigrams and trigrams features to train a SVM classifier for sentiment classification.
- **TextFeature** extracts word/character ngrams, sentiment lexicon features, negation features, etc. for a SVM classifier.
- **UPF** extracts user-leniencey features and product features from training data (Gao et al., 2013). These features can be concatenated with the features of *Trigram* and *TextFeature*.
- **AvgWordvec** averages the word embeddings in a document to generate the document representation as features for a SVM classifier.
- **SSWE** first learns the sentiment-specific word embeddings and then utilizes three kinds of pooling (i.e., max, min and average) to generate the document representation for a SVM classifier (Tang et al., 2014).
- **PV**(Paragraph Vector) is an unsupervised framework to learn distributed representations for text of any length (Le and Mikolov, 2014). (Tang

et al., 2015a) implements the distributed memory model of paragraph vectors (PV-DM) to get document representations for sentiment classification.

- **RNTN+RNN** models sentences using recursive neural tensor networks (RNTN) (Socher et al., 2013). Then sentence representations are fed into the recurrent neural networks (RNN) and their hidden states are averaged to get the document representation.

- **UPNN** designs preference matrices for each user and product to modify word representations (Tang et al., 2015b). Word representations are then fed into the convolution neural networks (CNNs) and concatenated with the user/product representation to generate document representation before a softmax layer. Without considering user and product information, the *UPNN(noUP)* method just uses CNN to model the documents.

- **NSC+UPA** proposes the hierarchical neural networks which are composed of two LSTM models to generate word and sentence representations (Chen et al., 2016). The combination of user and product information is used to generate attention to words and sentences on the sentence and document levels. The document representation is fed into a softmax layer. The *NSC* model is similar to *NSC+UPA*, but ignores user and product information and directly applies two layers of LSTM and attention mechanism to model sentences and documents using only document content.

When comparing with our model, we directly use the results of the above baselines reported in (Chen et al., 2016), as we conduct the experiments on the same datasets.

- **CA-null** is a simplified version of our CMA model without consideration of user and product information. We use one LSTM with attention to model sentences. Based on the sentence representations, we directly use the attention mechanism to model documents for sentiment classification.

The performance comparison of CMA and all baselines are shown in Table 2. All the baseline methods are divided into two categories: the first category only uses document content and the second comprehensive considers document, user and

Model	IMDB		Yelp 2013		Yelp 2014	
	Acc.	RMSE	Acc.	RMSE	Acc.	RMSE
Majority	0.196	2.495	0.411	1.060	0.392	1.907
Trigram	0.399	1.783	0.569	0.841	0.577	0.804
TextFeature	0.402	1.793	0.556	0.814	0.572	0.800

SSWE	0.312	1.973	0.549	0.849	0.557	0.851
PV	0.341	1.814	0.554	0.832	0.564	0.802
RNTN+RNN	0.400	1.764	0.574	0.804	0.582	0.821
UPNN(noUP)	0.405	1.629	0.577	0.812	0.585	0.808
NSC+LA	0.487	1.381	0.631	0.706	0.630	0.715
CA-null	0.491	1.408	0.635	0.689	0.640	0.690
Trigram+UPF	0.404	1.764	0.570	0.803	0.579	0.789
TextFeature+UPF	0.402	1.774	0.561	0.822	0.579	0.791
UPNN	0.435	1.602	0.596	0.748	0.608	0.764
NSC+UPA	0.533	1.281	0.650	0.692	0.667	0.654
CMA	0.540	1.191	0.664	0.677	0.676	0.637

Table 2: Methods Comparison on IMDB, Yelp 2013 and Yelp 2014 Datasets.

product information.

In the first category of methods, the *Majority* method is the worst, meaning the majority sentiment polarity occupies 19.2%, 42.1% and 39.2% of all samples. All the other methods are better than the *Majority* method, showing that manual or automatic features can both bring performance improvement for sentiment classification. Though techniques of deep neural networks are widely used and have made a success in document modeling, its simple application (e.g., *AveWordvec*, *PV*) does not achieve better results than using manually selected features (e.g., *Trigram*, *TextFeature*) with respect to the accuracy metric. As for the three kinds of carefully designed neural networks, the *CA-null* and *NSC+LA* methods exhibit obvious advantages with high accuracy and low RMSR, compared to the *RNTN+RNN* and *UPNN(noUP)* methods. The main reason may be that *CA-null* and *NSC+LA* can learn the long-distance dependencies with LSTM networks and make full use of the important words and sentences with attention. We can also see that *CA-null* outperforms *NSC+LA* regarding the accuracy on the three datasets. This verifies that we may not consider sentence dependence when modeling documents for sentiment classification, as the main difference between *CA-null* and *NSC+LA* is that *CA-null* does not apply LSTM to model sentences.

From Table 2, we observe that user and product information can promote the performance of sentiment classification. Even the worst method (*TextFeature+UPF*) in the second cate-

Model	IMDB		Yelp 2013		Yelp 2014	
	Acc.	RMSE	Acc.	RMSE	Acc.	RMSE
CA-null	0.491	1.408	0.635	0.689	0.640	0.690
CA- δ^u	0.513	1.397	0.641	0.688	0.653	0.687
CA- δ^p	0.508	1.423	0.640	0.694	0.652	0.685
CA- δ^{up}	0.520	1.281	0.645	0.684	0.658	0.670
MA-max	0.528	1.314	0.654	0.680	0.663	0.667
MA-avg	0.521	1.341	0.651	0.678	0.662	0.672
CMA	0.540	1.191	0.664	0.677	0.676	0.637

Table 3: Analysis of Cascading and Multiway Attention.

gory is comparable to the state-of-the-art system (*RNTN+RNN*) in the first category. For the methods with manually designed features, their performance improvement is smaller than those methods with deep learning methods. Both *Trigram-UPF* and *TextFeature-UPF* concatenate more user and product features, but have little improvement compared with *Trigram* and *TextFeature*. The reason may be that the text features are huge (1M trigram) enough and the newly added user and product features can not work well. Adding user and product information, *CMA* outperforms *CA-null* by about 5 percent with respect to the accuracy metric on IMDB dataset. At the same time, *CMA* performs stably better than *NSC+UPA* with higher accuracy and lower RMSE on three datasets, with cascading multiway attention on word and sentence levels and keeping independency between the sentences. This validates that only a combination of user and product information can not boost performance much and more ways of attention should be explored in text modeling. It is also noted that words need to be modeled with consideration of their dependence while sentences should be independently modeled.

3.2 Model Analysis

In this section, we design a series of models to verify the effectiveness of our model *CMA*. On one hand, we design three simplified models, i.e., *CA- δ^u* , *CA- δ^p* and *CA- δ^{up}* , which only consider one-way attention from user, product, combination of user and product respectively when modeling sentences and documents. On the other hand, we just keep the multiway attention on modeling sentences and directly adopt the maximization or average operation on sentence representations to model a document, which are named *MA-max* and *MA-avg* respectively. Table 3 shows the results of all the models.

From Table 3, we can see that *CA-null* gets the

worst result compared with other models utilizing user and product information, which indicates that both information is useful for document sentiment. The performance of $CA-\delta^u$ and $CA-\delta^p$ are worse than $CA-\delta^{up}$, this is because $CA-\delta^u$ and $CA-\delta^p$ just uses one kind of information (user or product), but $CA-\delta^{up}$ uses both information. *CMA* achieves a much better result than the ‘CA’ models, which can verify the effectiveness of introducing multiway attention. We also observe that $CA-\delta^u$ is slightly better than $CA-\delta^p$, verifying user information plays a more important role than product information as in (Chen et al., 2016).

As for *MA-max* and *MA-avg*, multiway attention on modeling sentences bring much performance improvement compared to *CA-null*, though the cascading structure is not adopted. *MA-avg* seems to treat each sentence equally while *MA-max* tries to seek the most represented sentences contributing to sentiment classification. We can see that *MA-max* performs better than *MA-avg*, verifying that sentences should not be treated equally and multiway attention are a good mechanism for computing the contributions of each sentence to representing a document.

We can also see that *CMA* achieves the best performance among all the models, since *CMA* fully considers the word importance to a sentence and sentence importance to a document via sentence-level and document-level multiway attention. Next, we give an example to illustrate the cascading multiway attention captured by *CMA*.

Case Study

Here, we use a five-star review document from Yelp as a case study, and the document is “*Biscuits made from scratch, not frozen. Homemade pancakes with real buttermilk, not from a mix or box. Homemade blueberry jam, no jam or can. True dinner coffee. A group of friendly, engaging staff. Five stars... need I say more.*”. We apply *CMA* on the document and achieve the correct sentiment polarity. Figure 2 visualizes the multiway attention weights on the sentence and document levels computed by *CMA*. We represent three ways of attention, i.e., user (δ^u), product (δ^p), and combination of user and product (δ^{up}), with blue, red and green color series respectively. The deeper color means higher weight.

Figure 2(a)~(f) display the three ways of attention to words for sentence1 ~ sentence6 respectively. We can see that different words are as-

signed high weight values when using different ways of attention. For example, for sentence1, the word “biscuits” is paid more attention from the user view while “frozen” is focused on from the product view and “made” is emphasized considering the combination of user and product. At the same time, an interesting phenomenon is that all the three views pay little attention to some common words like “,” and function words “a” “of”. This conforms to our intuition: some function words and punctuation marks contribute little to sentiment classification, but different words are focused on from different views. Thus, multiple ways of using user and product information can well gather information which is helpful to representing a sentence.

Figure 2(g) shows the three ways of attention to sentences for the example document. We can see that the three ways are consistent with focusing on the sixth sentence, which gives high attention weights to the words “five” and “stars” reflecting the sentiment polarity. From the user view, high attention is also paid to sentence5, which includes the obvious sentiment word “friendly”. Hence, we infer that the user may like to express his/her sentiment to a product with sentiment word. From the product view, we can see that the document representation is also closely related to many other sentences such as sentence2 (w.r.t food) and sentence5 (w.r.t. staff), which can show different attributes of a product.

This case study shows that cascading two layers of multiway attention are necessary to modeling a document in the sentiment classification task.

4 Related work

Document-level sentiment classification methods can be divided into two kinds of research lines, i.e., traditional machine learning methods and neural networks methods.

For the first kind of research line, Pang et al. (2002) validate the effectiveness of various machine learning methods with bag-of-words features on sentiment classification. Goldberg and Zhu (2006) use a graph-based semi-supervised learning algorithm with unlabeled data to predict the sentiment of reviews. There are also some work which focus on extracting effective features. Ganu et al. (2009) identify user experience information from free text. Qu et al. (2010) introduce a kind of bag-of-opinion representation.

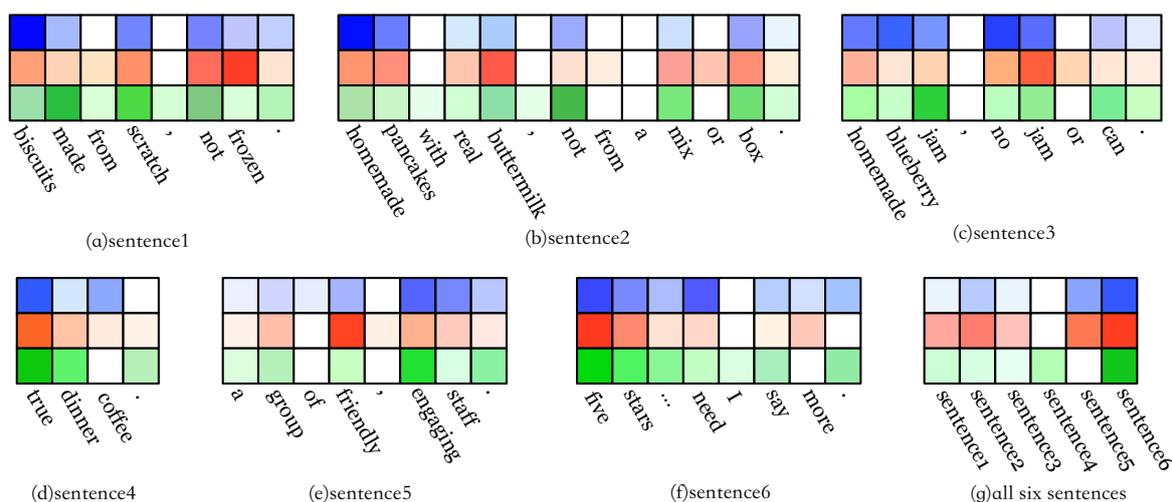

Figure 2: Case Study: Illustration of Attention Weights.

Kiritchenko et al. (2014) extract surface, semantic, and sentiment features from text. User information is also used in traditional methods. Tan et al. (2011) employ social relationships to improve user-level Twitter sentiment analysis. Gao et al. (2013) estimate the sentiment polarity by referring to the user leniency and product popularity computed during testing. Li et al. (2014) incorporate the user and product information into a topic model for sentiment analysis.

Recently, neural network approaches have achieved a comparable performance on document-level sentiment classification. Glorot et al. (2011) first propose a deep learning approach which learns to extract a meaningful representation for each review in an unsupervised fashion. Then, Socher et al. (2011, 2012, 2013) introduce recursive neural networks to document-level sentiment classification. Kim (2014) employ convolutional neural networks to model sentences with two kinds of embeddings for sentiment classification. Le and Mikolov (2014) introduce an unsupervised algorithm that learns fixed-length feature representations from variable-length pieces of texts. Tai et al. (2015) utilize tree-structured long-short memory networks to learn semantic representation for sentiment classification. In addition, user and product information are flexibly modeled for sentiment classification in the neural network methods (Tang et al., 2015b; Chen et al., 2016). Tang et al. (2015a) design preference matrices for each user and each product to tune word representations, based on which convolutional neural networks (CNNs) are used to model the whole doc-

ument. Chen et al. (2016) employ two layers of long-short term memory (LSTM) with attention to model sentences and documents.

5 Conclusion

In this paper, we propose the cascading multiway attention networks for document-level sentiment classification. The main idea of CMA is to use multiway attention rather than one-way attention to learn representations for sentences and documents, as user, product and their combination can provide different views for modeling text and weaken the dependencies between sentences for better depicting the influence from user preference for document sentiment. On the sentence level, CMA uses three ways of exploiting user and product information to generate attention to words and get sentence representations. On the document level, CMA keeps using the multiway attention mechanism to generate attention to sentences. Experimental results on IMDB, Yelp 2013 and Yelp 2014 verify that CMA can learn efficient representations for sentences and documents and provide rich information for judging the document-level sentiment polarity.

Abstract

Deep learning models have recently been applied successfully in natural language processing, especially sentiment analysis. Each deep learning model has a particular advantage, but it is difficult to combine these advantages into one model, especially in the area of sentiment analysis. In our approach, Convolutional Neural Network (CNN) and Long Short Term Memory (LSTM) were utilized to learn sentiment-specific features in a freezing scheme. This scenario provides a novel and efficient way for integrating advantages of deep learning models. In addition, we also grouped documents into clusters by their similarity and applied the prediction score of Naive Bayes SVM (NB-SVM) method to boost the classification accuracy of each group. The experiments show that our method achieves the state-of-the-art performance on two well-known datasets: IMDB large movie reviews for document level and Pang & Lee movie reviews for sentence level.

1 Introduction

The emergence of web 2.0, which allows users to generate content, is causing the rapid increase in the amount of data. This platform, which enables millions of users to share information and comments, has a high demand for extracting knowledge from user-generated content. An important information to be analyzed from those comments is opinions/sentiments, which express subjective opinions of particular users. Sentiment analysis is a fundamental task and has attracted a huge amount of research in recent years (Pang and Lee, 2008; Liu, 2012). The task calls for identifying the

sentiment polarity (positive, negative) of a comment or review.

Wang (2012) used a Support Vector Machine variant with Naive Bayes feature (NBSVM). Presenting a document or a sentence with Bag of bi-gram features, NBSVM consistently performs well across datasets of long and short reviews. Recently, the success of deep learning in natural language processing has led to many efficient methods for sentiment analysis such as Paragraph Vector (Le and Mikolov, 2014), CNN (Kalchbrenner et al., 2014; Kim, 2014; Zhang and Wallace, 2015), LSTM (Wang et al., 2015; Liu et al., 2015). In Paragraph Vector, Le and Mikolov employed the technique of Word embedding representation using neural networks (Bengio et al., 2003; Collobert and Weston, 2008; Mnih and Hinton, 2009; Turian et al., 2010; Mikolov et al., 2013) to represent a document or paragraph as a vector. This document modeling outperformed the Bag of Words model in sentiment analysis and information retrieval. Li (2015) has enhanced the architecture of Paragraph Vector by allowing the model to predict not only words but also n-gram features (DVngram). CNN is capable of capturing local relationships between neighbor words in a sentence but fails for long-distance dependencies. LSTM can handle CNN's limitation because it is able to memorize information for a long period of time. Our motivation is to build a combination approach taking the advantages of these methods.

In this paper, we separately designed CNN and LSTM models to encode sentiment information into feature vectors. To apply for sentiment classification, these sentiment-specific vectors and the semantic-specific DVngram vector were passed into the 3-layer neural network. In sentiment analysis, two sentences with a slight difference could provide opposite sentiments. Generative models, however, have a tendency to encode

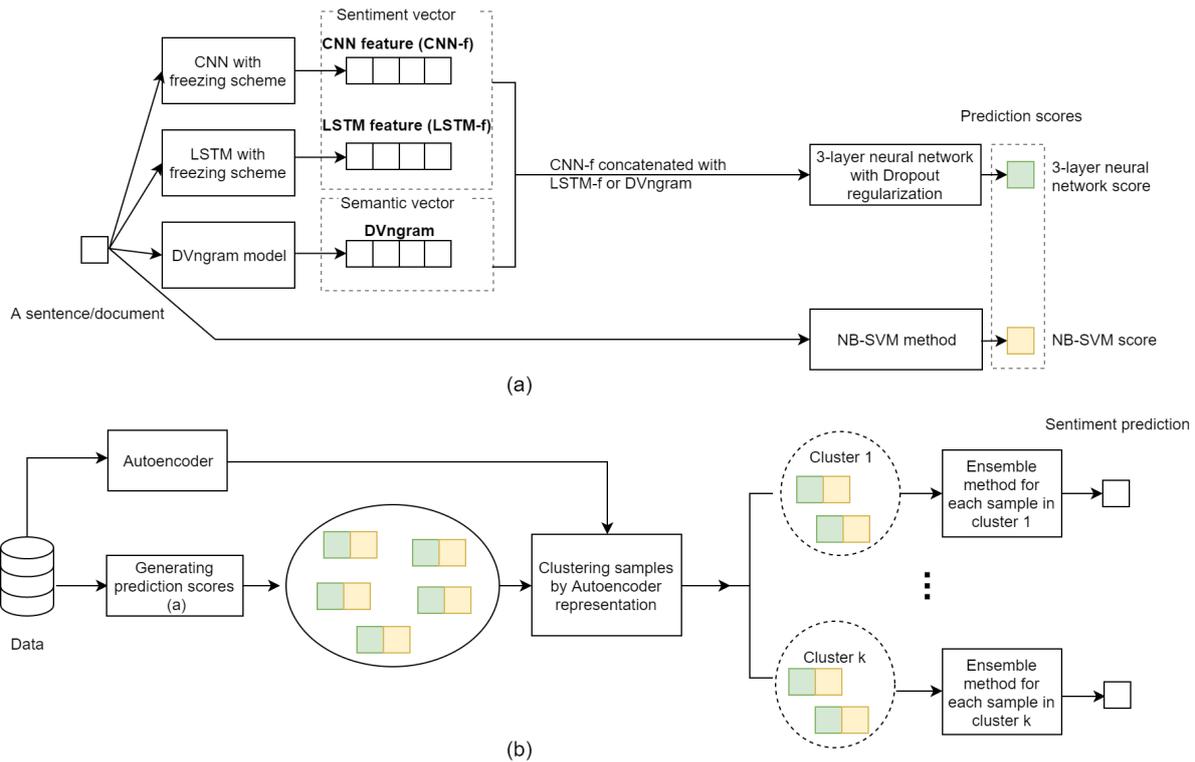

Figure 1: The proposed framework for sentiment analysis

similar sentences/documents into similar vectors. For that reason, we designed an autoencoder model to learn representation vectors for sentences/documents and used these vectors for clustering. The prediction score of NBSVM method is provided to enhance the sentiment prediction of each cluster. Figure 1 shows the architecture of our framework.

We compared our method with NBSVM, CNN, LSTM, Paragraph Vector, LinearEnsemble (Mesnil et al., 2014), DSCNN (Zhang et al., 2016) on three well-known datasets: IMDB large movie reviews (Maas et al., 2011) for document level, Pang & Lee (2005) movie reviews and Stanford Sentiment Treebank (Socher et al., 2013) for sentence level. The experimental results show that our method consistently performs well on both document and sentence level data. The main contributions of this work are as follows:

- We applied a freezing scheme to CNN and LSTM models for encoding sentiment information into vectors. These vectors provide a simple and efficient way to integrate the strong abilities of deep learning models.
- We proposed a scenario to divide data into groups of similar sentences/documents.

Then, each sentence/document in each group is represented by the prediction score of NB-SVM method and the prediction score of the proposed 3-layer neural network. We proposed an ensemble method to employ these scores.

2 Sentiment representation learning

In this section, we describe the freezing scheme to generate sentiment vectors from two models: (i) CNN, (ii) LSTM; and a method to employ these vectors. To feed into LSTM/CNN model, each word of a sentence/document is transformed into a word embedding vector using *Word2Vec*¹.

Le and Mikolov (2014) extended the word embedding learning model by incorporating paragraph information. Given a paragraph, Le's method captures and encodes semantics into a representation vector or a semantic feature.

This work inspired us to develop a document representation learning model to capture sentiment information. In our work, we proposed an approach to generating sentiment representation from CNN and LSTM models. Our idea is to train CNN and LSTM models under the sentiment classification task. In a deep learning network, we

¹<https://code.google.com/p/word2vec/>

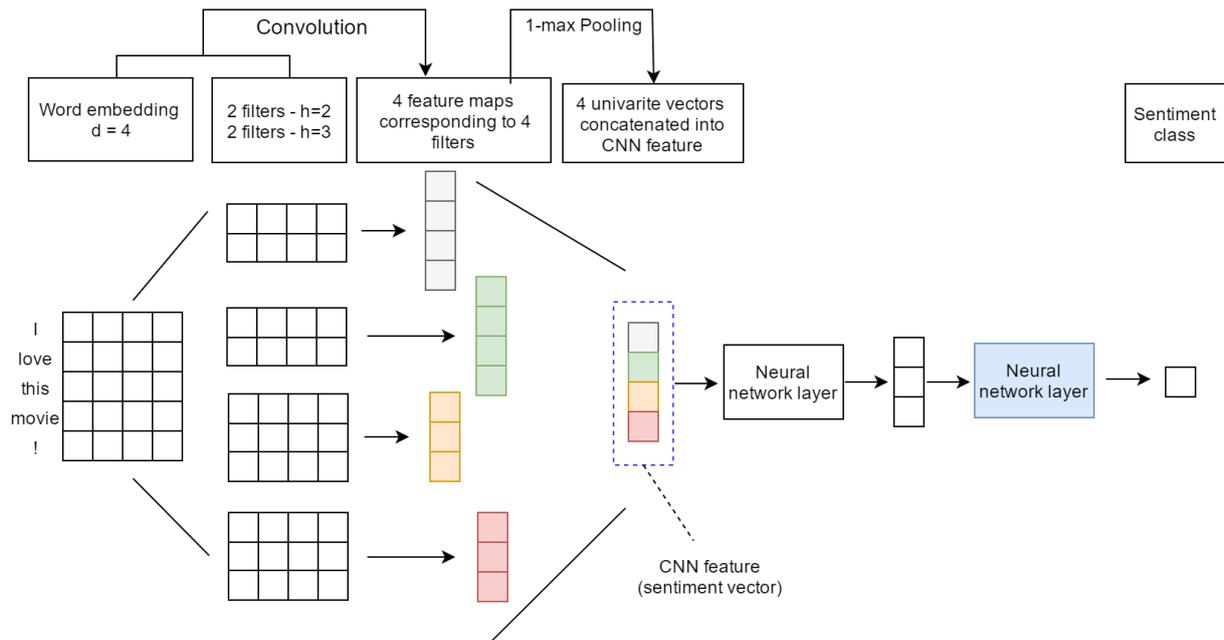

Figure 2: Illustration of our CNN framework to generate sentiment features. Given a sequence of d -dimension word embeddings ($d = 4$), the model applies 4 filters: 2 filters for region size $h = 2$ and 2 filters for region size $h = 3$ to generate 4 feature maps. During the training process, the parameters of the last neural network layer (blue one) are frozen (untrained)

could separate the model into two parts: (i) **Building target feature** - from input samples, the first part encodes target information into vectors, (ii) **Classifying layer** - the second part tries to learn a layer (or a boundary) for classifying these vectors into target labels. Sentiment vectors generated by a model, however, are much fitting to the classifying layer of this model. It is not efficient to combine two sentiment vectors generated from two models because each sentiment vector is fitting to its particular classifying layer. To address this problem, we proposed a freezing scheme. According to this scheme, the parameters of the classifying layer are initialized from the uniform distribution and in the training phase, these parameters are kept unchanged. This technique makes sentiment vectors not too fit to a particular classifying layer.

2.1 LSTM for sentiment feature engineering - LSTM feature

The LSTM architecture was introduced by Hochreiter (1997). By designing a memory cell preserving its state over a long period of time and non-linear gating units regulating information flow into and out of the cell, Hochreiter made LSTM able to capture efficiently long distance de-

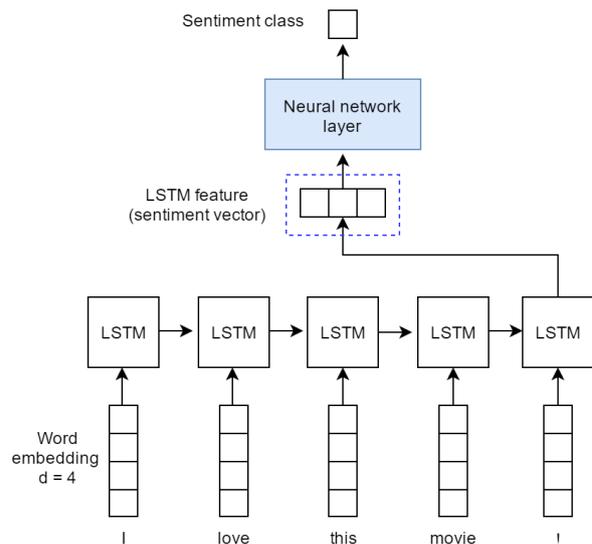

Figure 3: Illustration of our LSTM model to generate sentiment vectors. During the training process, the parameters of the neural network layer (blue one) are frozen (untrained)

pendencies of sequential data without suffering the exploding or vanishing gradient problem of Recurrent neural network (Goller and Kuchler, 1996).

Figure 3 explains how to employ the LSTM architecture for memorizing sentiment information

over sequential data. The model contains two parts: (i) **Building sentiment feature** - the LSTM layer encodes sentiment information of input into a fixed-length vector; (ii) **Classifying layer** - this sentiment-specific representation vector will be classified by the last neural network (NN) layer (the blue layer in Figure 3). As applying the freezing scheme, this NN layer’s parameters are unchanged during the training process.

2.2 CNN for sentiment feature engineering - CNN feature

We present a sentence of length s as a matrix $d \times s$, where each row is a d -dimension word embedding vector of each word. Given a sentence matrix \mathbf{S} , CNN performs convolution on this input via linear filters. A filter is denoted as a weight matrix W of length d and region size h . W will have $d \times h$ parameters to be estimated. For an input matrix $S \in \mathbb{R}^{d \times s}$, a feature map vector $O = [o_0, o_1, \dots, o_{s-h}] \in \mathbb{R}^{s-h+1}$ of the convolution operator with a filter W is obtained by applying repeatedly W to sub-matrices of S :

$$o_i = W \cdot S_{i:i+h-1} \quad (1)$$

where $i = 0, 1, 2, \dots, s - h$, (\cdot) is dot product and $S_{i:j}$ is the sub-matrix of \mathbf{S} from row i to j .

Each feature map O is fed to a pooling layer to generate potential features. The common strategy is 1-max pooling (Boureau et al., 2010). The idea of 1-max pooling is to capture the most important feature v corresponding to the particular feature map by selecting the highest value of that feature map:

$$v = \max_{0 \leq i \leq s-h} \{o_i\} \quad (2)$$

We have described in detail the process of one filter. Figure 2 shows an illustration of applying multiple filters with variant region sizes to obtain multiple 1-max pooling values. After pooling, these 1-max pooling values from feature maps are concatenated into a CNN feature carrying sentiment information. Intuitively, the CNN feature is a collection of maximum values from the feature maps. To make a connection to these values, we provide an NN layer to synthesize a high-level feature from the CNN feature. Finally, this high-level feature is passed to an NN layer with sigmoid activation to generate the probability distribution over sentiment labels.

In the training phase, similar to the strategy in our LSTM model, the last NN layer’s parameters

are kept untrained to make the sentiment vectors not too fit to a particular classifying layer.

2.3 Classifying with sentiment vectors

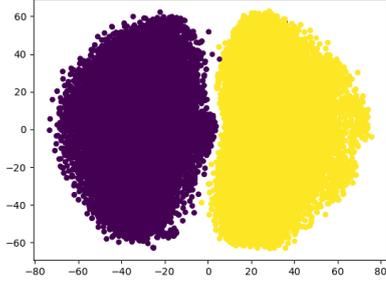

Figure 4 visualizes the results of encoding sentiments into vectors using our CNN model. As we can see in the development set, there are some unambiguous cases. Therefore, we add more information to CNN sentiment vectors by concatenating them with LSTM sentiment vectors or DVn-gram semantic vectors.

As CNN and LSTM sentiment vectors are, however, generated from models of sentiment classification, these vectors are easily separated in terms of sentimental categories by machine learning methods. In other words, a multi-layer NN sentiment classifier using both of these vectors as input reaches the state of perfect classification on the training set after a few epochs. In this case, the classifier’s parameters are not efficiently optimized and the classifier’s performance has no improvement on the testing set, compared with using LSTM or CNN for classification (or we call the model overfitting).

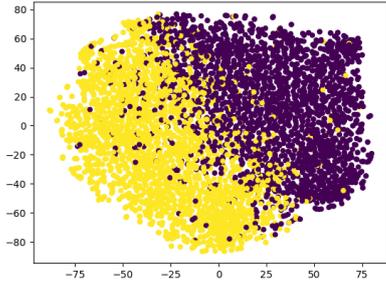

To address this problem, we employ a **3-layer NN** with Dropout regularization (Hinton et al., 2012) on the first and second layers. By randomly dropping out each hidden unit with a probability p on each presentation of each training case, Dropout prevents overfitting and provides a way to combine many variant NN architectures efficiently. By applying Dropout, our model has an ability to examine efficiently variant combination ways from feature vectors.

3 Ensemble with clustering support

As we discussed in Section 1, a slight difference between two sentences could lead to two opposite sentiments. However, similar sentences/documents have a tendency to be encoded into similar vectors by generative models. Therefore, it causes some difficulties in sentiment classification. To address this problem, we divided data into groups of similar sentences/documents and then provided an additional feature to boost the performance of classification in each group. For dividing data, we applied autoencoder models to encode word embedding representations of sentences/documents into fix-length vectors. These vectors then were used for clustering sentences/documents. For each sentence/document in

(a) Sentiment vectors in the train set

(b) Sentiment vectors in the development set

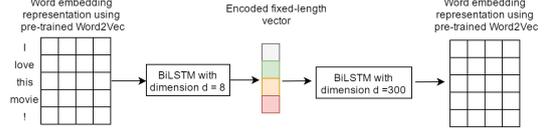

Figure 4: The t-SNE projection for IMDB dataset’s sentiment vectors (positive and negative) generated from our CNN model.

each cluster, the prediction score of the method in section 2 are combined with the prediction score of NBSVM. The reason for choosing NBSVM is that NBSVM is an efficient method not based on neural network architectures, and using Bag of Word model to represent sentences/documents, which is different from the word embedding representation. We consider NBSVM’s score as an additional channel and expect it to support well for each group of similarity sentences/documents in terms of word embedding representation.

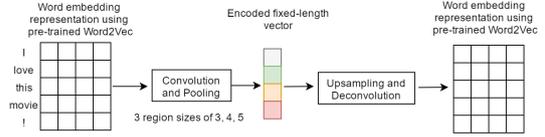

Given a sentence/document, we will have two prediction scores: one from the proposed method in section 2 and one from NBSVM. To employ these scores, we used a voting method. This scheme allows each classifier f_i to give a vote with a confident ratio r_i to the final probability score over classes distribution as follows:

$$p(c_i|x) = \frac{1}{N} \sum_{k=1}^N p_k(c_i|x)r_k \quad (3)$$

where c_i is the i th sentiment class, N is the number of classifiers, $p_k(c_i|x)$ is the prediction score of the classifier k on the i th class for a sentence/document x .

(a) BiLSTM model

(b) CNN model. In MR-L dataset, each region size has 300 filters. In MR-S and SST dataset, each region size has 100 filters

Figure 5: Autoencoder models

The objective of this ensemble method is to select a suitable confident ratio for each classifier to optimize the performance of classification. In our approach, a 2-layer NN is employed to define a voting architecture. We consider a feedforward process in NN as a scheme of voting and the NN’s weights as confident ratios. Adamax algorithm (Kingma and Ba, 2014) is applied to optimize the weights of the model.

Dataset	l	$train$	$test$	$ V $
MR-L	300	25000	25000	169940
MR-S	20	10662	cv	18765
SST	19	9613	1821	16185

Table 1: Summary statistic of datasets. l denotes the average length of reviews, $train$ and $test$ are sizes of the training set and the test set respectively, cv is 10-fold cross validation, and $|V|$ is vocabulary size.

4 Dataset and Experiment setup

4.1 Dataset

We evaluated our models on three well-known datasets. Table 1 shows the statistic summary of datasets.

- For document level, IMDB large movie review dataset **MR-L** is used. Each review contains numerous sentences (Maas et al., 2011).
- For sentence level, Pang & Lee (2005) provided **MR-S** dataset having one sentence per

movie review. In addition, we also did experiment on Stanford Sentiment Treebank SST (Socher et al., 2013) - an extension of MR-S with two labels (positive and negative). In SST, all sentences and phrases of the training set are used for training.

4.2 Experimental setup

To tune hyper-parameters of our models, we do a grid search on 30% of each dataset.

- For MR-L:
 - LSTM model has dimension $d = 32$.
 - CNN model: using 3 region sizes of 3, 4, 5; the number of each region size is 300 and the dimension of penultimate NN layer is 100.
 - 3-layer NN model for classification with sentiment vectors: the first NN layer has the same dimension as the input feature, and the dropout ratio $p = 0.9$; the second NN layer has the dimension of 64 and the dropout ratio $p = 0.5$.
 - Autoencoder models: we examined two autoencoder models - CNN and BiLSTM. The details are in Figure 5.
 - Clustering: k-mean is applied. The number of clusters is $k = 2$.
 - Ensemble model: the first NN layer has the dimension of $3 \times$ the input's dimension or the number of classifiers.
- For MR-S and SST: the same configuration as MR-L, except the number of each region size is 100.

For word vectors, we obtained pre-trained word vectors *Word2Vec*. Its vectors have the dimension of 300. In our LSTM and CNN models, these pre-trained word vectors are optimized during the training process.

5 Results and Discussion

We compared our models against the other methods showed in table 2 on the binary sentiment classification task. In SST dataset, we could not reproduce the result 88.1% of CNN (Kim, 2014). According to the empirical results, our method of combining feature vectors *3-layer NN* outperforms the individual methods: LSTM, CNN, and

DVngram. That proves the efficiency of the feature combination strategy. In addition, our ensemble method with clustering support outperforms the current state of the art method on MR-L and MR-S datasets. As we mentioned in Section 3, NBSVM uses a different way to present sentences/documents and a different approach to learning (a discriminative model), so it gives a significant support in our ensemble method. On document level, LSTM method produced a much lower performance than DVngram method. As a result, the feature vectors generated from LSTM model does not support as well as DVngram's vectors when combining with CNN feature vectors.

5.1 Freezing vs Unfreezing in the last NN layer of feature engineering phase

In the engineering phase, we freeze (untrain) the last NN layer's parameters to create efficient sentiment vectors. To evaluate the efficiency of this technique, we compared our vector's performance against the sentiment-specific vector from the unfreezing scheme. We passed these vectors to our 3-layer NN model to achieve the results (details in table 3). One interesting observation is that the performance of a feature vector in freezing mode is better than one in unfreezing mode for most of the cases. In addition, we combined a sentiment-specific vector with the semantic-specific vector - DVngram for evaluating the performance. In general, our freezing scheme provided a higher performance than the unfreezing scheme. The experimental results show that our freezing scheme works more efficiently on CNN model than LSTM model, especially in a case of combining a sentiment-specific vector and a semantic-specific vector.

5.2 Evaluation on combining features

In this section, we compared in performance our approach to combining features from variant models against **Merging scheme** which horizontally merges variant models (details in figure 6).

From the result showed in table 4, we found that our approach for feature vectors combination is applied more efficiently to CNN model than LSTM model. In the scheme of combining feature vectors, CNN feature vector provides a robust performance, while LSTM feature vector provides inconsistent results: better when combining with CNN feature vector, worse when combining with DVngram vector (compared with Merg-

Method		MR-S	MR-L	SST
LSTM		80.17	86.23	87.81

5.3 Error analysis

To get a better sense of the limitation of the proposed model, we manually inspect some cases of the wrong prediction, which are showed in table 5. These sentences are good examples of the proposed model’s weakness.

The first source of false hits is the lack of syntactic information. The model tried to identify sentiment words in a sentence (i.g. not, bad, at all) but it failed to interpret the whole sentence.

The second reason of the wrong prediction comes from missing context information. A word (i.g. foul, freaky) carries a positive or negative sentiment depend on context or domains. We believe that the promising direction in future work will be to improve the model for capturing syntactic and context information.

<i>id</i>	Sentence	<i>L</i>
1	<i>Not a bad journey at all.</i>	1
2	<i>The best way to hope for any chance of enjoying this film is by lowering your expectations.</i>	0
3	<i>You've seen them a million times.</i>	0
4	<i>A whole lot foul, freaky and funny.</i>	1

6 Related work

Sentiment analysis is a study of determining people’s opinions, emotions toward to entities. Taboada (2011) assigned sentiment labels to text by extracting sentiment words. Liu (2012) formulated the sentiment analysis as a classification task and applied machine learning techniques for this problem. In this approach, dominant research concentrated on designing effective features such as word ngram (Wang and Manning, 2012), emoticon (Zhao et al., 2012), sentiment words (Kiritchenko et al., 2014). However, designing handcraft features requires an intensive effort.

Recently, the emergence of deep learning models has provided an efficient way to learn continuous representation vectors for sentiment classification. Bengio (2003) and Mikolov (2013) introduced learning techniques for semantic word representation. By using a neural network in the context of a word prediction task, the authors generated word embedding vectors carrying semantic meanings. Embedding vectors of words which share similar meanings are close to each other. Semantic information maybe provides opposite opinions in different contexts. Therefore, some research (Socher et al., 2011; Tang et al., 2014) worked on learning sentiment-specific word representation by employing sentiment text. For sentence and document level, composition approach attracted many studies. Yessenalina and Cardie (2011) modeled each word as a matrix and used

iterated matrix multiplication to present a phrase. Deep recursive neural networks (DRNN) over tree structures were employed to learn sentence representation for sentiment classification such as DRNN with binary parse trees (Irsoy and Cardie, 2014), Recursive tensor neural network with sentiment treebank (Socher et al., 2013). CNN has recently been applied efficiently for semantic composition (Kim, 2014; Zhang and Wallace, 2015). This technique uses convolutional filters to capture local dependencies in term of context windows and applies a pooling layer to extract global features. Le and Mikolov (2014) applied paragraph information into the word embedding technique to learn semantic representation. Tang et al. (2015) used CNN or LSTM to learn sentence representation and encoded these semantic vectors in document representation by Gated recurrent neural network. Zhang (2016) proposed Dependency Sensitive CNN to build hierarchically textual representations by processing pretrained word embeddings. Wang (2016) used a regional CNN-LSTM to predict the valence arousal ratings of texts.

In our work, we designed a freezing approach for learning efficiently sentiment document representation from two variant deep-learning models: CNN and LSTM. Afterward, these sentiment-specific vectors and the semantic DVngram vector were employed for sentiment classification. This strategy captures the advantages of variant models by using vectors, which each model generated. We also used NBSVM in clustering mode to boost the performance of classification.

7 Conclusion

In this work, we introduced a novel approach to synthesize feature vectors for sentiment analysis from CNN, LSTM. These vectors provide a simple and efficient way to integrate the strong abilities of these models. For sentiment classification with CNN, LSTM vectors, we proposed a 3-layer neural network which efficiently takes advantages of these vectors. In addition, we proposed a strategy to cluster documents/sentences by their similarity. In each cluster, we applied an ensemble method of the 3-layer neural network and NBSVM. It achieves the state of the art results in the datasets: MR-S and MR-L. In the current work, we just focused on individual models. Research on applying combination models for feature engineering maybe provides interesting results.

Abstract

In this paper, we study domain adaptation with a state-of-the-art hierarchical neural network for document-level sentiment classification. We first design a new auxiliary task based on sentiment scores of domain-independent words. We then propose two neural network architectures to respectively induce document embeddings and sentence embeddings that work well for different domains. When these document and sentence embeddings are used for sentiment classification, we find that with both pseudo and external sentiment lexicons, our proposed methods can perform similarly to or better than several highly competitive domain adaptation methods on a benchmark dataset of product reviews.

1 Introduction

Sentiment classification is a fundamental task in opinion mining (Pang et al., 2002; Hu and Liu, 2004; Choi and Cardie, 2008; Nakagawa et al., 2010). Recently, with the advances of deep learning techniques for many NLP applications, various kinds of neural network (NN)-based models have been proposed for this task (Socher et al., 2013; Lei et al., 2015; Yang et al., 2016).

As with any supervised learning method, the NN-based models also suffer from the *domain adaptation* problem, where training data and test data come from different domains. The reason for this is that sentiments are often expressed with domain-specific words and expressions. For example, in the **Book** domain, expressions like *an insider's look* and *a must read* are usually positive, but they may not be useful for the **Kitchen** domain. Similarly, words such as *sharp* and *clean*,

which are positive in the **Kitchen** domain, can rarely be seen in the **Book** domain. Due to the high cost of obtaining labeled data, it would be very attractive if we can adapt a model trained on a *source domain* to a *target domain*.

A number of different models have been proposed for cross-domain sentiment classification, and the core idea of them is to learn a shared latent representation that is general across domains. Most of these studies can be categorized into two lines. The first line of work focuses on carefully designing some auxiliary prediction tasks to induce a robust cross-domain representation (Blitzer et al., 2007; Pan et al., 2010; Bollegala et al., 2015, 2016). With the trend of deep learning, another line of work centers on employing denoising auto-encoders to learn hidden representations across domains in a purely unsupervised learning manner (Glorot et al., 2011; Chen et al., 2012; Zhou et al., 2016).

However, most of the two lines of research are based on traditional discrete feature representations, and the induced shared representations are not necessarily specific to sentiment classification. In our recent work, we designed two simple auxiliary tasks, which are closely related to the actual end task, for sentence-level cross-domain sentiment classification (Yu and Jiang, 2016). Furthermore, we proposed to jointly learn domain-independent sentence embeddings based on the two auxiliary tasks together with the classifier for the end task in a unified NN framework. Although our joint learning model has been shown to outperform previous domain adaptation methods in sentence-level sentiment classification, it is unclear how to extend this to document-level sentiment classification since the two auxiliary tasks will become much less useful for documents.

In this paper, we aim to propose a domain adaptation method for document-level sentiment clas-

sification based on our earlier joint model (Yu and Jiang, 2016). Specifically, instead of predicting the occurrence of pivot words as in previous work (Blitzer et al., 2007; Yu and Jiang, 2016), we introduce a new auxiliary task based on sentiment scores of pivot words. Moreover, we propose two different architectures to incorporate the auxiliary task into a state-of-the-art hierarchical NN model for document-level sentiment classification, in which we respectively induce a shared document embedding for each document in both domains and a shared sentence embedding for each sentence in all documents. Evaluation on a widely used dataset about product reviews from four different domains shows that our methods can significantly outperform a number of baselines and are able to achieve comparable or even better results compared with a strong baseline proposed by us.

2 Related Work

Domain Adaptation: Domain adaptation has been extensively studied in recent years (Pan and Yang, 2010). In NLP, it has also attracted much attention, where most domain adaptation methods can be categorized into two groups: instance re-weighting (Jiang and Zhai, 2007; Xia et al., 2014) and shared representation learning (Blitzer et al., 2006; Daumé III, 2007; Titov, 2011). In this work, we follow the latter line of work, and focus on inducing a domain-independent feature space based on a recently proposed NN architecture.

Neural Networks for Sentiment Classification: With the recent trend of deep learning, a large amount of NN models, including Convolutional Neural Network (Kim, 2014), Recursive Neural Network (Irsoy and Cardie, 2014) and Recurrent Neural Network (Tai et al., 2015), have been proposed for sentiment classification. Although these models have achieved highly competitive results on different benchmarks, most of them are targeted at sentence-level sentiment classification. Considering that the relations between sentences are important for predicting the sentiment polarity of any document, Tang et al. (2015) proposed a hierarchical NN model to encode the relations between sentences for document-level sentiment classification. Since it has been shown to significantly outperform standard non-hierarchical models on several benchmarks, we try to apply this model to domain adaptation settings in this work.

Cross-Domain Sentiment Classification: For

sentiment classification, most existing domain adaptation methods focus on inducing shared representations across domains. One line of work tries to leverage the co-occurrences of domain-specific and domain-independent features to learn a general low-dimensional cross-domain representation (Blitzer et al., 2007; Pan et al., 2010; He et al., 2011; Bollegala et al., 2015; Bhatt et al., 2015). Another line of work is based on a purely unsupervised learning method, denoising auto-encoders, where the hidden layers in multi-layer neural networks are believed to be robust against domain shift (Glorot et al., 2011; Chen et al., 2012; Zhou et al., 2016). However, all these methods are still based on traditional discrete representations, and the shared representations are learned separately from the final classifier and therefore not directly related to sentiment classification. More recently, we proposed a unified neural model to jointly learn the shared sentence embeddings and the final classifier together for sentence-level sentiment domain adaptation (Yu and Jiang, 2016). But the auxiliary task in this earlier work is only designed for sentences; it will be less useful for documents. Moreover, the neural model is based on CNNs, which fail to achieve satisfactory results in document-level sentiment classification. Hence in this work, we focus on proposing a new auxiliary task for documents, followed by incorporating it into a state-of-the-art hierarchical NN model for document-level sentiment domain adaptation.

3 Methodology

In this section we present our domain adaptation method for document-level sentiment classification.

3.1 Problem Definition and Notation

Our task is sentiment classification at the document level. We assume that each input d is a document containing n sentences, and the i^{th} sentence contains a sequence of m_i words. Let us use $w_{i,j} \in \mathcal{V}$ to denote the j^{th} word of the i^{th} sentence, where \mathcal{V} is the vocabulary. Let $y \in \{+, -\}$ denote the sentiment label of input d , where $+$ and $-$ denote the positive sentiment and the negative sentiment, respectively.

We consider a cross-domain setting, in which we assume that we have a set of labeled training documents from a source domain, denoted by \mathcal{D}^s . In addition, we have a set of unlabeled documents

from a target domain, denoted by $\mathcal{D}^{t,u}$. Our goal is to train a good document-level sentiment classifier using \mathcal{D}^s and $\mathcal{D}^{t,u}$ so that the classifier can generally work well in the target domain. To evaluate the trained classifier, we test its performance on a set of labeled documents from the target domain, denoted by $\mathcal{D}^{t,l}$.

3.2 Method Overview

The core of our domain adaptation method is to use a domain-independent auxiliary task to help induce a cross-domain hidden representation that is useful for both source and target domains. The idea of learning cross-domain hidden representations by leveraging auxiliary tasks for domain adaptation is not new (Blitzer et al., 2006, 2007; Yu and Jiang, 2016; Ding et al., 2017). These previous studies essentially follow the multi-task learning framework (Ando and Zhang, 2005). The rationale behind them is that if there are some auxiliary tasks related to the actual prediction task and the labels of the auxiliary tasks can be easily obtained for both source and target domains, the induced low-dimensional feature space is a good representation for domain adaptation.

Our work follows this line of research and aims to extend our recently proposed domain adaptation method for sentence-level sentiment classification (Yu and Jiang, 2016). Our method is based on an existing hierarchical neural network (HNN) model for document-level sentiment classification proposed by Tang et al. (2015), which encodes each sentence in the input document into a sentence embedding vector through a CNN, followed by combining all sentence embeddings into a document embedding vector with a gated RNN. Different from Tang et al. (2015), however, we use the sentence embeddings or document embeddings for predicting not only the actual sentiment labels but also the labels of a carefully designed auxiliary task. Since the auxiliary task is domain-independent, we expect the sentence embeddings and document embeddings learned by our method to work well in both domains.

3.3 A Hierarchical Neural Network for Document-level Sentiment Classification

We first describe our baseline method for document-level sentiment classification. This is a HNN model proposed by Tang et al. (2015) that has been shown to significantly outperform simpler, non-hierarchical models. We re-implement

this model with some minor modifications.

Recall that an input document d is represented by a sequence of sentences, each containing a sequence of words, and $w_{i,j} \in \mathcal{V}$ is the j^{th} word of the i^{th} sentence in d . We use $\mathbf{x}_{i,j} \in \mathbb{R}^l$ to denote an l -dimensional dense embedding vector for word $w_{i,j}$, which is retrieved from a lookup table $\mathbf{X} \in \mathbb{R}^{l \times |\mathcal{V}|}$ for all words. We first apply a one-layer CNN (Kim, 2014) to obtain an embedding vector $\mathbf{z}_i \in \mathbb{R}^p$ for the i^{th} sentence: $\mathbf{z}_i = \text{CNN}_{\Theta_1}(\mathbf{x}_i)$, where Θ_1 denotes all the parameters in this CNN.

After obtaining the sentence embeddings for all the n sentences in d , we then apply an LSTM to sequentially combine all sentences together: $\mathbf{h}_i = \text{LSTM}_{\Theta_2}(\mathbf{h}_{i-1}, \mathbf{z}_i)$, where $\mathbf{h}_i \in \mathbb{R}^q$ is the i^{th} hidden state, and Θ_2 denotes all the parameters in the LSTM¹. Note that Tang et al. (2015) used bi-directional gated RNN to chain the sentences into a document embedding, but we did not observe any significant gain over LSTM based on our preliminary experiments.

Finally, a softmax classifier is learned to map the document representation \mathbf{h}_n to a label y :

$$p(y | \mathbf{h}_n) = \text{softmax}(\mathbf{W}\mathbf{h}_n + \mathbf{b}),$$

where $\mathbf{W} \in \mathbb{R}^{2 \times q}$ is a weight matrix and $\mathbf{b} \in \mathbb{R}^2$ is a bias vector.

In the following sections, we will present two NN architectures built on top of the baseline method that leverages an auxiliary task for domain adaptation of document-level sentiment classification. The first architecture uses a document-level auxiliary task to help induce a document-level hidden representation, while the second architecture uses a sentence-level auxiliary task to help induce a sentence-level hidden representation.

3.4 Document-level Shared Representation Learning for Domain Adaptation

Document-level Auxiliary Task

We first introduce an auxiliary task that is closely related to the original task of document-level sentiment classification. Our auxiliary task is inspired by our recent work for sentence-level cross-domain sentiment classification (Yu and Jiang, 2016). In this recently proposed method, we used two auxiliary tasks to induce shared sentence embeddings across domains. Considering

¹To simplify the discussion, we will not give the details of CNN and LSTM here. Interested readers can refer to Kim (2014) and Hochreiter and Schmidhuber (1997).

that an input sentence containing a positive (or negative) domain-independent sentiment word is more likely to express an overall positive (or negative) sentiment, the two auxiliary tasks are about whether an input sentence contains at least one positive or one negative domain-independent sentiment word, respectively.

Although the two auxiliary tasks have been shown to benefit sentence-level cross-domain sentiment classification, they may not work well in document-level sentiment classification. The reason is the following. In sentence-level sentiment classification, since sentences are short, a sentence is more likely about only one aspect of the topic being discussed, and it tends to express a consistent sentiment polarity towards that aspect. However, in document-level sentiment classification, a document may contain mixed opinions towards different aspects of the topic, and the sentiment polarities towards different aspects may differ. Moreover, at document level, there may also be comparison and contrast among different topics, and the sentiment polarities towards them could be different. In summary, it is highly possible for a document to contain both positive and negative domain-independent sentiment words. In this case, the two auxiliary tasks would not be of much use because most documents would have the same labels for both these two tasks².

To address this limitation, we propose an alternative auxiliary task based on sentiment scores of the domain-independent sentiment words. The intuition is as follows. Assume that we have an external sentiment lexicon, where each word is assigned a general sentiment score. For an input document, if it contains more domain-independent words with high positive sentiment scores, the document is more likely to express an overall positive sentiment, regardless of the domain the document is from. More importantly, the remainder of the document without domain-independent words may also contain domain-specific positive words or expressions.

Take the following review as an example.

One of the *best!* You will go **wrong** if you read this as an intro to deep learning. *Truly* an insider's look. A must read for everyone who *loves* neural networks.

²Based on our observation on a benchmark dataset collected by Blitzer et al. (2007), for almost all the 12 source/target pairs, over 90% of the reviews contained both positive and negative domain-independent sentiment words.

We can see that the document contains three words with high positive sentiment scores (shown in italic), and one word with a high negative sentiment score (shown in bold). But overall, its sentiment polarity is positive, which correlates with the sum of all the domain-independent words' sentiment scores. Then, if we hide all the domain-independent sentiment words and use the remaining domain-specific words to predict the overall sentiment score of the domain-independent sentiment words, it should be helpful for identifying some important domain-specific sentiment expressions such as *an insiders' look* and *a must read* in the example above.

Hence, we propose a new auxiliary task by predicting whether the sum of all the domain-independent sentiment words' sentiment scores is larger than, equal to or less than 0. It is worth noting that (1) given any sentiment lexicon, we can automatically derive the label of the auxiliary task³, and (2) the auxiliary task is closely related to the main binary sentiment classification task.

Formally, let us assume that we have a sentiment lexicon, which can be either directly taken from an external resource or derived from the labeled source domain data. Details of how the sentiment lexicon is obtained will be given in Section 3.7.1. Following SCL (Blitzer et al., 2007), we choose the words which frequently occur in both domains and have a high (positive or negative) sentiment score as the domain-independent sentiment words, and refer to them as pivot words. For each input document d , we use a special token *UNK* to substitute these pivot words, which follows the practice in our earlier work (Yu and Jiang, 2016). To be consistent with the notation before, let us use d' to denote the new document with *UNK* tokens and $w'_{i,j}$ the j^{th} token in the i^{th} sentence in d' . Let $\mathbf{x}'_{i,j} \in \mathbb{R}^l$ denote the embedding vector of $w'_{i,j}$. $\mathbf{x}'_{i,j}$ is the same as $\mathbf{x}_{i,j}$ when $w'_{i,j}$ is not *UNK*. When $w'_{i,j}$ is *UNK*, $\mathbf{x}'_{i,j}$ is set to be a special embedding vector for *UNK*. We then introduce an auxiliary label y' for d' , which indicates whether the sum of the sentiment scores of the pivot words in the original document d is larger than, equal to or less than 0. We further use $\mathcal{D}^{a,d}$ to denote documents with the document-level auxiliary labels derived from both \mathcal{D}^s and $\mathcal{D}^{t,u}$.

³For any sentiment lexicon, we can rescale its original sentiment scores to $[-K, K]$, where K can be any positive integer, and $-K$ and K respectively denote the most negative and the most positive sentiments. In this paper, we set K to 2.

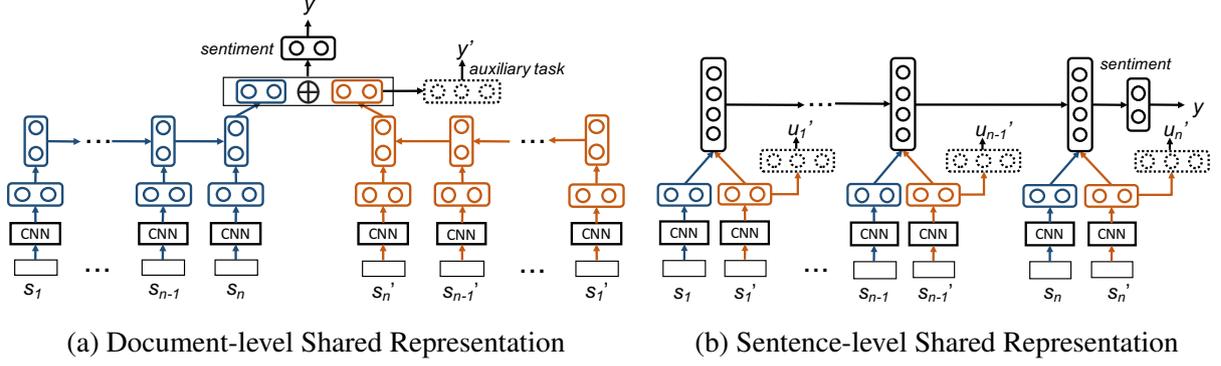

Figure 1: Overview of our proposed methods.

Document-level Shared Representation (DSR)

Now that we have defined the auxiliary task, we can present the NN architecture. Figure 1(a) gives the outline of this method, which essentially tries to directly learn an auxiliary hidden layer for each input document. For the i^{th} sentence in d' , we first use a CNN to obtain its auxiliary embedding vector $\mathbf{z}'_i = \text{CNN}_{\Theta'_1}(\mathbf{x}'_i)$. These sentence embeddings are further combined together with an LSTM parameterized by Θ'_2 , and the final hidden state \mathbf{h}'_n is fed to predict the auxiliary label y' :

$$p(y' | \mathbf{h}'_n) = \text{softmax}(\mathbf{W}'\mathbf{h}'_n + \mathbf{b}').$$

Besides, we also apply another CNN and LSTM to obtain the standard document representation \mathbf{h}_n , and concatenate it with the auxiliary hidden vector \mathbf{h}'_n to predict the sentiment label y :

$$p(y | \mathbf{h}_n, \mathbf{h}'_n) = \text{softmax}(\mathbf{W}(\mathbf{h}_n \oplus \mathbf{h}'_n) + \mathbf{b}).$$

3.5 Sentence-level Shared Representation Learning for Domain Adaptation

Unlike the first architecture, our second proposal focuses on learning an auxiliary hidden layer for each sentence in a given document. As illustrated in Figure 1(b), instead of using an overall auxiliary label for the whole document, we will have an auxiliary label for each sentence in the document.

Sentence-level Auxiliary Task

Although the auxiliary task in Section 3.4 is designed for documents, it is also suitable for sentences since if a sentence contains more domain-independent words with high positive sentiment scores, the rest of the sentence excluding these words may still express a positive sentiment.

To facilitate the discussion, let us use s_i to denote the i^{th} sentence in the original document d

and s'_i the i^{th} sentence in the modified document d' . We then introduce an auxiliary label u'_i for s'_i , which indicates whether the sum of the sentiment scores of the pivot words in s_i is larger than, equal to or less than 0. We further use $\mathbf{u}' \in \mathbb{R}^n$ to denote the auxiliary labels for all the n sentences in d' . Let $\mathcal{D}^{\text{a.s}}$ denote documents with the sentence-level auxiliary labels derived from both \mathcal{D}^{s} and $\mathcal{D}^{\text{t.u}}$.

Sentence-level Shared Representation (SSR)

Based on the sentence-level auxiliary task, we use two CNNs to obtain sentence embeddings \mathbf{z}_i and \mathbf{z}'_i , respectively for s_i and s'_i . Next, the auxiliary hidden layer \mathbf{z}'_i will be used for predicting the auxiliary label u'_i :

$$p(u'_i | \mathbf{z}'_i) = \text{softmax}(\mathbf{W}'\mathbf{z}'_i + \mathbf{b}').$$

Besides, we also concatenate \mathbf{z}_i and \mathbf{z}'_i together as a combined sentence embedding for the i -th sentence. Then, all the n combined sentence embeddings are further combined together via an LSTM:

$$\mathbf{h}_i = \text{LSTM}_{\Theta_2}(\mathbf{h}_{i-1}, (\mathbf{z}_i \oplus \mathbf{z}'_i)).$$

Finally, we feed the last hidden representation \mathbf{h}_n to predict the label of our main task:

$$p(y | \mathbf{h}_n) = \text{softmax}(\mathbf{W}\mathbf{h}_n + \mathbf{b}).$$

3.6 Parameter Learning

Since our two NN architectures consist of the main task and the auxiliary task, we jointly optimize them in a single loss function. For space limitation, here we only show the objective function for the first model, and the objective function for the latter one can be derived similarly. Using cross-entropy loss, we can learn $\Theta_1, \Theta_2, \Theta'_1, \Theta'_2, \mathbf{W}, \mathbf{b}$,

\mathbf{W}' and \mathbf{b}' by minimizing the following function:

$$\begin{aligned} & J(\Theta_1, \Theta_2, \Theta'_1, \Theta'_2, \mathbf{W}, \mathbf{b}, \mathbf{W}', \mathbf{b}') \\ = & -\left(\sum_{(d,y) \in \mathcal{D}^s} \log p(y | d) \right. \\ & \left. + \sum_{(d',y') \in \mathcal{D}^{a,d}} \log p(y' | d') \right). \end{aligned}$$

3.7 Implementation Details

3.7.1 Sentiment Lexicons

We use two kinds of sentiment lexicons, which we refer to as WN and MI.

WN is extracted from a well-known sentiment lexicon called SentiWordNet (Baccianella et al., 2010). Since the original sentiment scores in SentiWordNet are probabilities for each word being positive or negative, we rescale them to $[-2, 2]$. Also, for the same words with different part-of-speech tags, we only keep the sentiment score with the highest absolute value.

To reduce the reliance on external resources, we also experiment with another method based on mutual information (MI) on the source labeled data \mathcal{D}^s to automatically derive a pseudo sentiment lexicon. Specifically, we first extract only adjectives, adverbs and verbs from the documents in \mathcal{D}^s , and measure each remaining word’s MI with the positive and the negative classes:

$$r(w_i, y) = \log \frac{\tilde{p}(w_i, y)}{\tilde{p}(w_i)\tilde{p}(y)},$$

where w_i denotes the i^{th} word in \mathcal{V} , $y \in \{+, -\}$ is a sentiment label, and $\tilde{p}(w_i, y)$ is the empirical probability of observing w_i and y together. Then, we only keep those words with positive MI, i.e., $r(w_i, y) > 0$, and obtain two lists \mathcal{R}_+ and \mathcal{R}_- . Moreover, for each word $w \in \mathcal{R}_+$, we use its MI score as its sentiment score, while for each word $w \in \mathcal{R}_-$, we reverse its MI score as its sentiment score. Finally, we merge the two word lists to form the pseudo sentiment lexicon, and rescale the sentiment scores into $[-2, 2]$.

3.7.2 Pivot Words Selection

Recall that pivot words should frequently occur in both domains and be sentiment sensitive. Hence, we first choose those words occurring at least 10 times in \mathcal{D}^s and at least 30 times in $\mathcal{D}^{l,u}$ as pivot candidates⁴, and remove negation and stop words.

⁴The ratio between $|\mathcal{D}^s|$ and $|\mathcal{D}^{l,u}|$ is 1:3 in our dataset.

Then, we only keep those candidates with high sentiment scores ($[-2, -1]$ and $[1, 2]$ for WN or $[-2, -0.9]$ and $[0.9, 2]$ for MI) as the pivot words.

3.7.3 Training Details

In our domain adaptation setting, for the labeled data \mathcal{D}^s from the source domain, we have labels for both the main task and the auxiliary task, while for the unlabeled data $\mathcal{D}^{l,u}$ from the target domain, we only have labels for the auxiliary task. Hence, we adopted an alternating training approach, where in each epoch we first optimize all the model parameters given \mathcal{D}^s , and then switch to only optimizing the parameters corresponding to the auxiliary task (including $\Theta'_1, \Theta'_2, \mathbf{W}'$ and \mathbf{b}') given $\mathcal{D}^{l,u}$. During the training stage, we share the word embeddings of the actual task and our auxiliary task, and never update the word embedding of *UNK* by setting it as a zero vector.

4 Experiments

4.1 Experiment Settings

Datasets: To evaluate our proposed method, we conduct experiments on a benchmark dataset released by Blitzer et al. (2007). This dataset consists of Amazon product reviews from four different domains: Book, DVD, Electronics and Kitchen. Each domain has 1000 positive and 1000 negative reviews as well as 17547 unlabeled reviews on average. Since the number of unlabeled reviews in each domain is different, we randomly choose 6000 unlabeled reviews for each domain.

Following previous studies (Pan et al., 2010; Zhou et al., 2016), we consider 12 pairs of source-target domain pairs. For each pair, all the 2000 labeled reviews from the source domain are treated as training data. We randomly choose 200 positive and 200 negative reviews from the target domain as development data, and the remainder (i.e., 800 + 800 reviews) from the target domain as test data. Moreover, for domain adaptation methods, we also use the 6000 unlabeled reviews from the target domain during the training stage.

Methods for comparison:

- **Naive** is a non-domain-adaptive baseline based on traditional discrete representations.
- **SCL** is the Structural Correspondence Learning method, which uses all the non-pivot features to predict the occurrence of each pivot feature, and employs SVD on the learned weight vectors.

- **mDA** is one of the state-of-the-art methods, marginalized denoising auto-encoders (Chen et al., 2012), which learns a shared hidden representation by reconstructing pivot features.
- **HNN** is another non-domain-adaptive NN-based baseline as detailed in Section 3.3.
- **H-WN** simply combines **HNN** with our auxiliary task, which represents each label derived from our auxiliary task using **WN** as a three-dimensional one-hot vector and appends it to the document embedding \mathbf{h}_n in **HNN**, followed by a softmax classifier.
- **H-SCL** is a naive combination of **SCL** with **HNN**, which appends the induced representation from **SCL** to the document embedding in **HNN**, followed by a softmax classifier.
- **H-mDA** is similar to **H-SCL** but uses the hidden representation from **mDA**, and this can be considered as a strong baseline.

Meanwhile, to show the effectiveness of the proposed auxiliary tasks, we also use the two auxiliary tasks in our earlier work as the auxiliary task of our two architectures for comparison, respectively denoted by **DSRE** and **SSRE** (Yu and Jiang, 2016).

Besides, we consider four variants of our proposed methods, where the auxiliary tasks in **DSR** and **SSR** are derived from the pseudo sentiment lexicon, while the auxiliary tasks in **DSRW** and **SSRW** are based on SentiWordNet.

- **DSRE**, **DSR** and **DSRW** are based on our first NN architecture to learn document-level shared representations, as introduced in 3.4.
- **SSRE**, **SSR** and **SSRW** are based on our second NN architecture to induce sentence-level shared representations, as introduced in 3.5.

Hyperparameters: For **Naive**, we train linear classifiers with LibLinear⁵ by using unigrams and bigrams with a frequency of at least 5 as features. For **SCL** and **mDA**, we use mutual information to select pivot features, and the number of chosen pivots is tuned from {500, 1000, 1500, 2000} on the development set. In **SCL**, we tune the number of induced features K in {25, 50, 100}, and also use normalization and rescaling. In **mDA**, we employ the dropout noise strategy used by Yang and Eisenstein (2014) without any parameter. In

⁵<http://www.csie.ntu.edu.tw/~cjlin/liblinear/>

all the neural network models, we set the dimension of word embeddings l to 300, and initialize the lookup table \mathbf{X} with *word2vec*⁶. We set the non-linear activation function in CNN as ReLU, and set the sizes of hidden layers in both CNN and LSTM as 150, i.e., $p = q = 150$. All the models were trained using AdaGrad with a learning rate of 0.05 and a minibatch size of 5. Also, the dropout rate α equals 0.5, and all the model parameters are regularized with a L2 regularization strength of 10^{-4} .

4.2 Results

In Table 1, we report the results of all the methods. It is easy to see that the performance of **Naive** is very limited. **SCL** and **mDA** can outperform the baseline model respectively by 2.7 and 3.7 percentage points on average, which shows that these two methods are useful for domain adaptation based on discrete representations. However, we can also see that the performance of these domain adaptation methods is much lower than the hierarchical neural network model (**HNN**) based on continuous representations. This demonstrates that **HNN** is more robust against domain shift. But comparing the performance of **HNN** in standard in-domain and our cross-domain settings, we find that the in-domain performance still outperforms the cross-domain performance by 6.2 percentage points on average. This indicates that it will be more challenging and useful to develop domain adaptation methods based on such a competitive baseline.

Moreover, we can easily see that the performance of simply appending three-dimensional one-hot vector from the auxiliary task to **HNN** (i.e., **H-WN**) is close to the performance of **HNN** in most cases. In addition, although **SCL** can outperform **Naive** with a large margin on almost all the data set pairs, the performance of **H-SCL** is not satisfactory, which can only improve the baseline by 0.5 percentage point on average. But for **H-mDA**, although the shared hidden representations are also derived from discrete representations, it can improve the performance of **HNN** on all data set pairs except one. This implies that the derived shared hidden representations by **mDA** can generalize better across domains, and are generally useful for domain adaptation. Furthermore, it is easy to observe that by simply incorporating the

Table 1: Comparison of classification accuracies of different methods. † indicates that DSR and DSRW (or SSR and SSRW) are significantly better than HNN, H-WN, H-SCL and H-mDA, DSRE (or SSRE) with $p < 0.05$ based on McNemar’s paired significance test. **In-D** denotes the in-domain setting by splitting each target domain’s labeled reviews into 1400/200/400 as training, development and test sets.

two auxiliary tasks in our earlier work into our two architectures, the performance of **DSRE** is not satisfactory, but **SSRE** can perform the best on average among all the compared systems. This demonstrates that the two auxiliary tasks are more suitable in sentence level, but become less useful in document level, which agrees with the intuition behind our auxiliary task.

Finally, we observe that (1) all of our proposed methods can significantly outperform the baseline **HNN** in almost all the data set pairs, and perform better than **H-WN** and **H-SCL** in most cases, which shows that the idea of learning a hidden representation using our proposed auxiliary tasks is generally effective; (2) even compared with **H-mDA**, **DSR** can achieve comparable results while **SSR**, **DSRW** and **SSRW** can still achieve significantly better performance in most cases. We conjecture that the gains of our methods may come from the sharing between two word embedding lookup tables and joint learning of our auxiliary task and the actual task; (3) in comparison with **DSRE** and **SSRE**, **DSR** and **SSR** can bring improvements in both sentence level and document level on average, which shows the effectiveness of the proposed auxiliary task; (4) among our proposed models, we find that the performance of **DSR** and **SSR** is not stable: sometimes they can achieve the best result, but sometimes they perform even worse than or similar to the baseline **HNN**. In contrast, **DSRW** and **SSRW** can always outperform **HNN**, and perform better than **DSR** and **SSR** on average. This is intuitive since the sentiment scores in **MI**, derived from source la-

beled data, are specific to the source domain, while the sentiment scores in SentiWordNet are general across domains. Besides, we can also see that the gap between **SSR** and **SSRW** is much smaller than the gap between **DSR** and **DSRW**. This suggests that our document-level shared representation learning method is more sensitive to the quality of sentiment lexicons, and with a high quality sentiment lexicon, it can perform best on average.

4.3 Case Study

Finally, to explore how our proposed models help to improve the performance of **HNN** in the test data set, we conduct a case study on **B2D** to get a deeper insight of our model **DSR**.

Specifically, we sample several samples from the test data set, i.e., *DVD*. As shown in Table 2, **HNN** only correctly predicts the sentiment of the first document but gives wrong predictions on another two documents, since *worth watching* only occurs once in the source *Book* domain. However, our model **DSR** can make correct predictions for all of them. The reason is as follows. In Table 2, we can observe that in the unlabeled data from the *DVD* domain, *worth watching* often co-occur with some general positive sentiment words like *good*, *great*, *wonderful* and *fantastic*. Based on these unlabeled documents, **DSR** can implicitly learn that *worth watching* are highly correlated with the positive sentiment via our auxiliary task, and ultimately make correct predictions for the two test samples. This further indicates that compared with **HNN**, our models can identify more domain-specific sentiment words, and there-

Table 2: Examples drawn from **B2D** whose sentiment labels are incorrectly predicted by the baseline model (**HNN**) but correctly inferred by our model (**DSR**). The sentiment words specific to the target domain are in **bold** and *italic*, and the pivot sentiment words are only in **bold**. 0 and 1 denote the negative and positive sentiments respectively.

fore improve the performance.

5 Conclusions

We presented a domain adaptation method for document-level sentiment classification. We first devised a new auxiliary task based on sentiment scores of pivot words. Then, we proposed two neural network architectures to respectively induce shared document embeddings and sentence embeddings across domains. Experiment results show that with a pseudo sentiment lexicon, our methods can achieve comparable results compared with several highly competitive domain adaptation methods; and with an external sentiment lexicon, we can further boost the performance of both architectures to achieve the state-of-the-art result.

Abstract

The things people do in their daily lives can provide valuable insights into their personality, values, and interests. Unstructured text data on social media platforms are rich in behavioral content, and automated systems can be deployed to learn about human activity on a broad scale if these systems are able to reason about the content of interest. In order to aid in the evaluation of such systems, we introduce a new phrase-level semantic textual similarity dataset comprised of human activity phrases, providing a testbed for automated systems that analyze relationships between phrasal descriptions of people's actions. Our set of 1,000 pairs of activities is annotated by human judges across four relational dimensions including similarity, relatedness, motivational alignment, and perceived actor congruence. We evaluate a set of strong baselines for the task of generating scores that correlate highly with human ratings, and we introduce several new approaches to the phrase-level similarity task in the domain of human activities.

1 Introduction

Our everyday behaviors say a lot about who we are. The things we do are related to our personality (Ajzen, 1987), values (Rokeach, 1973), interests (Goecks and Shavlik, 2000), and what we are going to do next (Ouellette and Wood, 1998). While we cannot always directly observe what people are doing on a day-to-day basis, we have access to a large number of unstructured text sources that describe real-world human activity, such as news outlets and social media sites. Fiction and non-fiction writings often revolve around the things that people do, and even encyclopedic texts can

be rich in descriptions of human activities. Although many common sources of text contain human activities, reasoning about these activities and their relationships to one another is not a trivial task. Descriptions of human actions are fraught with ambiguity, subjectivity, and there are multitudinous lexically distinct ways to express highly similar events. If we want to gain useful insights from these data, it should be beneficial to develop effective systems that can successfully represent, compare, and ultimately understand human activity phrases.

In this paper, we consider the task of automatically determining the strength of a relationship between two human activities,¹ which can be helpful in reasoning about texts rich with activity-based content. The relationship between activities might be similarity in a strict sense, such as *watching a film* and *seeing a movie*, or a more general relatedness, such as the relationship between *turn on an oven* and *bake a pie*. Another way to categorize a pair of activities is by the degree to which they are typically done with a similar motivation, like *eating dinner with family* and *visiting relatives*. Or, in order to uncover which other behaviors a person is likely to exhibit, it might be useful to determine how likely a person might be to do an activity given some information about previous real-world actions that they have taken.

Success on our proposed task will be a valuable step forward for multiple lines of research, especially within the computational social sciences where human behavior and its relation to other variables (e.g., personality traits, personal values, or political orientation) is a key focus. Since the language human activities is so varied, it is not enough to store exact representations of activity

¹Throughout this paper, we use the word “activity” to refer to what a person does or has done. Unlike the typical use of this term in the computer vision community, in this paper we use it in a broad sense, to also encompass non-visual activities such as “make vacation plans” or “have a dream”.

phrases that are unlikely to appear many times. It would be useful to instead have methods that can automatically find related phrases and group them based on one (or more) of several dimensions of interest. Moreover, the ability to automatically group related activities will also benefit research in video-based and multimodal human activity recognition where there is need for inference about activities based on their relationships to one another.

Reasoning about the relationships between activity phrases brings with it many of the difficulties often associated with phrase-level semantic similarity tasks. It is not enough to know that the two phrases share a root verb, as the semantic weight of verbs can vary, such as the word “go” in the phrases *go to a bar* and *go to a church*. While these phrases have high lexical overlap and are similar in that they both describe a traveling type of activity, they are usually done for different motivations and are associated with different sets of other activities. In this case, we could only consider the main nouns (i.e., “bar” and “church”), but that approach would cause difficulties when dealing with other phrases such as *sell a car* and *drive a car*, which both involve an automobile but describe dissimilar actions. Therefore, successful systems should be able to properly focus on the most semantically relevant tokens with a phrase. A final challenge when dealing with human activity phrase relations is evaluation. There should be a good way to determine the effectiveness of a system’s ability to measure relations between these types of phrases, yet other commonly used semantic similarity testbeds (e.g., those presented in various Semeval tasks (Agirre et al., 2012, 2013; Marelli et al., 2014)) are not specifically focused on the domain of human activities. Currently, it is unclear whether or not the top-performing systems on general phrase similarity tasks will necessarily lead to the best results when looking specifically at human activity phrases.

To address these challenges, we introduce a new task in automatically identifying the strength of human activity phrase relations. We construct a dataset consisting of pairs of activities reportedly performed by actual people. The pairs that we have collected aim specifically to showcase diverse phenomena such as pairs containing the same verb, a range of degrees of similarity and relatedness, pairs unlikely to be done by the same type of person, and so forth. These pairs are each annotated by multiple human judges across the

following four dimensions:

- **Similarity:** The degree to which the two activity phrases describe the same thing. Here we are seeking semantic similarity in a strict sense. Example of high similarity phrases: *to watch a film* and *to see a movie*.
- **Relatedness:** The degree to which the activities are related to one another. This relationship describes a general semantic association between two phrases. Example of strongly related phrases: *to give a gift* and *to receive a present*.
- **Motivational Alignment:** The degree to which the activities are (typically) done with similar motivations. Example of phrases with potentially similar motivations: *to eat dinner with family members* and *to visit relatives*.
- **Perceived Actor Congruence:** The degree to which the activities are often done by the same type of person. Put another way, does knowing that a person often performs an activity increase human judges’ expectation that this person will also often do a second activity? Example of activities that might be expected to be done by the same person: *to pack a suitcase* and *to travel to another state*.

These relational dimensions were selected to cover a variety of types of relationships that may hold between two activity phrases. This way, automated methods that capture slightly different notions of similarity between phrases will potentially be able to perform well when evaluated on different scales. While the dimensions are correlated with one another, we show that they do in fact measure different things. We provide a set of benchmarks to show how well previously successful phrase-level similarity systems perform on this new task. Furthermore, we introduce several modifications and novel methods that lead to increased performance on the task.

2 Related Work

Semantic similarity tasks have been recently dominated by various methods that seek to embed segments of text as vectors into some high-dimensional space so that comparisons can be made between them using cosine similarity or other vector based metrics. While word embeddings have existed in various forms in the past (Church and Hanks, 1990; Bengio et al., 2003),

many approaches used today draw inspiration directly from shallow neural network based models such as those described in (Mikolov et al., 2013).² In the common skip-gram variant of these neural embedding models, a neural network is trained to predict a word given its context within some fixed window size. (Levy and Goldberg, 2014a) and (Bansal et al., 2014) extended the idea of context to incorporate dependency structures into the training process, leading to vectors that were able to better capture certain types of long-distance syntactic relationships. One of the major strengths of neural word embedding methods is that they are able to learn useful representations from extremely large corpora that can then be leveraged as a source of semantic knowledge on other tasks of interest, such as predicting word analogies (Pennington et al., 2014) or the semantic similarity and relatedness of word pairs (Huang et al., 2012).

Researchers have taken the powerful semi-supervised ability of these word embedding methods to aid in tasks at the phrase-level, as well. The most straightforward way to accomplish a phrase-level representation is to use some binary vector-level operation to compose pre-trained vector representations of individual words that belong to a phrase (Mitchell and Lapata, 2010). Other methods have sought to directly find embeddings for larger sequences of words, such as (Le and Mikolov, 2014) and (Kiros et al., 2015).

Semantic textual similarity tasks are often evaluated by computing the correlation between human judgements of similarity and machine output. The wordsim353 (Finkelstein et al., 2001) and simlex999 (Hill et al., 2016) resources provide a set of human annotated pairs of words, labeled for similarity and/or general association. Simverb-3500 (Gerz et al., 2016) was introduced to provide researchers with a testbed for verb relations, a specific yet important class of words that was less common in earlier word-level similarity data sets. SemEval has released a series of semantic text similarity tasks at varying levels of granularity, ranging from words to entire documents, such as the SICK (Sentences Involving Compositional Knowledge) dataset (Marelli et al., 2014) which is specifically crafted to evaluate the ability of systems to effectively compose individual word semantics in order to achieve the overall meaning of

²It is worth noting that (Levy and Goldberg, 2014b) show that these embeddings are actually implicitly factorizing a shifted version of a more traditional PMI word-context matrix, which is similar to the word co-occurrence matrix factorization approach used in (Pennington et al., 2014)).

a sentence. While many of these evaluation sets contain human activities to some degree, they also have contain other types of words or phrases due to the way in which they were created. For example, SICK contains actions done by animals such as *follow a fish*. Similarly, Simverb-3500 contains verbs that don't necessarily describe human activities, like *chirp* and *glow*, and does not contain phrase-level activities.

Several recent works have raised concerns over the standard evaluation approaches used in semantic textual similarity tasks. One potential issue is the use of inadequate metrics depending on the task that a practitioner is interested in tackling. While the Pearson correlation between human-judged similarity scores and predicted outputs is often used, this type of correlation can be misleading in the presence of outliers or nonlinear relationships (Reimers et al., 2016). Reimers et al. propose a framework for selecting a metric for semantic text similarity tasks, which we take into consideration when selecting our evaluation metric. Additionally, correlation with human judgments does not always give a good indication of success on some downstream applications, the human ratings themselves are somewhat subjective, and statistical significance is rarely reported in comparisons of word embedding methods (Faruqui et al., 2016). However, our goal in this work is not to evaluate the overall quality of distributional semantic models, but to find a method that has high utility in the domain of human activity relations, and so we do rely on comparisons with human judges as a means of assessment.

3 Data Collection and Annotation

One potential source of data containing people's self-reported descriptions of their activities is social media platforms, but these data are noisy and require preprocessing steps that, being imperfect, may propagate their own errors into the resulting data. In order to get a set of cleaner activities that people might actually talk about doing, we directly asked Amazon Mechanical Turk (AMT) workers to write short phrases describing five activities that they had done in the past week. We collected data from 1,000 people located in the United States for a total of 5,000 activities. The activity phrases were then normalized by converting them to their infinitive form (without a preceding "to"), correcting spelling errors, removing punctuation, and converting all characters to lowercase.

Activity	Prompt	User Selection
pay the phone bill	an activity that is EXTREMELY SIMILAR	pay one’s student loan bill
play softball	an activity that is SOMEWHAT SIMILAR	go bowling
take a bath	an activity that uses the SAME VERB	take care of one’s ill spouse
smoke	an activity that is RELATED, but not necessarily SIMILAR	get sick and go to the doctor
go out for ice cream	an activity that is NOT AT ALL SIMILAR	cash a check

Table 1: Examples of activity/prompt pairs and the corresponding activities that were selected by the annotators given the pair.

After removing duplicate entries (about 2,000) and any phrases referring specifically to doing work on AMT (e.g., those containing the tokens mTurk or Turkling, about 150 cases), we were left with a set of 2,909 unique activity phrases.

We acknowledge that this methodology introduces some bias since the workers all come from the United States, and it is therefore likely that our set of activity phrases describe things that are more commonly done by Americans than people from other regions. Furthermore, primacy and recency effects (Murdock Jr, 1962) may bias the types of items listed toward things done in the morning or just before logging onto the AMT platform. Based on this, we expect that our set of activities is not necessarily a representative sample of everything that people might do, but they are still descriptions of actual activities that real humans have done and are useful for our task.

3.1 Forming Pairs of Activities

Next, we sought to create pairs of activities that showcase a variety of relationship types, including varying degrees of similarity and relatedness. To achieve this, we turned to another group to human annotators. After reading through a document which oriented them to the task, the annotators were given the full list of activities in addition to a subset of randomly selected activity phrases. Each of these phrases was randomly paired with one of several possible prompts (see Table 1 for examples) which instructed the annotators how they should select a second activity phrase from the complete list in order to form a pair. Each prompt was sampled an equal number of times in order to make sure that the final set of pairs exhibited various types of relationships to the same degree. All annotators had access to a searchable copy of the full list, but the order of the activities was shuffled each time in order to avoid potential bias from the annotators selecting phrases near the top of the list, and a new shuffled version of the list was given after every 25 pairs created. While a suitable second activity phrase was not always present (e.g.,

no phrase in our dataset matches “an activity that uses the SAME VERB” as *choreograph a dance*), it is not crucial that all of these pairs fit the prompts exactly since these are only intended to approximate various phenomena, and the final annotations will be done without the knowledge of the prompts used to generate the pairs. In total, 12 unique annotators created 1,000 pairs of phrases.

3.2 Annotating Activity Pairs

All of the activity phrase pairs were uploaded to AMT in order to be labeled. For each pair, ten workers were asked to rate the similarity, relatedness, motivational alignment, and perceived actor congruence on a 5-point Likert-type scales (a total of 40,000 annotated data points). The workers were given a set of instructions that included descriptions of the four types of relationships with examples, including cases in which a pair might be related but not similar, motivationally aligned but not similar, etc. By asking the same set of people to label all four relational dimensions for a given pair, we hoped to make them cognizant of the differences between the scales.

The first three relationships were prompted for using the form: “To what degree are the two activities similar/related/of the same motivation?” and were coded as 0 (e.g., for responses of “not at all similar”) and the integers 1–4 with 4 representing the strongest relationship. Perceived actor congruence was solicited for using the form: “Person A often does *activity 1*, while person B rarely does *activity 1*. Who would you expect to do *activity 2* more often?” with choices ranging from “Most likely Person B” to “Most likely Person A.” Perceived actor congruence ranges from -2 to 2 and has the lowest score when Person B is chosen and the highest when Person A is chosen. A score of 0 on this scale means that judges were unable to determine whether Person A or Person B would be more likely to perform the action being asked about (i.e., *activity 2*). Each individual Human Intelligence Task (HIT) posted to AMT required an annotator to label 25 pairs so that we could reliably

Activity 1	Activity 2	SIM	REL	MA	PAC
go jogging	lift weights	1.67	2.22	2.89	1.11
read to one's kids	go to a bar	0	0	0	-1.29
take transit to work	commute to work	3.38	3.5	3.38	0.5
make one's bed	organize one's desk	0.58	1.29	1.57	0.71

Table 2: Sample activity phrase pairs and average human annotation scores given for the four dimensions: Similarity (SIM), Relatedness (REL), Motivational Alignment (MA) and Perceived Actor Congruence (PAC). SIM, REL, and MA are on a 0-4 scale, while PAC scores can range from -2 to 2.

	SIM	REL	MA	PAC
SIM	1.000	.962	.928	.735
REL		1.000	.932	.776
MA			1.000	.738
PAC				1.000

Table 3: Spearman correlations between the four relational dimensions: Similarity (SIM), Relatedness (REL), Motivational Alignment (MA) and Perceived Actor Congruence (PAC).

compute agreement, and a worker could complete as many HITS as they desired.

To remove potential spammers (annotators seeking quick payment who do not follow the task instructions), we first eliminated all annotations by any AMT workers who left items blank or selected the same score for every item for any of the four relationships in any of their completed HITS. Then, inter-annotator agreement was computed by calculating the Spearman correlation coefficient ρ between each annotator's scores and the average scores of all other AMT workers who completed the HIT, excluding those already thrown out during spammer removal. We then removed any annotations from workers whose agreement scores were more than three standard deviations below the mean agreement score for the HIT under the assumption that these workers were not paying attention to the pairs when selecting scores.

The final scores for each pair were assigned by taking the average AMT worker score for each relationship type. Some sample activities and their ratings are shown in Table 2. Averaged across all four relationship types, there is a good level of inter-annotator agreement at $\rho = .720$ (recomputed after spammer removal). The highest levels of agreement were found for similarity and relatedness ($\rho = .768$ for both), which is to be expected as these are somewhat less subjective than motivational alignment ($\rho = .745$) and perceived actor congruence ($\rho = .620$). These agreement scores can be treated as an upper bound for performance on this task; achieving a score higher than

SIM	REL	Activity 1	Activity 2
↑	↑	call one's mom	call dad
↑	↓	-	-
↓	↑	rake leaves	mow the lawn
↓	↓	go for a run	shop at a thrift store
SIM	MA	Activity 1	Activity 2
↑	↑	check facebook	check twitter
↑	↓	drive to missouri	go on a road trip
↓	↑	write a romantic letter	kiss one's spouse
↓	↓	cut firewood	trim one's beard
SIM	PAC	Activity 1	Activity 2
↑	↑	make a cherry pie	bake a birthday cake
↑	↓	have dinner with friends	eat by oneself
↓	↑	go to the gym	take a shower
↓	↓	read a novel	go to a party
REL	MA	Activity 1	Activity 2
↑	↑	gamble	go to the casino
↑	↓	go swimming	clean the pool

↓	↓	study abstract algebra	go to the state fair
REL	PAC	Activity 1	Activity 2
↑	↑	eat cereal	eat a lot of food
↑	↓	homeschool one's child	drive one's child to school
↓	↑	cut the grass	talk to neighbors
↓	↓	eat at a restaurant	cook beans from scratch
MA	PAC	Activity 1	Activity 2
↑	↑	go to the dentist	brush one's teeth
↑	↓	take the train to work	drive to work
↓	↑	walk one's dog	walk to the store
↓	↓	read	watch football all day

Table 4: Activity pairs from our dataset highlighting stark differences between the four relational dimensions. For each dimension, ↑ refers to phrases rated at least one full point above the middle value along the Likert scale, while ↓ indicates a score at least one full point below the middle value. No pairs with high similarity and low relatedness exist in the data.

these would mean that an automated system is as good at ranking activity phrases as the average human annotator.

3.3 Relationships Between Dimensions

While the four relationship types being measured are correlated with one another (Table 3.2), there were certainly cases in which humans gave different scores for each relationship type to the same pair which shed light on the nuanced differences between the dimensions. (Table 4). Therefore, it is not necessarily the case that the best method for capturing one dimension is also the most corre-

lated with human judgements across all four dimensions. However, it appears that similarity, relatedness, and motivational alignment are more highly correlated with one another than perceived actor congruence.

4 Methods

To determine how well automated systems are able to model humans' judgements of similarity, relatedness, motivational alignment, and perceived actor congruence, we evaluate a group of semantic textual similarity systems that are either commonly used or have shown state-of-the-art results. Each method takes two texts of arbitrary length as input and produces a continuous valued score as output. All of the methods are trained on outside data sources and many have been proposed as generalized embeddings that can be successful across many tasks. The methods we assess fall into three different categories: Composed Word-level Embeddings, Graph-based Embeddings, and Phrase-level Embeddings.

Activity Phrase Pre-processing. For the first two classes of methods, we experiment with several variations in the set of words being passed to the model as input in order to remove the influence of potentially less semantically important words. We do not apply these pre-processing approaches to the phrase-level embedding methods since those methods are designed specifically to operate on entire phrases (as opposed to the bag-of-words view that the other methods take). The five variations of each phrase we consider are:

Full: The original phrase in its entirety.

Simplified: Starting with the Full phrase, we remove several less semantically relevant edges from a dependency parse³ of the phrase, including the removal of determiners, coordinating conjunctions, adjectival modifiers, adverbs, and particles. This step is somewhat similar to performing stopword removal. For example, this filtering step would result in the bag of words containing “clean”, “living” and “room” for full phrase: *clean up the living room*.

Simplified - Light Verbs: Starting with the Simplified set of words, we remove the root verb of the activity if it is not the only word in the Simplified phrase and if it belongs to the following list of semantically light verbs (Kearns, 1988): “go”, “make”, “do”, “have”, “get”, “give”, “take”, “let”, “come”, and “put”. This means that we would

³We use the dependency parser from Stanford CoreNLP (<http://stanfordnlp.github.io/CoreNLP/>).

convert the phrase *go get a tattoo* to just *get a tattoo*, but *read a novel* would retain its verb and become *read novel* (i.e., it will remain equivalent to the Simplified variation).

Simplified - All Verbs: To compare against the effect of removing light verbs, this approach takes the Simplified phrase and removes the root verb unless the Simplified phrase only contains that one word. Performing this filtering step would convert the phrase *cook a sausage* to simply *sausage*.

Core: This method seeks to reduce the phrase to a single core concept. In many cases, this means simply using the root verb from the dependency parse. So, we might represent the phrase “clean up the living room” using only the word embedding for “clean”. However, we acknowledge that semantically light verbs such as “go”, “have”, and “do” would not adequately represent an entire activity, and so in the case of light verbs we instead select either the direct object or a nominal modifier that is connected to the root verb. If the noun selected as the core concept has another noun attached by a compound relationship, we also include that noun. This means, for example, that we would represent the phrase “go to an amusement park” as just “amusement park” when we are considering just the core concept.

4.1 Composed Word-level Embeddings

The methods in this section are based on word-level embeddings trained on some outside data. Since they operate at a word level, we apply a composition function to the words in a given phrase in order to achieve an embedding for the phrase. We tested both the arithmetic mean and element-wise multiplication for composition functions, but the former gave better performance and thus we do not report results found when using the element-wise product. Given an aggregate embedding for a phrase, we generate a score for each pair of activity phrases by computing the cosine similarity between the embeddings for the two phrases. We consider the following word-level methods:

Wiki-BOW: Skip Gram with Negative Sampling Word Embeddings trained on Wikipedia data using a context window of size 2 (Wiki-BOW2) and size 5 (Wiki-BOW5). These vectors are the same ones used in (Levy and Goldberg, 2014a).

Wiki-DEP: Skip Gram with Negative Sampling Word Embeddings trained on Wikipedia data with dependency-based contexts (Wiki-DEP) from (Levy and Goldberg, 2014a).

GoogleNews: Skip Gram with Negative Sampling Word Embeddings trained on the Google News

corpus from (Mikolov et al., 2013).

Paragram: Embeddings trained on the Paraphrase Database (Ganitkevitch et al., 2013) by fitting the embeddings so that the difference between the cosine similarity of actual paraphrases and that of negative examples is maximized (Wieting et al., 2015). We use the Paragram-Phrase XXL embeddings combined with the Paragram-SL999 embeddings, the latter of which has been tuned on SimLex999 (Hill et al., 2016). We also use a variation of Paragram Embeddings that employs counter fitting (Paragram-CF). This method further tunes the Paragram embeddings to capture a more strict sense of similarity rather than general association between words. This is accomplished via optimization with the goal of increasing the vectorspace differences between known antonyms and altering synonym embeddings to make them more similar to one another (Mrkšić et al., 2016).

Nondistributional vectors: Highly sparse vectors that encode a huge number of binary variables that capture interesting features about the words such as part of speech, sentiment, and supersenses (Faruqui and Dyer, 2015).

4.1.1 Graph-Based Embeddings

We also experiment with approaches that seek to incorporate higher order relationships between activity phrases by building semantic graphs that can be exploited to discover relations that hold between the phrases. Each graph G is of the form $G = (V, E)$ where V is a set of human activity phrases and E is some measure of semantic similarity, which is computed differently depending on the graph type. We run Node2vec (Grover and Leskovec, 2016) using the default settings to generate an embedding for each node in the graph and then measure the cosine similarity between nodes (phrases) to get the final system output. The types of graphs that we use are:

Similarity Graph: We first generate a fully connected graph of all activities in our dataset using a high performing semantic similarity method (Paragram in this case) as a way to generate edge weights. Next, we prune all edges with a weight less than some threshold. The results reported here use a threshold of .5 (on a 0-1 continuous scale). We also tried threshold values of .3, .4, and .6., but found them to produce inferior results for all dimensions.

People Graph: For each activity, we know at least four other activities that were done by the same person because each person submitted five activities. We add an unweighted edge to the graph

for each pair of activities that were done by the same person. On its own, this graph does not have enough information to be competitive, so we only report results for the combined graph.

Combined Graph: Here, we combine information from both the Similarity Graph and the People Graph. Since the People Graph is unweighted, we follow the approach used in (Tripodi and Pelillo, 2016) and compute the average weight of all edges in the Similarity Graph and assign this weight to all edges in the People Graph. We then add the edge weights of the two graphs, treating non-existent edges as edges with weight 0.

4.1.2 Phrase-level Embeddings

The methods in this section are designed to create an embedding directly from phrases of arbitrary length. Since these approaches are tailored toward phrases in their entirety, we do not evaluate them on the pre-processed variations of the phrases in our dataset. The phrase-level approaches we consider are:

Skip-thoughts vectors: This encoder-decoder model induces sentence level vectors by learning to predict surrounding sentences of each sentence in a large corpus of books (Kiros et al., 2015). The encoder is a recurrent neural network (RNN) which creates a vector from the words in the input sentence, and the RNN decoder generates the neighboring sentences. The model also learns a linear mapping from word-level embeddings into the encoder space to handle rare words that may not appear in the training corpus.

Charagram embeddings: Embeddings that represent character sequences (i.e., words or phrases) based on an elementwise nonlinear transformation of embeddings of the character n-grams that comprise the sequence (Wieting et al., 2016). Here we use the pre-trained charagram-phrase model.

5 Results

Because human annotations should fall on an ordinal scale rather than a ratio scale, it would not be fair to directly compare the average values human judges gave to the systems' output. Rather, the systems should be evaluated based on their ability to rank the set of phrases in the same order as the ranking given by the average human annotations scores for each dimension. Therefore, we calculate the Spearman Rank correlation between scores given by the automated systems and the human judges our final score for each system. In a previous study of evaluation metrics for intrinsic semantic textual similarity tasks, this metric was

Table 5: Spearman correlation between phrase similarity methods and human annotations across four annotated relations: Similarity (SIM), Relatedness (REL), Motivational Alignment (MA) and Perceived Actor Congruence (PAC). Top performing methods for each dimension are in bold font. * indicates correlation coefficient is not statistically significantly lower than the best method for that relational dimension ($\alpha = .05$).

recommended for tasks in which the ranking of all items is important (Reimers et al., 2016). Results for all methods using all phrase variations are shown in Table (Table 5).

For our dataset, Paragram in the Simplified - Light Verbs setting gives the best results for similarity, relatedness, and motivational alignment. It is somewhat expected that the same method has the best performance for these three dimen-

sions as they are strongly correlated with one another. Paragram in the Simplified - All Verbs setting gives the best result on perceived actor congruence. We can see that removing light verbs is a helpful step for most methods when trying to predict similarity, relatedness, and motivational alignment indicating that light verbs mostly add noise to the overall meaning of the phrases. Interestingly, the best results for perceived actor congruence come when ignoring all root verbs in longer phrases. This was a filtering step that led to decreased performance when ranking across the other three dimensions. This suggests that for determining perceived actor congruence, the context of the action found within a phrase is more important than the action itself. Based on statistical significance testing (Z-test using Fisher r-z transformation, single-tailed), however, we cannot be confident that all of these results will hold for larger sets of human activity phrase pairs, as several other methods had scores that were not found to be significantly lower than the best methods.

6 Conclusion

In this paper, we addressed the task of measuring semantic relations between human activity phrases. We introduced a new dataset consisting of human activity pairs that have been annotated based on their similarity, relatedness, motivational alignment, and perceived actor congruence. Using this dataset, we evaluated a number of semantic textual similarity methods to automatically determine scores for each of the four dimensions, and found that similarity between averaged paragram embeddings of the simplified phrases with light verbs removed was most highly correlated with human judgements of similarity, relatedness, and motivational alignment. The method that yielded the best result for the perceived actor congruence dimension also used the paragram embeddings, but when averaged across the simplified phrases with all verbs removed.

We believe there is still plenty of room for improvement on this task, and we hope that the release of our data will encourage greater participation on this task. Future work should explore methods to handle more subtle semantic differences between activities that we noticed are often missed by the automated methods including the effects of function words and polysemy. It should also be helpful to learn better weight-based composition methods (e.g., those proposed in (Yu and Dredze, 2015)) rather than filtering out words in a

rule-based fashion.

We make our dataset, including all activity pairs and averaged human ratings, publicly available at <http://lit.eecs.umich.edu/downloads.html>.

Abstract

Typically, relation extraction models are trained to extract instances of a relation ontology using only training data from a single language. However, the concepts represented by the relation ontology (e.g. *ResidesIn*, *EmployeeOf*) are language independent. The numbers of annotated examples available for a given ontology vary between languages. For example, there are far fewer annotated examples in Spanish and Japanese than English and Chinese. Furthermore, using only language-specific training data results in the need to manually annotate equivalently large amounts of training for each new language a system encounters. We propose a deep neural network to learn transferable, discriminative bilingual representation. Experiments on the ACE 2005 multilingual training corpus demonstrate that the joint training process results in significant improvement in relation classification performance over the monolingual counterparts. The learnt representation is discriminative and transferable between languages. When using 10% (25K English words, or 30K Chinese characters) of the training data, our approach results in doubling F1 compared to a monolingual baseline. We achieve comparable performance to the monolingual system trained with 250K English words (or 300K Chinese characters) With 50% of training data.

1 Introduction

Semantic relation extraction is critical to many applications including knowledge base population and question answering. The problem is well-studied when relation-specific annotations are available in a single target language. However, the same relations can be represented using a variety of languages. While the evidence of the relation in context is language specific (e.g. *John spent several years living in Beijing* vs *约翰在北京生活了几年*), the definition of relation itself is often language independent (e.g. *ResidesIn*) and the meaning should be preserved across languages.

We hypothesize that common, shared representation can be learnt when annotations are available in multiple languages and propose a bilingual relation extraction algorithm for this purpose. Our basic building blocks are Convolutional Neural Networks (CNN) with cross-lingual word embeddings (Ammar et al., 2016). This allows the system to capture lexical similarities across languages as well as phrase-level semantics. Building on CNNs with cross-lingual embeddings, the algorithm is a joint training algorithm which trains a model from annotated datasets in a pair of languages. We require that the annotated classes be consistent across languages, but do not require annotations over parallel (or comparable) text. The base system combines two objectives: an objective that predicts the correct relation labels in each dataset in one of the languages, and another objective to separately learn a shared representation across languages as well as language-specific representations. To further force the learnt representation to be discriminative among classes regardless of language, a discriminative objective for learning the ideal representation (Section 3.3) is added onto the shared, bilingual representation.

The final combined algorithm essentially learns two types of useful representations: a language-independent relation-specific representation with the shared neurons, and a language-dependent relation-specific representation with the language-specific neurons.

Our contributions are the following:

- Developing a bilingual transfer learning algorithm for relation extraction that can use independent multilingual corpora annotated with the same set of relations. Analysis shows that the representation is discriminative.
- Demonstrating that jointly training from two languages outperforms its monolingual counterparts significantly.
- Showing that knowledge can be transferred from resource-rich language to resource-poor languages: On the ACE multilingual training corpus, we achieve comparable performance with 50% of the target-language training data using our approach and are able to double performance with only 10% (250K words) of target language data. This provides a very cost effective way to develop relation extractors in new languages.

2 Related Work

Relation extraction is typically cast as a multi-class classification problem in which a supervised machine learning model is trained with labeled datasets for classifying relations. Traditional methods (Kambhatla, 2004; Zhou et al., 2005; Zhao and Grishman, 2005; Jiang and Zhai, 2007) either rely on a set of linguistic or semantic features, or use convolution tree kernels (Moscitti, 2006) with syntactic (Zhang et al., 2006), sub-sequence (Bunescu and Mooney, 2005b), or dependency trees (Bunescu and Mooney, 2005a) as means to represent input sentences. Recently, deep neural networks start to show promising results in relation extraction. In particular, Convolutional Neural Networks (Zeng et al., 2014a; dos Santos et al., 2015; Nguyen and Grishman, 2015), Recurrent/Recursive Neural Networks such as bidirectional LSTMs (Zhang et al., 2015), LSTM along shortest dependency paths (Xu et al., 2015), bidirectional tree-structured LSTM-RNNs (Miwa and Bansal, 2016) are shown to be effective. Attention mechanism (Wang et al., 2016) is also effective in further improving performance. Our baseline monolingual model is similar to (Nguyen and Grishman, 2015) and we do not require

parsing or composing multiple models.

There is very little work on multilingual relation extraction. (Qian et al., 2014) proposed an active learning approach for bilingual relation extraction with pseudo parallel corpora. (Kim et al., 2010) and (Kim et al., 2014) proposed cross-lingual annotation projection approach for relation detection with parallel corpora. In contrast, our work doesn't require parallel corpora nor Machine Translation. More recently, (Faruqui and Kumar, 2015) applied cross-lingual projection for open-domain relation extraction in languages other than English. (Blessing and Schütze, 2012) and Compositional Universal Schema (Verga et al., 2016) performs cross-lingual relation extraction with distant supervision (Mintz et al., 2009; Riedel et al., 2010; Surdeanu et al., 2012; Hoffmann et al., 2011; Ritter et al., 2013). These works are significantly different from ours in that they either operate in the open-domain (Faruqui and Kumar, 2015) without a pre-defined relation schema, or in a distant supervision setting with a KB as source of supervision. POLY (Nakashole et al., 2012) mines relational paraphrases from multilingual sentences which can be useful for relation extraction.

Besides relation extraction, (Huang et al., 2013) performs cross-language knowledge transfer with deep neural networks for speech recognition. (Guo et al., 2016) proposed a distributed representation-based framework for cross-lingual transfer learning for dependency parsers.

3 Bilingual Relation Extraction

Given a pair of monolingual corpora in two different languages and each corpus having been annotated with sentence-level relations¹ of pre-defined types, the goal of bilingual relation extraction is to learn *discriminative* representations to identify the relation between a pair of mentions, regardless of which language the mention pair comes from (*transferable across languages*). We achieve the goal of learning discriminative representation by joint supervision of classification (softmax) loss and ideal representation loss. We achieve the additional cross-lingual transferring goal by learning shared representation across languages.

As shown in Figure 1, our CNN-based bilingual relation extraction model consists of 4 main parts: (1) an embedding layer to encode words (in bilingual space), word positions, entity types and

¹A sentence with a pair of mentions will be annotated with a relation, if the relation holds between the pair of mentions.

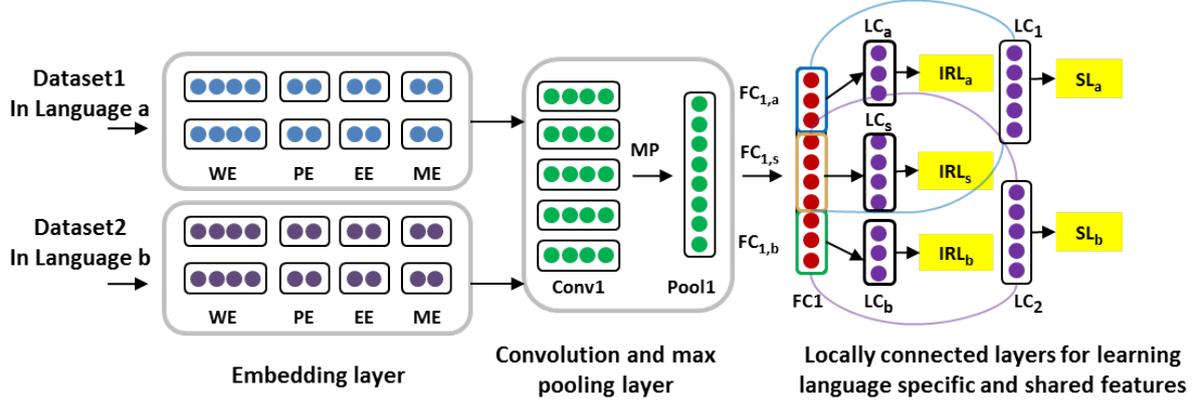

Figure 1: Bilingual relation extraction model trained with both softmax classification loss (SL) and ideal representation loss (IRL). IRL_a and IRL_b are language-specific ideal representation losses for language a and b respectively. IRL_s is the shared representation loss across 2 languages. $FC_{1,a}$ and $FC_{1,b}$ are 2 sets of language-specific neurons for language a and b , respectively. $FC_{1,s}$ is a set of shared neurons. SL_a and SL_b are the softmax classification losses for language a and b respectively.

mention levels by real-valued vectors; (2) a convolution and max pooling layer to generate a fixed-size feature vector for an input sentence; (3) 3 locally connected (LC) layers for learning language-specific and shared representations. These layers are learned to predict discriminative representation using proposed ideal representation loss (IRL) during training; (4) 2 LC layers for learning 2 relation classifiers with the softmax loss (SL). The 5 LC layers and the 5 prediction losses (3 IRLs and 2 SLs) are illustrated in Figure 1.

3.1 Embedding Layer

Word embeddings (WE) The inputs are sentences marked with pairs of mentions of interest. Given an input sentence \mathbf{x} of length t , we firstly transform each word into a real-valued vector of dimension d_1 by looking up a word embedding matrix $W^1 \in \mathbb{R}^{d_1 \times |V|}$, where V is a fixed-sized vocabulary. To project similar words in a pair of languages into close proximity, we use cross-lingual embedding trained with multiCCA (Ammar et al., 2016) to initialize W^1 . W^1 will also be finetuned during training.

MultiCCA only requires two monolingual corpora and a bilingual parallel dictionary. It first trains monolingual embeddings for each language independently from each monolingual corpus, capturing semantic similarity within each language. Then given the dictionary, it applies canonical correlation analysis (CCA) to estimate linear projections from the monolingual embeddings to bilingual embeddings. This makes translationally equivalent words in different languages to be embedded nearby each other.

Position embeddings (PE) The words close to the argument mentions are more informative to determine the relationship. Similar to (Santos et al., 2015), for each word, we map its relative distances to two argument mentions to two real-valued vectors of dimension d_2 by a embedding matrix $W^2 \in \mathbb{R}^{d_2 \times |D|}$, where D is the set of relative distances in a dataset. We obtain two vectors for each word with respect to the first and the second argument of the relation mention.

Entity type embeddings (EE) and mention level embeddings (ME) For each word, we map its entity type and mention level into real-valued vectors using embedding matrix $W^3 \in \mathbb{R}^{d_3 \times |E|}$ and $W^4 \in \mathbb{R}^{d_4 \times |M|}$ respectively. E is the set of entity types while M is the set of mention levels.

The final embedding dimension for each token is $n_1 = (d_1 + 2d_2 + d_3 + d_4)$. This layer will produce an embedding representation $\mathbf{x}^{(1)} \in \mathbb{R}^{n_1 \times t}$ when fed with an input sentence $\mathbf{x}^{(0)} = \mathbf{x}$. W^1, W^2, W^3, W^4 are parameters to be learnt via the end-to-end model.

3.2 Convolution and Max Pooling Layer

Relations can be expressed by words or their combinations. The model should utilize all local features extracted around each word in the sentence and predict the relation globally. Convolution operation is a natural approach to achieve this goal (Zeng et al., 2014b; Santos et al., 2015). Given a convolution filter i of window size k , the convolution operation on an input sentence \mathbf{x} will produce a score vector $\mathbf{z} = (z_1, \dots, z_{(t-k+1)})$, where $z_j = g_1(\mathbf{w}_i \mathbf{x}_j + b_i)$. $\mathbf{w}_i \in \mathbb{R}^{kn_1}$ are the linear transform parameters for filter i , \mathbf{x}_j denotes the

j -th context window in \mathbf{x} , b_i is a bias scalar and g_1 is a non-linear function such as the rectified linear unit (ReLU). Then the max operation is applied to identify the most informative n -gram feature from this score vector: $m_i = \max(\mathbf{z})$. We replicate this process for a set of filters with different window sizes to capture important n -gram features from an input sentence. The matrix $W^{(2)} = [\mathbf{w}_1, \dots, \mathbf{w}_{n_2}]$, where n_2 is the total number of filters, and vector $\mathbf{b}^{(2)} = [b_1, \dots, b_{n_2}]$ are parameters to be learnt in this convolution layer. Finally we obtain a fixed-sized feature vector $\mathbf{x}^{(2)} = \mathbf{m} = [m_1, \dots, m_{n_2}] \in \mathbb{R}^{n_2}$. The representation $\mathbf{x}^{(2)}$ is generated by taking max pooling over entire sentence with filters of multiple window sizes. To prevent these neurons that generate \mathbf{m} from co-adapting and force them to learn individual useful features, a dropout layer is added after the pooling layer for regularization.

We added a fully connected layer to combine information captured by these filters: $\mathbf{x}^{(3)} = g_2(W^{(3)}\mathbf{x}^{(2)} + \mathbf{b}^{(3)}) \in \mathbb{R}^{n_3}$. $W^{(3)}$ and $\mathbf{b}^{(3)}$ are parameters learnt in this layer, and g_2 is a non-linear function.

3.3 Learning Transferable, Discriminative Bilingual Representation

Given two sets of training examples X^a and X^b in two languages a and b , we aim at learning transferable, discriminative bilingual representations. We achieve this by weight sharing at a high-level layer. We further improve the discriminative power of learnt representations using ideal representation loss. The bilingual representation learning model is shown in Figure 1.

Shared and Language-specific Neurons We aim at not only learning representation shared by both languages, but also learning representation specific to each language. We partition the neurons in the $FC1$ layer into three disjoint sets: two language-specific sets ($FC_{1,a}$ and $FC_{1,b}$) and a shared bilingual set $FC_{1,s}$ to represent shared features across languages. We expect that $FC_{1,a}$ and $FC_{1,b}$ can model language-specific features, while the common set $FC_{1,s}$ can model the share features.

Discriminative Representation Learning As described in (Zeiler and Fergus, 2014; Krizhevsky et al., 2012), the neurons from high-level layers of a CNN tend to extract more abstract and class-specific features. If each neuron in a high-level layer of our CNN activates only when a specific relation is presented, this will lead to a discrimi-

native representation for relations. Such representation, when learnt across language, would be extremely useful for transferring useful information across languages for relation extraction.

To achieve this, we partition the neurons in each high-level layer into subsets, and encourage each subset to only represent sentences of one of the relation types. This results in an explicit correspondence between blocks of neurons and relation types. Specifically, we partition the neurons in each sub-layer (*i.e.*, LC_a , LC_b and LC_s) into disjoint subsets and associate each subset with one specific relation label. For sentences of different relation types, we represent them using disjoint subsets of neurons. To do so, we integrate the ideal representation loss introduced in (Jiang et al., 2011) into our objective function during training. Let $(\mathbf{x}_i; y_i)$ denote training example \mathbf{x}_i . The ideal representation loss can be defined as:

$$L_r = \|\mathbf{q}_i - \mathbf{c}_i\| \quad (1)$$

where $\mathbf{c}_i = W^{(l_d)}\mathbf{x}_i^{(l_d-1)} + \mathbf{b}^{(l_d)}$ is the *predicted representation* for example \mathbf{x}_i from locally connected layer $l_d = \{LC_a, LC_b, LC_s\}$. $\mathbf{x}_i^{(l_d-1)}$ is the representation of example \mathbf{x}_i from $FC_{1,a}$, $FC_{1,b}$ or $FC_{1,s}$. $W^{(l_d)}$ and $\mathbf{b}^{(l_d)}$ are linear transform parameters and bias parameters learnt from these locally connected layers. We define \mathbf{q}_i as the ideal representation corresponding to training sample \mathbf{x}_i from locally connect layer l_d . The non-zero values of \mathbf{q}_i occur at the indices where the training example \mathbf{x}_i and neurons from layer l_d shared the same relation label. For example, suppose we have six training samples $\{\mathbf{x}_1, \dots, \mathbf{x}_6\}$ and their relation labels $\mathbf{y} = [y_1, \dots, y_6] = [1, 1, 2, 2, 3, 3]$. Further assume layer l_d has six neurons $\{p_1, \dots, p_6\}$ with $\{p_1, p_2\}$ associated with label 1, $\{p_3, p_4\}$ label 2, and $\{p_5, p_6\}$ label 3. Then the ideal representations for these six samples are given by:

$$[\mathbf{q}_1, \dots, \mathbf{q}_6] = \begin{bmatrix} 1 & 1 & 0 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 1 & 0 & 0 \\ 0 & 0 & 1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 0 & 1 & 1 \end{bmatrix}, \quad (2)$$

where each column is an ideal discriminative representation corresponding to a training sample. Minimizing the ideal representation loss term ensure that the input sentence from the same type

have similar representations while those from different types have dissimilar representations.

Relation Classification We trained a pair of softmax classifiers for relation classification for language a and b . The softmax classification loss L_s^* , $* = \{a, b\}$ can be defined as:

$$L_s^* = -\log\left(\frac{e^{o_{y_i}}}{\sum_j e^{o_j}}\right) \quad (3)$$

where o_j is the j -th element of the predicted relation scoring vector from LC_1 or LC_2 layer in Figure 1. Let l_s denote these two locally connected layers, i.e., $l_s = \{LC_1, LC_2\}$. We have $\mathbf{o} = W^{(l_s)}\mathbf{x}_i^{(l_s-1)} + \mathbf{b}^{(l_s)}$, where $W^{(l_s)}$ and $\mathbf{b}^{(l_s)}$ are learnt parameters from layer l_s . $\mathbf{x}_i^{(l_s-1)}$ is the representation of example \mathbf{x}_i by concatenating the activations from $FC_{1,a}$ and $FC_{1,s}$, or $FC_{1,b}$ and $FC_{1,s}$.

We combine the ideal representation loss and softmax classification loss to obtain the final loss function for a training sample $(\mathbf{x}_i; y_i)$:

$$L(\mathbf{x}_i, y_i) = \begin{cases} L_s^a + \lambda(L_r^a + L_r^s) & \text{if } \mathbf{x}_i \text{ in lang. } a \\ L_s^b + \lambda(L_r^b + L_r^s) & \text{if } \mathbf{x}_i \text{ in lang. } b \end{cases} \quad (4)$$

where L_s^a and L_s^b are the softmax loss for samples in language a and b , respectively. They are computed via equation 3. The terms L_r^a , L_r^b are the ideal representation losses for language a and b respectively, while L_r^s is shared by both languages. The term L_r^* , $* = \{a, b, s\}$ can be computed by equation 1. We minimized equation 4 using stochastic gradient descent.

4 Experiments

Parameter setting In the embedding layer, we used the pretrained 100-dimension bilingual word embeddings in (Ammar et al., 2016) to initialize W^1 . We set the dimension of the other three embedding matrices W^2 , W^3 and W^4 to 50 and initialize them randomly. In the convolution layer, we set the filter widths to $[2, 3, 4, 5]$, and use 150 filters per width. The number of neurons in the $FC1$ layer ($FC_{1,a} \cup FC_{1,s} \cup FC_{1,b}$) is 300. We use \tanh for g_1, g_2 . All parameters are tuned with the ACE development set (described in next subsection). In bilingual experiments, we assigned 56 neurons² for each of $FC_{1,a}$ and $FC_{1,b}$ to learn

²We choose 56 to leave sufficient number of neurons for sharing across languages. We try 56, 63, 70 and no significant difference was observed.

language-specific features and the remaining neurons for language-shared features. λ is fixed to be 0.5. Training is done via stochastic gradient descent with Adam (Kingma and Ba, 2014) optimizer with a learning rate of 0.001.

Benchmarking baseline monolingual models

As we are not aware of prior work on bilingual relation extraction in similar settings, we first benchmark our baseline monolingual model on two popular monolingual datasets. We also use the ACE development dataset (described below) for tuning the parameters mentioned previously. The baseline monolingual model is similar to (Nguyen and Grishman, 2015) and only takes a English dataset as input. It is simplified from the model in Figure 1 by replacing the FC and LC layers with a fully-connected layer followed by a softmax loss. We evaluate it on two English datasets: the SemEval-2010 Task 8 dataset (Hendrickx et al., 2010) and the ACE 2005 dataset. The SemEval dataset contains 10,717 annotated examples (8,000 for training and 2,717 for testing). For ACE, to be comparable to state-of-the-art Neural Network models, we use the split in (Gormley et al., 2015; Nguyen and Grishman, 2015): find the ACE articles from news domains: broadcast conversation (bc), broadcast news (bn), newswire (nw), and uses news (bn & nw) as the training set, half of bc as the development set, the other half of bc as the test set. Table 1 and Table 2³ show that the performance of our monolingual baseline and various other systems. The monolingual model⁴ achieves higher performance than state-the-art CNN methods with similar structure and no additional semantic features.

For the rest of the experiments, we focus on bilingual experiments. We evaluated our model on the ACE 2005 multilingual training corpus⁵ which contains 596 English and 633 Chinese documents⁶. The ACE corpus consist of articles from weblogs, broadcast news, newsgroups, broadcast conversation, and is annotated exhaustively with

³The results reported in (Nguyen and Grishman, 2016) used a rich feature set (e.g., dependency parses). For fair comparison, we reported their results by running their code without those features.

⁴For fair comparison, we use the pre-trained word2vec word embeddings (Mikolov et al., 2013) with 300 dimensions for the monolingual experiments. For all other experiments, we use cross-lingual embeddings (Ammar et al., 2016).

⁵<https://catalog ldc.upenn.edu/LDC2006T06>

⁶The English and Chinese documents are not translation of each other.

Classifier	F1
SVM (Rink and Harabagiu, 2010)	77.6 (82.2)
CNN (Zeng et al., 2014a)	78.9 (82.7)
CNN (Nguyen and Grishman, 2015)	82.8
RNN (Socher et al., 2012)	74.8 (77.6)
MVRNN (Socher et al., 2012)	79.1 (82.4)
FCM (Yu et al., 2014)	80.6 (83.0)
Our English baseline	83.23

Table 1: Performance on SemEval-2010 Task 8 dataset (Hendrickx et al., 2010). The numbers inside parentheses are the systems using features such as WordNet (all systems), dependency parses (Yu et al., 2014) and Google n-grams (Rink and Harabagiu, 2010). Our approach does not use these features but still achieves the best result.

Classifier	P	R	F1
CNN (Nguyen and Grishman, 2016)	63.3	58.2	60.6
Our English baseline	62.1	60.1	61.1

Table 2: Performance on English ACE 2005 with the data split setting in (Gormley et al., 2015).

relations. For documents in English or Chinese, we collected all annotated relation mentions, and generated relation mentions for the *Other* class by sampling pairs of entity mentions within a sentence but is not annotated as having a relation. We refer to the resulted English dataset as *ACE05.ENG*, and refer to the Chinese ACE dataset as *ACE05.CHN* in the rest of this section. We divided relation mentions into 5 folds, performed cross-validation and averaged the results. As is standard (e.g. (Grishman et al., 2005)), we use the mention boundaries and types provided by the annotated data as input.

4.1 Comparing Bilingual Models to Alternative Approaches

To verify the effectiveness of our bilingual model, we compare four approaches:

- **Baseline:** We train two monolingual models on *ACE05.ENG* and *ACE05.CHN* respectively. These two models used bilingual word embedding and only used the softmax classification loss during training.
- **Bilingual-FT:** To see if having access to additional training data from another language helps, we pre-train each monolingual model with the other language(source)’s training dataset and then finetune it using the target language’s training dataset ⁷

⁷For example, we pre-train the Chinese model with *ACE05.ENG*, fine-tune with *ACE05.CHN*, then test with Chinese.

- **Bilingual-Joint** We train a bilingual model on the Chinese and English datasets jointly with the softmax loss. The model is similar to the bilingual model in Figure 1, but without the ideal representation losses ⁸.

- **Bilingual-Joint-IRL** We train the bilingual model on *ACE05.ENG* and *ACE05.CHN* jointly using the softmax and ideal representation loss (the complete model in Figure 1).

The results are summarized in Table 3. The pre-training approach (bilingual-FT), which pre-trains a model on the additional language’s dataset and then finetune on the target language dataset, achieves better results than training the monolingual baseline. The bilingual-Joint approach can simultaneously learn language-specific and shared bilingual representations, therefore it is able to generalize across languages while still making use of language-specific information. Its performance exceeds that of baseline and bilingual-FT. The bilingual-Joint-IRL method achieves the best result: it encourages the learnt representation to be discriminative among relation types. In particular, the learnt cross-lingual representation is encouraged to differentiate relation types regardless of language. It captures both language-specific and cross-lingual relation semantics, and thus has the best of both worlds.

4.2 Transfer representations to lower-resource languages

For just a handful of languages, (e.g. English, Chinese) corpora of relation annotation are readily available. However, for most languages few (if any) such resources exist. We show that our approach yields large gains in F1 when a small amount of *target* training is combined with large amounts of existing *source* annotation.

We demonstrate our model’s ability to use large amounts of *source* language data to supplement limited in-domain *target* language data with either Chinese and English as *target*. In each setting, we down-sample the *target* language dataset to 10%, 20%, 30%, 40% and 50% of its full training size and we report F1 in the test dataset in the *target* language. Figure 2 compares performance of *bilingual-Joint-IRL* with the performance of *baseline*. With access to existing, additional resources in the *source* through the bilingual model, performance on *target* doubles its F1 scores when only

⁸This performs bilingual representation learning by only sharing a subset of neurons in *FC1*

Approach	ACE05.ENG			ACE05.CHN		
	Precision	Recall	F1	Precision	Recall	F1
baseline	72.5	68.3	70.4	75.6	75	75.3
bilingual-FT	70.8	72.1	71.4	78.4	75.6	77.0
bilingual-Joint	72.6	73.3	72.9	77.7	76.4	77.1
bilingual-Joint-IRL	74.3	75.6	74.9	80.9	77.1	78.9

Table 3: Performances of the bilingual models on the ACE 2005 multilingual training corpus.

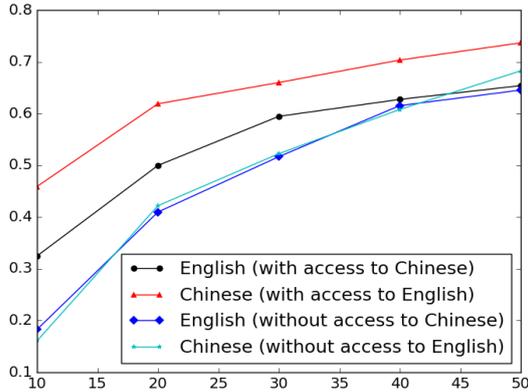

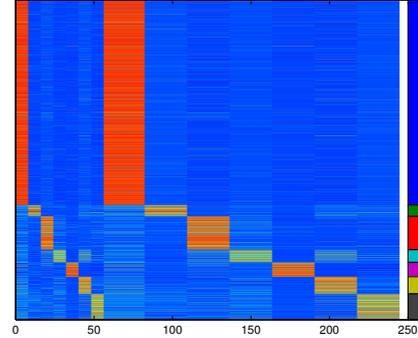

Figure 2: Performance of Chinese and English relation extraction by varying the size of in-domain training data. For the model with access to another language (*source*), we use the full dataset from the *source* but only a fraction of in-domain data in the *target* language. We sample each dataset from 10% to 50% with 10% as the incremental step size. x-axis is the percentage of training data in *target* is used, and y-axis shows F1 scores.

10% training data is available, and gains 30% to 66% relative improvement in F1 with 20% training data. The bilingual extractor trained with only 50% of the *target* training data achieves performance nearing (< 5% difference) that of the baseline approach using all of the *target* resources. This results provides a new and cost-effective way to perform relation extraction when resources are limited for a new language.

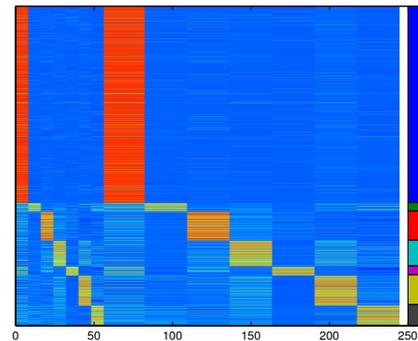

4.3 Analysis on learnt representation

Learning discriminative representations We use LC_a and LC_s to represent a sentence from language a , and use LC_b and LC_s to represent a sentence from language b . We visualize the predicted representations for testing examples in both English and Chinese in Figure 3. X-axis shows the 244 neurons⁹ from locally connect layers LC_a-LC_s , and LC_b-LC_s . Y-axis shows all testing examples (each row represents an example). Each

⁹The number of neurons in layers LC_a and LC_b are both 56, while layer LC_s contains 188 neurons.

(a) ACE05.ENG set

(b) ACE05.CHN set

Figure 3: Visualization of predicted presentation for test examples in both languages. X-axis indicates the 244 neurons from layers LC_a-LC_s (or LC_b-LC_s). Y-axis corresponds to the indices of test examples. The color shows strength of pairwise association between examples and neurons (the brighter the color, the stronger association). Each color in the color bar located at the right most of each subfigure represents one relation type for a subset of testing examples.

graph shows strong associations between testing examples from 7 types and 7 blocks of neurons in the hidden layer in 1) language-specific representations (the first 56 neurons as shows in x-axis [0, 55] in Figure 3 (a) and (b)) as well as 2) bilingual representation (the remaining 188 neurons as shown in x-axis [56,243] in each figure). The visualization is strongly block-diagonal. This shows that the learnt representation is discriminative in

Relation	English	Chinese
ORG-AFF	... while <u>japanese officials</u>应 <u>新加坡 总理吴作栋</u> 的邀请...
PHYS	... <u>which</u> is ... outside the center of <u>baghdad</u>前日在 <u>广州</u> 被公安 <u>寻回</u> ...
PART-WHOLE	...this is that <u>city hall</u> in <u>orlando</u> <u>亚齐省首府班达亚齐</u>
PER-SOC	...you go to your <u>grandma</u> 's house	该名 <u>家长</u> 起初以为 <u>孩子</u> <u>撒谎</u> ...
GEN-AFF	<u>joseph britt</u> of <u>kennesaw</u> , <u>ga</u> , recently...	<u>日本</u> <u>历史</u> 上有过 <u>女天皇</u>
ART	i `ve decided i `ll take the <u>train</u> home later	<u>我们</u> 的 <u>军舰</u> 在 <u>厂里</u> ...

Table 4: Examples of relation mentions that are found to be similar to its cross-lingual counterparts using our model. The two examples in each row is similar to each other.

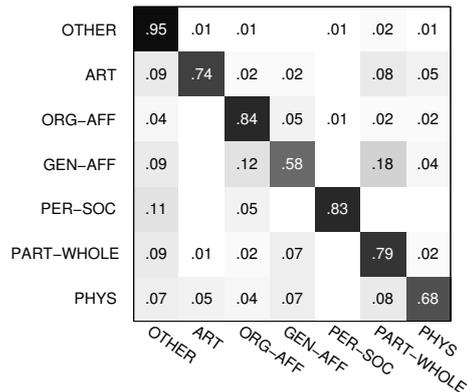

predicting relation types.

Confusion matrix on bilingual relation extraction To further understand the discriminative power of the bilingual model with regard to predicting relation types, we plot the confusion matrix using the bilingual model over all examples in the ACE datasets. Figure 4 shows that our model performs well on differentiating the classes. It also shows that our algorithm performs slightly worse in differentiating *PHYS*, *PART-WHOLE* and *GEN-AFF* relations, in both English and Chinese. This is caused by the trumping rules in ACE relation definition. ACE annotation guideline defines a relation *Org-Location-Origin* (a subtype of *GEN-AFF*) for locations of *ORG*'s, and defines another relation *Geographical* (a subtype of *PART-WHOLE*) for locations of facilities/locations/GPEs, and further defines a relation *Located* (as a subtype of *PHY*) to capture the physical location of a person. These relations share the same high-level semantics but are defined as different ACE types.

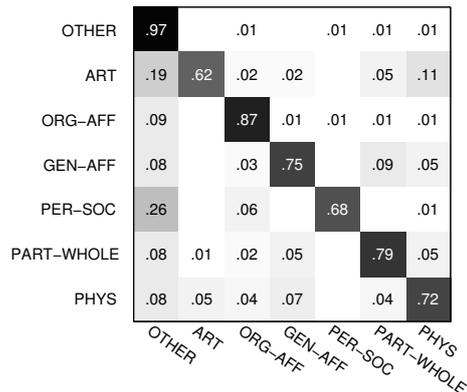

Examples of similar relation instances across languages We took the last-layer activations as a "relation embeddings" representation for each relation instance. To see how well the cross-lingual representation learning did, we calculated pairwise similarities¹⁰ between all relation instances in Chinese and English. Table 4 shows examples in which each pair of instances in the same row in the two languages are very similar¹¹ to each other. The model learns lexical similarity such as *japanese officials* and *新加坡 总理* (*Singapore prime minister*). It also knows *city hall in orlando* is similar to *亚齐省首府班达亚齐* (*Aceh capital of Banda Aceh*). It further learns complicated correspondence such as *you go to your grandma 's house* and *该名家长 起初以为孩子 撒谎* (*The*

¹⁰We use cosine distance as the similarity metric. The smaller cosine distance is, the more similar the pair.

¹¹Here we define *very similar* as ranked within top-50 most similar instances in the entire dataset, with regard to the query instance from the other language.

parent previously thought the child was lying) The diverse range of examples in Table 4 shows that the model not only captures lexical similarity, but also syntactic and long-range semantic similarities across the pair of languages.

5 Conclusion

We present a bilingual relation extraction algorithm to learn discriminative and transferable representation across languages via a Convolutional Neural Network. Experiments show that it outperforms monolingual algorithms and the baseline algorithms significantly both when large amounts

of data are available in both languages and when only limited training data is available in the target language.

Bilingual Word Embeddings for Bilingual Terminology Extraction from Specialized Comparable Corpora

Amir Hazem¹ Emmanuel Morin¹

¹ LS2N - UMR CNRS 6004, Université de Nantes, France
{amir.hazem, emmanuel.morin}@univ-nantes.fr

Abstract

Bilingual lexicon extraction from comparable corpora is constrained by the small amount of available data when dealing with specialized domains. This aspect penalizes the performance of distributional-based approaches, which is closely related to the reliability of word's co-occurrence counts extracted from comparable corpora. A solution to avoid this limitation is to associate external resources with the comparable corpus. Since bilingual word embeddings have recently shown efficient models for learning bilingual distributed representation of words, we explore different word embedding models and show how a general-domain comparable corpus can enrich a specialized comparable corpus via neural networks.

1 Introduction

Bilingual lexicon extraction from comparable corpora has shown substantial growth since the seminal work of Fung (1995) and Rapp (1995). Comparable corpora, which are comprised of texts sharing common features such as domain, genre, sampling period, etc. and without having a source text/target text relationship (McEnery and Xiao, 2007), are more abundant and reliable resources than parallel corpora. On the one hand, parallel corpora are difficult to obtain for language pairs not involving English. On the other hand, as parallel corpora are comprised of a pair of translated texts, the vocabulary appearing in the translated texts is highly influenced by the source texts. These problems are aggravated in specialized and technical domains.

Although it is easier to build large general-domain comparable corpora, specialized compa-

rable corpora are often of modest size (around 1 million words) due to the difficulty to obtain many specialized documents in a language other than English. Consequently, word co-occurrence counts of the historical context-based projection approach, known as the *standard approach* (Fung, 1995; Rapp, 1995), dedicated to bilingual lexicon extraction from comparable corpora are unreliable in specialized domain. This problem persists with other paradigms such as Canonical Correlation Analysis (CCA) (Gaussier et al., 2004), Independent Component Analysis (ICA) (Hazem and Morin, 2012) and Bilingual Latent Dirichlet Allocation (BiLDA) (Vulić et al., 2011).

A solution to avoid this limitation and to increase the representativity of distributional representations is to associate external resources with the specialized comparable corpus. These resources can be lexical databases such as WordNet which allows the disambiguation of translations of polysemous words (Bouamor et al., 2013) or general-domain data to improve word co-occurrence counts of specialized comparable corpora (Hazem and Morin, 2016).

Our work is in this line and attempts to find out how a general-domain data can enrich a specialized comparable corpora to improve bilingual terminology extraction from specialized comparable corpora. Since bilingual word embeddings have recently provided efficient models for learning bilingual distributed representation of words from large general-domain data (Mikolov et al., 2013), we contrast different popular word embedding models for this task. In addition, we explore combinations of word embedding models as suggested by Garten et al. (2015) to improve distributed representations. We compare the results obtained with the state-of-the-art context-based projection approach. Our results show under which conditions the proposed model can compete with state-

of-the-art approaches. To the best of our knowledge, this is the first time that word embedding models have been used to extract bilingual lexicons from specialized comparable corpora.

The remainder of this paper is organized as follows. Section 2 presents the two state-of-the-art approaches used to extract bilingual lexicons from comparable corpora. Section 3 describes the two data combination approaches adapted to Skip-gram and CBOW models (Mikolov et al., 2013). Section 4 describes the different linguistic resources used in our experiments. Section 5 is then devoted to a large-scale evaluation of the different proposed methods. Finally, Section 6 presents our conclusion.

2 State-of-the-Art Approaches

In this section, we describe the two state-of-the-art approaches used to extract bilingual lexicons from comparable corpora.

These approaches are both based on monolingual lexical context analysis and relies on the distributional hypothesis (Harris, 1968) which postulates that a word and its translation tend to appear in the same lexical contexts. This is the hypothesis that tends to be reduced to the famous sentence of the British linguist J. R. Firth (1957, p. 11) who said: “*You shall know a word by the company it keeps.*” even if the context was related to collocates.

The two approaches are known as distributional and distributed semantics (according to Hermann and Blunsom (2014)). The first one is based on vector space models while the second one is based on neural language models.

2.1 Context-Based Projection Approach

The historical context-based projection approach, known as the standard approach, has been studied by a number of researchers (Fung, 1998; Rapp, 1999; Chiao and Zweigenbaum, 2002; Morin et al., 2007; Prochasson and Fung, 2011; Bouamor et al., 2013; Morin and Hazem, 2016, among others). Its implementation can be carried out by applying the following steps:

1. For each word w of the source and the target languages, we build a context vector (resp. \mathbf{s} and \mathbf{t} for source and target languages) consisting in the measure of association of each word that appears in a short window of words

around w . The association measures traditionally studied are Mutual Information, Log-likelihood, and the Discounted Odds-Ratio.

2. For a word i to be translated, its context vector \mathbf{i} is projected from the source to the target language by translating each element of its context vector thanks to a bilingual seed lexicon.
3. The translated context vector $\bar{\mathbf{i}}$ is compared to each context vector \mathbf{t} of the target language using a similarity measure such as Cosine or weighted Jaccard. The candidate translations are then ranked according to the scores of a given similarity measure.

This approach is very sensitive to the choice of parameters. We invite readers to consult the study of Laroche and Langlais (2010) in which the influence of parameters such as the size of the context, the choice of the association and similarity measures have been examined.

In order to improve the quality of bilingual terminology extraction from specialized comparable corpora, Hazem and Morin (2016) have proposed two ways to combine specialized comparable corpora with external resources. The hypothesis is that word co-occurrences learned from a large general-domain corpus for general words improve the characterisation of the specific vocabulary of the specialized corpus. The first adaptation called Global Standard Approach (GSA) is basic and consists in building the context vectors from a comparable corpus composed of the specialized and the general comparable corpora. The second adaptation called Selective Standard Approach (SSA) is more sophisticated and comprises: i) independently building context vectors of the specialized and general comparable corpus and then ii) merging under certain conditions, specialized and general context vectors of the words belonging to the specialized corpus when they appear in the general corpus.

2.2 Word Embedding Based Approach

Bilingual word embeddings has become a source of great interest in recent times (Mikolov et al., 2013; Vulić and Moens, 2013; Zou et al., 2013; Chandar et al., 2014; Gouws et al., 2014; Artetxe et al., 2016, among others). Mikolov et al. (2013) was the first to propose a method to learn a linear transformation from the source language to the

target language to improve the task of lexicon extraction from bilingual corpora.

During the training time of Mikolov’s method, for all $\{x_i, z_i\}_{i=1}^n$ bilingual word pairs of the seed lexicon, the word embedding $x_i \in \mathbb{R}^{d_1}$ of word i in the source language and the word embedding $z_i \in \mathbb{R}^{d_2}$ of its translation in the target language are computed. A transformation matrix W such as Wx_i approximates z_i is then learned by the objective function as follows:

$$\min_W \sum_{i=1}^n \|Wx_i - z_i\|^2 \quad (1)$$

At prediction time, we can transfer the word embedding x for a word to be translated in the target language using the translation matrix such as $z = Wx$. The candidate translations are obtained by ranking the closest target words to z according to a similarity measure such as the Cosine measure.

Recently, Artetxe et al. (2016) presented an approach for learning bilingual mappings of word embeddings that preserves monolingual invariance using several meaningful and intuitive constraints related to other proposed methods (Faruqui and Dyer, 2014; Xing et al., 2015). These constraints are orthogonality, vectors length normalization for maximum cosine and mean centering for maximum covariance. Monolingual invariance tends to preserve the dot products after mapping, in order to avoid performance drop in monolingual tasks, while dimension-wise mean centering tends to insure that two randomly taken words would not be semantically related. This approach has shown meaningful improvements for both monolingual and bilingual tasks.

Other work has focused on learning bilingual word representations without word-to-word alignments of comparable corpora. Chandar et al. (2014) and Gouws et al. (2014) use multilingual word embeddings based on sentence-aligned parallel data whereas Vulić and Moens (2015, 2016) propose a model to induce bilingual word embeddings directly from document-aligned non-parallel data. These works are based on sentence- or document-aligned of general-domain comparable corpora and are outside the scope of this study. It is unlikely, not to say impossible, to find this type of alignment in a specialized comparable corpus.

3 Data Combination Using Neural Networks

Recently, Hazem and Morin (2016) have shown that using external data drastically improves the performance of the traditional distributional-based approach for the task of bilingual lexicon extraction from specialized comparable corpora. Mikolov et al. (2013) have also shown that distributed vector representations over large corpora in a continuous space model capture many linguistic regularities and key aspects of words. Based on these findings, we pursue the preceding works and propose different ways to combine specialized and general domain data using neural network models. We adapt the two data combination approaches proposed in Hazem and Morin (2016) (see Section 2.1) using Skip-gram and CBOW models (Mikolov et al., 2013). Inspired by the work of Garten et al. (2015) which studied different combinations of distributed vector representations for word analogy task, we also propose different Skip-gram and CBOW models combinations over specialized and general domain data.

3.1 Global Data Combination Using Neural Network Models

This approach can be seen as similar to the GSA approach (Hazem and Morin, 2016), the difference is that instead of using the context-based projection approach to build context vectors, we use the distributed Skip-gram or Continuous Bag-of-Words (CBOW) models proposed in Mikolov et al. (2013). Given a specialized and a general domain corpus, we create a new corpus which is the combination of both. We then learn a Skip-gram model (respectively a CBOW model) using this new generated corpus. We denote this approach by GSG for the global¹ Skip-gram model and GCBOW for the global CBOW model.

After combining the two corpora, the steps for extracting bilingual lexicons are as follows:

1. We first build a CBOW (respectively a Skip-gram) model for source and target languages.
2. Then, we apply bilingual mapping (Artetxe et al., 2016) between the source and the target CBOW models (respectively the Skip-gram models). The mapping step needs a bilingual dictionary to compute the mapping ma-

¹The term *global* refers to a global combination of data without any specific criterion.

trix. We used a dictionary subset of the 5,000 more frequent translation pairs. Different sizes of the seed dictionary have been studied and discussed in [Jakubina and Langlais \(2016\)](#). It should be noted that in our experiments, no great impact has been observed when varying the size of the dictionary subset.

3. For each word to be translated, we compute a Cosine similarity between its mapped embedding vector and the embedding vectors of all the target words.
4. Finally, we rank the candidates according to their similarity score.

3.2 Specific Data Combination Using Neural Network Models

This approach is in the line of the SSA ([Hazem and Morin, 2016](#)) approach but the idea is not exactly the same. Similarly to them we build two separate representations. One learned from a specialized domain corpus and the second learned from a general-domain corpus, but unlike them we concatenate the distributed models while they merge ² distributional context vectors.

Our goal is to capture the two word characterisations thanks to CBOW/Skipgram models. One is issued from the specialized domain and the other one from the general domain, to finally combine both representations in the perspective of obtaining a better word representation. Our approach is as follows:

1. We first build a CBOW (respectively a Skipgram) model for both specialized and general domain source and target languages.
2. Then, we concatenate source CBOW vectors (respectively Skipgram vectors) of the specialized and the general domain data. We apply the same process for specialized and general-domain target data.
3. We apply bilingual mapping ([Artetxe et al., 2016](#)) between the source and target concatenated vectors.
4. For each word to be translated, we compute a Cosine similarity between its mapped embedding vector and the embedding vectors of all the target words.

²The merging process can be seen as a simple vector addition.

5. Finally, we rank the candidates according to their similarity score.

3.3 Combining Distributed Representations

We follow the findings of [Garten et al. \(2015\)](#) where they have shown substantial improvements on a standard word analogy task, combining distributed vector representations (more specifically, vectors concatenation). They compared their hybrid methods and have shown their advantages especially when training data is limited, which is the main problem in the task of extracting bilingual terminology from specialized comparable corpora.

In our case, word embedding models lead to three different ways of concatenation. The first one is a CBOW model concatenation between the specialized and the general domain data. The second one is a Skip-gram model concatenation and the third one is a concatenation of both CBOW and Skip-gram models.

If for instance we have a 100 dimension specialized CBOW model and a 200 dimension general domain CBOW model. The concatenation will lead to a resulting 300 dimension CBOW model. If we also have a 100 dimension specialized Skip-gram model and a 200 dimension general domain Skip-gram model. The concatenation will lead to a resulting 300 dimension Skip-gram model. Finally, if we concatenate the CBOW and Skip-gram models, this will result in a 600 dimension combined model. This final concatenation process allows to take advantage of both CBOW and Skip-gram models and to learn a mapping matrix of the combined models. To our knowledge this is the first attempt to first encode $\text{CBOW} \hat{\ } \text{CBOW}$ ³, $\text{Skip-gram} \hat{\ } \text{Skip-gram}$ and $\text{CBOW} \hat{\ } \text{Skip-gram}$ models before learning a bilingual mapping matrix.

4 Data and Resources

In this section, we briefly outline the different textual resources used for our experiments: the comparable corpora, the bilingual dictionary and the terminology reference list. These textual resources are a subset of the data used in [Hazem and Morin \(2016\)](#).

³ $\text{CBOW} \hat{\ } \text{CBOW}$ stands for the concatenation of two CBOW vectors issued from two different training datasets.

4.1 Comparable corpora

The specialized comparable corpus consists of scientific papers collected from the Elsevier website⁴. The scientific papers were taken from the medical domain within the sub-domain of “breast cancer”. The breast cancer comparable corpus (BC) is composed of 103 English documents and 130 French documents.

The four general-domain comparable corpora are of different types and sizes often used in multiple evaluation campaigns such as WMT. News commentary corpus consists of political and economic commentary crawled from the web (NC), Europarl corpus is a parallel corpus extracted from the proceedings of the European Parliament (EP7), JRC acquis corpus is a collection of legislative European Union documents (JRC) and Common Crawl corpus (CC) which encompasses over petabytes of web crawled data collected over seven years. It should be noted that we do not take advantage of the parallel information encoded in the parallel corpora.

Table 1 shows the number of content words (# content words) for each corpus.

Comparable corpus	# content words	
	FR	EN
BC	8,221	79.07
NC	5.7M	4.7M
EP7	61.8M	55.7M
JRC	70.3M	64.2M
CC	91.3M	81.1M

Table 1: Characteristics of the specialized comparable corpus and the external data.

The documents were pre-processed through basic linguistic steps such as tokenization, part-of-speech tagging and lemmatization using the TTC TermSuite⁵ tool that applies the same method to several languages including English and French. Finally, the function words were removed thanks to a stopword list and the hapax⁶ were discarded.

4.2 Bilingual Dictionary

The bilingual dictionary is the French/English dictionary ELRA-M0033⁷ (243,539 entries). This re-

⁴www.elsevier.com

⁵code.google.com/p/ttc-project

⁶Tokens that appear only once in the corpus.

⁷catalog.elra.info/product_info.php?products_id=666

source is a general language dictionary which contains only a few terms related to the medical domain.

4.3 Gold Standard

The bilingual terminology reference list required to evaluate the quality of bilingual terminology extraction from comparable corpora has been derived from the UMLS⁸ meta-thesaurus. The terminology reference list is composed of 248 single word pairs for which each word appears at least 5 times in the comparable corpus. This list is of a standard size compared to other works such as Chiao and Zweigenbaum (2002): 95 single words, Morin et al. (2007): 100 single words and Bouamor et al. (2013): 125 and 79 single words.

5 Experiments and Results

The first piece of work comparing methods for identifying translation pairs in comparable corpora was presented in Jakubina and Langlais (2016). However the evaluation was conducted on Wikipedia, which is a general domain corpus. In our case, we are interested in specialized domains where there is a lack of specialized data. Our experiments aim at exploring word embeddings performance in specialized comparable corpora, which is to our knowledge, the first attempt at tackling this problem. Moreover, and as it has been pointed out in Mikolov et al. (2013), applications to low resource domains is a very interesting topic where there is still much to be explored.

In this section, we compare different word embedding representations for the extraction of bilingual terms from specialized comparable corpora. We contrast Skip-gram and CBOW models as well as different ways of combining them over specialized and general domain corpora.

5.1 Word2vec

For word2vec, we used as settings a window size of 10, negative sampling of 5, sampling of 1e-3 and training over 15 iterations. We applied both Skip-gram and CBOW models⁹ to create vectors of 100 dimensions. We used hierarchical softmax for training the Skip-gram model. Other settings were assessed but on average the chosen ones tend to give the best results on our data.

⁸www.nlm.nih.gov/research/umls

⁹To train word embedding models we used the gensim toolkit (Rehurek and Sojka, 2010)

<i>Corpus</i>	<i>CBOW</i>	<i>SG</i>	<i>Concat</i>
BC	17.1	12.8	20.8
NC	33.9	31.2	33.6
EP7	42.3	40.8	43.1
JRC	40.3	40.5	43.4
CC	60.9	56.0	61.0
BC \cup NC	42.9	37.7	46.3
BC \cup EP7	47.2	49.0	53.3
BC \cup JRC	49.9	46.5	53.0
BC \cup CC	67.7	63.2	68.4
BC \frown (BC \cup NC)	45.5	30.7	48.1
BC \frown (BC \cup EP7)	51.6	35.7	53.8
BC \frown (BC \cup JRC)	53.7	36.3	56.1
BC \frown (BC \cup CC)	70.7	40.2	70.9

Table 2: Results (MAP %) of word2vec using the Skip-gram model (noted SG), the Continuous Bag of Words model (noted CBOW) and the concatenation of both models (noted Concat). The window size was set to 10 and the vector size to 100.

5.2 Bilingual Mappings of Word Embeddings

For mapping words of the source language to the target language we follow the method presented in Artetxe et al. (2016) where they presented an efficient exact method to learn the optimal linear transformation that gives the best results in translation induction. While we contrasted different configurations of there framework, we only present the best results. We used the orthogonal mapping with length normalization and mean centering of vectors¹⁰.

5.3 Results

Table 2 shows the results of word2vec according to different configurations. The first column represents the corpora that have been used to train word2vec models. The first bloc lines compares the performance of word2vec models on the specialized breast cancer corpus (BC) and the four external data that are: news commentary (NC), EuroParl (EP7), JRC acquis (JRC) and common crawl (CC). The second bloc lines compares the models trained on the combination of BC with each external corpus. For instance BC \cup EP7 consists of training word2vec on the combination of BC and EP7. Finally, the third bloc lines shows the concatenation of two models, the first one trained on the specialized corpus (BC) and the second one trained on the combination of BC with a given external corpus (BC \cup EP7 for instance).

¹⁰These parameters have also shown the best results in Artetxe et al. (2016).

This is noted by BC \frown (BC \cup EP7) for the concatenation (represented by \frown) of vectors of BC with vectors of BC \cup EP7. The first column of the second and third blocs shows CBOW concatenation while the second shows Skip-gram concatenation. The third column shows CBOW and Skip-gram concatenation. Concatenate BC with BC \cup EP7 instead of BC with EP7 (noted BC \frown EP7) for instance, insures the presence of all specialized domain words in both models.

The first observation that can be seen from Table 2 is that the results are very low when using the specialized BC corpus only (the maximum obtained MAP is 20.8% for the Concat model). The second observation is that using external data only gives better results. The best obtained MAP score is 61.0% when using CC corpus. This is certainly due to the presence of medical terms in the general domain corpora which have been crawled from the web and can contain scientific pages. Over the first bloc lines results, we can see that CBOW model outperforms Skip-gram model in most cases which is not surprising in the sense that CBOW aims at characterising a word according to its context while Skip-gram characterises a context according to a given word. From this point CBOW is more appropriate for our task. However, combining both CBOW and Skip-gram as shown by the Concat model, always improves the MAP scores. This is an important finding that shows that both models are complementary.

According to the second bloc lines results, we

Word2vec + Mapping	BC _{concat}	CC _{concat}
<i>Unconstrained + Original</i>	11.4	48.0
<i>Orthogonal + Original</i>	19.5	69.9
<i>Unconstrained + Unit</i>	11.8	50.4
<i>Orthogonal + Unit</i>	19.0	70.1
<i>Unconstrained + Unit + Center</i>	12.3	54.0
<i>Orthogonal + Unit + Center</i>	20.8	70.9

Table 3: Results (MAP %) of word2vec using different mapping techniques.

	BC	NC	EP7	JRC	CC
<i>SA</i>	27.0	45.3	48.5	52.0	75.5
<i>GSA</i>	-	58.9	58.3	61.7	80.2
<i>SSA</i>	-	58.9	60.8	66.6	82.3
<i>GCBOV</i>	17.1	42.9	47.2	49.9	67.7
<i>GSG</i>	12.8	37.7	49.2	46.5	63.2
<i>GCBOV + GSG</i>	20.8	46.3	53.3	53.0	68.4
<i>SCBOV</i>	-	45.5	51.6	53.7	70.7
<i>SSG</i>	-	30.7	35.7	36.3	40.2
<i>SCBOV + SSG</i>	-	48.1	53.8	56.1	70.9

Table 4: Results (MAP %) of the *Standard Approach (SA)*, the *Global Standard Approach (GSA)* and the *Selective Standard Approach (SSA)* for the breast cancer corpus (BC) using the different external data (the improvements indicate a significance at the 0.001 level using the Student t-test).

observe that combining the specialized bilingual corpus (BC) with external data always improves the results. This can be noticed for the $BC \cup CC$ corpus where we increase the MAP score for CBOV from 60.9% to 67.7%, the MAP score for Skip-gram from 56% to 63.2% and the MAP score for the Concat approach from 61% to 68.4%. These are also interesting results which coincide with the observations of [Hazem and Morin \(2016\)](#). Hence, combining specific and general domain corpora before applying any model always benefits the task of bilingual terminology extraction.

Finally, for the third bloc lines where we combine the model issued from the first bloc (the BC model) and models issued from the second bloc lines ($BC \cup EP7$ for instance), two observations need to be pointed out. The first one is that for CBOV model concatenation we still get improvements as we can see for CC where we gain 3 points (from 67.7% to 70.7% of MAP score). The second surprising observation is that Skip-gram concatenation decreases the results. This drop may suggest that Skip-gram concatenation is not appropriate for this configuration. However the concatenation of CBOV and Skip-gram

models (the Concat approach) still improves the results as we can see for $BC \hat{\cup} (BC \cup JRC)$ where we move from 53% to 56.1% of MAP score and for $BC \hat{\cup} (BC \cup CC)$ where we increase the MAP score from 68.4% to 70.9%. For this last result the gain is not that important compared to the $CBOV \hat{\cup} CBOV$ model that obtains a MAP score of 70.7%.

In Table 3 we report a comparison of different mappings as studied in [Artetxe et al. \(2016\)](#). We contrast unconstrained and orthogonal mappings using original as well as length normalization (noted *unit*) and mean centering (noted *Center*). As we can see, the best results are those obtained using orthogonal mapping with length normalization and mean centering. We reach the same conclusions as [Artetxe et al. \(2016\)](#).

In Table 4 we present the results from [Hazem and Morin \(2016\)](#) of the standard approach (noted *SA*) using only specialized comparable corpora (BC) or using only external data (NC, EP7, JRC and CC), in addition to the two adapted standard approaches (noted *GSA* and *SSA*) using the combination of each specialized comparable corpus with each corpus of the external data. We also

report the best results of each of the three word embedding methods that we introduced earlier in Table 2.

Even if we obtained improvements over our different embedding models, we are still below the standard approach as seen in Table 4. The lack of specialized data may partially explain these lower results as well as the multiple tuning parameters of CBOW and Skip-gram models.

6 Conclusion

In this paper, we have proposed and contrasted different data combinations using neural networks for bilingual terminology extraction from specialized comparable corpora. We have shown under which conditions external resources as well as Skip-gram and CBOW models can be jointly used to improve the performance of bilingual terms extraction. If the results are encouraging, we were unable to compete with the results of the historical context-based projection approach. However, our findings may suggest a starting point of applying word embeddings and the multiple proposed variants to specialized domains as well as to other tasks. We hope this work will help to lead the way in exploring low resource domains such as specialized comparable corpora.

Acknowledgments

The research leading to these results has received funding from the French National Research Agency under grant ANR-17-CE23-0001 ADDICTE (Distributional analysis in specialized domain).

Abstract

In many languages such as Bambara or Arabic, tone markers (diacritics) may be written but are actually often omitted. NLP applications are confronted to ambiguities and subsequent difficulties when processing texts. To circumvent this problem, tonalization may be used, as a word sense disambiguation task, relying on context to add diacritics that partially disambiguate words as well as senses. In this paper, we describe our implementation of a Bambara tonalizer that adds tone markers using machine learning (CRFs). To make our tool efficient, we used differential coding, word segmentation and edit operation filtering. We describe our approach that allows tractable machine learning and improves accuracy: our model may be learned within minutes on a 358K-word corpus and reaches 92.3% accuracy.

1 Introduction

Bambara (Bamana, Bamanankan, ISO-369 Bam) is the most widely spoken language of the Manding language group. It is spoken mainly in Mali (and among the considerable Malian diaspora) by 12 to 15 million people. It is not an official language; however it is the major language (besides French) on Malian radio and TV broadcasts, there are newspapers in Bambara, it is broadly used in humanities and in primary schools, and it is taught at several universities around the world. In the Mande language family, Bambara is among the best described: there are numerous works on Bambara language, such as dictionaries (Bailleul, 2007; Dumestre, 2011), description of its grammar (Dumestre, 2003; Vydrin, 1999b,a).

Bambara is a tonal language, with the important drawback that its official orthography does not represent tones. Because several tonalized forms can correspond to some unaccented tokens, it makes word sense more ambiguous in corpus and imposes important challenges to NLP applications. Our goal is to remedy this issue by implementing an automatic tonalizer for Bambara, to improve subsequent NLP processings and facilitate linguistic analysis for Bambara.

2 Bambara Reference Corpus

Our work relies on an annotated corpus, the Bambara Reference Corpus (BRC, in French *Corpus Bambara de Référence*), a linguistically annotated corpus suitable both for linguistic research and for NLP tools development. Building BRC started in 2010 as a project conducted by a small group of specialists in Manding linguistics and computer sciences in Russia. Later on, colleagues from other countries (France, Germany) joined the team to provide more texts, clean the corpus, and automatically preprocess it. The corpus is available online since April 2012, most relevant information about the project may be found online¹ or in publications (Vydrin, 2013, 2014).

Part \ Type	Words (dist.)	Punct.
Non-disamb.	2,160,155 (58,277)	358,659
Disamb.	358,794 (23,875)	61,847

Table 1: Corpus statistics

Table 1 and Figure 1 present overall corpus statistics and characteristics². The corpus consists

¹<http://cormand.huma-num.fr/index.html>

²Corpus is continuously growing and contains, as of June 2017, 4,113,006 raw words and 903,585 in the disambiguated part.

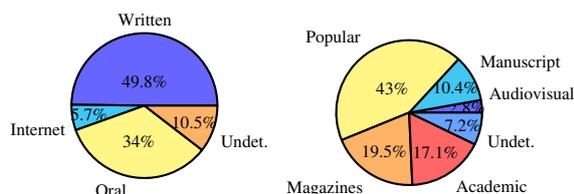

Figure 1: Corpus composition (medium, source)

of two parts: an automatically annotated subcorpus which contains ambiguous interpretations for each token (non-disambiguated), and a manually disambiguated subcorpus which serves as a gold-standard annotated dataset.

2.1 BRC Tools and Resources

The available data within the BRC project includes source text files and an electronic Bambara dictionary. Dedicated tools have been implemented to annotate the corpus. The collection of software tools developed for the BRC (parser, disambiguation interface, various auxiliary scripts) is called Daba (Maslinsky, 2014) and is available online³. Among them, a rule-based parser was built to bootstrap the annotation of the corpus.

Thanks to this data and these tools, a gold standard has been created by human annotators proficient in Bambara. This process is described in Figure 2: The parser’s output is reviewed, and annotation is done by selecting or editing required information for each wordform.

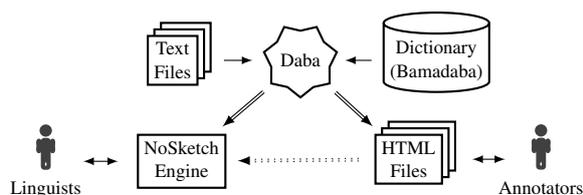

Figure 2: BRC data workflow

2.2 Main Goals for BRC

The project’s goal is to disambiguate the whole corpus. Wordform annotation is done for each wordform and for three main features:

- POS Tagging
- Tone Marker Restoration
- Gloss Assignment

³<https://github.com/maslinsky/daba>

We are currently working on these tasks by using sequential modeling with various additional techniques. For POS tagging, we use state of the art, Conditional random fields (CRFs; Lafferty et al. 2001) over 23 morpho-syntactic possible tags, our implementation reaches 94% accuracy, which is quite satisfying for such an under-resourced language.

For the tone marker restoration task, we considered using similar methods, but the tag set is much larger: 20,870 distinctive tonal forms are found, which prevents an efficient learning. We have to reduce training complexity by finding an adequate representation that will allow to model tone addition without listing every possible form.

2.3 Tone Markers in Bambara

The word-level tonal information is provided by tonal form or so-called diacritized form in the literature. The tone markers inserted in tonal form are mainly acute accent (´) for low tone, grave accent (`) for high tone, háček (ˇ) for phonetically rising tone and circumflex accent (^) for lexical rising tone. For instance, a non-tonalized token *tugu* can be tonalized as a noun *tùgu* (arms) or a verb *túgu* (to close) that we can find in its quasi-homonym list.

Ideally, the only difference between a tonalized token compared to its non-tonalized form is the presence of tone accents. In reality, annotators also often introduce other modifications, mainly typographic and orthographic correction. As we will see later, this fact makes it necessary to operate filtering on edit operations, in order to properly focus on tonalization operations.

To give an idea of tonal form variety, we propose to compare annotated tokens to their original forms. Related statistics are summarized in Table 2, showing that the probability for modifications other than tonalization during annotation is not negligible : 8.90% modification are related to other modification such as typographic or orthographic correction. We will have to take this into account for our system to focus on tonalization operations.

3 Problem Formulation

Our objective is to design a word sense disambiguation system for Bambara helping to choose the most correct interpretation from the quasi-homonym list provided for each token in the sub-

Operation	Ratio
Tonalization	38.73%
Other	8.90%
None	52.35%

Table 2: Distribution of edit operation to annotated forms receiving: only tone markers, other characters, or nothing (i.e., tonalized token is identical to its non-tonalized form)

corpus processed by Daba.

The drawback of modeling sequences of large-scale label set is the expensive computational cost needed to estimate CRF parameters. Indeed, the quasi-Newton method that CRF training employs for solving parameter estimation of CRF model has a computational cost proportional to M^2 where M is the size of label set (Sutton and McCallum, 2010). This makes CRF learning computationally expensive when labels are the set of possible tonalized words.

4 Related Works

4.1 Automatic Diacritization and Sub-word Level Modeling

Simard (1998) presented a method for accent insertion in French using a two-layers Hidden Markov Model (HMM) trained over a POS-tagged corpus while Tufiş and Chişu (1999) adapted a trigram tagger to this task for Romanian. Focused on word-level modeling, their method requires lexical resources.

Elshafei et al. (2006) use a single-layer HMM for diacritization of Arabic text. Scannell (2011) extended diacritization to uni-codification in African languages by solving it using a Naive Bayes classifier. Their models, trained with trigram features on word and character levels, do not need other resources than an accented corpus, so it is compatible with resource-scarce languages.

Nguyen et al. (2012) implemented a system for accent restoration in Vietnamese based on two different models including the CRFs. The training corpus is preprocessed and annotated to indicate, both at syllable and character levels, the accents to insert to recover diacritic forms. Learning how to infer diacritic forms is indirectly reached by learning their differential representation.

Some hybrid approaches were also proposed for Arabic Diacritization : Said et al. (2013) com-

bined a CRF and a morphological analyzer to improve diacritization accuracy, while Metwally et al. (2016) proposed a three-layer processing composed of a CRF, a HMM and a morphological analyzer.

4.2 Category Decomposition

In the domain of CRF-based tagging, the idea to decompose label set in small pieces to train in order to gain learning performance can be found in (Tellier et al., 2010). They proposed to map total label set to a category tree and experiment to train on labels in a cascade manner or to train independently on each label components which correspond to a sub-category and then recombine them to obtain the total label. They concluded that their method, coined “category decomposition”, improves greatly the time-wise efficiency of learning process.

5 Methodology

5.1 Fundamental Definitions

In the following, we will introduce essential elements to our methodology .

Let X, Y, Δ be three discrete random variables: non-tonalized token, tonalized token and code. X and Y take value from Ω (character set with or without diacritics) and Δ is either \emptyset (no modification) or a concatenation of codewords, where a codeword is a triplet containing operation type (insertion or deletion), position for operation and character (if insertion) from Σ :

$$\Sigma \equiv \{+1, -1\} \times \mathbb{N}_{>0} \times \Omega \quad (1)$$

We define E and D , respectively encoder and decoder functions, inverses of each other, such as:

$$\begin{aligned} \Delta &= E(Y; X) \\ Y &= D(\Delta; X) \end{aligned} \quad (2)$$

5.1.1 Entropy Reduction Ratio

r_E is called entropy reduction ratio of E as defined:

$$r_E(\Delta, Y) \equiv \frac{\mathcal{H}(Y)}{\mathcal{H}(\Delta)} \text{ or } \frac{\mathcal{H}(Y)}{\mathcal{H}(E(Y; X))} \quad (3)$$

for any Δ satisfying $\mathcal{H}(\Delta) \neq 0$.

We need to predict tonalization for every non-tonalized token value $X = x$. Instead of predicting on Y , we can predict first on Δ and decode

Δ to obtain Y indirectly by using the second relation in (2). This will allow to greatly reduce the number of possible values of our model: we predict differential codes instead of tonalized words themselves.

In the next subsections, we try to design an efficient encoder E which maximizes r_E so that the resulting code Δ has a reduced set of possible values, it is more easy for a CRF-based modeler to learn on Δ than on Y as explained in the last paragraph of section 3.

5.2 Tonalization as Edit Operations

To maximize r_E (i.e. reduce Δ), we use an algorithm to represent the difference between Y and X by a minimal sequence of basic operations required for recovering Y from X . These basic operations are known as edit operations that we will present in the following.

By edit operation s , we mean a mapping from string a to string b , where a, b are sets of string drawn from the alphabet Ω such that if a is expressed as concatenation of characters as $a_1 a_2 \dots a_{N-1} a_N$, then the mapping can be written as

$$b = s(a; \sigma) \quad (4)$$

where $\sigma = (m, p, c) \in \Sigma$ is a parameter tuple, m is an operation type indicator, p is a position parameter, c is a character involved by the operation.

And the mapping output b will be

$$b = \begin{cases} a_1 a_2 \dots a_{p-1} c a_p \dots a_N, & m = +1 \\ a_1 a_2 \dots a_{p-1} a_{p+1} \dots a_N, & m = -1 \end{cases} \quad (5)$$

We can see in (5), that when $m = +1$, s represents an insertion operation which consists in adding c just before the p -th character⁴ in a , while in the case of $m = -1$, s denotes a deletion operation which removes the p -th character from a .

5.2.1 Use of Wagner-Fischer Algorithm

For any pair of strings (x, y) , the Wagner-Fischer algorithm⁵ in (Wagner and Fischer, 1974) allows to obtain a minimal sequence $S = (\sigma_1, \sigma_2, \dots, \sigma_{M-1})$ such that:

$$\begin{aligned} A_{i+1} &= s(A_i; \sigma_i + (0, l_i, \emptyset)) \\ l_{i+1} &= l_i + m(\sigma_i) \\ A_0 &= x, A_M = y, l_0 = 0 \end{aligned} \quad (6)$$

⁴Or just after the $(p-1)$ -th character, when $p=N$

⁵In this article, we apply Wagner-Fischer algorithm in its special case where there are only 2 available edit operations against 3 edit operations including the substitution as in its general case.

Where $0 \leq M, 1 \leq i \leq M-1$, position parameters p of σ_i denoted by $p(\sigma_i)$ form an increasing series with respect to index i :

$$p(\sigma_i) \leq p(\sigma_{i+1}) \quad (7)$$

For the edit operations acting on the same position p , insertions must precede⁶ deletion as described below:

$$m(\sigma_i) \geq m(\sigma_{i+1}), \text{ if } p(\sigma_i) = p(\sigma_{i+1}) \quad (8)$$

Because it does not make sense to delete a character of a string twice, we assume that, for a given character position, only one deletion may occur:

Thus, $h(\sigma_i)$ below forms an increasing series

$$h(\sigma_i) \equiv 2 \cdot p(\sigma_i) + 0.5 \times [1 - m(\sigma_i)] \quad (9)$$

5.2.2 Encoder

If we set encoder $E(y; x)$ as an application of Wagner-Fischer algorithm on (x, y) , and δ as the concatenation of elements of S like

$$\delta = \sigma_1 \sigma_2 \dots \sigma_{M-1} \quad (10)$$

Then $E(y; x)$ is specified so that the first relation in (2) is satisfied.

5.2.3 Decoder

Moreover, if we choose $D(\delta; x)$ as an implementation of (6) applied on x with δ as parameter, this specifies a way to use x and the code δ to recovery y , and define a decoder.

To show that the entropy is effectively reduced, we will present experiments in section 8 for evaluation of entropy reduction ratio of r_E .

5.3 Segmentation

Segment decomposition of a string x is a mapping from a string x to strings called segments $x^{(1)} x^{(2)} x^{(3)} \dots x^{(L)}$ so that the concatenation of the latter is equal to the original string x .

We can then divide the resulting code δ in L code segments $\delta^{(1)} \delta^{(2)} \dots \delta^{(L)}$ described as:

$$\delta = \delta^{(1)} \delta^{(2)} \dots \delta^{(L)} \quad (11)$$

$\delta^{(i)}$ is the code segment (i.e. a sub-sequence of code δ) associated with $x^{(i)}$:

$$\delta^{(i)} = \sigma_{\min(S_i)} \dots \sigma_{\max(S_i)} \quad (12)$$

⁶Or we can also state that deletions precede insertions. In this case, the second relation of (6) will be different for that decoder to work properly. So this was our design choice.

where S_i is the set which contains the indices of all edit operations acting on segment $x^{(i)}$.

Furthermore, we define shifted version of $\delta^{(i)}$ as below

$$\delta'^{(i)} = \sigma'_{\min(S_i)} \dots \sigma'_{\max(S_i)} \quad (13)$$

where $\sigma'_{\min(S_i)} = \sigma_{\min(S_i)} + (0, -e_i, \emptyset)$, $e_i = \sum_{k=1}^{i-1} |x_k|$ position offset. It can be shown that y can be obtained by concatenation⁷ of decoding results of D on shifted code segment $\delta'^{(i)}$ as below

$$y = D(\delta'^{(1)}; x^{(1)}) D(\delta'^{(2)}; x^{(2)}) \dots D(\delta'^{(L)}; x^{(L)}) \quad (14)$$

Using the proposed segmentation allows to get the shifted code segment $\delta'^{(i)}$ associated with segment $x^{(i)}$. For obtaining y , it suffices to individually decode code segments $\delta'^{(i)}$ using the same decoder defined in (2). Hence, an encoder - decoder pair is indirectly specified as:

$$\begin{aligned} \delta'^{(i)} &= E'(y, x^{(i)}) \\ y^{(i)} &= D(\delta'^{(i)}, x^{(i)}) \end{aligned} \quad (15)$$

The segmentation technique allows a CRF-based system to learn $\delta'^{(i)}$ individually instead of a total code δ at once. The relation in (14) can then be used to recover y from predicted code segments $\delta'^{(i)}$ produced by CRF taggers.

To show the effect of segmentation on entropy reduction ratio $r_{E'}$, we will evaluate experiments in section 8 with different segmentation settings such as syllabification and fixed-width segmentation.

5.4 Edit Operation Filtering

As previously explained, segmentation on x leads to splitting code δ in several code segments $\delta^{(i)}$ (or its shifted version $\delta'^{(i)}$) because it regroups edit operations $\sigma_j = (m_j, p_j, c_j)$ inside δ by position parameter p_j .

Edit operation filtering allows to split each code segment $\delta^{(i)}$ in some subgroups by operation type m_i and character involved by operation c_i . But as opposed to segmentation, in the filtering process, some edit operations are dropped because of their irrelevance regarding our tonalization goal for Bambara.

⁷Alternatively, it is also possible to obtain the integral code δ from $\delta'^{(i)}$ using relations (11), (12), (13) and to get the underlying tonalized token y by direct decoding on the integral code δ .

First, we recall that the order of edit operations called σ'_k inside the sequence $\delta'^{(i)}$ is partially determined by their elements. It can be shown, more generally that the order restriction in (7), (8) leads directly to

$$p'_k < p'_l \implies k < l \quad (16)$$

$$m'_k > m'_l \wedge p'_k = p'_l \implies k < l \quad (17)$$

where $m'_k \equiv m(\sigma'_k)$, $p'_k \equiv p(\sigma'_k)$, $k \neq l$.

Thus, the order between any two edit operations in $\delta'^{(i)}$, called σ'_k, σ'_l is free only in the case of multiple insertion acting on the same position of a string, i.e. $m'_k = m'_l = +1$, $p'_k = p'_l$.

5.4.1 Tone Marker Filtering

The aim of tone marker filtering is to remove edit operations irrelevant to tonalization. It consists in removing all insertions of characters which are not considered as tone markers, and keeping only the first of all insertions (also only the first one of all tone deletions) operating on the same position (because neither multiple insertions nor multiple deletions are supposed to be present in pure tonalization).

In addition, the filter contributes to reduce the code so that the order of edit operations in filter output becomes totally determined by edit operation arguments (i.e. p and m) via relations (16)(17). Therefore, the indexing function h defined in 9 forms a strictly increasing series.

5.4.2 Edit Operation Decomposition

We define an edit operation dispatcher F_m as a mapping from input code δ_{in} to its sub-sequence described as:

$$F_m(\delta_{in}; k) = \sigma_{\min(V_k(\delta_{in}))} \dots \sigma_{\max(V_k(\delta_{in}))} \quad (18)$$

where $V_k(\delta)$ is the set which contains the indices of all edit operations in δ of type k , $k \in \{-1, +1\}$

For recall, the tone marker filter produces a code result in which $h(\sigma_i), i > 0$ forms a strictly increasing sequence. This property implies that there exists an inverse mapping from $\{F_m(\delta_{in}; k)\}_{k \in \{-1, +1\}}$ to δ_{in} if δ_{in} is a filtered result. We call this underlying mapping edit operation assembler.

6 System Architecture

In this section, we present the architecture of our system for automatic tone marker insertion for Bambara text by detailing its functional blocks and internal data flow.

6.1 Training Stage

At training stage, as shown in Figure 3, the tonalization system uses an encoder to represent the difference of the tonalized token value y relative to its original non-tonalized token value x by the code δ . The code δ as well as the non-tonalized token x are then fed into the code segmenter which breaks down δ in small shifted code segments $\delta^{(i)}$. The tone marker filter takes the shifted code segments, selects tone markers and sends its output to a dispatcher which distinguishes insertion and deletion operations.

In the following, two CRF models are trained individually on relation $(x, \delta_+^{(i)})$ and on relation $(x, \delta_-^{(i)})$ in the reference corpus.

6.2 Tonalization Stage

In tone recovery stage, the two trained CRF models are used to predict the two parts of shifted code segment $\delta_+^{(i)}$, $\delta_-^{(i)}$ from tonalized token x . Then they are fed to, as shown in Figure 4, an edit operation assembler to get predicted shifted code segment $\delta^{(i)}$; at the same time, the non-tonalized token x is re-segmented to get $x^{(i)}$. Then, the non-tonalized segment $x^{(i)}$ as well as the shifted code segment $\delta^{(i)}$ are sent to be decoded to obtain tonalized segment $y^{(i)}$ in decoder output. In the end, the decoded tonalized segments $y^{(i)}$ are reunited in the code assembler to give the estimated integral tonalized token value y .

7 Running examples

To illustrate more concretely how our system works at training stage, we propose in the following, two running examples: the first one shows how our system models a pure tonalization; the second one shows how the tone marker filter could be helpful when some typographic modifications are introduced in the tonalized form.

7.1 Example 1 (pure tonalization)

In this example, the system models the tonalization from *lakali* to *lákàlí*. Hence, x, y are set as

below:

$$\begin{aligned} x &= lakali \\ y &= lákàlí \end{aligned}$$

The tone encoder compares x and y , then outputs the differential representation as tonal code δ below:

$$\delta = [(+1, 2, \grave{)}, (+1, 4, \grave{)}, (+1, 6, \grave{)}]$$

In the above, the 3 codewords that δ contains represent the 3 tone markers inserted into x to model for this tonalization.

$$\begin{aligned} \delta^{(1)} &= [(+1, 2, \grave{)}] \\ \delta^{(2)} &= [(+1, 4, \grave{)}] \\ \delta^{(3)} &= [(+1, 6, \grave{)}] \end{aligned}$$

The syllabification is exemplified below on non-tonalized and tonalized form:

$$\begin{aligned} x^{(1)} &= la, y^{(1)} = lá \\ x^{(2)} &= ka, y^{(2)} = kà \\ x^{(3)} &= li, y^{(3)} = lí \end{aligned}$$

We observe that the 3 tone markers are all inserted after the second character for each of 3 syllables. Therefore, we got 3 shifted versions of code segments operating at position 2 as below.

$$\begin{aligned} \delta_+^{(1)} &= \delta^{(1)} = [(+1, 2, \grave{)}] \\ \delta_+^{(2)} &= \delta^{(2)} = [(+1, 2, \grave{)}] \\ \delta_+^{(3)} &= \delta^{(3)} = [(+1, 2, \grave{)}] \end{aligned}$$

As in this example, only the tone marker insertions are to be modeled, the tone marker filter, edit operation decomposition unit do not affect system result at training stage.

7.2 Example 2 (noisy tonalization)

The system models the tonalization from *taanikasegin* to *táa-ká-ségin*. Hence, x, y are set as below:

$$\begin{aligned} x &= taanikasegin \\ y &= táa - ká - ségin \end{aligned}$$

In the following, we show the syllabification result of y presented with its related to non-tonalized

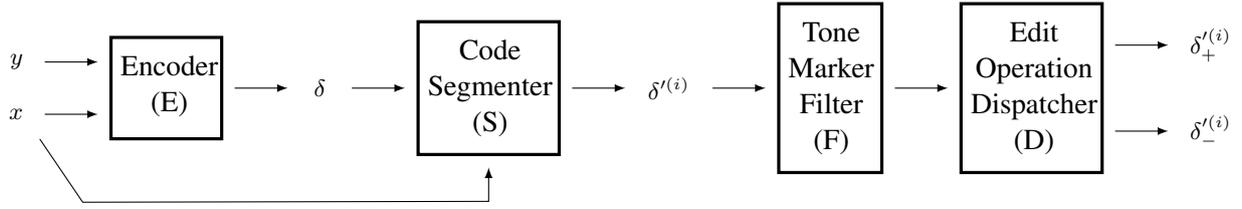

Figure 3: Block diagram for the proposed Bambara tonalization system at training stage

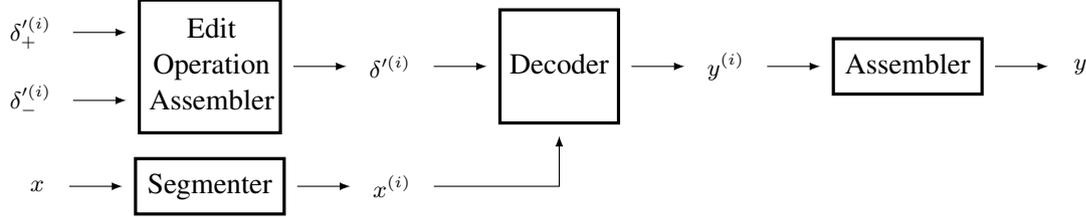

Figure 4: Block diagram for the proposed Bambara tonalization system at tonalization stage

form.

$$\begin{aligned} x^{(1)} &= taani, y^{(1)} = t\acute{a}a- \\ x^{(2)} &= ka, y^{(2)} = k\acute{a}- \\ x^{(3)} &= se, y^{(3)} = s\acute{e} \\ x^{(4)} &= y^{(4)} = gin \end{aligned}$$

Subsequently, 7 codewords are obtained from differential tone encoding, then departed in 4 code segments corresponding to 4 syllables:

$$\begin{aligned} \delta^{(1)} &= [(+1, 2, \grave{)}, \\ &\quad (+1, 3, -), (-1, 4, n), (-1, 5, i)] \\ \delta^{(2)} &= [(+1, 7, \grave{)}, (+1, 7, -)] \\ \delta^{(3)} &= [(+1, 9, \grave{)}] \\ \delta^{(4)} &= \emptyset \end{aligned}$$

As a remark, the first syllable in the above is the most concerned by noise : one dash symbol insertion and 2 character removals are observed. The tone marker filter removes all character deletions and insertions in code segments. Therefore, tonalization is modeled by only tone marker insertions as below:

$$\begin{aligned} \delta_+^{(1)} &= \delta^{(1)} = [(+1, 2, \grave{)}] \\ \delta_+^{(2)} &= \delta^{(2)} = [(+1, 2, \grave{)}] \\ \delta_+^{(3)} &= \delta^{(3)} = [(+1, 2, \grave{)}] \\ \delta_+^{(4)} &= \delta^{(4)} = \emptyset \end{aligned}$$

Here, we found a tonalization representation similar to the one from the preceding example: insertion of a tone marker at position 2 for some syllables.

8 Experiment

8.1 Experiment Setup

The disambiguated corpus of BRC which contains tonalized tokens is chosen as training data. The train data then is split into training and evaluation data sets with ratio $p : (1 - p)$. By default, p is set to 50% for efficiency reason.

For CRF implementation, we use CRFSuite as open-source library with I-BFGS algorithm specified as training method, Viterbi algorithm as inference method (Okazaki, 2007).

The segmentation mode is specified by the integer w described in the following : $w = -1$ indicates a syllabification (as obtained by BRC morphological parser), $w = 0$ for no segmentation and $w > 0$ signals a w -width regular segmentation⁸.

We denote different configurations of our system by their functional layout at training stage. For specifying the functional layout, the following symbols D, F, S, E are used to indicate respectively four constituent blocks of the system : D for edit operation decomposition block, F for tone marker filter block, S for segmentation block, E for encoder block, and \circ denotes an inter-block connection. For example, $S \circ E$ represents an encoder followed by a segmenter as system.

⁸A regular segmenter forms a segment of every w successive characters, from left to right (i.e. in direction of writing of Bambara), in its input string. By exception, the last segment at output contains the rest of the string which has not yet been segmented so that we allow it to be equal or shorter than a segment of w characters.

8.2 Feature Engineering

The feature patterns we created are the same for all CRF models. The features are generated for each segment⁹ for tokens in the training data $x^{(i)}$.

For each segment, features indicate:

- At segment (sub-word) level
 - Previous, current and next segment
 - Substring containing all vowels for current segment
 - Position of current segment (integer) relative to beginning or ending of word
 - Typography of segment: all capital letters, presence of numbers or punctuation marks
- At word level
 - Previous, current and next words
 - Prefix and suffix for previous, current and next words
 - Position of current word (integer) relative to beginning or ending of sentence

8.3 Evaluation Measure

As shown by the example of the section 7.2, the tonalized token y can itself be noisy. On the other hand, we are particularly interested in errors introduced by CRF-based in predicting $\delta_+^{(i)}, \delta_-^{(i)}$ from x . Consequently, our accuracy evaluation is based on the comparison of two tokens described as below:

- A gold standard according to tonalization filtering (i.e. typographic modification are not expected)
- The token tonalized by our system, resulting from applying $\delta_+^{(i)}, \delta_-^{(i)}$ (predicted by the CRFs) to the segments $x^{(i)}$

8.4 Experiment Results

8.4.1 Coding and Segmentation

The entropy for the tonalized token Y that we calculated on the disambiguated part of BRC is 8.73 bits of entropy for 20,870 distinctive tonal forms. As shown in Table 3, the tonalization representation produced by tone encoder Δ has only 3.38 bits of entropy (1,273 distinctive codes). In other

⁹If the edit operation decomposition is used, as we use two CRF models, features are generated on segment components (for insertion and for deletion) individually

word, the entropy is reduced by a factor of 2.58 by only using the differential tone encoder. If segmentation is also used, shorter segments lead to greater entropy reduction. The extreme case is to segment by character ($w = 1$), leading to an entropy reduction ratio of 4.82, and implies character-level processing.

8.4.2 Segmentation and Operation Filtering

Table 4 presents an experiment on the impact of system configuration (related to Figure 4) and segmentation mode on tonalization accuracy and training time of our system. For comparison, the accuracy of a baseline based on majority voting method is also provided in the last row.

We note first that segmentation improves accuracy. Syllabification as well as regular segmentation with a fixed width close to averaged syllable length (3.24 characters) gives the best result in accuracy (0.92). Regarding system configuration, accuracy is generally preserved over the four different configurations except of when applying operation decomposition without filtering. This can be explained by the fact that decomposition is not totally recoverable as mentioned in section 5.4.2 for data which is not processed by tone marker filter, it can introduce some errors within assembler at tonalization phase and degrades its accuracy.

Training time is dramatically reduced by segmentation and by edit operation decomposition. This may sometimes be at the cost of accuracy, but syllabification or fixed segmentation with width $w = 2$ is a nice trade-off, preserving accuracy and keeping training time acceptable.

Those experiments allow to state that segmentation is gainful both for accuracy and training time (see last column). Decomposition and filtering do not have a tremendous impact on accuracy, but are unavoidable to be able to train models on the whole dataset in reasonable time.

8.4.3 Effect of Train Size and Error Analysis

Figure 5 shows how the training set size influences the tonalization accuracy and training time. We can see the progress in accuracy with respect to training set size is less considerable when $p \geq 50\%$ than when $p < 50\%$. The training time increases dramatically with respect to training set size.

Table 5 shows distribution of errors which occur in automatic tone insertion (not in tone deletion). The error occurs due to a bad prediction in

Entropy \ Width w	-1 (Syllabe)	1	2	3	4	5	6	0

character to insert but correct prediction in character position is prevalent (58.52%) and the silence (40.08%) which is a false negative case is also very frequent. Prediction error only in character position is as weak (1.17%) as error rate (0.023%) for both character position and symbol error. This shows that our system correctly predicts positions (mainly at beginning of words) and that most of the errors are due to the difficulty to predict if a tone has to be added, and which one.

Table 6: Confusion matrix on prediction of tone markers

Table 6 presents the confusion matrix of the error occurring due to bad prediction in character mentioned previously in Table 5. It shows that these errors are mainly due to the confusion between low tone (´) and high tone (`), which are the two most frequent markers in BRC.

9 Conclusion

In this paper, we presented our Bambara tonalization system for automatic detection of tone markers in Bambara. Our experiments show that using segmentation both increases tonalization accuracy and greatly reduces training time. Our differential encoder reduces entropy of labels to be predicted, making CRF learning efficient and allowing to implement a tone marker filter and edit operation decomposition unit within the tonalization process. The tone marker filter plays the role of normalizer of tonalized token to learn in training phase and in normalizing the token, it leads to reduce training time. The edit operation decomposition unit which follows the filter split the tokens in insertion and deletion of tone markers, allows to accelerate furthermore the training time reduction without altering tonalization accuracy.

Joint Learning of Dialog Act Segmentation and Recognition in Spoken Dialog Using Neural Networks

Tianyu Zhao and Tatsuya Kawahara

{zhao, kawahara}@sap.ist.i.kyoto-u.ac.jp

Abstract

Dialog act segmentation and recognition are basic natural language understanding tasks in spoken dialog systems. This paper investigates a unified architecture for these two tasks, which aims to improve the model’s performance on both of the tasks. Compared with past joint models, the proposed architecture can (1) incorporate contextual information in dialog act recognition, and (2) integrate models for tasks of different levels as a whole, i.e. dialog act segmentation on the word level and dialog act recognition on the segment level. Experimental results show that the joint training system outperforms the simple cascading system and the joint coding system on both dialog act segmentation and recognition tasks.

1 Introduction

Recently the burst of interactive assistants and chatbots leads to an increasing interest of dialog systems. Natural language understanding (NLU), as an important component of dialog system, is usually responsible for dialog act (DA) or dialog intent tagging, where text classification techniques are necessary. Dialog act (also speech act) is a representation of the meaning of a sentence at the level of illocutionary force (Stolcke et al., 2000). For instance, a sentence “*How is the weather?*” belongs to the dialog act class *Question*. For another sentence, “*The weather is quite good today.*”, if it follows a previous *Question* sentence, it should be an *Answer* to the question. Otherwise it is likely to be a *Statement*. Therefore, DA recognition requires us to understand the sentence from semantic, pragmatic and syntactic aspects, and its context plays an important role as well.

Words	hi	my	name	is	Erica
Segment	E	I	I	I	E
DA	Greeting	Statement			

Table 1: DA segmentation and recognition.

The prerequisite for DA recognition is to split a sequence of words into segments, each of which corresponds to one DA unit. Especially for spoken dialog systems, NLU is based on Automatic Speech Recognition (ASR) hypotheses or transcripts, in which we cannot make any assumption of punctuation such as periods, commas and question marks for segmentation. Therefore DA segmentation becomes essential for spoken dialog systems. As the example given in Table 1 shows, a long utterance is firstly split into two segments “*hi*” and “*my name is Erica*”, to which DA tags “*Greeting*” and “*Statement*” are assigned afterwards. DA segmentation is a sequence labeling task and an “IE” tag coding scheme is adopted to describe segment boundaries, where “I” denotes “inside” of a segment and “E” denotes the “end”. While the DA segmentation is a pre-process of DA recognition, recognition of DA in the sequence helps segmentation. Thus, DA segmentation and recognition are two highly related tasks. We can expect that joint learning of these two tasks can improve the performance of models. In this paper we investigate architectures of joint learning of DA segmentation and recognition, and analyze their performances. DA segmentation is a sequence labeling task on the word level and DA recognition is a classification task on the DA segment level. Our model is flexible and can be applied to tasks of different levels.

The rest of this paper is structured as follows. Section 2 gives a literature review. Section 3 describes a hierarchical neural network model for

DA recognition and explains its ability to model sequential short texts. Section 4 focuses on joint learning of DA segmentation and recognition, and explores three models for joint tasks. Section 5 shows experimental results on three tasks using the proposed models. Lastly in Section 6 and 7 we discuss the results and give a conclusion.

2 Related Works

In the task of DA recognition, Shriberg et al. (1998) applied decision tree using rich features and emphasized the importance of prosodic features. Stolcke et al. (2000) used HMM to capture the intrinsic patterns of DA sequence. Variants of neural network have been recently used in this task. In (Lai et al., 2015), a recurrent convolutional neural network is applied to text classification, which consists of a RNN layer and a max-pooling layer over it. Ji et al. (2016) proposed a latent variable RNN for modeling discourse relations between sentences. Khanpour et al. (2016) investigated RNNs with different settings of hyperparameters. A hierarchical neural network was introduced by Lee and Derroncourt (2016). It firstly uses a RNN layer or a CNN layer to generate vector representations of short texts. Then a two-layer feedforward ANN takes a sequence of these vector representations to predict the probability distribution of output labels. Li and Wu (2016) used gated RNN for both vector representation generation and classification in their hierarchical model. We base our work on hierarchical neural network for DA recognition and propose a unified architecture for joint DA segmentation and recognition, which is discussed in Section 4.

3 Hierarchical Neural Network

When we regard DA recognition as a text classification task, there are two difficulties in accurately recognizing a DA. In the first place, texts in DA recognition are often limited to a small number of words while tasks such as sentiment analysis and news topic categorization aim to classify fairly long documents and can exploit mainly n-gram models. Compared with long documents, dialog utterances have much fewer words and it is difficult to extract enough information from simple word co-occurrence features. Secondly, it is of great importance to consider contexts in DA recognition. For instance, a sentence “the weather is quite good today” is regarded as an *Answer* if

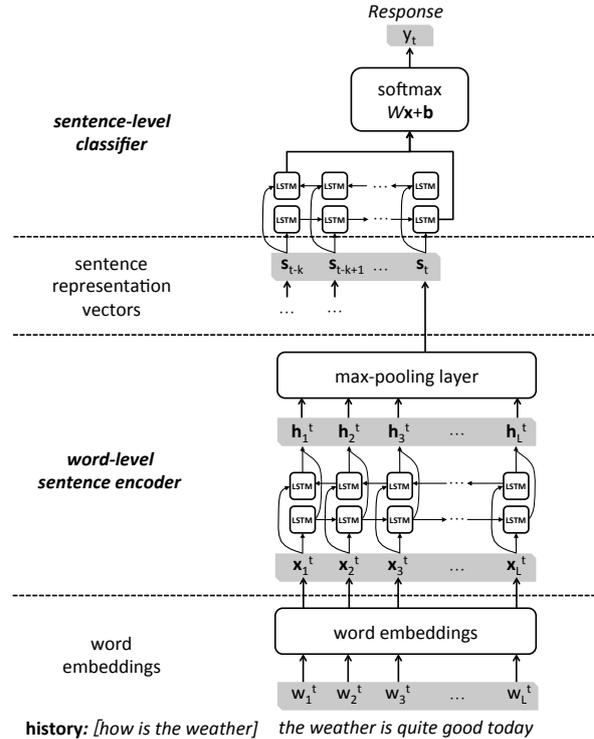

Figure 1: Hierarchical neural network: an example of input and output is given in the figure.

it appears after another speaker questioning the weather. Otherwise, it is a *Statement*.

In order to address aforementioned problems, we use a hierarchical neural network for DA recognition. The hierarchical model firstly takes distributed word representation as input, which contains richer semantic information than n-gram features do. Secondly, it exploits history information to recognize DA tags of ambiguous utterances such as “the weather is quite good today”. The general architecture of the hierarchical neural network consists of a sentence encoder and a classifier. A sentence encoder neural network encodes a sequence of words into a vector (sentence representation vector) of a fixed length, which will be explained in Section 3.1. A classifier neural network predicts the label given representation vectors of the corresponding sentence and its preceding sentences, which will be explained in Section 3.2. The architecture of hierarchical neural network used in our work is shown in Figure 1.

3.1 Sentence Representation

A sentence encoder encodes a sequence of words into a fixed-length vector. By training the encoder, it obtains the ability to mine useful task-related information from a word sequence. We choose Bidi-

rectional Long Short-Term Memory (BiLSTM) - a variant of RNN. LSTM (Hochreiter and Schmidhuber, 1997) can better avoid the vanishing gradient problem compared with normal RNNs, thus it is suitable for processing information through many time steps.

Input words $w_{1:L}^t$ are firstly converted to word embeddings through a lookup table in word embedding layer. Given word embeddings $x_{1:L}^t$, BiLSTM outputs hidden states $h_{1:L}^t$, where an output hidden state \overrightarrow{h}_i is the concatenation of forward hidden state \overrightarrow{h}_i and backward hidden state \overleftarrow{h}_i . We use a max pooling layer to extract the most informative features over time, and produce a single vector s_t as the encoding of word sequence $w_{1:L}^t$.

3.2 Sequence Classification

Given sentence encoding vectors $s_{t-k:t}$, we use the second neural network to predict the label of the t -th sentence. We use a history of length k instead of the whole history since dialog act usually depends on the very late history and it also accelerates training. Again we use BiLSTM and it works in a similar manner as the BiLSTM sentence encoder does but without max pooling layer, since the latest sentence provides the most information for DA recognition. Given the final hidden state, a fully-connected layer with a softmax function outputs the predicted label y_t .

4 Joint Learning

Joint learning (multi-task learning) is an approach to learn from several related tasks in parallel so that it improves the model’s ability to generalize features, and promotes its performance on the different tasks. In natural language processing (NLP), many higher-level tasks usually depend on outputs from lower-level tasks, for example named entity recognition (NER) relies on part-of-speech (POS) tagging. Hence there are many cases where models can benefit from joint learning.

Collobert and Weston (2008) introduced a neural network-based joint architecture making minimal assumption of feature engineering, and also concluded three kinds of joint model, i.e. cascading features, shallow joint training, and deep joint training. A cascading model, however, does not include any joint learning procedure, and shallow joint training is actually to convert tags of different tasks into one tag. In the rest of this paper, we will name them cascading model, joint cod-

ing model, and joint training model for accuracy. Zheng et al. (2013) applied a joint coding method to Chinese word segmentation and POS tagging by changing POS labels using a “BIES” tag coding scheme. Peng and Dredze (2016) improved NER by word representation learnt in word segmentation task using a LSTM-CRF model. Yang et al. (2016) proposed a multi-task cross-lingual model for sequence labeling tasks using RNN-CRF structures. These approaches to joint learning mostly attempt to learn shared representation of words and characters from different tasks.

Unlike aforementioned NLP tasks, DA segmentation and recognition deal with units of different levels, i.e. word level and DA segment level. Joint learning of these two tasks does not naturally fit in the architectures above. Previous works usually use joint coding methods. Zimmermann 2006 (2006) used a hidden-event language model for sequence labeling of DA type and its boundary on word level. It also exploits prosodic features in classification. Zimmermann (2009) and Quarterono et al. (2011) applied conditional random field (CRF) and the former also investigated how different tag coding schemes affect the model’s performance. Granell et al. (2009) incorporated syntactic features and used a combination of a HMM at the lexical level and a Language Model (LM) at the DA level. Hakkani-Tür et al. (2016) used a single sequence labeling LSTM model for joint semantic frame parsing, where sentence-level intent and domain tags are predicted at the last token of the sentence. An encoder-decoder-pointer framework was used for chunking in (Zhai et al., 2017), where segmentation was done by a pointer network and labeling was done by a decoder LSTM.

To our knowledge, there is no previous work on neural network based joint model applied to joint learning of DA segmentation and recognition. In this section, we investigate cascading model, joint coding model, and joint training model using neural networks. In the joint coding model, joint tag coding is used to combine segmentation and recognition tags and leads to a word-level sequence labeling task. For cascading and joint training models, the proposed architectures can deal with tasks of different unit levels and the hierarchical model introduced in Section 3 is integrated to make use of contextual information.

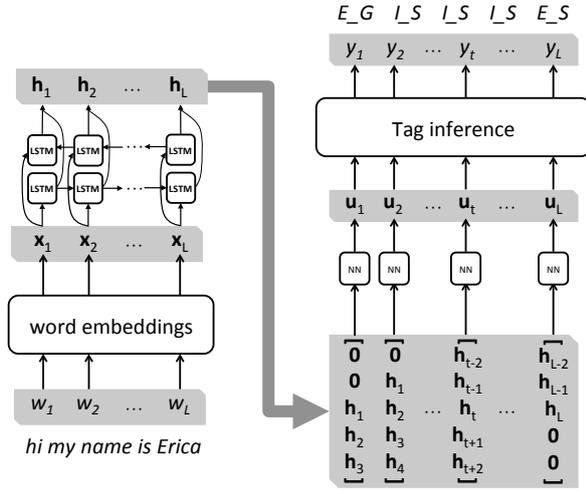

Figure 2: Joint coding model: an example of input and output is given in the figure.

4.1 Joint Coding Model

4.1.1 Joint Coding

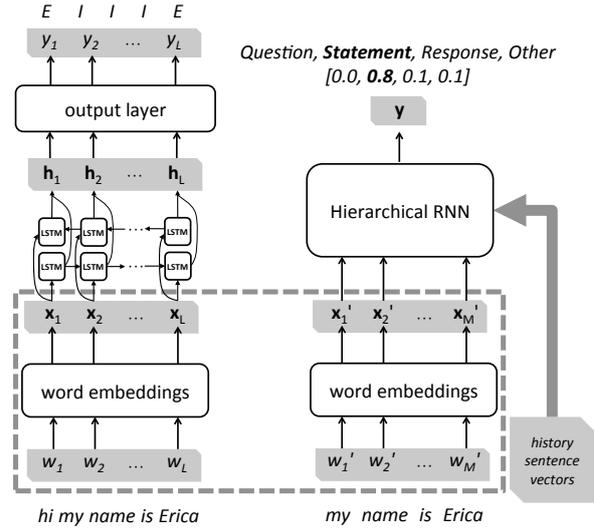

In the joint coding method, one single model predicts labels of DA segmentation and recognition at the same time, so that the units of these two tasks should keep consistency. We use a joint tag coding scheme to combine labels of segmentation and recognition and make them a word-level sequential labeling problem as shown in Table 2. This allows us to use one single sequential labeling model to solve two tasks simultaneously. The proposed joint coding model is given in Figure 2.

4.1.2 Tag Score

A sequence of words $w_{1:L}$ is firstly mapped to word embeddings $x_{1:L}$, then we feed them to the following RNN layer which produces hidden states $h_{1:L}$. In order to provide contextual information explicitly, when we predict a label for the i -th step, we also make use of hidden states of preceding steps (h_{i-1} , h_{i-2} , etc.) and succeeding steps (h_{i+1} , h_{i+2} , etc.). The concatenated vector $[h_{i-2}, h_{i-1}, h_i, h_{i+1}, h_{i+2}]$ is then fed to a neural network layer that computes a tag score s_i , where $s_i \in \mathbb{R}^{|C|}$, the t -th element in s_i indicates the score of choosing the t -th tag at the i -th step, and $|C|$ is the number of tag classes.

4.1.3 Tag Inference

Since there often exists invalid tag sequences such as an “E_S” following an “I_Q” and we would like to penalize such invalid tag transitions, we apply a post process to compute the optimal tag sequence considering the transition probabilities by using a

(a) Segmentation component

(b) Recognition component

Figure 3: Cascading model and joint training model: in cascading model, part (a) on the left is a component for segmentation and part (b) on the right is for DA recognition. In joint training model, word embedding layers in dashed line rectangle are shared by both segmentation and recognition models. An example of input and output is given in the figure.

transition score matrix A_{mn} , which indicates the score of jumping from m -th tag to the n -th tag. Let s_i^t denotes the t -th element of s_i , the score of a tag sequence $t_{1:L}$ is defined as:

$$score(t_{1:L}) = \sum_{i=1}^L (A_{t_{i-1}t_i} + s_i^t), \quad (1)$$

and we use the Viterbi algorithm to find the optimal tag sequence $t_{1:L}^*$ that maximizes the sequence score:

$$t_{1:L}^* = \arg \max_{\forall t_{1:L}} score(t_{1:L}). \quad (2)$$

4.2 Cascading Model and Joint Training Model

DA segmentation splits a sequence of words into segments, and DA recognition assigns a dialog act type to them. Thus, these two tasks are naturally conducted in a cascading manner. The proposed cascading model is shown in Figure 3.

The left part is a sequential labeling model for segmentation. Similar to the joint coding model, a word embedding layer and a layer of RNN are used to produce a sequence of hidden states $h_{1:L}$.

Words	hi	my	name	is	Erica	nice	to	meet	you
Segmentation	E	I	I	I	E	I	I	I	E
DA	Greeting	Statement				Greeting			
Joint tag coding	E_G	IS	IS	IS	E_S	IG	IG	IG	E_G

Table 2: Joint “IE” tag coding scheme, where “I” and “E” refer to “inside” and “end” respectively. We concatenate segmentation tag with DA tag to produce coded tags. For example, “E.S” denotes the end of a *Statement* segment.

Then the top layer outputs predicted labels $y_{1:L}$. The right part of Figure 3 uses the hierarchical neural network model introduced in Section 3. In order to provide contextual information, we also maintain a history of sentence representation vectors of previous sentences using the same hierarchical neural network.

Joint training model can be seen as a cascading model with shared components. As shown in Figure 3, the proposed model uses only one set of word embeddings compared with the cascading one, while other task-specific parts are still separated. By updating the shared word embeddings using errors from both tasks, the model is expected to learn features from DA segmentation and recognition and improve its ability of generalization.

5 Experimental Evaluations

In order to evaluate our models, we conducted three sets of experiments:

- **Segmentation task:** evaluate models’ DA segmentation performance only.
- **Recognition task:** evaluate models’ DA recognition performance given correct segments.
- **Joint segmentation and recognition task:** evaluate models’ DA segmentation and recognition jointly, where predicted segments are given for DA recognition.

For each set of experiments, we also vary the length of history k for the cascading model and the joint training model.

5.1 Data Set

We use a one-to-one Japanese chatting corpus collected using a conversational android ERICA (Glas et al., 2016; Inoue et al., 2016). It is annotated with 4 DA tags (i.e. *Question*, *Statement*, *Response* and *Other*) following standards in (Bunt et al., 2010). Table 3 presents related statistics.

Corpus Statistics	
# of classes	4
avg. # of segments per session	165
avg. # of segments per turn	1.76
# of training sessions	30
# of test sessions	8

Table 3: Corpus statistics.

5.2 Implementation

We implemented the proposed models with *TensorFlow*¹. Neural networks are trained using the Adam optimizer (Kingma and Ba, 2014). We use an initial learning rate of 0.0001 which decays in half when the objective loss does not decrease. A dropout layer of 0.25 dropout probability is added before every RNN layer for regularization. We choose 128 as the word embedding dimension since it works well in most NLP tasks. To find out how history length k affects the models, we experimented on k of 1, 3, 5, 10, 20. We also test CRFs implemented by *CRF++*² for comparison in our experiments.

5.3 Evaluation Metrics

For the segmentation task, we use the DA Segmentation Error Rate (DSER) in (Zimmermann et al., 2005). The DSER is the percentage of segments that are incorrectly segmented, i.e. its left or right boundary differs from the reference boundaries. Accuracy, Macro F1 measure, and Weighted F1 measure are used for evaluation of the recognition task since it is a text classification problem. For the joint task, we use the DA Error Rate (DER) which is the same as the DSER but also considers the DA type for correctness. Table 4 demonstrates the calculation of DSER and DER.

¹<https://www.tensorflow.org/>

²<https://taku910.github.io/crfpp/>

Reference Prediction	E_G	LS	LS	E_S	I_Q	I_Q	E_Q	LS	E_S
	E_G	LS	LS	LS	E_S	I_Q	E_Q	LR	ER
DSER	✓		×			×			✓
DER	✓		×			×			×

Table 4: An example of DSER and DER metrics. The DSER equals 0.5 (2/4) and the DER equals 0.75 (3/4).

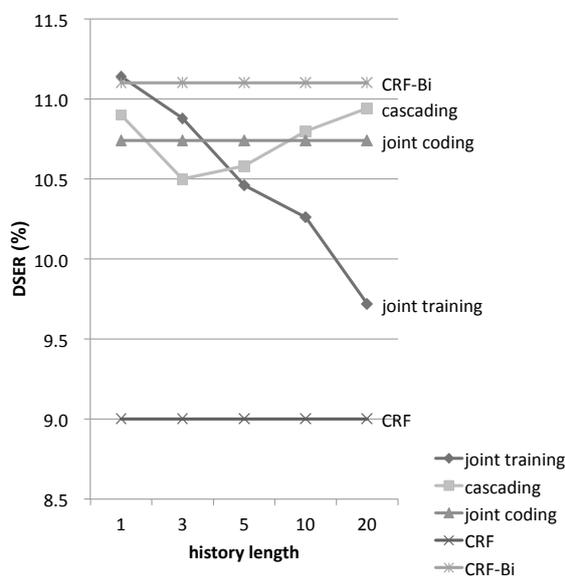

Figure 4: Results of the segmentation task.

5.4 Segmentation Result

In this task, a set of experiments are conducted to evaluate the model performances on DA segmentation specifically. We apply our models to segment every turn in dialogs, where one turn refers to a sequence of consecutive words uttered by one speaker without being interrupted by another speaker. We compare the cascading model, the joint coding model and the joint training model. Two CRFs are used for comparison. A simple CRF uses unigrams and bigrams of w_{t-2} , w_{t-1} , w_t , w_{t+1} , w_{t+2} as features, where w_t is the current word. Another CRF additionally uses the last tag as a feature and is named CRF-Bi in the following experiments.

Figure 4 shows the results of the segmentation task. The joint training model achieves 9.7% DSER at a history length of 20, which is comparable to CRF’s 9.0% (without a significant difference), and it outperforms the cascading model’s 10.5% at a history length of 3. The joint coding model lags behind slightly with the DSER of 10.7% and CRF-Bi gets a DSER of 11.1%.

5.5 Dialog Act Recognition Result

In the task of DA recognition, we evaluate the model performances of DA recognition. Therefore, we directly use ground-truth segments as inputs and predict a DA label for these segments. We only compare the cascading model and the joint training model in the recognition task because the joint coding model and CRFs are sequence labeling models and they do not naturally fit the text classification task.

As shown in Figure 5, the joint training model gets better results than the cascading model according to all three metrics. The joint training model achieves the best results of 78.0% accuracy, 77.4% Macro F1 measure and 78.1% Weighted F1 measure at the history length of 10, while the cascading model reaches 77.2%, 76.5% and 77.4% respectively. A significant improvement is obtained when we increase the history length from 1 to 3.

5.6 Joint Segmentation and Recognition Result

In the joint task, segmentation and recognition performances are evaluated jointly. We firstly segment each turn in dialogs into segments, then use the predicted segments as inputs of DA recognition. As in the segmentation task, we compare our proposed models and two CRFs.

Figure 6 shows the results of the joint task. The joint training model has the lowest error rate of 27.3% at the history length of 10, gaining an absolute improvement of 1.6% compared with the cascading model’s 28.9%. CRF-Bi, CRF and the joint coding model got the DSER of 33.5%, 36.8% and 37.1% respectively.

6 Discussion

In the segmentation task, CRF using only n-gram features obtains a result of 9.0%, though there is not a statistically significant difference in performance between CRF and the joint training model, whose DSER is 9.7%. We conjecture that the re-

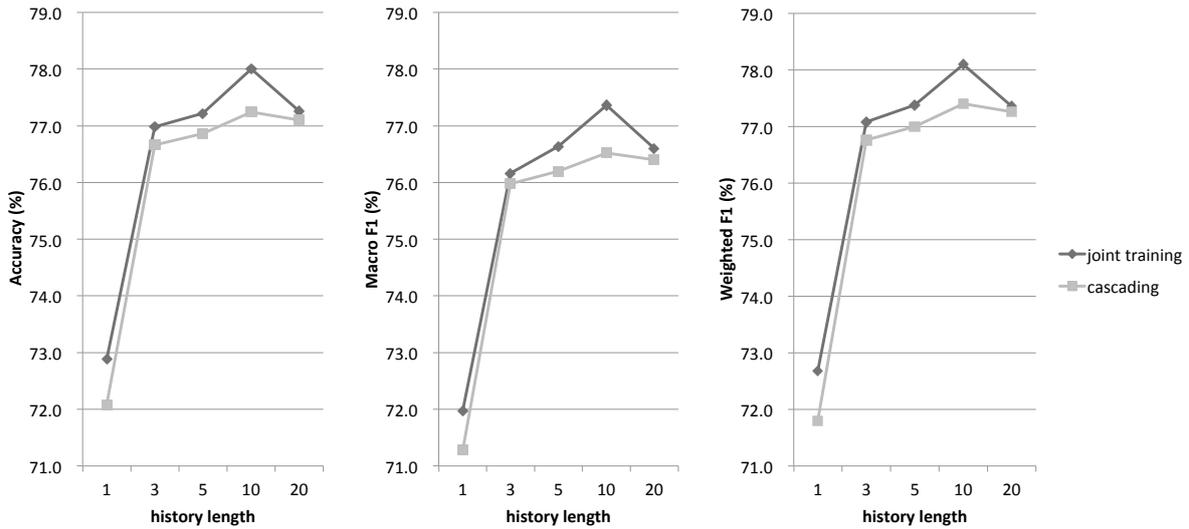

Figure 5: Recognition results evaluated using Accuracy, Macro F1 measure and Weighted F1 measure.

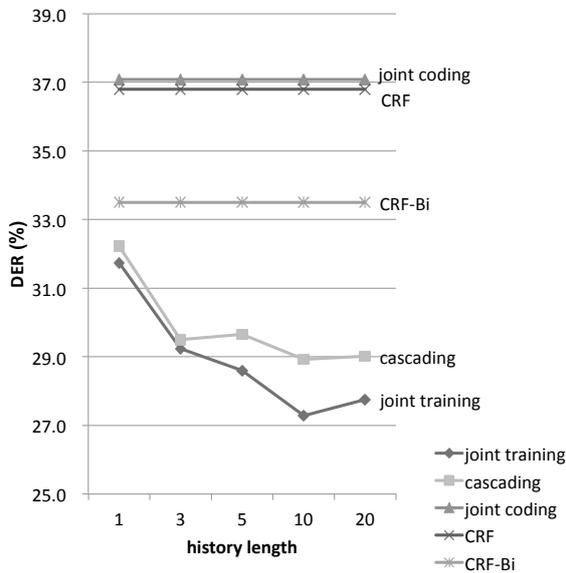

Figure 6: Results of the joint task.

result is due to that the boundaries of DA segments in Japanese are usually marked with words such as “*masu*”, “*desu*”, “*kedo*”, and considering simple n-gram features can cover most of the cases in DA segmentation. CRF-Bi, which uses a previous tag as additional feature, has a higher error rate of 11.1% compared with CRF using n-grams. It implies that extra information (previous segmentation tag and dialog act tag) may hurt the model’s performance in the sense of segmentation. However, by comparing the results of the cascading joint model and the joint training model (10.5% DSER of the cascading model and 9.7% DSER of

the joint training model), we can see that our joint training method is able to extract useful information from DA recognition task for segmentation and improve our models’ ability of segmentation.

In the DA recognition task, we compare the best results of the cascading model and the joint training model at a history length of 10. Similar to aforementioned conclusion, joint training helps the joint training model outperform the cascading model by 0.8% in accuracy, 0.9% in Macro F1 measure and 0.7% in Weighted F1 measure. Thus we can conclude that joint training can also learn features from segmentation task to help recognize DA tags.

In the joint evaluation, we observe that even though CRFs obtain fairly good results in the segmentation task, they significantly lag behind the proposed cascading model and the joint training model. The hierarchical neural network introduced in Section 3 makes use of contexts and contributes to the improvement. Similarly, CRF-Bi gets a better result of 33.5% DER than CRF’s 36.8%, which implies that contextual information (previous tag) plays an important role in DA recognition.

Finally the joint coding model has an acceptable result of segmentation but a very low performance in the joint task. There are three possible reasons: (1) The joint coding model only uses surrounding words as context instead of previous sentences, thus it fails to capture DA relations while the proposed hierarchical neural network is able to. (2) Failure in learning from the recognition

task can degrade the model’s performance on the segmentation task. (3) Lastly but the most important, DA recognition requires understanding of the whole segment. In the architecture of joint coding model, however, it has to predict the type of DA tag at the very beginning of a segment. Although a short context (i.e. 5 words in our experiments) is available, the model still cannot make use of complete information of the corresponding segment.

7 Conclusion

In this work, we explored joint learning of dialog act (DA) segmentation and recognition. To exploit contextual information in DA recognition, we introduced a hierarchical neural network architecture that incorporates history utterances. Based on the hierarchical neural network, we investigated three models for joint DA segmentation and recognition, i.e. cascading model, joint coding model, and joint training model. Our proposed models can (1) integrate the hierarchical neural network and (2) combine tasks of different levels (word level and DA segment level) in a unified architecture.

Three sets of experiments were carried out to evaluate the proposed models’ performances on the segmentation task, the DA recognition task and the joint task. Experimental results showed that (1) contextual information plays an important role in DA recognition; (2) the cascading model and the joint training model outperform CRF baselines significantly (4.6% and 6.2% in DER respectively) in the joint task while having comparable performances in the segmentation task; (3) the joint training model outperforms the cascading model in all three tasks. The result demonstrates that joint training can learn useful generalized features.

other topic actively. Moreover, user satisfaction can be taken as a metric for evaluating the quality of a given dialogue session and the overall performance of a dialogue agent. In practice, user satisfaction could also be considered as the additional criterion for response selection or generation, which tend to intuitively take semantic relevance oriented features for model training. The adoption of user satisfaction is possible to provide a different view to optimize the models, so as to further improve user experience along the road beyond relevance, e.g., avoiding the responses that are relevant but lack of sociality (Higashinaka et al., 2015).

It is not a trivial task to predict negative feedbacks in the conversation flows between human being and dialogue agents. Generally, people tend to not express their dissatisfaction explicitly, thus, there are generally no clear signals before users turn angry and terminate dialogues, or people continue the conversations although they are not satisfied already. Apparently, it is unwise to introduce rating or other explicit feedback mechanisms into the dialogue flows considering the user experience issues. Meanwhile, this problem cannot be covered by classical sentiment analysis task because users' sentiment intention tends to be not obvious, and more importantly, the facts causing negative feedbacks are much more complicated than sentiment polarities as shown by Figure 1, in which the appropriateness of a certain response might be decided not only by itself, but also by the context.

In order to estimate the risk of dissatisfaction occurring in the human-computer dialogue sessions, in this work, we explore the feasibility of predicting users' emotional negative feedback caused by the dialogue agents' replies based on the dialogue contexts. To our knowledge, this is the first work attempting to discover the implicit factors causing users' dissatisfaction in dialogue agents' logs with deep learning models. Noticing that the occurrence of negative feedbacks depends on a complicated semantic mechanism and conversational contexts play an important role in this issue, this paper proposes to address the problem by learning to represent the possible determinant with different models. Especially, the proposed architecture based on Gated Convolutional Recurrent Neural Networks (GCRNN) is used to represent sequence of relations between the last response and the earlier utterances. Experimentally, it out-

performs existing conversational models, which indicates that the sequence of relation between utterances encodes the possibility of user's dissatisfaction. Besides, data augmentation with distance supervision method is also discussed in this work.

2 Related Work

2.1 Emotion prediction

Predicting sentiment category of text has been extensively studied. Most works focus on the sentiment orientations expressed by the writers in movie/product reviews or tweets (Pang et al., 2002; Hu and Liu, 2004; Go et al., 2009). However, the reader's emotion is not always consistent with that of the writer's (Yang et al., 2007). Thus, Lin et al. (2007) explore to predict the feelings that readers may have after reading particular articles. However, in this dissatisfaction prediction task, the user is not only the reader of the session text, but also the writer of some utterances. Therefore, some clues of the particular user's emotion may be contained in the context.

Modelling emotion in human-human conversation has been explored (Herzig et al., 2016; Tokuhisa and Terashima, 2006). However, triggers for negative emotion in human-computer dialogue might be different (e.g., low readability or relevance). The works of Tokuhisa et al. (2009) and Yu et al. (2016)'s analysed the emotion of a particular utterance in human-computer dialogue based on the textual features containing in the very sentence. Different from their studies analysing the explicit textual feedback, this work predicts the impending emotion based on the context because the cause of emotion of readers contains in the existing text (Li and Xu, 2014).

2.2 Conversation Modelling

Traditional conversation modelling mainly focuses on the one-turn conversations (aka. message-response pairs) (Banchs and Li, 2012; Ameixa et al., 2014; Ritter et al., 2011; Ji et al., 2014), while recent works show more interest in multi-turn dialogues.

The generation-based approaches model the context and generate the responses at the same time (Vinyals and Le, 2015), while the retrieval based studies model the sessions after knowing all utterances, which is more relevant to this work. Xu et al. (2016) represent sequence of utterances with recurrent neural networks (RNNs). The topic

or intention in a dialogue session is relatively constant. In this perspective, all the utterances in the same session is homogenous and could be composed within RNNs. However, the influences of user’s queries and the agent’s responses are different in predicting user’s emotion. Therefore, a targeted structure considering such heterogeneity is proposed in this work.

Wu et al. (2016) represent the relevance between utterances with CRNN architecture. Different from their work focusing on word-level matching with attention pooling on the convolutional result, we leverage a gate operation to simulate the sentence-level interaction.

3 Predicting Methodology

The task of predicting impending dissatisfaction could be formulated as: given the existing utterances (EU) that contain no agent-cause dissatisfaction, predicting the agent-cause dissatisfaction $D_1 \in \{0, 1\}$ of user at impending turn ($r = 1$), given the existing utterances (EU) that contain no agent-cause dissatisfaction.

$$EU = \{Q_{-n+1}, R_{-n+1}, \dots, Q_{-1}, R_{-1}, Q_0, R_0\} \quad (1)$$

where Q_{-n} and R_{-n} respectively represent the user’s query and computer response n round before current turn. For this work focusing on the agent-caused dissatisfaction, those queries Q_{-n} with negative emotion not related to the robot are not considered as negative feedback.

There are several possible factors influencing the emotion of the users, such as (1) the last response of the robot R_0 , (2) the relation of Q_0 and R_0 , (3) the sequence of context in the conversational sessions EU and (4) the sequence of relations between R_0 and the other utterances $UE - \{R_0\}$. In this session, we will discuss the factors above and learn the representation of them with deep neural network.

3.1 Utterance Modelling

The last response of the robot R_0 is the most straightforward factor that may cause the antipathy towards the agent. Predicting the negative emotions according to the latest response can be considered as reader-side emotion classification. In this work, such single sentence is modelled with convolutional neural network (CNN) with max pooling, and then classified in the full-connected

softmax layer (Kim, 2014). The illustration of the utterance model for R_0 is shown in Figure 2(b).

In this paper, all representations of utterances are attracted with CNN structure described in Figure 2(a). An n -word utterance can be represented as:

$$\mathbf{e}_{1:n} = \mathbf{e}_1 \oplus \mathbf{e}_2 \oplus \dots \oplus \mathbf{e}_n \quad (2)$$

where \mathbf{e}_n is the embedding of n th word in the utterance and \oplus refers to concatenation operator. In the convolutional process, the word window starting with the i th word and scanned by a s -width filter j can be represented $\mathbf{e}_{i:i+s-1}$. And the activations corresponding with filter j in convolutional layer can be computed as:

$$c_i^j = f(\mathbf{w}^j \cdot \mathbf{e}_{i:i+s-1} + b^j) \quad (3)$$

where f is the non-linear activation function (ReLU is utilized in this work). And \mathbf{w}^j and b^j represent the weight matrix and bias respectively. Finally, max-over-time pooling is leveraged. The activations corresponding with filter j in the pooling layer can be computed as:

$$\hat{c}^j = \max\{c_1^j, c_2^j, \dots, c_{n-s+1}^j\} \quad (4)$$

3.2 Utterance Pair Modelling

Recent works improve response ranking by model the semantic matching of query-response pairs (Qiu and Huang, 2015; Yin et al., 2015). The assumption implied in these works is that user experience is influenced by the relation of Q_0 and R_0 . We model such relation with Architecture-I in Hu et al.’s (2014) work, where the representations of the query and the response are learned with two CNNs respectively and the concatenation of the representations is used as input of a multi-layer perceptron (MLP) classifier that measures the appropriateness.

3.3 Utterance Sequence Modelling

As shown in example in Figure 1, the latest response is active and related to the query, but may not appropriate in the context. Recent works encode the sequence of utterances with recurrent neural network based encoder-decoder to generate responses (Serban et al., 2016; Shang et al., 2015). However, in this work, the prediction is made with all existing utterances being known. The convolutional recurrent neural network has been proven to be effective in encoding the sequence of representations of text (Kalchbrenner and Blunsom, 2013;

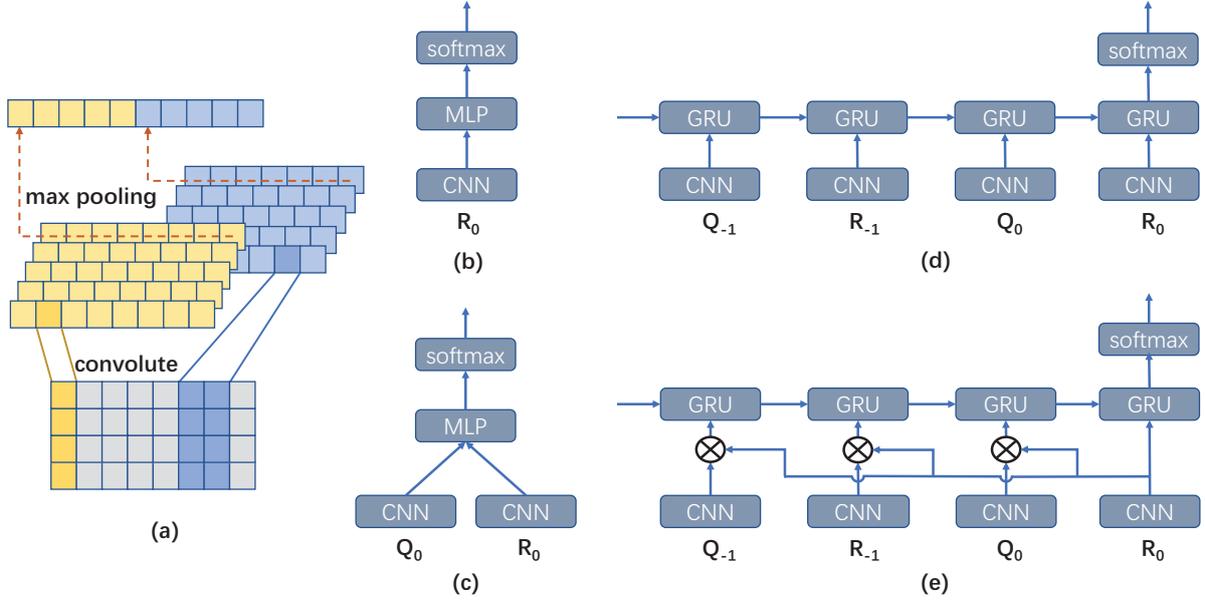

Figure 2: Structures for modelling different influential factors of negative feedbacks.

Li et al., 2016; Zhou et al., 2015). Thus, in this work, the sequence of existing utterances EU is modelled with CRNN, and the output of last time step R_0 is considered as the final representation of the sequence to be input to softmax classifier. The structure is shown in Figure 2(d), and Gated Recurrent Units (GRUs) are used in the structure.

A GRU stores context information in the internal memory structure. It performs comparably with long short-term memory (LSTM) and has lower complexity (Chung et al., 2014). There are two gates in the j th GRU structure, the update gate z_t^j and reset gate r_t^j , both gates are decided by the current input \mathbf{x}_t and previous hidden activation \mathbf{h}_{t-1} :

$$z_t^j = \sigma(W_z \mathbf{x}_t + U_z \mathbf{h}_{t-1})^j \quad (5)$$

$$r_t^j = \sigma(W_r \mathbf{x}_t + U_r \mathbf{h}_{t-1})^j \quad (6)$$

where W and U is the weight matrices, while σ refers to the sigmoid function. The hidden activation h_t^j of the GRU at time t can be computed as:

$$h_t^j = (1 - z_t^j) h_{t-1}^j + z_t^j \tilde{h}_t^j \quad (7)$$

where h_{t-1}^j refers to the hidden activation of previous time step and \tilde{h}_t^j is the current candidate activation:

$$\tilde{h}_t^j = \tanh(W \mathbf{x}_t + U(\mathbf{r}_t \odot \mathbf{h}_{t-1}))^j \quad (8)$$

GRUs compose the current and previous information with the gated units, and store the sequence representation in the memory.

3.4 Relation Sequence Modelling

Different from the intentions or topics of utterances being relatively constant in dialogue sessions, emotional influence of each utterance varies. For instance, the queries and responses are heterogeneous in a session. Queries are expressions of dissatisfaction, while responses are the reason of displeasure. The relations between particular response and context queries (or other responses) influence the user's emotion.

As shown in the example in Figure 1, the last response R_0 conveys conflicting emotion with the earlier utterances Q_{-2} , R_{-2} and Q_{-1} . The human user is probably unprepared for such rapid change in emotion and exhibits dissatisfaction. The consistency of mood is a kind of relation between sentences and the sequence of such consistency between sentence pairs can be treated as the emotional consistency of the whole conversation.

However, traditional RNNs are not adequate to represent such consistency. Therefore, we attempt to model the sequence of relation between utterances. As mentioned in the beginning of Section 3, the existing utterances EU contain no agent-cause dissatisfaction, which means Q_0 and the utterances before Q_0 are not the direct causes negative feedback. Thus, we only focus on the relation between the last response and the earlier utterances. The architecture is shown in Figure 2(e), the representation of earlier utterances \mathbf{x}_t ($t \neq 0$)

are gated by representation of R_0 :

$$\mathbf{x}_t = \mathbf{c}_t \odot \mathbf{m}_t \quad (9)$$

where \mathbf{c}_t is the output of convolutional neural network sentence model. And the matching gate \mathbf{m}_t is influenced by the particular utterance \mathbf{c}_t and the latest response \mathbf{c}_0 .

$$\mathbf{m}_t = \sigma(W_m \mathbf{c}_t + U_m \mathbf{c}_0) \quad (10)$$

While the input of the last time step is the representation of R_0 itself ($\mathbf{x}_0 = \mathbf{c}_0$). Gating operation has been shown effective in further mapping abstract feature of convolutional result by involving additional information (Wang et al., 2015; Dauphin et al., 2016). With such structure, the emotional consistency of utterances could be extracted and the influence of latest response on negative feedback could be encoded.

4 Experiments

4.1 Dataset

The anonymized multi-turn dialogue session data is provided by a Chinese commercial intelligent agent service. There are 2 million sessions in the dataset, most of which contain task-oriented dialogues. However, we focus on those only including chat, and the amount of such pure chat sessions is 260,867.

As described in the introduction, the task is to predict the impending dissatisfaction given $n + 1$ round context. Thus, a sample in the dataset should contains utterances and label of following emotional polarity. In fact, the lengths of human-computer dialogue sessions vary within relatively wide range. To eliminate the influences from session length, n is set to 2 in this work. The appearance of dissatisfaction will be predicted based on 3 turns (0, 1 and 2) of dialogue (as shown in Figure 1). 40,000 of the non-task-oriented sessions are manual annotation to construct the data set. If a session has a negative feedback, the 3 turns of utterances before this feedback will be treated as positive (with dissatisfaction) sample. Otherwise, if there’s no negative feedback, we randomly select continuous 3-turn utterances as a negative (without dissatisfaction) sample.

Two experienced annotators (long term employed for text annotation) are scheduled to label the sessions independently. If disagreement appears, a third senior annotator is invited to decide the final tag. Finally, 30,034 sessions meeting

Category	Amount
total sessions	2,000,000
pure chat sessions	260,867
sessions for manually labelling	40,000
two annotators agreement	28,651
the third annotator decision	11,349
gold standard	30,039
negative in gold standard	17,618
positive in gold standard	12,421

Table 1: Statistical information of the dataset.

the requirements (non-negative sessions or negative sessions with 3 three turns or more utterances before the negative expressions) are used as gold-standard dataset. Some statistical information of the dataset is shown in Table 1.

4.2 Pre-training

4.2.1 Fragment Extraction

The manually labelled gold standard dataset might be insufficient for learning deep neural models. Thus, a distance supervision strategy is designed to obtain augmented data. We summarize 56 patterns of highly probable negative expressions as strict patterns (SP) and 86 patterns of possible or ambiguous negative feedbacks as uncertain patterns (UP). It is noted that the SP is a subset of UP. The sessions containing no utterances matching UP are considered as non-negative. While the utterances (1)containing any SP and (2)with no utterances in the above 3 turns match any UP are treated as negative feedbacks and the fragments are tagged as dissatisfaction ones. In this way, both positive and negative samples of dissatisfaction are automatically detected.

Besides the pure chat sessions, those task-oriented ones also contain multi-turn chat fragment. Therefore, the augmentation strategy is carried out on all available sessions and obtains 1,612,426 distance supervised labelled fragments. It is worthy to note that there may be multiple available fragments in a single session, those fragments (without overlap) are all extracted in the augmentation process.

4.2.2 Balanced Dataset Construction

In fact, the extraction strategy above may lead to a different distribution with the real-world data. Taking the cheerful response R_0 in Figure 1 as an example, most users in bad mood would be upset after the agents reply with such cheer. These users

tend to express dissatisfaction towards the agents and the dissatisfactions are detected with designed patterns. While in the situations where the users are happy, the cheerful response result in a virtuous cycle and may not be selected as R_0 (may be selected as R_{-1} or R_{-2}). Therefore, such cheerful response is likely to closely related to the dissatisfaction.

To avoid such false association rules, we select the same number of positive and negative samples if R_0 is the same and obtain 335,314 fragments as balanced distance supervised labelled data.

4.3 Experimental Settings

All the neural network models are implemented with TensorFlow toolkit³. The max length of the input sentence is set to 10 and all sentences are padded to the max length with zero vectors. 32 filters are used for each filter size, while the sizes of word embeddings, hidden layer in RNN and full-connected layer are all set to 64.

The weights between full-connected layers are initialized with Xavier initializer (Glorot and Bengio, 2010), while the weights and biases in the convolutional layer are initialized with random numbers on uniform distribution $\mathcal{U}\{-0.2, 0.2\}$. Word embeddings are randomly initialized with uniform distribution $\mathcal{U}\{-0.1, 0.1\}$ and fine-tuned during training.

Batch learning is conducted with a batch size of 500. The learning rate of the training process is 0.001 while that of pre-training process is 0.005. 10-fold cross validation are implemented with 80% data as training set, and validation and test set divide equally the rest 20% samples. Early stopping is carried out on validation set during training. Training process stops when there's no better validation result within 5 epochs.

4.4 Competitor Models

SVM- R_0 : Support vector machine (SVM) are widely used as classifiers for sentiment analysis tasks (Pang et al., 2002). In this work, TF-IDF features based on uni-grams in R_0 are involved to build baseline model.

SVM- Q_0R_0 and **SVM- EU** : To make use of more context information, we involve Q_0 - R_0 pair by connecting them into a whole and uni-gram TF-IDF features of the connection result are used as

input of a SVM classifier. In the same way, the all sentences in EU are also used in the SVM model. **UM- Q_0R_0** and **UM- EU** : Similar to SVM, utterance model (UM) shown in Figure 2(b) is also designed to analyse a single sentence (or document). Thus, we leverage connection results of Q_0 - R_0 pair and EU to introduce context utterance.

UPM- EU : Besides Q_0 - R_0 pair, the utterance pair model (UPM) could also be used to encode all sentences in EU . Each sentence is modelled by CNN respectively and the representations are concatenated in the hidden layer.

4.5 Experimental Results

4.5.1 Comparison with Baselines

We compare the models corresponding to the factor assumptions describe in section 3, including utterance model (UM), utterance pair model (UPM), utterance sequence model (USM) and relation sequence model (RSM) with the competitor systems. The numbers in Table 2 show the proportion of the particular model accurately predicting the emotional polarities. The neural models are pre-trained with balanced distance supervised labelled data, and tuned with the manually annotated samples.

Model	Accuracy
SVM- R_0	0.5486
SVM- Q_0R_0	0.5603
SVM- EU	0.5616
UM- R_0	0.5495
UM- Q_0R_0	0.5579
UM- EU	0.5638
UPM- Q_0R_0	0.5723
UPM- EU	0.5781
USM- EU	0.6022
RSM- EU	0.6106

Table 2: Accuracies of different models.

Firstly, the last computer's response R_0 is the basic feature that makes the prediction effective. Comparing the models involving Q_0 - R_0 pair and EU with those only use R_0 , we can easily find that the context provides more information about the trend of emotion.

SVM achieves comparable results with CNN based utterance model. We see that the convolutional process with a fixed-size filter encodes the similar information with n-gram features in SVM.

UPM outperforms UM with both Q_0 - R_0 pair

³www.tensorflow.org/

and *EU*. UPM connects the abstract representation in the hidden layer, while UM connects the sentences into a whole as input. Although their structures are similar as shown in Figure 2, the logic depths of the two models are different. UM composes word embedding of all sentences in the convolutional process to learn an emotional representation, while UPM gets emotion features in two steps (composing word representation in convolutional layer and then adding mapped the sentence embedding after pooling). In practice, UPM works as a hierarchical compositional model. Such strategy makes the internal compositional process more flexible and expressive. In this way, the hidden layer simulates the relation between sentences in a more appropriate manner.

The CRNN based models (USM-*EU* and RSM-*EU*) achieve a significant improvement over other approaches including UPM (according to the two-sided paired t-test with a confidence level of $\alpha = 0.05$). UPM maps the representation of sentences to the same space and adds up the mapping result as the conversation representation. However, such process is less expressive than CRNN. In the test process, the weight matrix that mapping sentence representations in UPM is constant after training and the contribution of each sentence to the conversation is relatively fixed. While the GRUs in the CRNN could select the information resource flexibly through the reset gate r and update gate z , controlling the influence of particular sentence according to the context (Chung et al., 2014). Moreover, the gating process is a kind of multiplicative operation between sentence embeddings. Such multiplicative compositional functions are more expressive in simulating interaction between abstract features than additive ones (Socher et al., 2013; Irsoy and Cardie, 2015). Thus, CRNN based models handle the interaction between utterances in a more flexible way than UPM.

RSM is more effective than USM according to the results in Table 2. This is due to the fact that the gated operation makes it possible to adjust sentence representation according to R_0 . Therefore, besides the interaction between adjacent utterances handled by the recurrent structure, the influence of interaction between R_0 and other utterances can be involved into the final representation and distance relation and consistency could be encoded.

4.5.2 Case Study

In order to illustrate the difference between USM and RSM in an intuitive way, we calculate the risk of negative feedback for each time step in these two recurrent models with the input of the session shown in Figure 1. The outputs of recurrent layer of each time step are used as inputs of the full-connection layer and the softmax regression results are considered as the probabilities of user’s dissatisfaction.

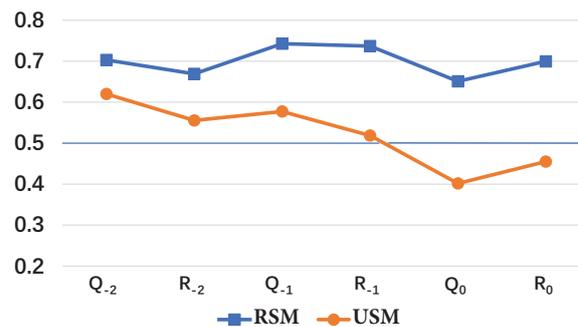

Figure 3: The probabilities of negative feedback for each utterance in sessions in Figure 1.

The line chart of the sequence of probabilities of the two models are shown in Figure 3. The tendencies of these two line are similar. It is due to the fact that the gates controlled by R_0 shrink the activations of recurrent layer and adjust the scales of values without changing the quadrant or feature space.

For the same utterance Q_{-2} , there’s a difference between the probabilities of these two models, and the gap between the two line get more obvious after Q_{-1} is input. Both Q_{-2} and Q_{-1} contains negative emotions and possibly lead to dissatisfaction. Thus, the probabilities of negative feedback increase at the corresponding time step. However, the gated activations in RSM change more sharply. It indicates that the emotional inconsistency between R_0 and these two user messages lead to a further increasing of risk through the gated adjustment.

Finally, the RSM predicts that the negative feedback will occur in the next time step (with the probabilities larger than 0.5), which is true according to the corpus. However, the USM fails to make the correct prediction.

4.5.3 Comparison of Pre-training Strategies

As discussed in Subsection 4.2, different pre-training strategies are implemented during the

Models	NPT	UPT	BPT
UM- R_0	0.5365	0.5232	0.5495
UPM- Q_0R_0	0.5619	0.5547	0.5623
USM-EU	0.5865	0.5808	0.6022
RSM-EU	0.5939	0.5782	0.6106

Table 3: Comparison of accuracies with no pre-training (NPT), unbalanced pre-training (UPT) and balanced pre-training (BPT)

training process. The comparison of accuracy of these strategies are shown in Table 3.

Unbalanced pre-training strategy leads to a worse performance than only using manually labelled data. As discussed in 4.2.2, when a false rule is learned, a particular R_0 is associated with a wrong label, which hurts the performance obviously. Moreover, during the experimental process of unbalanced pre-training, it is observed that the models involving more context achieve better result than those only using R_0 as input. It is due to that the existence of the strong correlation between R_0 and the label itself is an inaccurate pattern, no matter whether the label is correct. The pre-training data encoding such strong correlation will makes the models ignore the context utterance and convergence to the local optimum only related to R_0 .

However, the balanced pre-training dataset is effective in initializing the networks. The experimental results show that the balanced pre-training improves the performance of the networks. The underlying reason is that the pre-training process provides a better initialization for the networks, and the converging process of tuning continues based on an initial optimization.

4.5.4 Other Discussions

Directionality: Bi-directional and backward-directional recurrent networks are tested. Both structures lead to drop in accuracy (about 1%). We see that the last response R_0 is the essential determinant of emotion, the basic forward RNN structure has a bias on the last time steps for being free from the influence of small recurrent connection weight matrix. While adding backward-directional processing involving more parameters and weaken the influence of R_0 and Q_0-R_0 pair.

Filter Size: Inspired by the SVM baseline models performing not worse than the utterance model, we introduce 1×1 filters, working together with 2×1 ones, and such setting achieves an improve-

ment by about 1% than only using 2×1 ones (from 0.6019 to 0.6106 with RSM). In practice, the larger filter size (e.g. 3, 4 or 5) leads to instability in the prediction. It is due to the fact that the utterances conversations are relatively short. Features within a uni-gram or bi-gram window is eligible for representing the emotional information. Although covering some sparse features, involving more larger filters results in risk of over-fitting.

5 Conclusion and Future Work

In this paper, we propose the problem of predicting users impending negative feedbacks by modelling the context queries and replies in human-agent conversation. Four kinds of influencing factors, (1) the computer’s last response R_0 , (2) the relation of last turn dialogue pair Q_0-R_0 , (3) the sequence of all utterance and (4) the sequence of relation between utterances, are modelled with deep neural networks. The experimental results show that these factors indeed influence the emotional trend. We have encoded the possibility of dissatisfaction by representing the sequence of relation between utterances with a gated convolutional recurrent neural network. Tested on the real-world human-agent dialogue dataset, the proposed architecture outperforms the existing conversation models. Besides, balanced sampling on distance supervision labelled data are shown to be reliable in network pre-training.

The accuracies of prediction is only about 60%, we see that different users show different emotional feedbacks towards the same context. Thus, there are a few potential explorations: (1) build corpus on fine-grained emotional categories and (2) predict the emotional distribution on these categories instead of classifying into a certain one. Moreover, we would like to apply the emotional risk to the response ranking to improve the user experience of dialogue system.

Finding Dominant User Utterances And System Responses in Conversations

Dhiraj Madan and Sachindra Joshi

IBM Research Labs

{dhimadan, jsachind@in.ibm.com}

Abstract

There are several dialog frameworks which allow manual specification of intents and rule based dialog flow. The rule based framework provides good control to dialog designers at the expense of being more time consuming and laborious. The job of a dialog designer can be reduced if we could identify pairs of user intents and corresponding responses automatically from prior conversations between users and agents. In this paper we propose an approach to find these frequent user utterances (which serve as examples for intents) and corresponding agent responses. We propose a novel SimCluster algorithm that extends standard K-means algorithm to simultaneously cluster user utterances and agent utterances by taking their adjacency information into account. The method also aligns these clusters to provide pairs of intents and response groups. We compare our results with those produced by using simple K-means clustering on a real dataset and observe upto 10% absolute improvement in F1-scores. Through our experiments on synthetic dataset, we show that our algorithm gains more advantage over K-means algorithm when the data has large variance.

1 Introduction

There are several existing works that focus on modelling conversation using prior human to human conversational data (Gašić et al., 2013; Young et al., 2013; Henderson et al., 2014). (Higashinaka et al., 2011) models the conversation from pairs of consecutive tweets. Deep learning based ap-

proaches have also been used to model the dialog in an end to end manner (Vinyals and Le, 2015; Serban et al., 2015). Memory networks have been used by Bordes et al (2016) to model goal based dialog conversations. More recently, deep reinforcement learning models have been used for generating interactive and coherent dialogs (Li et al., 2016) and negotiation dialogs (Lewis et al., 2017).

Industry on the other hand has focused on building frameworks that allow manual specification of dialog models such as api.ai¹, Watson Conversational Services², and Microsoft Bot framework³. These frameworks provide ways to specify *intents*, and a *dialog flow*. The user utterances are mapped to intents that are passed to a dialog flow manager. The dialog manager generates a response and updates the dialog state. See Figure 1 for an example of some intents and a dialog flow in a technical support domain. The dialog flow shows that when a user expresses an intent of *#laptop_heat*, then the system should respond with an utterance “*Could you let me know the serial number of your machine*”. The designer needs to specify intents (for example *#laptop_heat*, *#email_not_opening*) and also provide corresponding system responses in the dialog flow. This way of specifying a dialog model using intents and corresponding system responses manually is more popular in industry than a data driven approach as it makes dialog model easy to interpret and debug as well as provides a better control to a dialog designer. However, this is very time consuming and laborious and thus involves huge costs.

One approach to reduce the task of a dialog designer is to provide her with frequent user intents and possible corresponding system responses in

¹<https://api.ai/>

²<https://www.ibm.com/watson/developercloud/conversation.html>

³<https://dev.botframework.com>

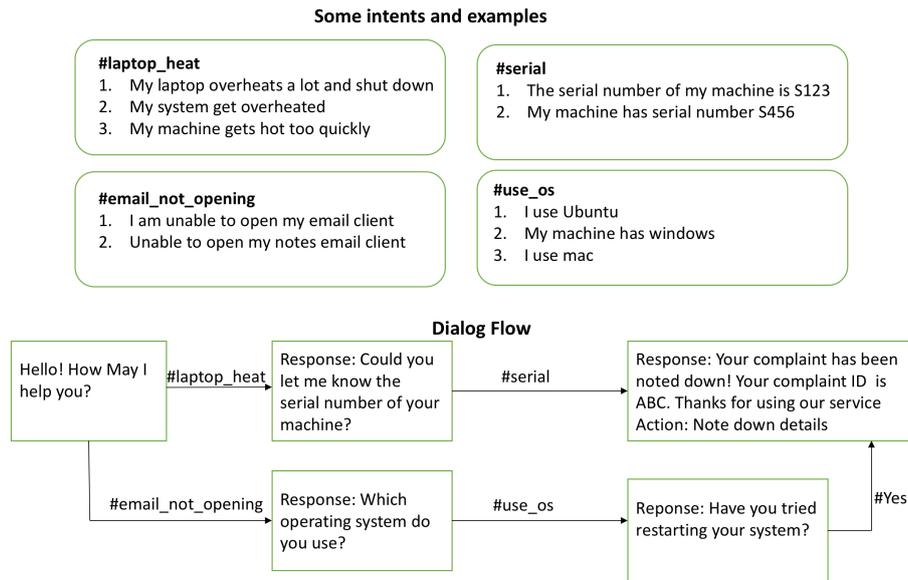

Figure 1: Some intents and dialog flow

a given domain. This can be done by analysing prior human to human conversations in the domain. Figure 2(a) provides some example conversations in the technical support domain between users and agents.

In order to identify frequent user intents, one can use existing clustering algorithms to group together all the utterances from the users. Here each cluster would correspond to a new intent and each utterance in the cluster would correspond to an example for the intent. Similarly the agents utterances can be clustered to identify system responses. However, we argue that rather than treating user utterances and agents responses in an isolated manner, there is merit in jointly clustering them. There is adjacency information of these utterances that can be utilized to identify better user intents and system responses. As an example, consider agent utterances A.2 in box A and A.2 in box C in Figure 2(a). The utterances “Which operating system do you use?” and “What OS is installed in your machine” have no syntactic similarity and therefore may not be grouped together. However the fact that these utterances are adjacent to the similar user utterances “I am unable to start notes email client” and “Unable to start my email client” provides some evidence that the agent utterances might be similar. Similarly the user utterances “My system keeps getting rebooted” and “Machine is booting time and again” (box B and D in Figure 2(a))- that are syntactically not simi-

lar - could be grouped together since the adjacent agent utterances, “Is your machine heating up?” and “Is the machine heating?” are similar.

Joint clustering of user utterances and agent utterances allow us to align the user utterance clusters with agent utterance clusters. Figure 2(b) shows some examples of user utterance clusters and agent utterance clusters along with their alignments. Note that the user utterance clusters can be used by a dialog designer to specify intents, the agent utterance clusters can be used to create system responses and their alignment can be used to create part of the dialog flow.

We propose two ways to take adjacency information into account. Firstly we propose a method called *SimCluster* for jointly or simultaneously clustering user utterances and agent utterances. *SimCluster* extends the K-means clustering method by incorporating additional penalty terms in the objective function that try to align the clusters together (described in Section 3). The algorithm creates initial user utterance clusters as well as agent utterance clusters and then use bi-partite matching to get the best alignment across these clusters. Minimizing the objective function pushes the cluster centroids to move towards the centroids of the aligned clusters. The process implicitly ensures that the similarity of adjacent agent utterances affect the grouping of user utterances and conversely similarity of adjacent user utterances affect the grouping of agent utterances. In our sec-

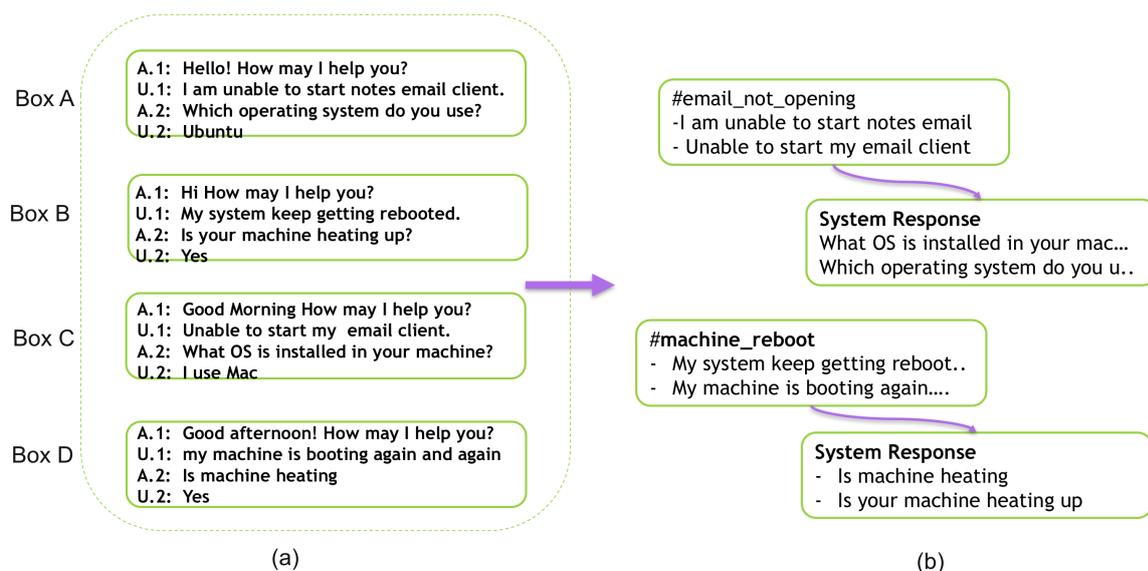

Figure 2: Some sample conversations and the obtained clusters

ond approach we use the information about neighbouring utterances for creating the vector representation of an utterance. For this we train a sequence to sequence model (Sutskever et al., 2014) to create the vectors (described in Section 5).

Our experiments described in section 5 show that we achieve upto 10% absolute improvement in F1 scores over standard K-means using SimCluster. Also we observe that clustering of customer utterances gains significantly by using the adjacency information of agent utterances whereas the gain in clustering quality of agent utterances is moderate. This is because the agent utterances typically follow similar syntactic constructs whereas customer utterances are more varied. Considering the agent utterances into account while clustering users utterances is thus helpful. The organization of the rest of the paper is as follows. In Section 2 we describe the related work. In Section 3 we describe our problem formulation for clustering and the associated algorithm. Finally in sections 4 and 5 we discuss our experiments on synthetic and real datasets respectively.

2 Related Work

The notion of adjacency pairs was introduced by Sacks et al (1974) to formalize the structure of a dialog. Adjacency pairs have been used to analyze the semantics of the dialog in computational

linguistics community (Palomar and Martínez-Barco, 2000). Clustering has been used for different tasks related to conversation. (Ritter et al., 2010) considers the task of discovering dialog acts by clustering the raw utterances. We aim to obtain the frequent adjacency pairs through clustering. There have been several works regarding extensions of clustering to different scenarios such as:-

1. Co-clustering : Co-clustering considers the setting where data and features are clustered simultaneously. Dhillon (2001) considers a spectral graph theoretic approach to co-cluster documents and words simultaneously. Dhillon, Mallela and Modha (2003) consider an information theoretic formulation of co-clustering.
2. Multi task learning: Multi task learning considers task of learning from multiple domains simultaneously (Caruana, 1998). Gu and Zhou (2009) consider the problem of multi task clustering wherein they cluster multiple domains simultaneously and utilize the relation of the domains to enhance clustering performance. Their model consists a reduced subspace in which the projection of vectors from the two domains have similar distribution. They then try to learn this common subspace and the clusters simulta-

neously. Our scenario differs from multi task learning since here the distributions across the domains tend to be different. (The domains being the possible utterances of user and agent).

3. Transfer learning considers the task of transferring the knowledge across similar tasks (Danyluk et al., 2009). Bhattacharya et al (2012) consider the task of clustering in the target domain using the given clusters in a source domain. They formulate the problem of minimizing a weighted sum of the energy function in the clustering, along with the energy of aligning the clusters of the two domains. This setting differs from ours since again the utterances in the two domains can be very different. Moreover unlike the task of transfer learning we do not have clusters in any of the domains. However we do have information regarding the adjacency of utterances between the two domains.

3 The Proposed Approach

In this section we describe our approach SimCluster that performs clustering in the two domains simultaneously and ensures that the generated clusters can be aligned with each other. We will describe the model in section 3.1 and the algorithm in Section 3.2.

3.1 Model

We consider a problem setting where we are given a collection of pairs of consecutive utterances, with vector representations $\{x^{(i)}, y^{(i)}\}_{i=1}^m$ where $x^{(i)}$ s are in speaker 1's domain and $y^{(i)}$ s are in speaker 2's domain. We need to simultaneously cluster the utterances in their respective domains to minimize the variations within each domain and also ensure that the clusters for both domains are close together.

We denote the clusters for speaker 1's domain by $\{C_j^x\}_{j=1}^k$ with their respective means $\{\mu_j^x\}_{j=1}^k$. We denote the clusters assignments for $x^{(i)}$ by $ca^x(i) \in \{1, 2, \dots, k\}$.

We denote the clusters for second speaker by $\{C_j^y\}_{j=1}^k$ with their respective means $\{\mu_j^y\}_{j=1}^k$. We denote the clusters assignments for $y^{(i)}$ by $Ca^y(i) \in \{1, 2, \dots, k\}$. The usual energy function has the terms for distance of points from their corresponding cluster centroids. To be able to ensure

that the clusters in each domain are similar, we also consider an alignment between the centroids of the two domains. Since the semantic representations in the two domains are not comparable we consider a notion of **induced** centroids.

We define the induced centroids $\widetilde{\{\mu_j^x\}}_{j=1}^k$ as the arithmetic means of the points $\{x^{(i)}\}$ s such that $y^{(i)}$'s have the same cluster assigned to them. Similarly, we define $\widetilde{\{\mu_j^y\}}_{j=1}^k$ as the arithmetic means of $\{y^{(i)}\}$ s such that $x^{(i)}$ s have the same cluster assigned to them. More formally, we define these induced centroids as:-

$$\widetilde{\{\mu_j^x\}} = \frac{\sum_{i:Ca^y(i)=j} x^{(i)}}{|\{i : Ca^y(i) = j\}|}$$

and

$$\widetilde{\{\mu_j^y\}} = \frac{\sum_{i:Ca^x(i)=j} y^{(i)}}{|\{i : Ca^x(i) = j\}|}$$

The alignment between these clusters given by the function $ma : [k] \mapsto [k]$, which is a bijective mapping from the cluster indices in speaker 1's domain to those in speaker 2's domain. Though there can be several choices for this alignment function, we consider this alignment to be a matching which **maximizes the sum of number of common indices** in the aligned clusters. More formally we define

$$N(j_1, j_2) = |\{i : x^{(i)} \in C_{j_1}^x \text{ and } y^{(i)} \in C_{j_2}^y\}|$$

Then the matching ma is defined to be the bijective function which maximizes $\sum_{j=1}^k N(j, ma(j))$. We consider a term in the cost function corresponding to the sum of distances between the original centroids and the matched induced centroids. Our overall cost function is now given by:-

$$\begin{aligned} J = & \alpha \left(\sum_{i=1}^m \|x^{(i)} - \mu_{Ca^x(i)}^x\|^2 \right. \\ & \left. + \sum_{i=1}^m \|y^{(i)} - \mu_{Ca^y(i)}^y\|^2 \right) \\ & + (1 - \alpha) \left(\sum_{j=1}^k \|\mu_j^x - \widetilde{\mu_{ma(j)}^x}\|^2 \cdot |C_j^x| \right. \\ & \left. + \sum_{j=1}^k \|\mu_j^y - \widetilde{\mu_{ma^{-1}(j)}^y}\|^2 \cdot |C_j^y| \right) \end{aligned}$$

We explain the above definition via an example. Consider the clusters shown in Figure 3. Here the ma would match C_1^x to C_1^y , C_2^x to C_3^y and C_3^x to C_2^y , giving a match score of 6. Since $y^{(1)}$, $y^{(2)}$ and $y^{(4)}$ are present in the cluster C_1^y , $\widetilde{\mu}_1^x$ is given by $\frac{x^{(1)}+x^{(2)}+x^{(4)}}{3}$. Similarly

$$\widetilde{\mu}_2^x = \frac{x^{(3)} + x^{(8)} + x^{(9)}}{3}$$

$$\widetilde{\mu}_3^x = \frac{x^{(5)} + x^{(6)} + x^{(7)}}{3}$$

In a similar manner, $\widetilde{\mu}^y$ s can also be defined. Now the alignment terms are given by:-

$$\|\mu_1^x - \widetilde{\mu}_1^x\|^2 |C_1^x| + \|\mu_2^x - \widetilde{\mu}_3^x\|^2 |C_2^x| + \|\mu_3^x - \widetilde{\mu}_2^x\|^2 |C_3^x| + \|\mu_1^y - \widetilde{\mu}_1^y\|^2 |C_1^y| + \|\mu_2^y - \widetilde{\mu}_3^y\|^2 |C_2^y| + \|\mu_3^y - \widetilde{\mu}_2^y\|^2 |C_3^y|$$

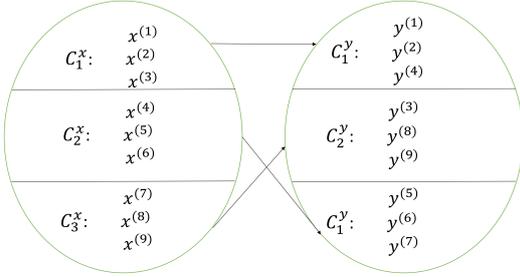

Figure 3: Sample clusters with matching

3.2 SimCluster Algorithm

To minimize the above energy term we adopt an approach similar to Lloyd's clustering algorithm (1982). We assume that we are given a set of initial seeds for the cluster centroids $\{\mu_j^x\}_{j=1}^k$ and $\{\mu_j^y\}_{j=1}^k$. We **repeat** the following steps iteratively:-

1. Minimize the energy with respect to cluster assignment keeping centroids unchanged. As in standard K-means algorithm, this is achieved by updating the cluster assignment, Ca^x for each index i to be the cluster index j which minimizes $\|x^{(i)} - \mu_j^x\|^2$. Correspondingly for Ca^y , we pick the cluster index j' which minimizes $\|y^{(i)} - \mu_{j'}^y\|^2$.
2. Minimize the energy with respect to the centroids keeping cluster assignment unchanged. To achieve this step we need to minimize the energy function with respect to the centroids μ_j^x and $\mu_{j'}^y$. This is achieved by setting

$\nabla_{\mu_j^x} J = 0$ for each j and $\nabla_{\mu_{j'}^y} J = 0$ for each j' . Setting $\nabla_{\mu_j^x} J = 0$, we obtain

$$\mu_j^x = \alpha \left(\frac{\sum_{i:Ca^x(i)=j} x^{(i)}}{|C_j^x|} \right) + (1 - \alpha) \widetilde{\mu}_{ma(j)}^x$$

or equivalently

$$\mu_j^x = \alpha \left(\frac{\sum_{i:Ca^x(i)=j} x^{(i)}}{|C_j^x|} \right) + (1 - \alpha) \left(\frac{\sum_{i:Ca^y(i)=ma(j)} x^{(i)}}{|C_j^y|} \right)$$

Similarly, setting $\nabla_{\mu_{j'}^y} J = 0$, we obtain

$$\mu_{j'}^y = \alpha \left(\frac{\sum_{i:Ca^y(i)=j'} y^{(i)}}{|C_{j'}^y|} \right) + (1 - \alpha) \left(\frac{\sum_{i:Ca^x(i)=ma^{-1}(j')} y^{(i)}}{|C_{j'}^x|} \right)$$

3. Finally we update the matching between the clusters. To do so, we need to find a bipartite matching match on the cluster indices so as to maximize $\sum_{j=1}^k N(j, ma(j))$. We use Hungarian algorithm (Kuhn, 1955) to perform the same i.e. we define a bipartite graph with vertices consisting of cluster indices in the two domains. There is an edge from vertex representing cluster indices j (in domain 1) and j' in domain 2, with weight $N(j, j')$. We find a maximum weight bipartite matching in this graph.

Similar to Lloyd's algorithm, each step of the above algorithm decreases the cost function. This ensures that the algorithm achieves a local minima of the cost function if it converges. See Algorithm 2 for a formal description of the approach. The centroid update step of the above algorithm also has an intuitive explanation i.e. we are slightly moving away the centroid towards the matched induced centroid. This is consistent with our goal of aligning the clusters together in the two domains.

3.3 Alignment

The algorithm above maintains a mapping between the clusters in each speaker's domain. This mapping serves to give us the alignment between the clusters required to provide a corresponding response for a given user intent.

Algorithm 1 SimCluster

-
- 1:
- procedure**

We generated the dataset from the above sampling process with means selected on a 2 dimensional grid of size 3×3 with variance set as $\frac{1}{2}$ in each dimension. 10000 sample points were gener-

ated. The parameter α of the above algorithm was set to 0.5 and k was set to 9 (since the points could be generated from one of the 9 gaussians with centroids on a 3×3 grid).

We compared the results with simple K-means clustering with k set to 9. For each of these, the initialization of means was done using D^2 sampling approach (Arthur and Vassilvitskii, 2007).

4.1 Evaluation and Results

To evaluate the clusters we computed the following metrics

1. ARI (Adjusted Rand Index): Standard Rand Index is a metric used to check the clustering quality against a given standard set of clusters by comparing the pairwise clustering decisions. It is defined as $\frac{a+b}{a+b+c+d}$, where a is the number of true positive pairs, b is the number of true negative pairs, c is the number of false positive pairs and d is the number of false negative pairs. Adjusted rand index corrects the standard rand index for chance and is defined as $\frac{\text{Index} - \text{Expected index}}{\text{Max Index} - \text{Expected index}}$ (Rand, 1971).

We compute ARI score for both the source clusters as well as the target clusters.

2. F1 scores: We also report F1 scores for the pairwise clustering decisions. In the above notation we considered the pair-precision as $\frac{a}{a+c}$ and recall as $\frac{a}{a+d}$. The F1 measure is the Harmonic mean given as $\frac{2PR}{P+R}$.

We used the gaussian index from which an utterance pair was generated as the ground truth label, which served to provide ground truth clusters for computation of the above evaluation metrics. Table 1 shows a comparison of the results on SimCluster versus K-means algorithm. Here our SimCluster algorithm improves the F1-scores from 0.412 and 0.417 in the two domains to 0.442 and 0.441. The ARI scores also improve from 0.176 and 0.180 to 0.203 and 0.204.

4.1.1 Variation with variance

We also performed experiments to see how the performance of SimCluster is affected by the variance in the cluster (controlled by the generative process in Algorithm 2). Intuitively we expect SimCluster to obtain an advantage over simple K-means when variance is larger. This is because at larger variance, the data points are more likely to be generated away from the centroid due to which they might be clustered incorrectly with the points from neighbouring cluster. However if the corresponding point from the other domain is generated closer to the centroid, it might help in clustering the given data point correctly. We performed these experiments with points generated from Algorithm 2 at different values of variance. We generated the points with centroids located on a grid of size 3×3 in each domain. The value of k was set to 9. The experiment was repeated for each value of variance between 0.1 to 1.0 in the intervals of 0.1. Figures 4 and 5 show the percentage improvement on ARI score and F1 score respectively achieved by SimCluster (over K-means) versus variance.

5 Experiments on Real Dataset

5.1 Description and preprocessing of dataset

We have experimented on a dataset containing Twitter conversations between customers and Amazon help. The dataset consisted of 92130 conversations between customers and amazon help. We considered the conversations with exactly two speakers Amazon Help and a customer. Consecutive utterances by the same speaker were concatenated and considered as a single utterance. From these we extracted adjacency pairs of the form of a

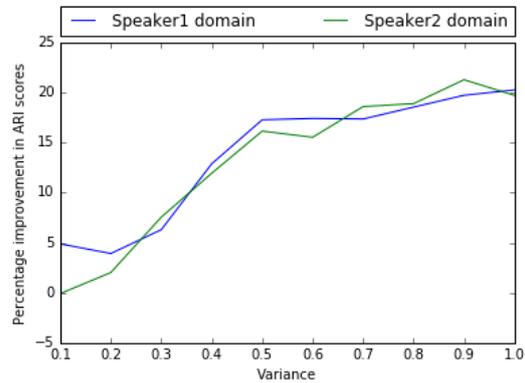

Figure 4: Improvement in ARI figures achieved by SimCluster versus variance

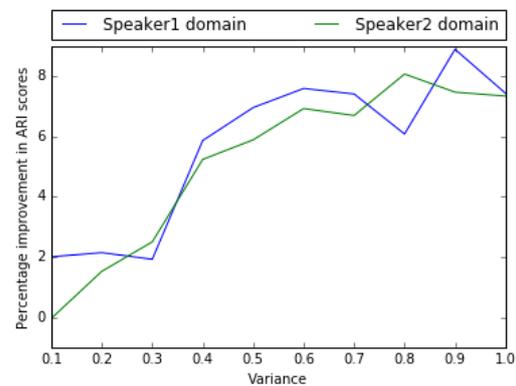

Figure 5: Variation of Improvement in F1 score figures achieved by SimCluster versus variance

customer utterance followed by an agent (Amazon Help) utterance. We then selected the utterance pairs from 8 different categories, like late delivery of item, refund, unable to sign into the account, replacement of item, claim of warranty, tracking delivery information etc. A total of 1944 utterance pairs were selected.

To create the vector representation we had used two distinct approaches:-

1. Paragraph to vector approach (Doc2Vec) by Le and Mikolov (2014). Here we trained the vectors using distributed memory algorithm and trained for 40 iterations. A window size of 4 was used.
2. We also trained the vectors using sequence to sequence approach (Sutskever et al., 2014), on the Twitter dataset where we considered the task of predicting the reply of Amazon Help for customer's query and vice versa. The encoded vector from the input sequence forms the corresponding vector representa-

	Customer		Agent	
	F1-score	ARI	F1-score	ARI
K-means (Doc2Vec)	0.787	0.150	0.783	0.136
SimCluster (Doc2Vec)	0.88	0.19	0.887	0.192
K-means (Seq2Seq)	0.830	0.159	0.900	0.218
SimCluster (Seq2Seq)	0.860	0.181	0.916	0.218

Table 2: Performance of SimCluster versus K-means clustering on both Doc2Vec as well as seq2seq based vectors

Clusters in user domain	Clusters in agent domain
no refund got for the refund request made on 12 ... 11 days & counting on a refund . was promised 3-5 days ... yes i contacted my bank 2 days ... there is no sign of an amazon refund processing . @amazon refer screen shot ..When will i get my refund ?... ... I have to wait 3-5 business days for Amazon to refund me money You can view your order refund status here ... It can take up to 10 business days ... the refund has been processed ... if you have received the refund reference number then ... contact support team ... I'm glad to hear it was delivered , but I'm sorry it was a day late ... I'm sorry your order is late ! When you contacted us...

Table 3: Sample clusters in user and agent domains. Utterances in bold are those which were not in the given cluster using K-means, but could be correctly classified with the cluster using SimCluster

tion. For the task of generating the agent’s response for customer utterance the encoding from the input sequence (in the trained model) forms the vector representation for the customer utterance. Similarly for the task of generating the previous customer utterance from the agent’s response, the intermediate encoding forms the vector representation for the agent utterance. We used an LSTM based 3-layered sequence to sequence model with attention for this task.

We ran the K-means clustering algorithm for 5 iterations followed by our SimCluster algorithm for 30 iterations to form clusters in both the (customer and agent) domains. The hyper parameter(α) is chosen based on a validation set. We varied the value of α from 0.5 to 1.0 at intervals of 0.025. The initialization of centroids was performed using D^2 sampling approach (Arthur and Vassilvitskii, 2007).

5.2 Results

For the clusters so obtained we have computed F1 and ARI measures as before and compared with the K-means approach. We used the partitioning formed by the 8 categories (from which the utterance pairs were selected) as the ground truth clustering.

Table 2 summarizes the results. We observe that for K-means algorithm, the vectors generated from sequence to sequence model perform better than

the vectors generated using paragraph to vector for both the domains. This is expected as the vectors generated from sequence to sequence model encode some adjacency information as well. We further observe that the SimCluster approach performs better than the K-means approach for both the vector representations. It improves the F1-scores for Doc2Vec representation from 0.787 and 0.783 to 0.88 and 0.887 in the two domains. Also the F1-scores on Seq2Seq based representation improve from 0.83 and 0.9 to 0.86 and 0.916 using SimCluster. However the gains are much more in case of Doc2Vec representations than Seq2Seq representations since Doc2Vec did not have any information from the other domain where as some amount of this information is already captured by Seq2Seq representation. Moreover it is the clustering of customer utterances which is likely to see an improvement. This is because agent utterances tends to follow a generic pattern while customer utterances tend to be more varied. Considering agent utterances while generating clusters in the user domain thus tends to be more helpful than the other way round.

Table 3 shows qualitative results on the same dataset. Column 1 and 2 consists of clusters of utterances in customer domain and agent domain respectively. The utterances with usual font are representative utterances from clusters obtained through K-means clustering. The utterances in bold face indicate the similar utterances which were incorrectly classified in different clusters us-

ing K-means but were correctly classified together with the utterances by SimCluster algorithm.

6 Conclusions

One of the first steps to automate the construction of conversational systems could be to identify the frequent user utterances and their corresponding system responses. In this paper we proposed an approach to compute these groups of utterances by clustering the utterances in both the domains using our novel SimCluster algorithm which seeks to simultaneously cluster the utterances and align the utterances in two domains. Through our experiments on synthetically generated dataset we have shown that SimCluster has more advantage over K-means on datasets with larger variance. Our technique improves upon the ARI and F1 scores on a real dataset containing Twitter conversations.

Abstract

One of the major drawbacks of modularized task-completion dialogue systems is that each module is trained individually, which presents several challenges. For example, downstream modules are affected by earlier modules, and the performance of the entire system is not robust to the accumulated errors. This paper presents a novel end-to-end learning framework for task-completion dialogue systems to tackle such issues. Our neural dialogue system can directly interact with a structured database to assist users in accessing information and accomplishing certain tasks. The reinforcement learning based dialogue manager offers robust capabilities to handle noises caused by other components of the dialogue system. Our experiments in a movie-ticket booking domain show that our end-to-end system not only outperforms modularized dialogue system baselines for both objective and subjective evaluation, but also is robust to noises as demonstrated by several systematic experiments with different error granularity and rates specific to the language understanding module¹.

1 Introduction

In the past decade, goal-oriented dialogue systems have been the most prominent component in today's virtual personal assistants, which allow users to speak naturally in order to accomplish tasks more efficiently. Traditional systems have a rather complex and modularized pipeline, consisting of a language understanding (LU) module, a dialogue

manager (DM), and a natural language generation (NLG) component (Rudnicky et al., 1999; Zue et al., 2000; Zue and Glass, 2000).

Recent advances of deep learning have inspired many applications of neural models to dialogue systems. Wen et al. (2017) and Bordes et al. (2017) introduced a network-based end-to-end trainable task-oriented dialogue system, which treated dialogue system learning as the problem of learning a mapping from dialogue histories to system responses, and applied an encoder-decoder model to train the whole system. However, the system is trained in a supervised fashion: not only does it require a lot of training data, but it may also fail to find a good policy robustly due to lack of exploration of dialogue control in the training data. Zhao and Eskenazi (2016) first presented an end-to-end reinforcement learning (RL) approach to dialogue state tracking and policy learning in the DM. This approach is shown to be promising when applied to the task-oriented dialogue problem of guessing the famous person a user thinks of. In the conversation, the agent asks the user a series of *Yes/No* questions to find the correct answer. However, this simplified task may not generalize to practical problems due to the following:

1. **Inflexible question types** — asking request questions is more natural and efficient than *Yes/No* questions. For example, it is more natural and efficient for the system to ask “*Where are you located?*” instead of “*Are you located in Palo Alto?*”, when there are a large number of possible values for the location slot.
2. **Poor robustness** — the user answers are too simple to be misunderstood, so the system lacks the robustness against noise in real user utterances.
3. **User requests during dialogues** — in a task-oriented dialogue, user may ask questions for

¹The source code is available at: <https://github.com/MiuLab/TC-Bot>.

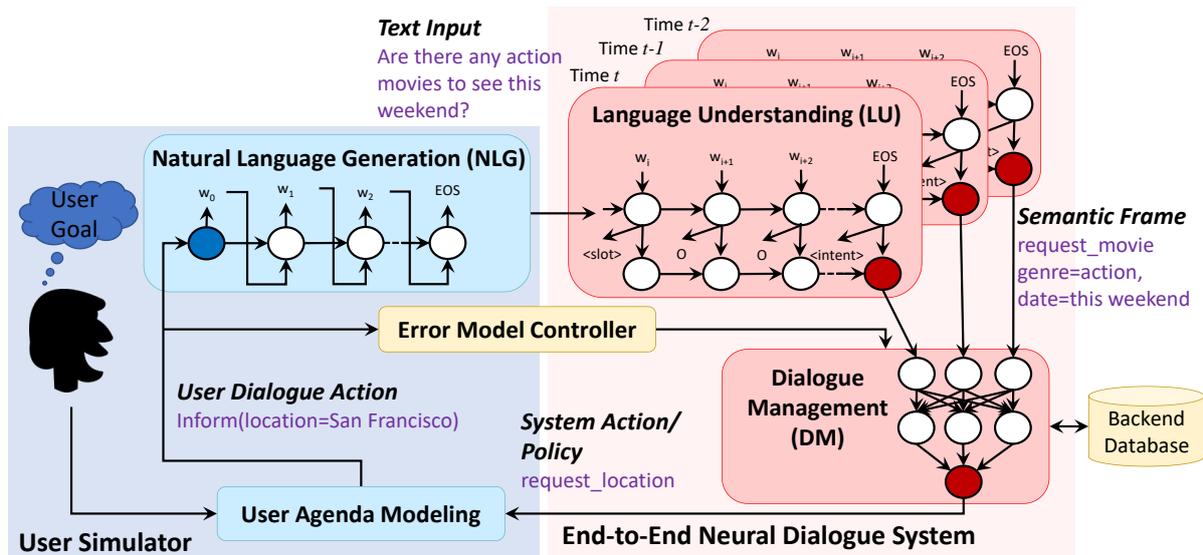

Figure 1: Illustration of the end-to-end neural dialogue system: given user utterances, reinforcement learning is used to train all components in an end-to-end fashion.

selecting the preferred slot values. In a flight-booking example, user might ask “*What flight is available tomorrow?*”.

For the second issue, Su et al. (2016) briefly investigated the effect of dialogue action level semantic error rates on the dialogue performance. Lemon and Liu (2007) compared policy transfer properties under different environments, showing that policies trained in high-noise conditions have better transfer properties than those trained in low-noise conditions. Recently, Dhingra et al. (2017) proposed an end-to-end differentiable KB-Infobot to provide the solutions to the first two issues, but the last one remained unsolved.

This paper addresses all three issues above by redefining the targeted system as a task-completion neural dialogue system. Our framework is more practical in that the information can be easily accessed by the user during the conversations, while the final goal of the system is to complete a task, such as movie-ticket booking. This paper is the first attempt of training a real-world task-completion dialogue system in an end-to-end fashion by leveraging supervised learning and reinforcement learning techniques. To further understand the robustness of reinforcement learning based dialogue systems, we conduct extensive experiments and quantitative analysis on a fine-grained level of LU errors, and provide meaningful insights on how the language understanding component impacts the overall performance of the

dialogue system.

Our contributions are three-fold:

- **Robustness** — We propose a neural dialogue system with greater robustness by automatically selecting actions based on uncertainty and confusion by reinforcement learning. We also provide the first systematic analysis to investigate the impact of different types of natural language understanding errors on dialogue system performance. We show that slot-level errors have a greater impact on the system performance than intent-level ones, and that slot value replacement degrades the performance most. Our findings shed some light on how to design multi-task natural language understanding models (intent classification and slot labeling) in the dialogue systems with consideration of error control.
- **Flexibility** — The system is the first neural dialogue system that allows user-initiated behaviors during conversations, where the users can interact with the system with higher flexibility that is important in realistic scenarios.
- **Reproducibility** — We demonstrate how to evaluate RL dialogue agents using crowd-sourced task-specific datasets and simulated users in an end-to-end fashion, guaranteeing reproducibility and consistent comparisons of competing methods in an identical setting.

Figure 2: An example utterance with annotations of semantic slots in IOB format (S) and intent (I), B-date and I-date denote the date slot.

2 Proposed Framework

The proposed framework² is illustrated in Figure 1. It includes a user simulator (left part) and a neural dialogue system (right part). In the user simulator, an agenda-based user modeling component based at the dialogue act level is applied to control the conversation exchange conditioned on the generated user goal, to ensure the user behaves in a consistent, goal-oriented manner. An NLG module is used to generate natural language texts corresponding to the user dialogue actions. In a neural dialogue system, an input sentence (recognized utterance or text input) passes through an LU module and becomes a corresponding semantic frame, and an DM, which includes a state tracker and policy learner, is to accumulate the semantics from each utterance, robustly track the dialogue states during the conversation, and generate the next system action.

2.1 Neural Dialogue System

Language Understanding (LU): A major task of LU is to automatically classify the domain of a user query along with domain specific intents and fill in a set of slots to form a semantic frame. The popular IOB (in-out-begin) format is used for representing the slot tags, as shown in Figure 2.

$$\begin{aligned}\vec{x} &= w_1, \dots, w_n, \langle \text{EOS} \rangle \\ \vec{y} &= s_1, \dots, s_n, i_m\end{aligned}$$

where \vec{x} is the input word sequence and \vec{y} contains the associated slots, s_k , and the sentence-level intent i_m . The LU component is implemented with a single LSTM, which performs intent prediction and slot filling simultaneously (Hakkani-Tür et al., 2016; Chen et al., 2016):

$$\vec{y} = \text{LSTM}(\vec{x}). \quad (1)$$

The LU objective is to maximize the conditional probability of the slots and the intent \vec{y} given the

²The source code is available at: <https://github.com/MiuLab/TC-Bot>

word sequence \vec{x} :

$$p(\vec{y} | \vec{x}) = \left(\prod_i^n p(s_i | w_1, \dots, w_i) \right) p(i_m | \vec{y}).$$

The weights of the LSTM model are trained using backpropagation to maximize the conditional likelihood of the training set labels. The predicted tag set is a concatenated set of IOB-format slot tags and intent tags; therefore, this model can be trained using all available dialogue actions and utterance pairs in our labeled dataset in a supervised manner.

Dialogue Management (DM): The symbolic LU output is passed to the DM in the dialogue act form (or semantic frame). The classic DM includes two stages, *dialogue state tracking* and *policy learning*.

- **Dialogue state tracking:** Given the LU symbolic output, such as `request(moviename; genre=action; date=this weekend)`, three major functions are performed by the state tracker: a symbolic query is formed to interact with the database to retrieve the available results; the state tracker will be updated based on the available results from the database and the latest user dialogue action; and the state tracker will prepare the state representation s_t for policy learning.
- **Policy learning:** The state representation for the policy learning includes the latest user action (e.g., `request(moviename; genre=action; date=this weekend)`), the latest agent action (`request(location)`), the available database results, turn information, and history dialogue turns, etc. Conditioned on the state representation s_t from the state tracker, the policy π is to generate the next available system action a_t according to $\pi(s_t)$. Either supervised learning or reinforcement learning can be used to optimize π . Details about RL-based policy learning can be found in section 3.

Prior work used different implementation approaches summarized below. Dialogue state tracking is the process of constantly updating the state of the dialogue, and Lee (2014) showed that there is a positive correlation between state tracking performance and dialogue performance. Most production systems use manually designed heuristics, often based on rules, to update the dialogue

states based on the highly confident output from LU. Williams et al. (2013) formalized the tracking problem as a supervised sequence labeling task, where the input is LU outputs and the output is the true slot values, and the state tracker’s results can be translated into a dialogue policy. Zhao and Eskenazi (2016) proposed to jointly train the state tracker and the policy learner in order to optimize the system actions more robustly. Instead of explicitly incorporating the state tracking labels, this paper learns the system actions with implicit dialogue states, so that the proposed DM can be more flexible and robust to the noise propagated from the previous components (Su et al., 2016; Liu and Lane, 2017). A rule-based agent is employed to warm-start the system, via supervised learning on labels generated by the rules. The system is then further trained end-to-end with RL, as explained in section 3.

2.2 User Simulation

In order to perform end-to-end training for the proposed neural dialogue systems, a user simulator is required to automatically and naturally interact with the dialogue system. In the task-completion dialogue setting, the user simulator first generates a user goal. The agent does not know the user goal, but tries to help the user accomplish it in the course of conversations. Hence, the entire conversation exchange is around this goal implicitly. A user goal generally consists of two parts: *inform_slots* for slot-value pairs that serve as constraints from the user, and *request_slots* for slots whose value the user has no information about, but wants to get the values from the agent during the conversation. The user goals are generated using a set of labeled conversational data.

User Agenda Modeling: During the course of a dialogue, the user simulator maintains a compact, stack-like representation called *user agenda* (Schatzmann and Young, 2009), where the user state s_u is factored into an agenda A and a goal G . The goal consists of constraints C and request R . At each time-step t , the user simulator generates the next user action $a_{u,t}$ based on the current state $s_{u,t}$ and the last agent action $a_{m,t-1}$, and then updates the current status $s'_{u,t}$.

Natural Language Generation (NLG): Given the user’s dialogue actions, the NLG module generates natural language texts. To control the quality of user simulation given limited labeled data, a

hybrid approach including a template-based NLG and a model-based NLG is employed, where the model-based NLG is trained on the labeled dataset with a sequence-to-sequence model. It takes dialogue acts as input, and generates sentence sketch with slot placeholders via an LSTM decoder. Then a post-processing scan is performed to replace the slot placeholders with their actual values (Wen et al., 2015). In the LSTM decoder, we apply beam search, which iteratively considers the top k best sub-sentences when generating the next token.

In the hybrid model, if the user dialogue actions can be found in the predefined sentence templates, the template-based NLG is applied; otherwise, the utterance is generated by the model-based NLG. This hybrid approach allows a dialogue system developer to easily improve NLG by providing templates for sentences that the machine-learned model does not handle well.

2.3 Error Model Controller

When training or testing a policy based on semantic frames of user actions, an error model (Schatzmann et al., 2007) is introduced to simulate noises from the LU component, and noisy communication between the user and the agent in order to test the model robustness. Here, we introduce different levels of noises in the error model: one type of errors is at the *intent* level, another is at the *slot* level. For each level, there are more fine-grained noises.

Intent-Level Error: At the intent level, we categorize all intents into three groups:

- *Group 1:* general *greeting*, *thanks*, *closing*, etc.
- *Group 2:* users may *inform*, to tell the slot values (or constraints) to the agent, for example, `inform(moviename='Titanic', starttime='7pm')`.
- *Group 3:* users may *request* information for specific slots. In a movie-booking scenario, users might ask “`request(starttime; moviename='Titanic')`”.

In the specific task of movie-booking, for instance, there exist multiple *inform* and *request* intents, such as `request_starttime`, `request_moviename`, `inform_starttime` and `inform_moviename`, etc. Based on the above intent categories, there are three types of intent errors:

- *Random error (IO):* the random noisy intent from the same category (*within group error*)

or other categories (*between group error*).

- *Within-group error (I1)*: the noisy intent is from the same group of the real intent, for example, the real intent is `request_theater`, but the predicted intent from LU module might be `request_moviename`.
- *Between-group error (I2)*: the noisy intent is from the different group, for example, a real intent `request_moviename` might be predicted as the intent `inform_moviename`.

Slot-level Error: At the slot level, there are four error types:

- *Random error (S0)*: to simulate the noise that is randomly set to the following three types.
- *Slot deletion (S1)*: is to simulate the scenario where the slot is not recognized by the LU component.
- *Incorrect slot value (S2)*: is to simulate the scenario where the slot name is correctly recognized, but the slot value is wrong, e.g., wrong word segmentation.
- *Incorrect slot (S3)*: is to simulate the scenario where both the slot and its value are incorrectly recognized.

3 End-to-End Reinforcement Learning

To learn the interactive policy of our system, we apply reinforcement learning to the DM training in an end-to-end fashion, where each neural network component can be fine tuned. The policy is represented as a deep Q-network (DQN) (Mnih et al., 2015), which takes the state s_t from the state tracker as input, and outputs $Q(s_t, a; \theta)$ for all actions a . Two important DQN tricks, target network usage and experience replay are applied, where the experience replay strategy is changed for the dialogue setting.

During training, we use ϵ -greedy exploration and an experience replay buffer with dynamically changing buffer size. At each simulation epoch, we simulate N ($N = 100$) dialogues and add these state transition tuples (s_t, a_t, r_t, s_{t+1}) to the experience replay buffer for training. In one simulation epoch, the current DQN will be updated multiple times (depending on the batch size and the current size of experience replay buffer). At the last simulation epoch, the target network will be replaced by the current DQN, the target DQN network is only updated for once in one simulation epoch.

The experience replay strategy is critical for RL training (Schaul et al., 2015). In our buffer update

strategy, we accumulate all experience tuples from the simulation and flush the pool till the current RL agent reaches a success rate threshold (i.e., a threshold which is equal to the performance of a rule-based agent), and then use the experience tuples from the current RL agent to re-fill the buffer. The intuition is that the initial performance of the DQN is not strong enough to generate good experience replay tuples, thus we do not flush the experience replay pool till the current RL agent can reach a certain success rate (for example, the success rate of a rule-based agent). In the rest of the training process, at every simulation epoch, we estimate the success rate of the current DQN agent (by running it multiple dialogues on simulated users). If the current DQN agent is better than the target network, the experience replay buffer will be flushed.

4 Experiments

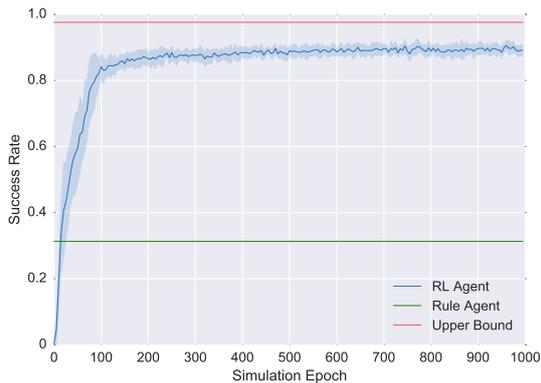

We consider a task-completion dialogue system for helping users book movie tickets. Over the course of conversation, the dialogue system gathers information about the customer’s desires and ultimately books the movie tickets. The environment then assesses a binary outcome (success or failure) at the end of the conversation, based on (1) whether a movie is booked, and (2) whether the movie satisfies the users constraints.

Dataset: The raw conversational data were collected via Amazon Mechanical Turk, with annotations provided by domain experts. In total, we have labeled 280 dialogues, and the average number of turns per dialogue is approximately 11. The annotated data includes 11 dialogue acts and 29 slots, most of the slots are *informable* slots, which users can use to constrain the search, and some are *requestable* slots, of which users can ask values from the agent. For example, *numberofpeople* cannot be a requestable slot, since arguably user knows how many tickets he or she wants to buy. The detailed annotations can be found in Appendix A.

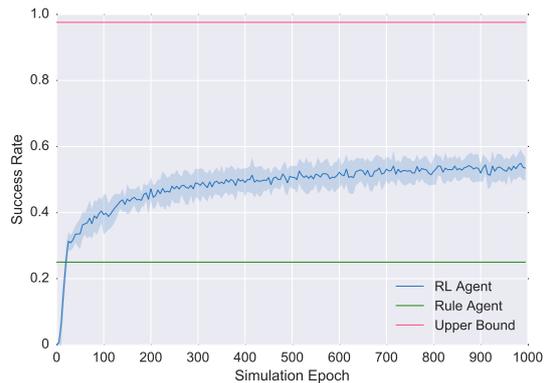

4.1 Simulated User Evaluation

Two sets of experiments are conducted in the DM training, where two input formats are used for training the RL agents:

1. *frame-level semantics*: when training or testing a policy based on semantic frames of user

(a) Frame-level semantics for training

(b) Natural language for end-to-end training

Figure 3: Learning curves for policy training (average of 10 runs). The blue solid lines show the rule agent performance, where we employ to initialize the experience replay buffer pool; the orange dotted line is the optimal upper bound, which is the percentage of reachable user goals.

Setting	Intent Error		Slot Error		
	Type	Rate	Type	Rate	
Basic	B1	0.00	0: random	0.10	
	B2	0: random	0.10	0: random	
	B3	0.20	0.20	0.20	
Intent	I0	0: random	0.10		
	I1	1: within group	0.10		
	I2	2: between group	0.10	0: random	
	I3	0: random	0.00	0.05	
	I4	0: random	0.10		
Slot	S0		0: random	0.10	
	S1		1: deletion	0.10	
	S2		2: value	0.10	
	S3	0: random	0.10	3: slot	0.10
	S4		0: random	0.00	
	S5		0: random	0.10	
	S6		0: random	0.20	

Table 1: Experimental settings with different intent/slot error types described in section 2.3 and different error rates.

actions, a noise controller described in section 2.3 is used to simulate LU errors and noisy communications between the user and the agent.

2. *natural language*: when training or testing a policy on natural language level, in which LU and NLG may introduce noises. In our experiments, the NLG decoder uses *beam_size* = 3 to balance speed and performance.

Figure 3(a) shows a learning curve for the dialogue system performance trained with the frame-level information (user semantic frames and system actions), where the number is the average of 10 runs. Figure 3(b) is a learning curve for the system trained at the natural language level. In

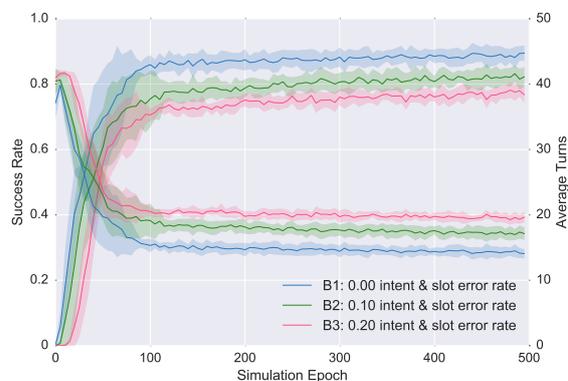

Figure 4: Learning curves for different LU error rates.

both settings, the RL agents significantly outperform the rule-based systems, showing the potential of a neural dialogue system that can perform real-world tasks and be improved autonomously through interactions with users. Also, the end-to-end system in Figure 3(b) takes longer for the RL agent to adapt to the noises from LU and NLG, indicating the difficulty of maintaining the system robustness. The consistently increasing trend of our proposed end-to-end system also suggests greater robustness in noisy, real-world scenarios. To further investigate and understand the real impact of the LU component to the robustness of RL agent in the dialogue system, we conduct a series of experiments under different error settings (intent and slot errors from LU) summarized in Table 1, where the learning curves are averaged over 10 runs.

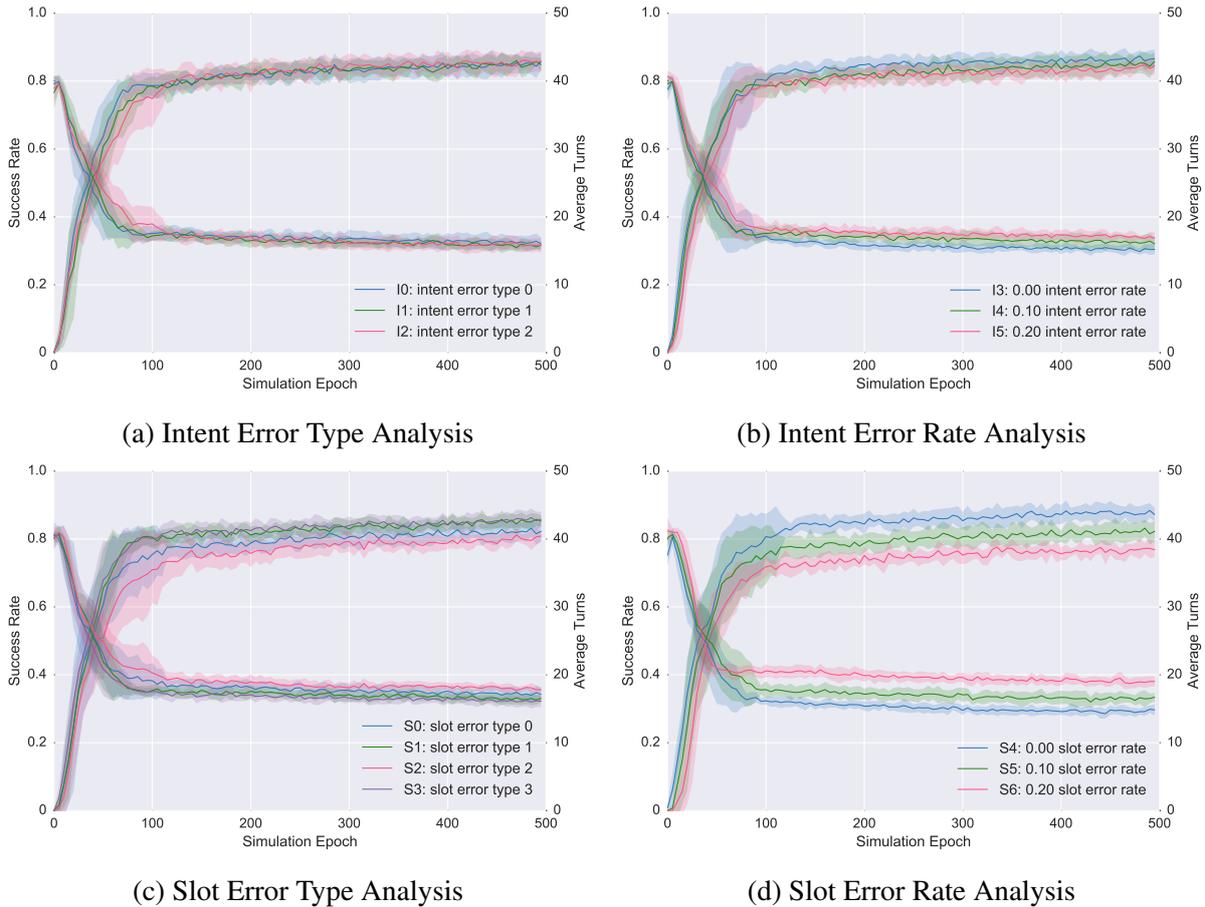

Figure 5: Learning curves of the different intent and slot errors in terms of success rate (left axis) and average turns (right axis).

4.2 Basic Error Analysis

The group of basic experiments (from B1 to B3) are in the settings that combine the noise from both intent and slot: 1) For both intent and slot, the error types are random, and the error rates are in $\{0.00, 0.10, 0.20\}$. The rule-based agent reports 41%, 21%, and 12% success rates under 0.00, 0.10, and 0.20 error rates respectively. In contrast, the RL-based agent achieves 90%, 79%, and 76% success rate under the same error rates, respectively. We compare the performance between two types of agents and find that the RL-based agent has greater robustness and is less sensitive to noisy inputs. Therefore, the following experiments are performed using a RL dialogue agent due to robustness consideration. From Fig. 4, the dialogue agents degrade remarkably when the error rate increases (leading to lower success rates and higher average turns).

4.3 Intent Error Analysis

To further understand the impact of intent-level noises to dialogue systems, two experimental groups are performed: the first group (I0–I2) focuses on the difference among all intent error types; the second group (I3–I5) focuses on the impact of intent error rates. Other factors are identical for the two groups, with the random slot error type and a 5% slot error rate.

4.3.1 Intent Error Type

Experiments with the settings of I0–I2 are under the same slot errors and same intent error rate (10%), but with different intent error types: I1 includes the noisy intents from the same categories, I2 includes the noisy intents from different categories, and I0 includes both via random selection. Fig. 5(a) shows the learning curves for all intent error types, where the difference among three curves is insignificant, indicating that the incorrect intents have similar impact no matter what categories they

belong to.

4.3.2 Intent Error Rate

Experiments with the settings I3–I5 investigate the difference among different intent error rates. When the intent error rate increases, the dialogue agent performs slightly worse, but the difference is subtle. It suggests that the RL-based agent has better robustness to noisy intents. As shown in Fig. 5(a,b), all RL agents can converge to a similar success rate in both intent error type and intent error rate settings.

4.4 Slot Error Analysis

We further conducted two groups of experiments to investigate the impact of slot-level noises where other factors are fixed — with the random intent error type and a 10% intent error rate.

4.4.1 Slot Error Type

Experiments (S0 – S3) investigate the impact of different slot error types. Corresponding learning curves are given in Fig. 5(c). Among single error types (S1–S3), *incorrect slot value* (S2) performs worst, which means that the slot name is recognized correctly, but a wrong value is extracted with the slot (such as wrong word segmentation); in this case, the agent receives a wrong value for the slot, and eventually books a wrong ticket or fails to book it. The probable reason is that the dialogue agent has difficulty identifying the mistakes, and using the incorrect slot values for the following dialogue actions could significantly degrade the performance. Between *slot deletion* (S1) and *incorrect slot* (S3), the difference is limited, indicating that the RL agent has similar capability of handling these two kinds of slot-level noises.

4.4.2 Slot Error Rate

Experiments with the settings from S4 to S6 focus on different slot error rates (0%, 10%, and 20%) and report the results in Fig. 5(d). It is clear from Fig. 5(d) that the dialogue agent performs worse as the slot error rate increases (the curve of the success rate drops and the curve of average turns rises). Comparing with Fig. 5(b), the dialogue system performance is more sensitive to the slot error rate than the intent error rate.

4.5 Human Evaluation

We further evaluated the rule-based and DQN agents against real human users recruited from

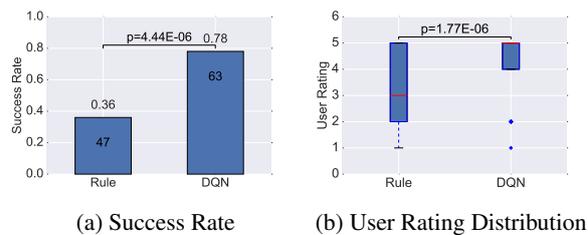

Figure 6: Performance of the rule-based agent versus DQN agent tested with real users: (a) success rate, number of tested dialogues and p-values are indicated on each bar; (b) Distribution of user ratings for two agents (difference in mean is significant with $p < 0.01$).

the authors affiliation, where the DQN agent was trained on the simulated user in the frame-level with 5% random slot errors. In each dialogue session, one of the agents was randomly picked to converse with a user, and the user was presented with a predefined user goal sampled from our corpus, and was instructed to converse with the agent to complete the presented task. At the end of each session, the user was asked to give a rating on a scale from 1 (worst) to 5 (best) based on both *naturalness* and *coherence* of the dialogue. We collected a total of 110 dialogue sessions from 8 human users. Figure 6(a) presents the performance of these agents against real users in terms of success rate. Figure 6(b) shows the subjective evaluation in terms of user rating. For all the cases, the RL agent significantly outperforms the rule-based agent for both objective (success rate) and subjective evaluation (user rating).

5 Discussion and Future Work

This paper presents an end-to-end learning framework for task-completion neural dialogue systems. Our experiments, both on simulated and real users, show that reinforcement learning systems outperform rule-based agents and have better robustness to allow natural interactions with users in real-world task-completion scenarios. Furthermore, we conduct a series of extensive experiments to understand the impact of natural language understanding errors on the performance of a reinforcement learning based, task-completion neural dialogue system. Our empirical results suggest several interesting findings: 1) slot-level errors have a greater impact than intent-level errors; A possible explanation is related to our dialogue action rep-

resentation, *intent(slot-value pairs)*. If an intent is predicted wrong, for example, *inform* was predicted incorrectly as *request_ticket*, the dialogue agent can handle this unreliable situation and decide to make confirmation in order to keep the correct information for the following conversation. In contrast, if a slot *moviename* is predicted wrong, or a slot value is not identified correctly, this dialogue turn might directly pass the wrong information to the agent, which might lead the agent to book a wrong ticket. Another reason is that the dialogue agent can still maintain a correct intent based on slot information even though the predicted intent is wrong. In order to verify the hypotheses, further experiments are needed, which we leave as future work. 2) different slot error types have different impacts on the RL agents. 3) RL agents are more robust to certain types of slot-level errors — the agents can learn to double-check or confirm with users, at the cost of slightly longer conversations.

Finally, it should be noted that the experiments in this paper focus on task-completion dialogues. Another type of dialogues known as chit-chats has different optimization goals (Li et al., 2016). It would be interesting to extend our analysis from this paper to chit-chat dialogues to gain useful insights for impacts of LU errors.

Abstract

We propose an end-to-end neural network to predict the geolocation of a tweet. The network takes as input a number of raw Twitter metadata such as the tweet message and associated user account information. Our model is language independent, and despite minimal feature engineering, it is interpretable and capable of learning location indicative words and timing patterns. Compared to state-of-the-art systems, our model outperforms them by 2%-6%. Additionally, we propose extensions to the model to compress representation learnt by the network into binary codes. Experiments show that it produces compact codes compared to benchmark hashing algorithms. An implementation of the model is released publicly.¹

1 Introduction

A number of applications benefit from geographical information in social data, from personalised advertising to event detection to public health studies. Sloan et al. (2013) estimate that less than 1% of tweets are geotagged with their locations, motivating the development of geolocation prediction systems.

Han et al. (2012) introduced the task of predicting the location based only the tweet message. A key difference to previous work is that the prediction is made at message or tweet level, while predecessor methods tend to focus on user-level prediction (Backstrom et al., 2010; Cheng et al., 2010). Since then, various methods have been proposed for the task (Han et al., 2014; Chi et al., 2016; Jayasinghe et al., 2016; Miura et al.,

2016), although most systems are engineered for a particular platform and language (e.g. website-specific parsers and language-specific tokenisers and gazetteers). Another strand of research leverages the social network structure to infer location; Jurgens et al. (2015) provided a standardised comparison of these systems. Our focus in this paper is on using only the tweets, although Rahimi et al. (2015) showed that the best approach maybe to combine both types of information.

In applications where fast retrieval of co-located tweets is necessary (e.g. disaster detection), efficient representation of large volume of tweets constitute an important issue. Traditionally, hashing techniques such as locality sensitive hashing (Indyk and Motwani, 1998) are used to compress data into binary codes for fast retrieval (e.g. with multi-index hash tables (Norouzi et al., 2012, 2014)), but it is not immediately clear how they can interact with raw Twitter metadata — as they often require a vector as input — and incorporate supervision.²

To this end, we propose an end-to-end neural network for tweet-level geolocation prediction. Our network is designed to be interpretable: we show it has the capacity to automatically learn location indicative words and activity patterns from different regions.

Our contribution in this paper is two-fold. First, our model outperforms state-of-the-art systems by 2-6%, even though it has minimal feature engineering and is completely language-independent, as it uses no gazetteers or language preprocessing tools such as tokenisers or parsers. Second, our network can further compress learnt representations into compact binary code that incorporates information about the tweet and its geolocation. To the best of our knowledge, this is the first end-to-end hashing method for tweets.

¹<https://github.com/jhlau/twitter-deepgeo>

²In our case, the supervised information is the geolocation of tweets.

2 Related Work

Early work in geolocation prediction operated at the user-level. [Backstrom et al. \(2010\)](#) developed a methodology to predict the location of a user on Facebook by measuring the relationship between geography and friendship networks, and [Cheng et al. \(2010\)](#) proposed a content-based prediction system to predict a Twitter user’s location based purely on his/her tweet messages. [Han et al. \(2012\)](#) introduced tweet-level prediction, where they first extract location indicative words by leveraging the geotagged tweets and then train a classifier for geolocation prediction using the location indicative words as features. Extending on this, systems were developed to better rank these location indicative or geospatial words by locality ([Chang et al., 2012](#); [Laere et al., 2014](#); [Han et al., 2014](#)). More recently, [Han et al. \(2016\)](#) proposed a shared task for Twitter geolocation prediction, offering a benchmark dataset on the task.

Hashing is an effective method to compress data for fast access and analysis. Broadly there are two types of hashing techniques: data-independent techniques which design arbitrary functions to generate hashes, and data-dependent techniques that leverage pairwise similarity in the training data ([Chi and Zhu, 2017](#)). Locality-sensitive hashing (`lsh`: [Indyk and Motwani \(1998\)](#)) is a widely-known data-independent hashing method that uses randomised projections to generate hashcodes. It preserves data characteristics and guarantees the collision probability between data points. `fasthash` ([Lin et al., 2014](#)), on the other hand, is a supervised data-dependent hashing that incorporates label information to determine pairwise similarity. It uses decision tree based hash functions and graph cut-based binary code inference to deal with high dimensionality training data.

3 Geolocation Prediction

3.1 Dataset

We use the geolocation prediction shared task dataset ([Han et al., 2016](#)) for our experiments. There are 2 proposed tasks, predicting geolocation given: (1) a tweet (tweet-level); and (2) a collection of tweets by a user (user-level). For each task, there is a hard classification evaluation setting for predicting a city class, and a soft evaluation setting for predicting latitude and longitude coordinates.

We explore only the more challenging tweet-

Partition	#Tweets	#Characters
Training	8.9M	554M
Development	7.2K	439K
Test	10K	629K

Table 1: Dataset statistics.

level prediction task. In terms of evaluation setting, we experiment with the hard classification setting, where the network is required to predict one out of 3362 cities. Note that the metadata of a tweet includes not only the message but a variety of information such as creation time and user account data such as location and timezone.

Training, development and test partitions are provided by the shared task organisers.³ We preprocess the data minimally, removing tweets that have less than 5 characters in the training partition (development and testing data is untouched) and keeping all character types that have occurred 5 times or more in training. Unseen character tokens are represented by `<UNK>`. Preprocessed statistics of the dataset is given in Table 1.

3.2 Network Architecture

The overall architecture of our model (henceforth `deepgeo`) is illustrated in Figure 1. `deepgeo` uses 6 features from the metadata: (1) tweet message; (2) tweet creation time; (3) user UTC offset; (4) user timezone; (5) user location; and (6) user account creation time.⁴

Each feature from the metadata is processed by a separate network to generate a feature vector \mathbf{f}_j . These feature vectors are then concatenated (with dropout applied) and connected to the penultimate layer:

$$\hat{\mathbf{f}} = \mathbf{f}_1 \oplus \mathbf{f}_2 \dots \oplus \mathbf{f}_N \quad (1)$$

$$\mathbf{r} = \tanh(\mathbf{W}_r \hat{\mathbf{f}}) \quad (2)$$

where N is the number of features (6 in total), $\mathbf{r} \in \mathbb{R}^R$ is the hidden representation at the penultimate layer and \mathbf{W}_r is model parameter. For brevity, we omit biases in equations.

\mathbf{r} is fully connected to the output layer and activated by softmax to generate a probability distribution over the classes. The model is trained with

³The organisers provide full metadata for the test partition but only the tweet IDs for training and development partitions. We collect metadata for training/development tweets using the Twitter API.

⁴We also tested user description and username, but preliminary experiments found these features are not very useful.

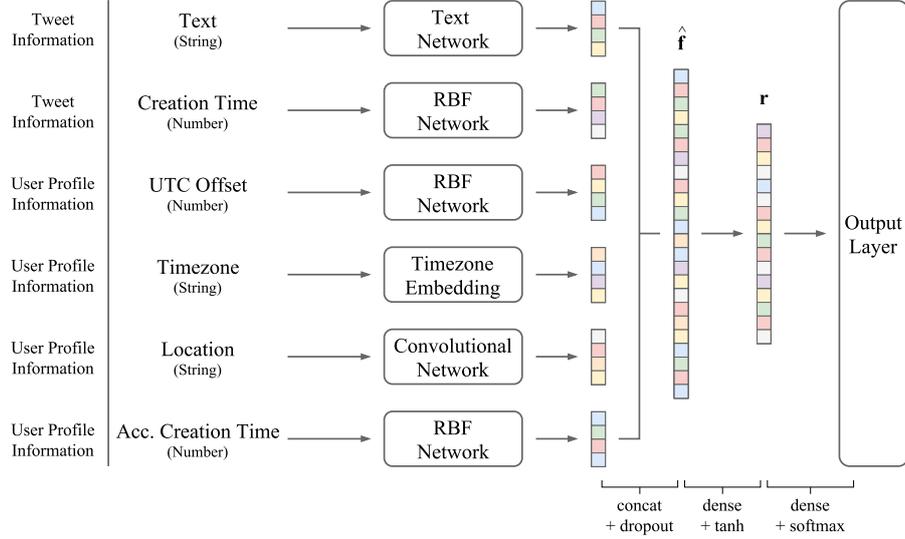

Figure 1: Overall architecture of `deepgeo`.

minibatches and optimised using Adam (Kingma and Ba, 2014) with standard cross-entropy loss.

We design several networks for the raw features. The first is a character-level recurrent convolutional network with a self-attention component for processing the tweet message (Section 3.2.1). The second is an RBF network⁵ for processing numbers (Section 3.2.2). The third is a simple convolutional network for processing user location (Section 3.2.3), and the last is an embedding matrix for user timezone. We treat the timezone as a categorical feature, and learn embeddings for each timezone (309 unique timezones in total). Note that these feature-processing networks are disjointed and there is no parameter sharing between them.

3.2.1 Text Network

For the tweet message, we use a character-level recurrent convolutional network (Lai et al., 2015), followed by max-over-time pooling with a fixed window size and an attentional component to generate the feature vector, as illustrated in Figure 2.

Let $\mathbf{x}_t \in \mathbb{R}^E$ denote the character embedding of the t -th character, we run a bi-directional LSTM network (Hochreiter and Schmidhuber, 1997) to generate the forward and backward hidden states \mathbf{h}_t^f and \mathbf{h}_t^b respectively.⁶ We then concatenate the left and right context’s hidden states with \mathbf{x}_t and

generate:

$$\begin{aligned}\hat{\mathbf{x}}_t &= \mathbf{h}_{t-1}^f \oplus \mathbf{x}_t \oplus \mathbf{h}_{t+1}^b \\ \mathbf{g}_t &= \text{ReLU}(\mathbf{W}_g \hat{\mathbf{x}}_t)\end{aligned}$$

where $\hat{\mathbf{x}}_t \in \mathbb{R}^{3E}$, $\mathbf{W}_g \in \mathbb{R}^{O \times 3E}$ and $\mathbf{g}_t \in \mathbb{R}^O$. We iterate for each character to generate \mathbf{g}_t for all time steps (\mathbf{W}_g can be interpreted as O convolutional filters each with a window of $3 \times E$ striding 3 steps at a time). Next, we apply max-over-time (narrow) pooling with window size P over the vectors:

$$\hat{\mathbf{g}}_t = \max(\mathbf{g}_t, \mathbf{g}_{t+1}, \dots, \mathbf{g}_{t+P-1})$$

where $\hat{\mathbf{g}}_t \in \mathbb{R}^O$ and \max is a function that returns the element-wise maxima given a number of vectors of the same length. If there are T characters in the tweet, this yields $(T - P + 1)$ $\hat{\mathbf{g}}$ vectors, one for each span.

By setting $P = T$, we could generate one vector for the whole tweet. The idea of using a smaller window is that it enables a self-attention component, thereby allowing the network to discover the saliency of a character span — for our task this means attending to location indicative words (Section 3.4). We define the attention network as follows:

$$\begin{aligned}\alpha_t &= \mathbf{v}^\top \tanh(\mathbf{W}_v \hat{\mathbf{g}}_t) \\ \mathbf{a} &= \text{softmax}(\alpha_0, \alpha_1, \dots, \alpha_{T-P})\end{aligned}$$

where $\mathbf{W}_v \in \mathbb{R}^{V \times O}$, $\mathbf{v} \in \mathbb{R}^V$ and $\mathbf{a} \in \mathbb{R}^{T-P+1}$. Given the attention, we compute a weighted mean

⁵Also known as mixture density network.

⁶LSTM is implemented using one layer without any peephole connections and forget biases are initialised with 1.0.

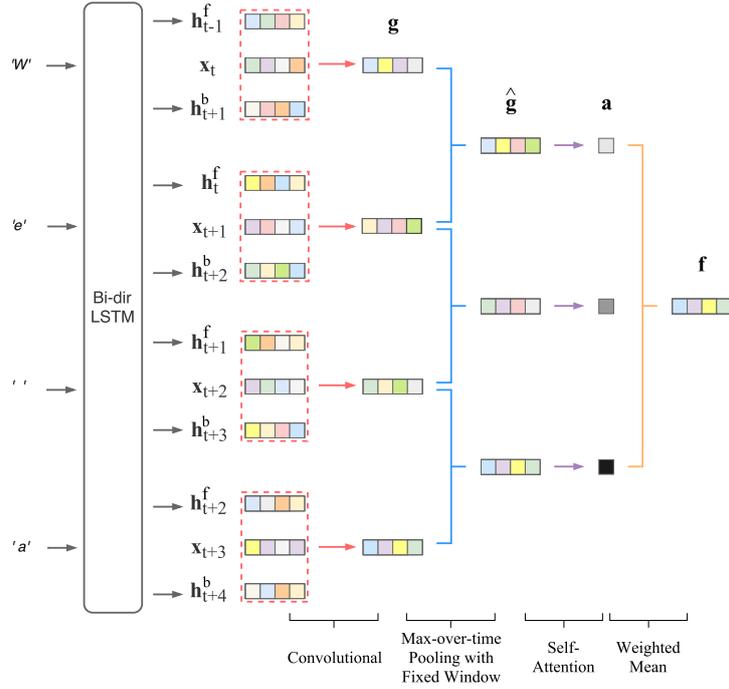

Figure 2: Text Network.

to generate the final feature vector:

$$\mathbf{f}_{\text{text}} = \sum_{t=0}^{T-P} \mathbf{a}_t \hat{\mathbf{g}}_t$$

where \mathbf{a}_t denotes the t -th element in \mathbf{a} , and $\mathbf{f}_{\text{text}} \in \mathbb{R}^O$.

3.2.2 RBF Network

There are three time features in the metadata: tweet creation time, user account creation time and user UTC offset. The creation times are given in UTC time (i.e. not local time), e.g. *Thu Jul 29 17:25:38 +0000 2010* and the offset is an integer.

For the creation times, we use only time of the day information (e.g. *17:25*) and normalise it from 0 to 1.⁷ UTC offset is converted to hours and normalised to the same range.⁸

The aim of the network is to split time into multiple bins. We can interpret each hour as one bin (24 bins in total) and tweets originated from a particular location (e.g. Europe) favour certain hours or bins. This preference of bins should be different to tweets from a distant location (e.g. East Asia). Assuming each bin follows a Gaussian distribution, then the goal of the network is to learn

⁷As an example, *17:25* is converted to 0.726.

⁸UTC offset minimum is assumed -12 and maximum +14 based on: https://en.wikipedia.org/wiki/List_of_UTC_time_offsets.

the Gaussian means and standard deviations of the bins.

Formally, given an input value u , for bin i the network computes:

$$r_i = \exp\left(\frac{-(u - \mu_i)^2}{2\sigma_i^2}\right)$$

where r_i is the output value and μ_i and σ_i are the parameters for bin i . Let B be the total number of bins, the feature vector generated by a RBF network is given as follows:

$$\mathbf{f}_{\text{rbf}} = [r_0, r_1, \dots, r_{B-1}]$$

where $\mathbf{f}_{\text{rbf}} \in \mathbb{R}^B$.

3.2.3 Convolutional Network

Location is a user self-declared field in the metadata. As it is free-form text, we use a standard character-level convolution neural network (Kim, 2014) to process it. The network architecture is simpler compared to the text network (Section 3.2.1): it has no recurrent and self-attention layers, and max-over-time pooling is performed over all spans.

Let $\mathbf{x}_t \in \mathbb{R}^E$ denote the character embedding of the t -th character in the tweet. A tweet of T characters is represented by a concatenation of its character vectors: $\mathbf{x}_{0:T-1} = \mathbf{x}_0 \oplus \mathbf{x}_1 \oplus \dots \oplus \mathbf{x}_{T-1}$. We

use convolutional filters and max-over-time (narrow) pooling to compute the feature vector:

$$\mathbf{g}_t = \text{ReLU}(\mathbf{W}_g \mathbf{x}_{t:t+Q-1})$$

$$\mathbf{f}_{\text{conv}} = \max(\mathbf{g}_0, \mathbf{g}_1, \dots, \mathbf{g}_{T-Q})$$

where Q is the length of the character span, $\mathbf{W}_g \in \mathbb{R}^{O \times QE}$ (\mathbf{W}_g can be interpreted as O convolutional filters each with a window of $Q \times E$) and $\mathbf{g}_t, \mathbf{f}_{\text{conv}} \in \mathbb{R}^O$.

3.3 Experiments and Results

We explore two sets of features for predicting geolocation, using: (1) only the tweet message; and (2) both tweet and user metadata. For the latter approach, we have 6 features in total (see Figure 1). Classification accuracy is used as the metric for evaluation.

We tune network hyper-parameter values based on development accuracy; optimal hyper-parameter settings are presented in Table 2. The column “Message-Only” uses only the text content of tweets, while “Tweet+User” incorporates both tweet and user account metadata.

For tweet message and user location, the maximum character length is set to 300 and 20 characters respectively; strings longer than this threshold are truncated and shorter ones are padded.⁹ Models are trained using 10 epochs without early stopping. In each iteration, we reset the model’s parameters if its development accuracy is worse than that of previous iteration.

We compare `deepgeo` to 3 benchmark systems, all of which are systems submitted to the shared task (Han et al., 2016):

Chi et al. (2016) propose a geolocation prediction approach based on a multinomial naive Bayes classifier using a combination of automatically learnt location indicative words, city/country names, #hashtags and @mentions. A frequency-based feature selection strategy is used to select the optimal subset of word features.

Miura et al. (2016) experiment with a simple feedforward neural network for geolocation classification. The network draws inspiration from `fastText` (Joulin et al., 2016), where it uses mean word vectors to represent textual features and has only linear layers. To incorporate multiple

⁹Tweets can exceed the standard 140-character limit due to the use of non-ASCII characters.

Network	Hyper-Parameter	Message-Only	Tweet+User

features — tweet message, user location, user description and user timezone — the network combines them via vector concatenation.

Jayasinghe et al. (2016) develop an ensemble of classifiers for the task. Individual classifiers are built using a number of features independently from the metadata. In addition to using information embedded in the metadata, the system relies on external knowledgebases such as gazetteer and IP lookup system to resolve URL links in the message. They also build a label propagation network that links connected users, as users from a sub-network are likely to come from the same location. These classifiers are aggregated via voting, and weights are manually adjusted based on development performance.

We present test accuracy performance for all systems in Table 3. Using only tweet message as feature, `deepgeo` outperforms Chi et al. (2016) by a considerable margin (over 6% improvement), even though `deepgeo` has minimal feature en-

Table 5: Feature ablation results.

engineering and is trained at character level. Next, we compare `deepgeo` to Miura et al. (2016). Both systems use a similar set of features from the tweet and user metadata. `deepgeo` sees an encouraging performance, with almost 2% improvement. The best system in the shared task, Jayasinghe et al. (2016), remains the top performer. Note, however, that their system depends on language-specific processing tools (e.g. tokenisers), website-specific parsers (e.g. for extracting location information from user profile page on Instagram and Facebook) and external knowledge sources (e.g. gazetteers and IP lookup) which were inaccessible by other systems.

To better understand the impact of each feature, we present ablation results where we remove one feature at a time in Table 5. We see that the two most important features are the user location and tweet message. These observations reveal that self-declared user location appears to be a reliable source of location, as task accuracy drops by almost half when this feature is excluded. For the other features, they generally have a small or neg-

ligible impact.

3.4 Qualitative Analyses

The self-attention component in the text network (Section 3.2.1) captures saliency of character spans. To demonstrate its effectiveness, we select a number of tweets from the test partition and present the top-3 spans that have the highest attention weights in Table 4.

Interestingly, we see that whenever a location word is in the message, `deepgeo` tends to focus around it (e.g. *Louisville* and *Newcastle*). Occasionally this can induce error in prediction, e.g. in the second last example the network focuses on *Ottawa* even though the word has little significance to the true location (*Toronto*). Focussing on the right span does not necessarily result in correct prediction as well; as we see in the third example the network focuses on *Moncton* but predicts a neighbouring city *Halifax* as the geolocation.

Next, we look at the Gaussian mixtures learnt by the RBF network. Using the gold-standard city labels, we collect bin weights (f_{rbf}) for tweet creation times (from test data) for 6 cities and plot them in Figure 3. Each Gaussian distribution represents one bin, and its weight is computed as a mean weight over all tweets belonging to the city (line transparency indicates bin weight). Bins that have a mean weight < 0.075 are excluded.

For London (Figure 3c), we see that most tweets are created from 10:00–20:00 local time.¹⁰ For Jakarta (Figure 3e), tweet activity mostly centers around 11:00–23:00 local time (04:00–16:00 UTC

¹⁰London’s UTC offset is +00 so no adjustment is necessary to convert to local time.

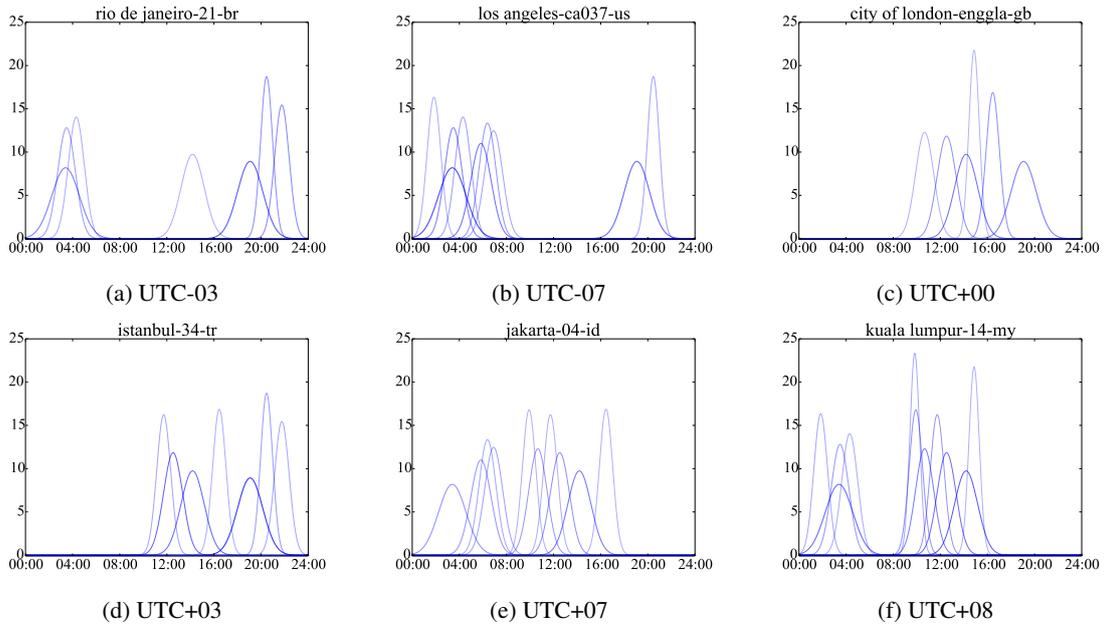

Figure 3: Tweet creation time distribution for 6 cities. Times in all plots are in UTC time. Sub-caption indicates a city’s UTC offset.

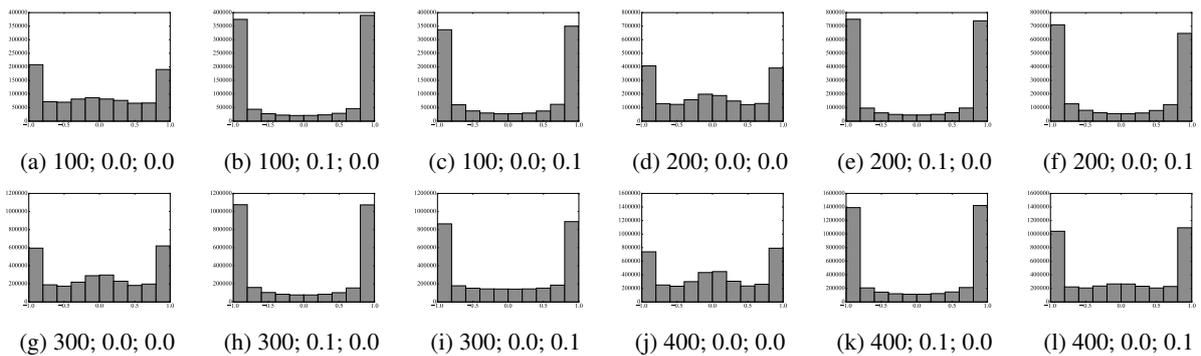

Figure 4: Histogram of r element values. Fields in the subcaptions denote vector dimension (R), corruption level (σ) and l scaling factor (α). Range of y-axis for the same vector dimension is standardised.

time). Most cities share a similar activity period, with the exception of Istanbul (Figure 3d): Turkish people seems to start their day much later, as tweets begin to appear from 15:00–01:00 local time (12:00 to 22:00 UTC time).

Another interesting trend we find is that for two cities (Los Angeles and Kuala Lumpur), there is a brief period of inactivity around noon (12:00) to evening (18:00) in local time. We hypothesise that most people are working during these times, and are thus too busy to use Twitter.

4 Hashing: Generating Binary Code For Tweets

`deepgeo` creates a low-dimensional dense vector representation (\mathbf{r}) for a tweet in the penultimate

layer. This representation captures the message, user timezone and other metadata (including the city label) that are incorporated to the network during training.

Storing the dense vector representation for a large volume of tweets can be costly.¹¹ If we can compress the dense vectors into compact binary codes, it would save storage space, as well as enabling more efficient retrieval of co-located tweets, e.g. using multi-index hash tables for K -nearest neighbour search (Norouzi et al., 2012, 2014).

Inspired by denoising autoencoders (Yu et al., 2016; Vincent et al., 2010), we *binarise* the dense

¹¹If a tweet is represented by a vector of 400 32-bit floating point numbers, 1B tweets would take 1.6TiB of space.

200	0.428	0.417	0.414
300	0.420	0.416	0.422
400	0.428	0.419	0.418

Table 7: Classification performance for deepgeo with the addition of noise and loss term l .

vector generated by deepgeo by adding Gaussian noise. The intuition is that the addition of noise sharpens the activation values in order to counteract the random noise.

Equation (1) is thus modified to: $\hat{\mathbf{f}} = (\mathbf{f}_1 \oplus \mathbf{f}_2 \dots \oplus \mathbf{f}_N) + \mathcal{N}(0, \sigma^2)$, where $\mathcal{N}(0, \sigma^2)$ is a zero-mean Gaussian noise with standard deviation (or corruption level) σ .¹²

In the addition to the Gaussian noise, we also experiment with an additional loss term l to penalise elements that are not in the extrema: $l = \alpha \times \frac{1}{R} \sum_{i=0}^{R-1} |(\mathbf{r}_i - 1)(\mathbf{r}_i + 1)|$, where \mathbf{r}_i is the i -th element in \mathbf{r} and α is a scaling factor. We set $\sigma = \alpha = 0.1$, as both values were found to provide good performance.

To better understand the effectiveness of the noise and loss term l in binarising the vector values, we present a histogram plot of \mathbf{r} element values from test data in Figure 4, for $R = 100, 200, 300, 400$. We see that the addition of noise and l helps in pushing the elements to the extrema. The noise term appears to work a little better than l , as the frequency for the -1.0 and $+1.0$ bins is higher. We also observe that there is a small increase in middle/zero values as R increases from 100 to 400, suggesting that there are more unused hidden units when number of parameters increases. We present classification accuracy performance when we add noise (deepgeo+noise) and l (deepgeo+loss) in Table 7. The performance drops a little, but generally stays within a gap of 1%. This suggests that both noise and l

¹²Dropout is applied to $\hat{\mathbf{f}}$, i.e. after the addition of noise.

works well in binarising \mathbf{r} without trading off classification accuracy significantly.

Next we evaluate the retrieval performance using the binary codes. We binarise \mathbf{r} for development and test tweets using the sign function. Given a test tweet, we retrieve the nearest development tweets based on hamming distance, and calculate average precision.¹³ We aggregate the retrieval performance for all test tweets by computing mean average precision (MAP).

For comparison, we experiment with two hashing techniques: lsh (Indyk and Motwani, 1998) and fasthash (Lin et al., 2014) (see Section 2 for system descriptions). The input required for both lsh and fasthash is a vector. We test 2 types of input for these methods: (1) a word2vec baseline, where we concatenate mean word vectors of the tweet message, user account’s time-zone and location, resulting in a 900-dimension vector;¹⁴ and (2) deepgeo representation \mathbf{r} . The rationale for using deepgeo as input is to test whether its representation can be further compressed with these hashing techniques.¹⁵

We present MAP performance for all systems in Table 6. Looking at deepgeo systems (column 2–4), we see that adding noise and l helps, although the impact is greater when the bit size is large (300/400 bits). For lsh, which uses no label information, word2vec input produces poor binary code for retrieval. Changing the input to deepgeo improves retrieval considerably, implying that the representation produced by deepgeo captures geolocation information.

fasthash with word2vec input vector performs competitively. For smaller bit sizes (100 or 200), however, the gap in performance is substan-

¹³We remove 1328 test tweets that do not share city labels with any development tweets.

¹⁴300-dimension word2vec (skip-gram) vectors are trained on English Wikipedia.

¹⁵lsh and fasthash are trained using 400K tweets due to large memory requirement. We also tested these models using only 150K tweets, and found marginal performance improvement from 150K to 400K, suggesting that they are unlikely to improve even if it is trained with the full data.

tial. Pairing fasthash with deepgeo produces the best retrieval performance: for 200/300/400 bits it outperforms deepgeo+noise by 2–4%. Interestingly for 100 bits fasthash is unable to compress deepgeo’s representation any further, highlighting the compactness of deepgeo representation for smaller bit sizes.

5 Conclusion

We propose an end-to-end method for tweet-level geolocation prediction. We found strong performance, outperforming comparable systems by 2–6% depending on the feature setting. Our model is generic and has minimal feature engineering, and as such is highly portable to problems in other domains/languages (e.g. Weibo, a Chinese social platform, is one we intend to explore). We propose simple extensions to the model to compress the representation learnt by the network into binary codes. Experiments demonstrate its compression power compared to state-of-the-art hashing techniques.

Abstract

When reporting the news, journalists rely on the statements of stakeholders, experts, and officials. The attribution of such a statement is *verifiable* if its fidelity to the source can be confirmed or denied. In this paper, we develop a new NLP task: determining the verifiability of an attribution based on linguistic cues. We operationalize the notion of verifiability as a score between 0 and 1 using human judgments in a comparison-based approach. Using crowdsourcing, we create a dataset of verifiability-scored attributions, and demonstrate a model that achieves an RMSE¹ of 0.057 and Spearman’s rank correlation of 0.95 to human-generated scores. We discuss the application of this technique to the analysis of mass media.

1 Introduction

An attribution occurs when an author or speaker represents the discourse, attitude, or inner state of an external source (Piazza, 2009). Attributions are found in virtually every genre of discourse (Fairclough, 1995), but are fundamental to news reporting, where attribution to credible sources is a basic feature of objective, unbiased “hard news” (Esser and Umbricht, 2014). Recently news media have come under increasing scrutiny for spreading biased and even fabricated information². This trend suggests the need for scalable, computational approaches to understanding attribution.

From a natural language processing perspective, attribution is a fundamental phenomenon that

touches a broad set of applications, including summarization, question answering, information extraction, and discourse analysis. Once content is scoped under attribution, its contribution to the discourse can change substantially depending on the source of the attribution and their relationship to the statement. For instance, in 2001 U.S. President George W. Bush famously warned that in fighting terrorists, nations were either “with us or against us”³. This statement was threatening not only because it was made by the president, or because it was blunt, but because such blunt statements are not normally made by national leaders. If they are to reach human-level performance, systems for automated text understanding must not only accurately segment attribution in the flow of text, but also represent the many ways that attributions can differ rhetorically.

One important way in which attributions can differ, particularly with respect to news reporting, is in their *verifiability*, the ease with which an attribution’s fidelity to the source can be checked. Consider the following hypothetical attributions:

Lindsay Walls, CEO of Inovatron, said in a press release yesterday *that the “allegations of intentionally selling sub-par product are completely unfounded.”*

A **source** close to the issue hinted *that quality control standards had been on the decline.*

The former attribution is more verifiable insofar as it attributes a specific statement to a specific person who, in theory, could be asked to corroborate it. The latter is harder to verify. The source is not named, and even if it were known, it is not clear how it could be confirmed that such “hints”

were given. Note that verifiability does not depend on the truth of a statement, nor its fidelity to the source, but rather on the *ability to confirm or deny* its fidelity.

The ability to confirm or deny an attribution’s fidelity is not binary, but rather occupies a continuum of difficulty, which can depend on whether the source was precisely identified, and how definite the reported statement or content was. Therefore, we operationalize verifiability as a continuous variable between 0 and 1. Attributions are scored by having humans compare attributions and judge which are more verifiable.

We build a dataset⁴ of verifiability-scored attributions on top of the Penn Attribution Relations Corpus, version 3 (PARC3) (Pareti, 2012, 2015). PARC3, derived from the Penn Discourse Tree-Bank, consists of Wall Street Journal news articles in which attributions have been manually annotated.

Prior work investigating sourcing typically relies on a binary concept of named versus anonymous sources (Wulfemeyer and McFadden, 1986). It is also common to distinguish between verbatim quotes, mixed quotes, and paraphrases (also known as reported speech) (Sundar, 1998). Therefore, we create a baseline model of verifiability based on these features. In reality, the sources of attributions span the range from completely obscured to named with credentials and affiliations, along with intermediate examples such as “Whitehouse official” or “company spokesperson”. We compare the baseline model to a more sophisticated model that considers a large number of syntactic and semantic cues based on the source and other parts of the attribution⁵. Using ablation testing, we assess the contribution that these various features make to the regression of verifiability.

Before concluding the paper, we discuss the applications of automated verifiability scoring to the study of attribution in mass media. We explore the feasibility of an end-to-end system that extracts attributions from raw text and then scores the attribution’s verifiability, by implementing an existing attribution extraction pipeline from prior work (Pareti et al., 2013). We analyze how errors cascade through the coupled extraction-regression pipeline, which illuminates the challenges to the

end-to-end version of the task for future work.

2 Related work

2.1 Computational approaches to attribution

The extraction of attributions from text requires (1) the detection of attributed content (e.g. a quotation), and (2) linking of that content to a source entity. Although detection of enquoted text is trivial, a great deal of attributed content is not found within quotes.

The earliest systems attempt to attribute quotations in children’s stories to the correct speaker (Zhang et al., 2003; Mamede and Chaleira, 2004). These systems used rule-based approaches, and although they achieved high accuracy on extracting quotations, their accuracy in attributing them to the correct speaker was quite low. The performance of these systems was also highly dependant on the genre of material.

In news text, a substantial fraction of attributions are much harder to extract, being signaled by the discursive structure of the text instead of by explicit quotation marks (O’Keefe et al., 2012). Early systems for extracting and linking attributions in this domain assumed low recall to achieve higher precision (Pouliquen et al., 2007; de Moraes et al., 2009). To perform well in such domains, a machine learning approach was needed. Elson and McKeown provided the first contribution in this direction (2010). However, their approach relied on gold-standard labels for attributions occurring earlier in the text as features to extract later attributions. In 2012, the first practical machine learning-based approach capable of extracting attributions from non-annotated news text was developed using a sequence labelling approach (O’Keefe et al., 2012).

Further efforts were spurred by the development of corpora with annotated attributions, including PARC3 (Pareti, 2012, 2015). In PARC3 an attribution consists of: (1) a source to whom content is being attributed, (2) the content being attributed, and (3) the cue phrase referring to the act of attribution (e.g. “said”, “according to”). PARC3 enabled the development of an attribution extraction system that we replicate to investigate end-to-end attribution extraction and verifiability regression (Pareti et al., 2013). This multi-step extraction pipeline first identifies candidate reporting words (e.g. *said*, *lamented*), and uses these as features to extract the attribution content. Using the ex-

⁴cs.mcgill.ca/~enewel3/publications/verifiability-IJCNLP-2017-09

⁵github.com/networkdynamics/Verifiability-IJCNLP-2017

tracted content, candidate source entities are identified and correct links are found using a classifier. The source entity and cue word are then expanded deterministically into a source *span* and cue *span*, which collects informative modifiers such as the source's affiliation.

2.2 Attribution and verifiability in news

Attribution plays a fundamental yet complex role in news reporting. It is the “bread and butter” of hard news journalism (Sundar, 1998). However, attribution affords the author the opportunity to frame or interpret information by proxy. Attributions tend to have evaluative content, suggesting that “external voices are allowed to speak their minds much more loudly than journalists” (Jullian, 2011), yet the rhetorical use of attributions is often subtle (Fairclough, 1995).

The credibility of attributions is fundamental to trust in the media. As Burriss (1988) states, “one of the basic tenets of journalism is that news reports are supposed to deal with verifiable facts... Unfortunately the public who receive the news generally has no way to independently verify the accuracy of a news story and must thus depend upon (1) the reputation of the news organization, (2) the reputation of the reporter, or (3) information within the story itself, in order to determine the accuracy of a news report.” Journalists do not always provide the information necessary to verify an attribution (Adams, 1962; Wulfemeyer, 1985; Wulfemeyer and McFadden, 1986). Anonymous sourcing has recently been criticized for distorting coverage of the 2016 presidential campaign (Silver, 2017), but the practice has been recognized and cautiously accepted by media researchers and practitioners for decades (Wulfemeyer, 1985; Boeyink, 1990; Duffy and Freeman, 2011). Anonymizing sources does tend to undermine the credibility of a story (Sternadori and Thorson, 2009; Pjesivac and Rui, 2014; Mackay and Bailey, 2012), though not in all cases (Sundar, 1998), and there is variation in the kinds of unnamed sources who are found credible (Adams, 1962; Riffe, 1980). A typical set of “code-words” are often applied to veil source identity (e.g. “official” or “spokesman”) (Burriss, 1988), with the choice of terms having significant impact on the credibility of the report (Adams, 1962). Direct quotes also appear to enhance credibility compared with paraphrases (Sundar, 1998). Thus, re-

searchers have recently tracked the use of anonymous sources over time and across cultures (Esser and Umbricht, 2014; Lee and Wang, 2016).

2.3 Conceptualizing verifiability

Source anonymity is just one aspect of the problem of how attributions might be used to influence reader interpretations. Popper 2003 argued that any knowledge claim possesses a *degree of verifiability*⁶: the extent to which it is possible to test for evidence that could corroborate or contradict it. Claims with higher verifiability are more credible even prior to testing because authors have less incentive to be accurate when making unverifiable claims (Margolin and Monge, 2013). For example, since no one can know whether an anonymous source really made the statement attributed to them in a news article, the reporter could distort or even fabricate the attributed statement.

Source identification aside, we note that Popper emphasized the form of the proposition, for example, claims made with qualifiers or weak quantifiers. Additionally, physical and technical barriers also apply (Deutsch, 1997). Sources who are difficult to access or that lack a platform from which to correct mis-attribution are less verifiable. The language of attributed content may also matter: verbal categories can be vague or sharp (Hampton, 2007), modifying the extent to which claims made with them are verifiable.

3 Operationalizing verifiability

3.1 Task definition

As mentioned, the ability to confirm or deny the fidelity of an attribution occupies a sliding scale of difficulty, so we operationalize verifiability as a quantity between 0 and 1. Similar to credibility or relevancy, verifiability fundamentally reflects the perceptions on the part of readers. Although it is possible, at least in principle, to directly test the difficulty of verifying a given attribution, the psycholinguistic notion of verifiability is more relevant to characterizing mass media production and consumption.

To approximate the perceptions of the general public, we use crowdsourced human judgments in creating the ground truth verifiability-scored dataset. Crowdworkers were shown pairs of attributions, and asked to decide which is more ver-

⁶Popper technically refers to “falsifiability” which is the inverse of verifiability.

ifiable (we describe the details of the annotation setup below). Various methods exist to convert pairwise comparisons into a set of scores (e.g. (Kiritchenko and Mohammad, 2016)). We use the Bradley Terry model (Hunter, 2004) to assign verifiability scores, and then shift and scale the scores to fall into the $[0, 1]$ interval.

As discussed above, methods for extracting attributions from raw text have been developed in prior work. Therefore, this task focuses on the regression of perceived verifiability from text that has already been annotated with attributions in PARC3 annotation style.

3.2 Dataset annotation

Annotation was carried out using the CrowdFlower platform⁷. Crowdworkers were shown pairs of attributions, and asked to consider the effort required to confirm or deny the fidelity of each. They were asked to select the attribution that was easiest to verify from each pair.

In judging verifiability, it is reasonable to expect that the precision with which a source is identified would be the major determinant in most cases. This creates a risk that crowdworkers will begin to rely only on source definiteness, rather than judging attribution verifiability holistically. Thus, we took steps to ensure that crowdworkers were vigilant to verifiability cues of various kinds. As part of general quality control, crowdworkers had to complete 7 out of 10 training / test examples correctly to ensure they understood the task, and then maintain this proportion of correct responses on test examples randomly dispersed throughout the annotation tasks. To address the specific concern that crowdworkers may become overly reliant on source definiteness, we selected training / test examples to which the correct answers depended on a variety of cues. Test examples were collected by performing a pilot round of annotation with 8 expert annotators, and selecting from the high-agreement examples.

Attributions were presented within the full sentence(s) that contained them. Limiting the context to the containing sentence(s) did not appear to interfere with annotation during the pilot round. Nevertheless, we took steps to mitigate effects from the loss of context. In the majority of cases where the definiteness of the source plays an important role in determining verifiability, the most

useful context is likely to be how the source was first introduced in the article, e.g. whether the source's name and affiliation were given. To bring that context into the attribution, we used the CoreNLP coreference resolution software (Manning et al., 2014) to augment the source. Whenever a source was mentioned using a personal pronoun, we interpolated the pronoun using the representative coreferent mention, except where that mention already occurred in the sentence. Thus, for example,

“I don't know,” she said,
might become

“I don't know,” Lindsay Walls, CEO of
Inovatron said.

Spot checks of 100 pronoun-containing attributions in PARC3 showed that this produced reliable, grammatical interpolations. However, similarly interpolating non-personal pronouns and references such as “the company” was not reliable. We instructed workers to consider, when faced with such references, whether it appeared that the reference was to a specific named individual / entity. Thus, the worker should treat “a company” differently from “the company”. We included many test examples in which workers had to act on that instruction to get the correct answer.

Attributions were presented with the source, cue, and content highlighted, to ensure that workers knew what specific attribution they they were annotating.

We solicited comparisons involving 2100 attributions, presented as 39930 unique pairs, with each pairing annotated by at least 3 workers (increased to 5 when the first judgments were non-unanimous), resulting in 140277 total pairwise comparisons. The data comprise annotations from 337 workers. These figures exclude the discarded data from 70 crowdworkers that had poor performance on training / test examples. Every attribution in the dataset was compared to at least 20 other attributions. After 20 pairings, we found that the verifiability scores and the model regression error (to be discussed below), had become relatively stable, as can be seen in **Fig. 1**.

Annotation proceeded in two phases (not including the pilot round). In the first phase, we randomly sampled 100 attributions from PARC3 and solicited an exhaustive set of annotations on all 4950 pairs. This gave highly accurate scores for a small subset of annotations. In the second

⁷crowdflower.com

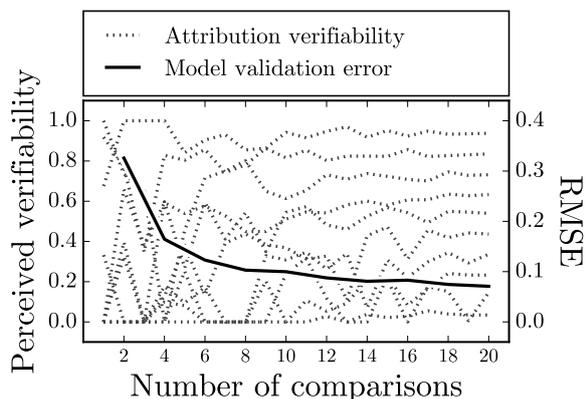

Figure 1: Estimated verifiability scores converged as a function of the number of comparisons per attribution increased, reducing error in the model.

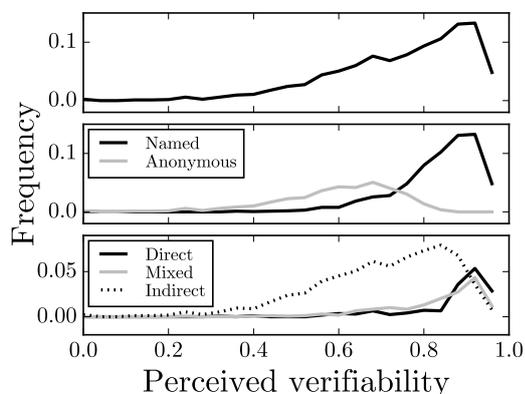

Figure 2: Distribution of crowdsourced verifiability scores for 2100 attributions (top), conditioned on the presence of ORG and PERS named entities (middle) and attribution directness (bottom).

phase, 2000 randomly sampled attributions were systematically compared to the attributions scored in phase 1. Each phase-2 attribution was paired with two phase-1 attributions randomly drawn from each decile of verifiability, giving twenty pairings each.

After the pairwise comparison data were collected we estimated the maximum-likelihood latent verifiability scores in a Bradley-Terry model using a majorization-minimization algorithm (Hunter, 2004), then linearly transformed the verifiability scores to fall in the range $[0, 1]$.

3.3 Annotation results

The resulting scores for the 2100 attributions produced a smooth unimodal distribution across a range of perceived verifiability (Fig. 2). In a plot of the latent scores inferred for a Bradley-Terry model, the distance between two scores is a direct

representation of the probability that the higher-scoring item would “win” in a comparison with the other⁸. The distribution has most of its mass near verifiability score 0.9, showing that most attributions adhere to a high standard of verifiability. In addition, we see heavy tail of low perceived verifiability. This distribution is, *prima facie*, consistent with the competing journalistic norms of transparent attribution and source protection.

It would be reasonable to have expected the distribution to be somewhat more clustered, with peaks in the data corresponding to discrete features such as named vs. anonymous sources (Wulfemeyer and McFadden, 1986) or direct vs. indirect quotes (Sundar, 1998). These features would have clear bearing on efforts to verify an attribution and should be fairly universally recognizable. The distribution instead suggests there is a diversity of factors that contribute to perceived verifiability and that focusing solely on one or two discrete, a priori obvious indicators to analyze attribution behavior conceals a great deal of variation. As shown in Fig. 2 source anonymity and quote directness do have explanatory power, however they appear unable to explain the continuum of perceived verifiabilities.

3.4 Inter-annotator agreement

Inter-annotator agreement serves as a standard check to ensure that workers understood and reliably performed the task. In this case some care is needed in interpreting the inter-annotator agreement, however: we expect a certain amount of in-built disagreement due to comparisons made between attributions having very close verifiability scores. In fact, the Bradley-Terry model (and other methods for deriving scores from pairwise comparisons) is predicated on the notion that two items have similar latent score precisely when workers are unable to reliably decide which is to be preferred (i.e. which has higher verifiability).

For this reason, the agreement level for attributions having sufficiently similar scores will necessarily be low. To properly assess reliability for this kind of annotation, it is necessary to disaggregate the comparisons based on how far apart the compared attributions are in verifiability score.

To ensure that disaggregated agreement scores

⁸The probability of a worker judging a_1 to be more verifiable than a_2 , given they have verifiability scores v_1 and v_2 , is modeled as $\Pr(a_1 \succ a_2) = (1 + e^{\beta(v_2 - v_1)})^{-1}$, where β is the scale parameter used to transform scores to $[0, 1]$.

Separation	0	1	2	3	4
Agreement	.174	.363	.651	.825	.904

Table 1: Krippendorff’s α for comparisons between attributions from quintiles of given separation. A separation of 0 means comparisons between attributions in the same quintile.

are unbiased, we use half of the pairings in the dataset to assign scores, and then assess agreement on the other half. Using the scores derived from half the data, we divide the attributions into quintiles. We then assess agreement on comparisons that are made between attributions from quintiles having a given separation.

For example, all comparisons made between attributions from the same quintile have separation 0, while comparisons made between attributions from adjacent quintiles have separation 1. The agreements associated to each level of separation are shown in **Table 1**. As the separation between attributions is increased, the level of agreement monotonically increases, becoming very high (Krippendorff’s α 0.904) for comparisons between attributions from the highest and lowest quintiles. This indicates that once we factor out disagreement due to perceived similarity of attributions, workers were able to understand and perform the task with high reliability.

4 Modeling verifiability

In the PARC3 annotation style, an attribution consists of a *source*, the attributed *content*, and a *cue*, such as “said” or “according to”, signalling the existence of an attribution. A priori, any of the three parts of an attribution (source, cue, content) could contribute to the perceived verifiability of an attribution. In addition to the baseline model based on source anonymity and whether the attribution is a direct, indirect, or mixed quote, we also test a “feature-rich” model based on a large number of features extracted from attributions’ source, cue, and content, listed in **Table 2** (the baseline model is based on features S2 and C4). We test multiple regression algorithms for both the baseline and rich feature set, and we do feature ablation to optimize the feature-rich model. In the next subsection, we discuss the selection of features and ablation results, then in the following section, we describe the learning algorithms and the best results achieved for the baseline and feature-rich models.

	Feature set	RMSE _{<i>i</i>}	Δ_{-i} RMSE $\times 10^3$
source	S All source features	.093	14.09
	S1 Length	.124	1.70
	S2 Anonymity	.110	1.34
	S3 Each of 7 NE types	.102	.79
	S4 Head’s determiner	.164	.52
	S5 Head lemma	.115	.46
	S6 Head plural	.152	.15
	S7 Fuzzy quantifiers	.159	.04
	S8 Pronoun ⁹	.163	.03
	S9 Date or numeric NEs	.164	-.04
S10 Head’s amod	.164	-.09	
cue	Q All cue features	.134	8.11
	Q1 LIWC dictionary counts	.137	.88
	Q2 Lemmatized BOW	.136	.39
	Q3 Length	.161	-.02
Q4 Cue class	.142	-.33	
content	C All content features	.139	1.90
	C1 Date or numeric NEs	.163	.13
	C2 Fract. enquoted tokens	.149	.01
	C3 PERS or ORG NEs	.164	-.05
	C4 Direct, indirect, mixed	.149	-.11
	C5 Each of 7 NE types	.161	-.22
C6 Length	.153	-.59	

Table 2: Features for verifiability regression. RSME when using the feature on its own (RMSE_{*i*}), and drop in RMSE occurring when the feature is removed from a model built from all features (Δ_{-i} RMSE). Entries sorted in descending order of Δ_{-i} RMSE.

4.1 Feature design and selection

For the sake of continuity, as we describe features, we will also discuss the results of ablating them. Ablation results are based on the training-set performance of a Support Vector Regressor (SVR), optimizing for minimum root mean squared error (RMSE) between predicted verifiability scores and those derived from human annotations. The full set of features is listed in **Table 2**. For ablation testing, we assessed each feature in two contexts: (1) as the only feature used, and (2) as the only feature left out. While the first measures the straightforward predictiveness of the feature, the second measures the marginal improvement in the context of other features and is used for final feature selection in the feature-rich model.

Source features. Based on the CoreNLP named entity recognition (NER) software (Manning et al., 2014), we created features indicating whether any of the 7 types¹⁰ of named entities (NEs) were present in the source (feature S3, **Ta-**

⁹Aside from “he”, “she”, and “they”, which are interpolated.

¹⁰CoreNLP recognizes seven types of named entities: PERS, ORG, DATE, MONEY, DURATION, PERCENT, NUMBER.

ble 2). This feature was beneficial both alone and in the context of other features. We also included a feature encoding the anonymity of the source, based on whether either a PERS or ORG NE was present (this was one of the baseline features, S2). Although this may seem redundant with S3, encoding the source anonymity in this way boosted performance even in the context of S3. Several of the other NEs are number-like: we also created a feature indicating whether any number-like NE was present (S9), but it hindered performance in the context of other features.

When not a NE, the head of the source span is often a title (“director”), occupation (“lawyer”), or collective designation (“homeowners”). Intuitively, pluralized designations seem more nebulous, so we introduced a feature indicating whether the head of the source span is pluralized (S6). Although less predictive on its own, this feature did provide a benefit to the model in the context of other features.

Similarly, the determiner of the head of the source can influence definiteness: consider “a lawyer” versus “the lawyer”. We added feature S4 indicating the kind of determiner used, if any, which also made an important contribution to the overall model.

Quantifiers such as “most”, “some”, “many”, and “several”, can also render a source imprecise, so we included a feature indicating the presence of such quantifiers or the word “source(s)” (S7). In ablation testing this feature marginally improved the model’s accuracy in the context of other features.

We included the lemma of the head (S5), which made a notable contribution. This feature subset likely suffered from sparsity, so its contribution might be more important given a larger training set.

Modifiers to the source could also influence verifiability, so we included features for the lemma of tokens under the `amod` dependency tree relation to the head (S10)¹¹. This feature did not benefit the model, but again may perform better in larger datasets.

The source feature providing the greatest contribution in the context of other features was the length of the source (S1) (although on its own it is less predictive than source anonymity, S2). In-

tuitively, the longer the specification of the source, the more definite it is, and the more verifiable. The strong performance of this feature suggests additional features might account more specifically for language not accounted for by other features which contribute to verifiability.

Cue features. We derived four features from the cue, which were lemmatized bag-of-words (Q2), length (Q3), counts of words belonging to each of the LIWC dictionaries (Q1) (Tausczik and Pennebaker, 2010), and the presence of specific sets of reporting verbs (Q4). This last (Q4) was based on our observation that reporting verbs either indicate the statement neutrally (‘said’, ‘reported’), qualify the statement as true (‘confirmed’, ‘showed’), indicate an intention (‘will’, ‘plans’), or call to question whether the statement is true (‘believes’, ‘claimed’). The liwc dictionary counts (Q1) and lemmatized bag-of-words (Q2) both made substantial contributions to model accuracy.

Content features. A verbatim attribution seems inherently easier to verify than a paraphrase, so attribution directness was included (C4). Ablation testing showed that attribution directness was actually detrimental to the regression overall and was a poor predictor alone. However, we created a more nuanced representation of quote directness based on the fraction of enquoted words (C2), which was marginally beneficial.

Given that verifiability depends not on the truth of a statement, but on the ability to check the fidelity of the attribution to the source, one might expect that (aside from attribution directness) the content would have little effect on verifiability. However, it is inherently harder to verify the attribution of a vague paraphrase, which could be consistent with a wider range of original statements. Conversely, numerical quantities and the naming of people and organizations should increase the verifiability. As we did for the source, we included features representing the 7 types of named entities (C5), a feature indicating either PERS or ORG (C3), and a feature indicating numerical entities (C1). The numeric entities feature did indeed improve model accuracy although the other features derived from NEs in the content did not.

Finally, we included the length of the content (C6), but this feature was detrimental to the model.

Ablating feature blocks. Considering the role that they play in attribution, one would expect

¹¹Based on the CoreNLP dependency parse (Manning et al., 2014)

Model	RMSE	ρ
baseline	0.102	0.833
feature-rich	0.057	0.951

Table 3: Test-set RMSE and Spearman’s rank correlation (ρ) for each model.

that, overall, the source would be most informative due to its importance in being able to trace the attribution to a specific person, group, or artifact, followed by the cue, due to the fact that the cue describes the act of attribution and can indicate the certainty or degree of interpretive licence exercised by the author (e.g. if the cue is “hinted”).

To test the importance of the source, cue, and content, we ablate each set of features as a whole, the results of which are indicated in **Table 2** by the rows that have feature symbols containing only an ‘S’, a ‘Q’, or a ‘C’ (with no number). These results confirm that the source is most informative, followed by the cue.

4.2 Models training and testing

We randomly separated the dataset of 2100 quotes into a testing and training set of 420 and 1680 attributions each. Using the training set, we used three learners to optimize the performance on models using the baseline set of features, and a rich set of features (those contributing positively to model accuracy in the context of other features, see third column of **Table 2**). The learners included linear regression with lasso regularization, a support vector classifier (SVC) that predicts the quintile from which an attribution was drawn (and returns the median score), and a support vector regressor (SVR). The support-vector-based models used linear, quadratic, and radial basis function as kernels. Using cross-validation on the training set, we optimized the learner selection, kernel selection, and learner hyperparameters, and performed ablation testing for the feature-rich model. Optimization was based on minimizing the RMSE. SVR performed best for both the baseline and ablation-optimized feature sets.

The optimized baseline and feature-rich model were then each run once on the test set, with the results summarized in **Table 3**.

RMSE gives a measure of error between the model’s predicted scores, and the true verifiability scores. It’s dimensionality and scale are equivalent to those of the variable predicted, so it can be

Verif.: quintile actual predicted	Attribution
1 0.316 0.482	<i>It is rumored to be bound for a new model in the luxury Acura line in the U.S.</i>
2 0.698 0.676	Earlier U.S. trade reports have complained of videocassette piracy in Malaysia and disregard for U.S. pharmaceutical patents in Turkey
3 0.802 0.766	South Korea announced \$450 million in loans to the financially strapped Warsaw government.
4 0.884 0.887	Mr. Paul has been characterised as “the Great Gatsby or something,” complains Karen E. Brinkman, an executive vice president of CenTrust
5 0.960 0.959	“It has an archival, almost nostalgic quality to it,” says Owen B. Butler, the chairman of the applied photography department at Rochester Institute of Technology.

Table 4: Selected attributions from each quintile of the verifiability-scored subset of PARC3 along with model predictions.

compared to the range of values across which verifiability varies; the feature-rich RMSE was 5.7% of the prediction range. In many applications, the absolute verifiability may be less important than the relative verifiability. Both the baseline and the feature-rich model achieve relatively high Spearman’s rank correlations ($p \ll 0.001$). The feature-rich model provides a substantial improvement in performance over the baseline, both in RMSE and rank correlation. This shows that a richer set of features, beyond source anonymity and quote directness, is needed to explain the perception of attribution verifiability.

A selection of attributions from each quintile, along with their human-judged and model-predicted verifiability scores are shown in **Table 4**. These examples demonstrate how the model has learned to consider various features in regressing verifiability. Aside from the first, each of the examples in **Table 4** contains a named entity, however, it would appear that the model has learned to attribute less verifiability to location names than names of individuals. Additionally, in the example from quintile 2, we can see that the head of the source is the word “reports”, which is likely what has led to its appropriately lower predicted score: it would be quite difficult, though possible, to comb through a sufficient number of U.S. trade

reports to reach a verdict about the fidelity of this attribution.

5 Application to the analysis of mass media

Journalists are frequently forced to decide whether given sources are sufficiently credible and relevant to cite, while balancing transparent attribution against the source's potential interest in remaining anonymous. It is reasonable to wonder what influences and biases exert themselves on such decisions.

If there are systematic influences at play, it should be possible to find evidence in the distribution of verifiability, and its correlation with publishers, topics, positions on given issues, and political alignments. To look for such patterns at scale, it will be necessary to create an end-to-end system for attribution extraction and verifiability regression.

Although prior work demonstrates good performance on attribution extraction, and we demonstrate accurate verifiability regression here, our initial investigations of an end-to-end extraction and regression system show that errors during extraction lead to large negative errors in verifiability (i.e. underestimates) during regression. This is especially true when there are errors in extracting the source span. Investigating verifiability at scale will require some combination of: (a) further improvements to extraction accuracy, (b) discarding poorly extracted attributions (with loss of recall), and (c) adjustment of the extraction / regression models to reduce error cascading, which we hope to investigate in future work.

6 Conclusion

Attribution is a critical feature of journalism, and a fundamental, challenging natural language phenomenon. We have introduced a new NLP task consisting of the prediction of attributions' perceived verifiability according to human judgments. We provide a dataset of verifiability-scored attributions based on a subset of PARC3.

Our models show that source anonymity and quote directness alone are insufficient to explain the continuum of perceived verifiability, but a richer set of linguistic features enables accurate verifiability regression. The source appears to be the dominant factor determining an attribution's verifiability, with an important contribution also

coming from the cue, and a slight contribution from the content.

This new task, along with existing work in attribution extraction, creates a new opportunity to study attribution practices in mass media, at scale, and shed light on the shifting landscape of journalistic norms.

Acknowledgments

We thank Silvia Pareti for helpful discussions about PARC3 and attribution extraction.

Abstract

Several studies have demonstrated how language models of user attributes, such as personality, can be built by using the Facebook language of social media users in conjunction with their responses to psychology questionnaires. It is challenging to apply these models to make general predictions about attributes of communities, such as personality distributions across US counties, because it requires 1. the potentially inavailability of the original training data because of privacy and ethical regulations, 2. adapting Facebook language models to Twitter language without retraining the model, and 3. adapting from users to county-level collections of tweets. We propose a two-step algorithm, *Target Side Domain Adaptation* (TSDA) for such domain adaptation when no labeled Twitter/county data is available. TSDA corrects for the different word distributions between Facebook and Twitter and for the varying word distributions across counties by adjusting *target side* word frequencies; no changes to the trained model are made. In the case of predicting the Big Five county-level personality traits, TSDA outperforms a state-of-the-art domain adaptation method, gives county-level predictions that have fewer extreme outliers, higher year-to-year stability, and higher correlation with county-level outcomes.

1 Introduction

Social media platforms offer an effective— and widely used— platform for administering surveys to individuals to measure their personality, socioeconomic status, mental and physical well-being, and political orientation, which can then be combined with user posts to build language-based predictive models of user attributes, traits and behaviors. As compared to surveys, language models can be used to assess personality and well-being across communities of the U.S, at a scale not easily achieved by surveys (Eichstaedt et al., 2015). In comparison, Twitter is a more effective tool to mine geographic trends from language, since tweets are publicly accessible, and one in five

tweets can be mapped to the county from which they were sent (Schwartz et al., 2013b). However, to our knowledge, there are no tweet-based models of personality which are comparable in accuracy to the Facebook language models of personality.

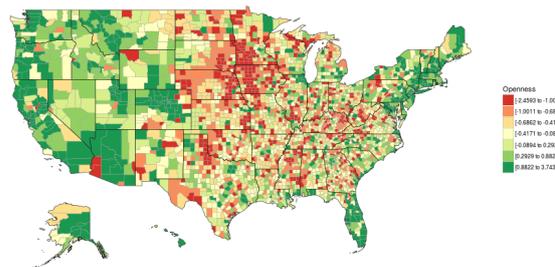

Figure 1: Predictions for county-level openness to experience created by applying a user-level Facebook model for openness on TSDA adjusted Twitter county data

Personality, as measured by the “Big Five” of *openness*, *conscientiousness*, *extraversion*, *agreeableness* and *neuroticism* is known to vary regionally worldwide (Rentfrow et al., 2013) and to cluster geographically in the United States (Rentfrow et al., 2013; Florida, 2002). In this paper, we wish to infer the regional variations of the Big Five Personality traits across the United States, through five language models trained on Facebook posts. We formulate our problem as one of domain adaptation - adapting Facebook models for Twitter’s vocabulary, and adapting user-level models for county-level predictions. Figure 1 provides the county-level predictions for the psychological trait of *openness* to experience. At the individual level, *openness* has been found to be correlated with a higher education level and better academic performance (Poropat, 2009). At the regional level, we

expect to replicate survey results from Rentfrow et al. (Rentfrow et al., 2013), which have demonstrated that regional variations in personality are stable over time, and correlate with key political, economic, social and health metrics.

We combine two forms of target side adaptation in this paper: first, we adapt from Facebook to Twitter; next, we compensate for the variation introduced by the fact that Tweets within each county have significant correlation, leading to spuriously high frequencies of various words in various counties, significantly reducing the predictive accuracy there of the source models. The remainder of the paper first motivates our domain adaptation problem and provides a background on the specific problem of personality prediction. We then situate our method within the field of domain adaptation. Next, we present the TSDA algorithm which, like other popular domain adaptation algorithms, is frustratingly easy (Daumé III, 2007). Finally, we demonstrate that TSDA improves the quality of county-level predictions by (a) removing extreme predictions, (b) improving year-to-year stability, (c) increasing average magnitude of correlations between predicted county-level personality and measured health and well-being metrics with which the personality constructs are known to correlate, and decreasing correlations where correlations are not expected.

1.1 The Need for Target Side Adaptation

Applying user-level language models learned on Facebook to make county-level predictions on Twitter poses three main challenges. The first challenge, typically addressed by traditional domain adaptation methods, is the difference in vocabulary between Facebook and Twitter, which motivates the need for domain transfer. For instance, “rt” is one of the most frequent Twitter ‘words’, but rare on Facebook. Secondly, although typical domain adaptation methods expect the availability of labeled training data, in this case there are new challenges due to the sensitivity of data. In cases where NLP is used to address social science problems, the training data is often unavailable when it comprises personally identifiable information, or when sharing would violate privacy and ethical regulations. Thus, an appropriate unsupervised domain adaptation approach would expect only a trained model – not the original data – to be available for predicting outcomes.

A third challenge is that there is a need to disambiguate words which have vastly different frequencies and often entirely different meanings in different counties. The implications of this artifact of the data are obvious when, on reviewing the relative ranking of counties by personality traits, it is observed that the most predictive features for the most- or least-scoring counties, often comprise words which are being used in a different local context (see Table 2). An appropriate domain adaptation approach should account for these local differences, and still generate a generic set of domain adapted features for all counties, rather than 3142 feature sets adapted to each of the counties individually.

We introduce *Target Side Domain Adaptation* (TSDA), an unsupervised method which adapts the target county-level data from Twitter to be more accurately predicted from the source user-level Facebook models *using no labels on the target Tweets or counties and without altering the source-side model*. We call it “Target Side” to emphasize that no retraining of the model is done during the domain adaptation. We assume no labels on the target side, and so only make use of the differences between the source and target distributions of the features. An important assumption in this paper is that differences in the frequencies for the same word among counties, reflects differences in its local meaning. TSDA works particularly well with words, since (a) words vary widely in frequency across domains, and (b) words vary widely in frequency and meaning across domains.

2 Background

2.1 Personality Traits

We take as our core case study extrapolating personality, as measured in individual level questionnaires, to the ‘average’ personality for a county. There is a rising research area of “Geographical Psychology” (Rentfrow and Jokela, 2016), which looks at region variations in different psychological traits such as personality, and their correlation with physical and mental well-being.

As a surrogate for large scale surveying, we propose using peoples’ social media language to estimate their personality. Such language-based models based on Facebook posts have been built using data from roughly 70,000 people who took personality tests and shared their test results and Facebook posts with researchers (Schwartz et al.,

2013a). These models have proven to be as accurate at estimating personality as estimates from people’s friends (Park et al., 2014). However at first blush, such use of Facebook only pushes the problem one level back, as even 70,000 Facebook users give poor coverage of 100 out of over 3,000 US counties. To get good coverage, we shift to a more open social media platform, Twitter.

Twitter is readily available and allows free access to its streaming API. Even though only a few percent of tweets come with latitude and longitude, roughly 20% of the Tweets from the US can still be mapped to their county of origin. Many language-based models of user traits including demographics (Rao et al., 2010; Burger et al., 2011), personality (Schwartz et al., 2013a), socioeconomic status (Preoȃuc-Pietro et al., 2015), popularity (Lampos et al., 2014) and political orientation (Pennacchiotti and Popescu, 2011) have been made from social media language. A number of these models are based on labels of individual tweets (e.g., using Amazon’s Mechanical Turk); collecting questionnaire data and the Tweets from the same user is harder, in part due to restrictions on Amazon’s terms of use for Mechanical Turk. Facebook requires consenting users to share their data, but while obtaining consent, it is easy to ask users questions to assess their personality, or to ask them to share other data such as their electronic medical records (Smith et al., 2017).

Thus, we face the technical question: How can we take a model trained to predict user attributes such as personality from Facebook language at the individual user level and use it to predict average personality from Twitter language at the county level? This requires a double domain adaptation: firstly from Facebook to Twitter, and secondly from users to counties. This domain adaptation is complicated by the fact that we have virtually no county-level personality measures to use to guide the domain adaptation; it must be unsupervised.

2.2 Domain Adaptation Background

Our task can be characterized as domain adaptation, or the closely related transfer learning (Pan and Yang, 2010), where we are adapting from a *source domain*: the words users use on their Facebook posts and associated user labels to a *target domain*: county-level Twitter language, where we want, but do not have, labels on the counties. Most prior work on domain adaptation has focused on

the case where some labels are available on both the source and target domains, and is usually done by combining (often in some weighted fashion) training data sets or, less commonly, trained models from the source and target domains (Daume III and Marcu, 2006). Both of these approaches require at least some labeled target data, which we lack. Thus, methods such as EasyAdapt++ (Daum  III et al., 2010), which encourages source and target models to agree on unlabeled data cannot be used here.

In this paper, we have compared our proposed TSDA framework against the Correlation Alignment (CORAL) approach, an unsupervised approach which aims to minimize domain shift by linearly transforming the covariance matrix of the target distribution to be as similar as possible (under the Frobenius norm) to the source distribution (Sun et al., 2015). It is similar in principle to the study by Daum  and Marcu, which applied Canonical Correlation Analysis (CCA) perform unsupervised machine translation by calculating the cosine similarity of projections in a lower dimensional space (Daum  III and Jagarlamudi, 2011). Transfer Component Analysis (TCA) is a more computationally expensive approach, which exploits the Maximum Mean Discrepancy Embedding (MMDE) metric for comparing the distributions between the source and target domain in the Reproducing Kernel Hilbert Space (RKHS) representation (Pan et al., 2011).

3 Target Side Domain Adaptation

Our Target Side Domain Adaptation (TSDA) is a two step process. The first step attempts to minimize the impact of spatially correlated word tokens in the county-level Twitter data by down-scaling the counts of words that are over-represented in some counties. The second step then removes words that have significantly different frequencies between Facebook and Twitter. Note that TSDA does not use any target-side labels. It is instead predicated on the assumption that any large differences in word frequencies between source and target will interfere with the correct generalization; we do not need to know anything about the model in order to do the domain adaptation, instead we use the observed distributions of words on the target side.

Our domain adaptation is motivated by the observation that word frequencies in counties may

have multiple meanings, and that some counties will tend to use an alternative meaning more than others. More formally, we assume that word counts in each county are a mixture of the “true word frequencies” generated by the latent variable being estimated, such as personality combined with county-specific “noise” driven by different word meanings. For example, counties might use the word “jazz” proportionally to how open to experience they are, but a small number of counties (e.g. Salt Lake City) might also use it to refer to a sports team.

Because most words in most counties are generated based on the latent variables of interest (personality), we can compute the distribution of each word across counties (i.e. the distribution on the target side), identify the outliers (words in counties unlikely to come from the main meaning), and then replace them with an imputed value (e.g. the mean frequency for that word).

3.1 Step 1: Target-Side Adjustment

As the first step, we adjust the Twitter county-level word frequencies to help mitigate the influence of spatial variations and confounds in word use. This is done by identifying outlier feature values for a given county, and replacing them with the mean feature value across all counties. Extreme values can come from several sources. Common instances of such outliers are: (i) a concert or sports game in a small city, which can lead to disproportionately many mentions of e.g., Bieber or Cowboys. (ii) Some communities have unusually high concentrations of different ethnic groups, who may infuse their nominally English language tweets with Tagalog or Indonesian words. These words, present in small numbers on the source language training set, can significantly skew predictions.

We propose an extremely simple, robust method to address this problem: For each word w_j , for the 5% of counties with the largest word frequencies $w_{j,c}$, replace $w_{j,c}$ with the imputed \bar{w}_j and then renormalize each county’s word frequencies such that they sum to one.

We attempted using matrix imputation-based values from Singular Value Decomposition (SVD) as in (Troyanskaya et al., 2001) for imputation, as an alternative to using the mean frequency of words; however, we found that it did not make a significant difference on this data set. Also note

that in each county, different words are replaced with their imputed values. No single adjustment to the source model is possible; each county effectively gets its own model - because, removing the same 5% of features from all counties would leave in too many harmful features, while removing a feature which is an “outlier” in any county from all other counties would remove too many features that are truly predictive, and also harm model accuracy.

3.2 Step 2: Source to Target Adjustment

The second step is to adjust frequencies for words that vary in usage between Facebook and Twitter. As in Step 1, our assumption is that differences in frequency correspond to differences in meaning. Accordingly, for each word in a county, we compute a ratio of its mean frequency for Facebook users, to the mean frequency for Twitter counties. Then, if the ratio for a word lies close to 1.0, word frequencies in the target Twitter counties are replaced with their corresponding means from the source data.

Specifically, we compute

$$\frac{|\bar{w}_j^F - \bar{w}_j^T|}{\bar{w}_j^F + \bar{w}_j^T} > \epsilon$$

Where \bar{w}_j^F is the mean of word frequency j for Facebook users and \bar{w}_j^T is the mean of word j for Twitter counties. In practice we used $\epsilon = 0.8$.

Note that the two domain adaptation steps, although superficially similar, are in fact qualitatively different. In the second step (Facebook to Twitter adaptation) the feature removal is “global”, so one could easily remove the features that vary most between the source and target domains and then retrain the source Facebook model without those features. For the first step (cross-county regularization), no such simple retraining is possible.

4 Data and Model Description

Facebook user-level models were built using data consisting of 65,896 observations of statuses and personality questionnaire answers. Each user posted at least 1,000 words and answered a set of at least 20 questions to derive a score for each of the Big Five personality traits. Statuses for each of the Facebook users were tokenized, unigram word counts extracted, and converted to term frequencies by dividing the resulting word counts for each

user by that user’s total word count. An elastic net regularized linear regression model utilizing a feature selection pipeline described in (Park et al., 2014) was then trained on each of the personality traits.

We used Twitter data comprising the 10% random sample from years 2012-14. We mapped tweets to US counties using the method of Schwartz et al. (2013), which is based on latitude/longitude coordinates, and the self-reported location field when available. Roughly one fifth could be successfully mapped resulting over 150 million geolocated tweets. Only those counties with at least 40,000 words were kept, yielding 2,468 counties for 2012, 2,651 for 2013, and 2,197 for 2014.

5 Evaluation of TSDA for Known Outcomes

We first evaluate our predictions by comparing them to five state-level average personality scores (Rentfrow et al., 2013), where we have enough surveys to get a ‘ground truth’. The results suggest that TSDA works well when the county-level scores are further aggregated to the state level (Rentfrow and Jokela, 2016). Table 1 shows Pearson r between average state personality predictions (population weighted average of the county predictions) and the ‘ground truth’.

The baselines were calculated using predictions with no domain adaptation, with CORAL, and with retrained models on the TCA-transformed features both with and without the feature selection pipeline used in the other models. Recall that CORAL adjusts the source features to the target features using a transformation selected using an L_2 (Frobenius norm) loss; such methods work poorly when a small number of extreme values need to be removed.

Additionally, we used this state-level ground truth to test the sensitivity of our method to variation in the step 1 and step 2 parameters. Results showed a statistically significant increase in correlation using 0.8 over 0.9 in step 2 while the variation in the step 1 parameter is less clear. When step 2 uses 0.8, we see openness, conscientiousness and extraversion correlations strengthening with increasing step 1 parameter, agreeableness decreasing, and neuroticism remaining constant. The average increase in performance of TSDA with the range of parameters tested was also statis-

Baselines	O	C	E	A	N
No domain adaptation	.47	.08	.49	.44	.53
CORAL	.14	.19	.20	-.16	.26
TCA no feature selection	.70	.26	-.06	.64	.47
TCA feature selection	.53	.28	-.16	.63	.48

TSDA		O	C	E	A	N
Step 1	Step 2					
1%	0.8	.61	.09	.50	.49	.57
2%	0.8	.63	.10	.50	.48	.57
5%	0.8	.69	.11	.52	.45	.58
10%	0.8	.71	.13	.52	.45	.57
1%	0.9	.59	.08	.49	.43	.56
2%	0.9	.61	.09	.48	.42	.56
5%	0.9	.69	.10	.49	.41	.57
10%	0.9	.71	.14	.48	.42	.56

Table 1: Pearson r between target side state-level predictions and ‘ground truth’ state personalities (Rentfrow et al., 2013). The first baseline uses the naive predictions, the second uses the CORAL method, and the third and fourth use the TCA method first without and then with the feature selection pipeline used in the other models. TSDA results are shown for a variety of parameters for steps 1 and 2, but in practice we use 5% and 0.8.

tically significant above the no domain adaptation baseline.

6 Unsupervised Validation Method

Validating unsupervised domain adaptation often presents a challenge, when no ground truth is available. We refer to the set of validity criteria developed by social scientists, such as testing *reliability*, the degree to which an assessment tool produces stable and consistent results e.g. over time and *external validity*, the degree to which the results generalize to other settings (ecological validity) and other people (population validity), as well as *predictive validity*, the ability of a stipulated theoretical construct (like Openness to Experience) to predict (correlate with) behavioral or other *criterion*, outcomes that it is theorized to relate to. In this paper, we demonstrate a three-pronged approach to validation, which relies on the fact that the predictions on the many targets (counties) should be (a) normally distributed as they capture natural phenomena, (b) consistent from year to year, (c) correlated with other state- and county-level outcomes such as education, income, health, and happiness which have been measured. Evaluating domain adaptation to a target domain which has no labeled ground truth presents a novel problem. We want, for example to predict the extraversion of different counties, but do not have sufficient data to know, for example, what the mean extraversion scores are of even hundreds of counties.

We propose a three-pronged approach to validating a domain adaptation method on a set of target observations (counties, here) where we have no ground truth:

1) Are the distributions of the predicted attributes reasonable? We know, for example, that personality scores are, by construction, Gaussian at the individual level, and that averaging these Gaussians should give a distribution of mean county-level personalities that are Gaussian. However, as shown below, we find our county-level predictions to be far from a normal distribution, with some predictions lying over 10 standard deviations from the mean. We use kurtosis as a concrete metric to assess the impact of domain adaptation on predictions.

2) Are the estimates stable? We know that personality at the level of individuals is relatively stable over time; average personality in a county level should be extremely stable from year to year. However, this wasn't the case for our county-level predictions. We use year to year Pearson correlation between predictions as the benchmark metric to measure stability; domain adaptation should increase these correlations.

3) Do estimates correlate as expected with other outcomes? We know that personality correlates with many measurable outcomes for which we *do* have county-level measurements such as health and subjective well-being. A good domain adaptation should produce personality predictions which correlate more highly with such outcomes, while reducing unexpected correlations.

7 Results

We now demonstrate the utility of TSDA by modeling how personality, as estimated using language on Facebook, can be used to predict county-level average personality from Twitter language.

We use the widely used Five Factor Model (or Big 5) of personality (thousands of papers have been written using it) (McCrae and John, 1992; Digman, 1990), which classifies personality traits into five dimensions: *extraversion* (outgoing, talkative, active), *agreeableness* (trusting, kind, generous), *conscientiousness* (self-controlled, responsible, thorough), *neuroticism* (anxious, depressive, touchy), and *openness* (intellectual, artistic, insightful) all measured using the revised neo personality inventory (Costa and McCrae, 2008).

7.1 Qualitative Analysis of TSDA

Recall that the first step of TSDA removes the most different 5% of each feature across counties, replacing them with imputed values, while step 2 removes the words that have the most different frequencies between Facebook and Twitter.

We first look at which words counts are being adjusted. Since step 1 imputes new frequencies for different words for each county, too many words are replaced to show them all. As representative examples, we show in Table 2 the 10 words with the largest change after TSDA step 1 for San Francisco, Salt Lake, and Philadelphia counties. These words, selected *without* looking at the labels, are removed from the model (replacing them with their mean values). We can also look, after the fact, and see which of the removed words had the most influence on the prediction. The 10 words which most affected the predicted openness when they were removed for each of the same three counties are shown in Table 3.

We can also see which words most affected the predicted openness when they were removed from Venango County, PA, one of two counties with extremely low predicted openness: ‘yg, ini, sama, ada, lagi, yang, aku, hari, yaa, ga’. These words, lyrics from an Indonesian song, show what can go wrong when models are applied to different domains (counties and years here); a previously rare meme becomes common in one county, making predictions for it highly inaccurate.

Table 4: Features measured most different by TSDA Step 2 on three years of Twitter data. Reported both for features that occurred more on Facebook (the left) and those occurring more on Twitter (the right). All comparison were made with the same source Facebook data.

A consequence of readjusting frequencies of words that differ widely between source and target is that words representing years (e.g. ‘2015’) have very different frequencies in the year that the post or tweet was written. Certain celebrity names behave similarly. Since we often predict on different years than we train, such time-correlated features are frequently dropped out.

7.2 Unsupervised Validation

As described above, we validate our model in three ways, measuring prediction 1) normality/kurtosis 2) year to year stability and 3) correlation to other county- and state-level outcomes.

Measuring Normality with kurtosis in Figure 2 shows that there were clear problems with the naive method. The personality measures were constructed to be normally distributed, therefore one should expect a sample of personality predictions to be approximately normally distributed with kurtosis near 3. This is clearly not the case with the original predictions, with a three year averaged kurtosis ranging between 8 and 36. The TCA and CORAL baseline predictions also had

Personality	Original	Step 1	Step 2	TSDA
O	35.33	3.01	27.63	2.99
C	22.22	4.10	8.47	3.60
E	24.99	6.41	16.43	3.90
A	8.95	2.68	10.84	2.75
N	10.56	2.61	17.97	2.71

Figure 2: Three year average of county prediction kurtosis

Personality	Original	Step 1	Step 2	TSDA
O	.83	.93	.82	.93
C	.76	.83	.82	.85
E	.49	.57	.51	.65
A	.84	.89	.82	.88
N	.81	.81	.78	.81

Figure 3: Pearson correlations between 2012 and 2013 predicted county-level personalities.

high kurtosis, with the TCA predictions ranging from 10 to 24 and CORAL from 6 to 69. TSDA however fixes this issue; all the predictions have kurtosis values between 2 and 4 when both steps of TSDA have been applied.

Year to Year Stability was assessed by correlating county-level predictions from one year to the following. Figure 3 shows that TSDA increased correlations for predictions that already appeared stable and those with lower correlations. When viewed in conjunction with Figure 2, one can see that the initially high correlations for openness and neuroticism, and to a lesser extent some other predictions, were due to high leverage points.

Spurious (county-specific) words that are stable from year to year can cause both high kurtosis and high year to year correlations. Spurious words that vary year to year, perhaps due to a local meme or news story, cause low year-to-year stability.

Correlations between Predicted Personality and County Health and Well-being were calculated. Successful domain adaptation should increase these correlations – or at least drive them towards what is expected from the previous literature. Figure 4 shows the average correlations across three years between observed county-level outcomes and personality predictions both original and post-TSDA word frequencies. We focus first on the overall results. TSDA yields an average increase in correlation magnitude of 11% above the original unadjusted correlations, when averaged over all the personality factors and outcomes listed in the table, as expected. However, some correlations increased due to domain adaptation, while some decreased. We asked a personality psychologist to frame hypotheses for the re-

relationship of personality traits with other county-level outcomes, based on findings from the psychology literature and her considerable experience in the same domain. We tested our findings against these hypotheses, provided in Figure 4 and reflect the expected positive or negative relationship between the five personality traits and income, life satisfaction, mental health, education and income.

Hypothesis	O	C	E	A	N
Mentally Unhealthy Days		-	-	-	+
Life Satisfaction	+	+	+	+	-
Education	+	+			-
Income		+	+	-	-
No domain adaptation					
Mentally Unhealthy Days	-.03	-.04	-.04	-.06	.06
Life Satisfaction	.11	.20	.01	.13	-.17
Education	.32	.31	-.03	.22	-.30
Income	.18	.12	.01	.13	-.09
TSDA					
Mentally Unhealthy Days	.00	-.07	-.04	-.11	.10
Life Satisfaction	.12	.23	.00	.13	-.21
Education	.55	.35	-.25	.07	-.49
Income	.38	.11	-.15	-.01	-.25

Figure 4: **Top:** Individual-level correlation direction between personality traits and health, well-being, and socioeconomic status measures as predicted by a personality expert, supplemented by meta-analytic findings published in psychology where readily available (Roberts et al., 2007). **Middle:** Pearson r between original county-level personality predictions and externally measured metrics. **Bottom:** Pearson r between county-level predictions using TSDA and the same externally measured metrics.

We see that our predictions mostly accord with the personality literature, and that domain adaptation often strengthens the correlations that we expected and weakens the correlations that had been predicted from language, but were not expected. In particular, in the original data, there is a predicted strong correlation between agreeableness and education. Given the high kurtosis in agreeableness, this correlation is suspicious. TSDA reduces this correlation from 0.22 to 0.07, much more in line with what would be expected.

Several noteworthy correlations are found in our data, and strengthened by TSDA.

- Openness is known to correlate positively with higher educational attainment. This correlation increases 72% from 0.32 to 0.55 when TSDA is used.
- Conscientiousness is known to correlate positively with life satisfaction, education and income, and negatively with mentally unhealthy days. Our results are consistent with this.

7.3 TSDA: Contribution of the two steps

Both steps of TSDA contribute to its performance, as shown in Figures 2 and 3.

Step 1 (Between County normalization) appears mostly responsible for the final reduction in kurtosis from TSDA and on its own adds some increased year to year stability. It also significantly increased the county-level predictions' correlations with socioeconomic status, and health and well-being measures and removed the spurious correlation between agreeableness and education which was observed in both the naive application of the model and in results only relying on TSDA step 2.

Step 2 (Facebook to Twitter normalization) on its own gave mild improvements in kurtosis (Figure 2), but inconsistent performance in year-to-year stability and external county-level correlations. It is when step 2 is applied after step 1 that the method is truly able to find differing features that, when replaced with the source feature means, provide overall better predictions.

8 Conclusion

We have shown that the naive approach to applying Facebook user-level language models to county-level Twitter language has inherent problems due to two separate domain adaptation problems: the differences in Facebook to Twitter word token frequencies, and the spatially correlated terms introduced when aggregating tweets to counties. These problems were discovered when we constructed a list of counties with the most extreme predicted personalities (e.g., 'the 10 most agreeable counties in the US') and found our estimates to be many standard deviations outside what is plausible. We introduce Target Side Domain Adaptation (TSDA), which adjusts the observed word counts in the target (county-level Twitter) domain, leaving the source domain model unchanged, and we propose a set of validation methods based on assessing normality, year-to-year prediction stability, and the correlation of predictions with other outcomes measured on the target counties.

TSDA works particularly well with words, since words vary widely in frequency and meaning across domains and, critically, variations in frequency tend to be associated with differences in meaning. It has the further advantage that it does not require retraining the model; instead, the fea-

ture values passed to the model are readjusted. This could be particularly important when the original training data cannot be shared, for example when it contains personal health data or (as is the case here) private social media data, which are impossible to truly anonymize for sharing.

Abstract

In the wake of a polarizing election, social media is laden with hateful content. To address various limitations of supervised hate speech classification methods including corpus bias and huge cost of annotation, we propose a weakly supervised two-path bootstrapping approach for an online hate speech detection model leveraging large-scale unlabeled data. This system significantly outperforms hate speech detection systems that are trained in a supervised manner using manually annotated data. Applying this model on a large quantity of tweets collected before, after, and on election day reveals motivations and patterns of inflammatory language.

1 Introduction

Following a turbulent election season, 2016’s digital footprint is awash with hate speech. Apart from censorship, the goals of enabling computers to understand inflammatory language are many. Sensing increased proliferation of hate speech can elucidate public opinion surrounding polarizing events. Identifying hateful declarations can bolster security in revealing individuals harboring malicious intentions towards specific groups.

Recent studies on supervised methods for online hate speech detection (Waseem and Hovy, 2016; Nobata et al., 2016) have relied on manually annotated data sets, which are not only costly to create but also likely to be insufficient to obtain wide-coverage hate speech detection systems. This is mainly because online hate speech is relatively infrequent (among large amounts of online

contents) and tends to transform rapidly following a new trigger event. Our pilot annotation experiment with 5,000 randomly selected tweets shows that around 0.6% (31 tweets) of tweets are hateful. The mass-scale (Yahoo!Finance online comments) hate speech annotation effort from Yahoo! (Nobata et al., 2016) revealed that only 5.9% of online comments contained hate speech. Therefore, large amounts of online texts need to be annotated to adequately identify hate speech. In recent studies (Waseem and Hovy, 2016; Kwok and Wang, 2013), the data selection methods and annotations are often biased towards a specific type of hate speech or hate speech generated in certain scenarios in order to increase the ratio of hate speech content in the annotated data sets, which however made the resulting annotations too distorted to reflect the true distribution of hate speech. Furthermore, inflammatory language changes dramatically following new hate “trigger” events, which will significantly devalue annotated data.

To address the various limitations of supervised hate speech detection methods, we present a weakly supervised two-path bootstrapping approach for online hate speech detection that requires minimal human supervision and can be easily retrained and adapted to capture new types of inflammatory language. Our two-path bootstrapping architecture consists of two learning components, an explicit slur term learner and a neural net classifier (LSTMs (Hochreiter and Schmidhuber, 1997)), that can capture both explicit and implicit phrasings of online hate speech.

Specifically, our bootstrapping system starts with automatically labeled online hateful content that are identified by matching a large collection of unlabeled online content with several hateful

slur terms. Then two learning components will be initiated simultaneously. A slur term learner will learn additional hateful slur terms from the automatically identified hateful content. Meanwhile, a neural net classifier will be trained using the automatically labeled hateful content as positive instances and randomly sampled online content as negative instances. Next, both string matching with the newly learned slur terms and the trained neural net classifier will be used to recognize new hateful content from the large unlabeled collection of online contents. Then the newly identified hateful content by each of the two learning components will be used to augment the initially identified hateful content, which will be used to learn more slur terms and retrain the classifier. The whole process iterates.

The design of the two-path bootstrapping system is mainly motivated to capture both explicit and implicit inflammatory language. Explicit hate speech is easily identifiable by recognizing a clearly hateful word or phrase. For example:

(1) *Don't talk to me from an anonymous account you faggot coward, whither up and die.*

(2) *And that's the kind of people who support Trump! Subhumans!*

In contrast, implicit hate speech employs circumlocution, metaphor, or stereotypes to convey hatred of a particular group, in which hatefulness can be captured by understanding its overall compositional meanings, For example:

(3) *Hillary's welfare army doesn't really want jobs. They want more freebies.*

(4) *Affirmative action means we get affirmatively second rate doctors and other professionals.*

Furthermore, our learning architecture has a flavor of co-training (Blum and Mitchell, 1998) in maintaining two learning components that concentrate on different properties of inflammatory language. By modeling distinct aspects of online hate speech, such a learning system is better equipped to combat semantic drift, which often occurs in self-learning where the learned model drifts away from the esteemed track. Moreover, training two complementary models simultaneously and utilizing both models to identify hate speech of different properties in each iteration of the learning process is important to maintain the learning momentum and to generate models with wide coverage. Indeed, our experimental results have shown that the

two-path bootstrapping system is able to jointly identify many more hate speech texts (214,997 v.s 52,958 v.s 112,535) with a significantly higher F-score (48.9% v.s 19.7% v.s 26.1%), when compared to the bootstrapping systems with only the slur term learner and only the neural net classifier. In addition, the evaluation shows that the two-path bootstrapping system identifies 4.4 times more hateful texts than hate speech detection systems that are trained using manually annotated data in a supervised manner.

2 Related Work

Previous studies on hate speech recognition mostly used supervised approaches. Due to the sparsity of hate speech overall in reality, the data selection methods and annotations are often biased towards a specific type of hate speech or hate speech generated in certain scenarios. For instance, Razavi et al. (2010) conducted their experiments on 1525 annotated sentences from a company's log file and a certain newsgroup. Warner and Hirschberg (2012) labeled around 9000 human labeled paragraphs from Yahoo!'s news group post and American Jewish Congress's website, and the labeling is restricted to anti-Semitic hate speech. Sood et al. (2012) studied use of profanity on a dataset of 6,500 labeled comments from Yahoo! Buzz. Kwok and Wang (2013) built a balanced corpus of 24582 tweets consisting of anti-black and non-anti black tweets. The tweets were manually selected from Twitter accounts that were believed to be racist based upon their reactions to anti-Obama articles. Burnap and Williams (2014) collected hateful tweets related to the murder of Drummer Lee Rigby in 2013. Waseem and Hovy (2016) collected tweets using hateful slurs, specific hashtags as well as suspicious user IDs. Consequently, all of the 1,972 racist tweets are by 9 users, and the majority of sexist tweets are related to an Australian TV show.

Djuric et al. (2015) is the first to study hate speech using a large-scale annotated data set. They have annotated 951,736 online comments from Yahoo!Finance, with 56,280 comments labeled as hateful. Nobata et al. (2016) followed Djuric et al. (2015)'s work. In addition to the Yahoo!Finance annotated comments, they also annotated 1,390,774 comments from Yahoo!News. Comments in both data sets were randomly sampled from their corresponding websites with a fo-

cus on comments by users who were reported to have posted hateful comments. We instead aim to detect hate speech w.r.t. its real distribution, using a weakly supervised method that does not rely on large amounts of annotations.

The commonly used classification methods in previous studies are logistic regression and Naive Bayes classifiers. Djuric et al. (2015) and Nobata et al. (2016) applied neural network models for training word embeddings, which were further used as features in a logistic regression model for classification. We will instead train a neural net classifier (Kim, 2014; Lai et al., 2015; Zhou et al., 2015) in a weakly supervised manner in order to capture implicit and compositional hate speech expressions.

Xiang et al. (2012) is related to our research because they also used a bootstrapping method to discover offensive language from a large-scale Twitter corpus. However, their bootstrapping model is driven by mining hateful Twitter users, instead of content analysis of tweets as in our approach. Furthermore, they recognize hateful Twitter users by detecting explicit hateful indicators (i.e., keywords) in their tweets while our bootstrapping system aim to detect both explicit and implicit expressions of online hate speech.

3 The Two-path Bootstrapping System for Online Hate Speech Detection

3.1 Overview

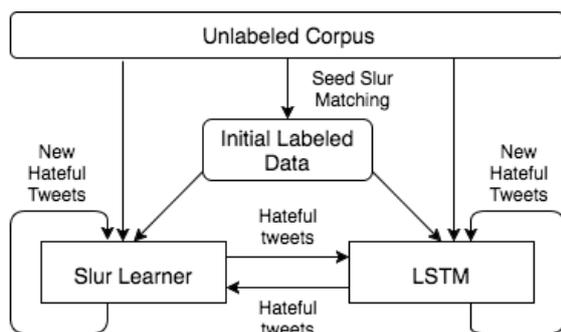

Figure 1: Diagram of co-training model

Figure 1 illustrates that our weakly supervised hate speech detection system starts with a few pre-identified slur terms as seeds and a large collection of unlabeled data instances. Specifically, we experiment with identifying hate speech from tweets. Hateful tweets will be automatically identified by matching the large collection of unlabeled tweets

with slur term seeds. Tweets that contain one of the seed slur terms are labeled as hateful.

The two-path bootstrapping system consists of two learning components, an explicit slur term learner and a neural net classifier (LSTMs (Hochreiter and Schmidhuber, 1997)), that can capture both explicit and implicit descriptions of online hate speech. Using the initial seed slur term labeled hateful tweets, the two learning components will be initiated simultaneously. The slur term learner will continue to learn additional hateful slur terms. Meanwhile, the neural net classifier will be trained using the automatically labeled hateful tweets as positive instances and randomly sampled tweets as negative instances. Next, both the newly learned slur terms and the trained neural net classifier will be used to identify new hateful content from the unlabeled large collection of tweets. The newly labeled hateful tweets by each of the two learning components will be used to augment the initial slur term seed identified hateful tweet collection, which will be used to learn more slur terms and retrain the classifier in the next iteration. The whole process then iterates.

After each iteration, we have to determine if a stopping criterion is met and we should terminate the bootstrapping process. In general, a tuned threshold score is applied or a small annotated dataset is used to evaluate the learned classifiers. We adopt the latter method. Specifically, the bootstrapping system stops when the precision of the LSTM classifier is lower than 0.6 when evaluated using an existing small annotated tweet set (Waseem and Hovy, 2016).

3.2 Automatic Data Labeling of Initial Data

Seeing a hate slur term in a tweet strongly indicates that the tweet is hateful. Therefore, we use 20 manually selected slur terms to match with a large unlabeled tweet collection in order to quickly construct the initial small set of hateful tweets. Table 1 shows the 20 seed slurs we used.

bimbo	chink	commie	coon	cunt
fag	faggot	feminazi	honky	islamist
libtard	muzzie	negro	nigger	paki
skank	subhuman	tranny	twat	wanker

Table 1: Seed slurs

We obtained our initial list of slurs from Hate-

base¹, the Racial Slurs Database², and a page of LGBT slang terms³. We ranked the slur terms by their frequencies in tweets, eliminating ambiguous and outdated terms. The slur "gypsy", for example, refers to derogatorily to people of Roma descent, but currently in popular usage is an idealization of a trendy bohemian lifestyle. The word "bitch" is ambiguous, sometimes a sexist slur but other times innocuously self-referential or even friendly.

For these reasons, we only selected the top 20 terms we considered reliable (shown in Table 1). We use both the singular and the plural form for each of these seed slur terms.

3.3 Slur Term Learner

The slur term learning component extracts individual words from a set of hateful tweets as new slurs. Intuitively, if a word occurs significantly more frequently in hateful tweets than in randomly selected tweets, this term is more likely to be a hateful slur term. Following this intuition, we assign a score to each unique unigram that appears 10 or more times in hateful tweets, and the score is calculated as the relative ratio of its frequency in the labeled hateful tweets over its frequency in the unlabeled set of tweets. Then the slur term learner recognizes a unigram with a score higher than a certain threshold as a new slur. Specifically, we use the threshold score of 100 in identifying individual word slur terms.

The newly identified slur terms will be used to match with unlabeled tweets in order to identify additional hateful tweets. A tweet that contains one of the slur terms is deemed to be a hateful tweet.

While we were aware of other more sophisticated machine learning models, one purpose of this research is to detect and learn new slur terms from constantly generated user data. Therefore, the simple and clean string matching based slur learner is designed to attentively look for specific words that alone can indicate hate speech. In addition, this is in contrast with the second learning component that uses a whole tweet and model its compositional meanings in order to recognize implicit hate speech. These two learners are complementary in the two-path bootstrapping system.

¹<https://www.hatebase.org>

²<http://www.rsd.org>

³https://en.wikipedia.org/wiki/List_of_LGBT_slang_terms

3.4 The LSTM Classifier

We aim to recognize implicit hate speech expressions and capture composite meanings of tweets using a sequence neural net classifier. Specifically, our LSTM classifier has a single layer of LSTM units. The output dimension size of the LSTM layer is 100. A sigmoid layer is built on the top of the LSTM layer to generate predictions. The input dropout rate and recurrent state dropout rate are both set to 0.2. In each iteration of the bootstrapping process, the training of the LSTM classifier runs for 10 epochs.

The input to our LSTM classifier is a sequence of words. We pre-process and normalize tokens in tweets following the steps suggested in (Pennington et al., 2014). In addition, we used the pre-processing of emoji and smiley described in a preprocess tool⁴. Then we retrieve word vector representations from the downloaded⁵ pre-trained word2vec embeddings (Mikolov et al., 2013).

The LSTM classifier is trained using the automatically labeled hateful tweets as positive instances and randomly sampled tweets as negative instances, with the ratio of POS:NEG as 1:10. Then the classifier is used to identify additional hateful tweets from the large set of unlabeled tweets. The LSTM classifier will deem a tweet as hateful if the tweet receives a confidence score of 0.9 or higher. Both the low POS:NEG ratio and the high confidence score are applied to increase the precision of the classifier in labeling hateful tweets and control semantic drift in the bootstrapping learning process. To further combat semantic drift, we applied weighted binary cross-entropy as the loss function in LSTM.

3.5 One vs. Two Learning Paths

As shown in Figure 1, if we remove one of the two learning components, the two-path learning system will be reduced to a usual self-learning system with one single learning path. For instance, if we remove the LSTM classifier, the slur learner will learn new slur terms from initially seed labeled hateful tweets and then identify new hateful tweets by matching newly learned slurs with unlabeled tweets. The newly identified hateful tweets will be used to augment the initial hateful tweet collection and additional slur terms can be learned from the enlarged hateful tweet set. The process

⁴<https://pypi.python.org/pypi/tweet-preprocessor/0.4.0>

⁵<https://code.google.com/archive/p/word2vec/>

will iterates. However as shown later in the evaluation section, single-path variants of the proposed two-path learning system are unable to receive additional fresh hateful tweets identified by the other learning component and lose learning momentum quickly.

3.6 Tackling Semantic Drifts

Semantic drift is the most challenging problem in distant supervision and bootstrapping. First of all, we argue that the proposed two-path bootstrapping system with two significantly different learning components is designed to reduce semantic drift. According to the co-training theory (Blum and Mitchell, 1998), the more different the two components are, the better. In evaluation, we will show that such a system outperforms single-path bootstrapping systems. Furthermore, we have applied several strategies in controlling noise and imbalance of automatically labeled data, e.g., the high frequency and the high relative frequency thresholds enforced in selecting hate slur terms, as well as the low POS:NEG training sample ratio and the high confidence score of 0.9 used in selecting new data instances for the LSTM classifier.

4 Evaluations

4.1 Tweets Collection

We randomly sampled 10 million tweets from 67 million tweets collected from Oct. 1st to Oct. 24th using Twitter API. These 10 million tweets were used as the unlabeled tweet set in bootstrapping learning. Then we continued to collect 62 million tweets spanning from Oct.25th to Nov.15th, essentially two weeks before the US election day and one week after the election. The 62 million tweets will be used to evaluate the performance of the bootstrapped slur term learner and LSTM classifier. The timestamps of all these tweets are converted into EST. By using Twitter API, the collected tweets were randomly sampled to prevent a bias in the data set.

4.2 Supervised Baselines

We trained two supervised models using the 16 thousand annotated tweets that have been used in a recent study (Waseem and Hovy, 2016). The annotations distinguish two types of hateful tweets, sexism and racism, but we merge both categories and only distinguish hateful from non-hateful tweets.

First, we train a traditional feature-based classification model using logistic regression (LR). We apply the same set of features as mentioned in (Waseem and Hovy, 2016). The features include character-level bigrams, trigrams, and four-grams.

In addition, for direct comparisons, we train a LSTM model using the 16 thousand annotated tweets, using exactly the same settings as we use for the LSTM classifier in our two-path bootstrapping system.

4.3 Evaluation Methods

We apply both supervised classifiers and our weakly supervised hate speech detection systems to the 62 million tweets in order to identify hateful tweets that were posted before and after the US election day. We evaluate both precision and recall for both types of systems. Ideally, we can easily measure precision as well as recall for each system if we have ground truth labels for each tweet. However, it is impossible to obtain annotations for such a large set of tweets. The actual distribution of hateful tweets in the 62 million tweets is unknown.

Instead, to evaluate each system, we randomly sampled 1,000 tweets from the whole set of hateful tweets that *had been tagged as hateful* by the corresponding system. Then we annotate the sampled tweets and use them to estimate precision and recall of the system. In this case,

$$precision = \frac{n}{1000}$$

$$recall \propto precision \cdot N$$

Here, n refers to the number of hateful tweets that human annotators identified in the 1,000 sampled tweets, and N refers to the total number of hateful tweets the system tagged in the 62 million tweets. We further calculated system recall by normalizing the product, $precision \cdot N$, with an estimated total number of hateful tweets that exist in the 62 million tweets, which was obtained by multiplying the estimated hateful tweet rate of 0.6%⁶ with the exact number of tweets in the test set. Finally, we calculate F-score using the calculated recall and precision.

Consistent across the statistical classifiers including both logistic regression classifiers and

⁶We annotated 5,000 tweets that were randomly sampled during election time and 31 of them were labeled as hateful, therefore the estimated hateful tweet rate is 0.6% (31/5,000).

LSTM models, only tweets that receive a confidence score over 0.9 were tagged as hateful tweets.

4.4 Human Annotations

When we annotate system predicted tweet samples, we essentially adopt the same definition of hate speech as used in (Waseem and Hovy, 2016), which considers tweets that explicitly or implicitly propagate stereotypes targeting a specific group whether it is the initial expression or a meta-expression discussing the hate speech itself (i.e. a paraphrase). In order to ensure our annotators have a complete understanding of online hate speech, we asked two annotators to first discuss over a very detailed annotation guideline of hate speech, then annotate separately. This went for several iterations.

Then we asked the two annotators to annotate the 1,000 tweets that were randomly sampled from all the tweets tagged as hateful by the supervised LSTM classifier. The two annotators reached an inter-agreement Kappa (Cohen, 1960) score of 85.5%. Because one of the annotators became unavailable later in the project, the other annotator annotated the remaining sampled tweets.

4.5 Experimental Results

Supervised Baselines

The first section of Table 2 shows the performance of the two supervised models when applied to 62 million tweets collected around election time. We can see that the logistic regression model suffers from an extremely low precision, which is less than 10%. While this classifier aggressively labeled a large number of tweets as hateful, only 121,512 tweets are estimated to be truly hateful. In contrast, the supervised LSTM classifier has a high precision of around 79%, however, this classifier is too conservative and only labeled a small set of tweets as hateful.

The Two-path Bootstrapping System

Next, we evaluate our weakly supervised classifiers which were obtained using only 20 seed slur terms and a large set of unlabeled tweets. The two-path weakly supervised bootstrapping system ran for four iterations. The second section of Table 2 shows the results for the two-path weakly supervised system. The first two rows show the evaluation results for each of the two learning components in the two-path system, the LSTM classifier and the slur learner, respectively. The third

row shows the results for the full system. We can see that the full system **Union** is significantly better than the supervised LSTM model in terms of recall and F-score. Furthermore, we can see that a significant portion of hateful tweets were identified by both components and the weakly supervised LSTM classifier is especially capable to identify a large number of hateful tweets. Then the slur matching component obtains a precision of around 56.5% and can identify roughly 3 times of hateful tweets compared with the supervised LSTM classifier. The last column of this section shows the performance of our model on a collection of human annotated tweets as introduced in the previous work (Waseem and Hovy, 2016). The recall is rather low because the data we used to train our model is quite different from this dataset which contains tweets related to a TV show (Waseem and Hovy, 2016). The precision is only slightly lower than previous supervised models that were trained using the same dataset.

Table 3 shows the number of hateful tweets our bootstrapping system identified in each iteration during training. Specifically, the columns **Slur Match** and **LSTMs** show the number of hateful tweets identified by the slur learning component and the weakly supervised LSTM classifier respectively. We can see that both learning components steadily label new hateful tweets in each iteration and the LSTM classifier often labels more tweets as hateful compared to slur matching.

Furthermore, we found that many tweets were labeled as hateful by both slur matching and the LSTM classifier. Table 4 shows the number of hateful tweets in each of the three segments, hateful tweets that have been labeled by both components as well as hateful tweets that were labeled by one component only. Note that the three segments of tweets are mutually exclusive from others. We can see that many tweets were labeled by both components and each component separately labeled some additional tweets as well. This demonstrates that hateful tweets often contain both explicit hate indicator phrases and implicit expressions. Therefore in our two-path bootstrapping system, the hateful tweets identified by slur matching are useful for improving the LSTM classifier, vice versa. This also explains why our two-path bootstrapping system learn well to identify varieties of hate speech expressions in practice.

One-path Bootstrapping System Variants

Classifier	Precision	Recall	F1	# of Predicted Tweets	# of Estimated Hateful
Supervised Baselines					
Logistic Regression	0.088	0.328	0.139	1,380,825	121,512
LSTMs	0.791	0.132	0.228	62,226	49,221
The Two-path Weakly Supervised Learning System					
LSTMs	0.419	0.546	0.474	483,298	202,521
Slur Matching	0.565	0.398	0.468	261,183	147,595
Union	0.422	0.580	0.489	509,897	214,997
Union*	0.626*	0.258*	0.365*	-	-
Variations of the Two-path Weakly Supervised Learning System					
Slur Matching Only	0.318	0.143	0.197	166,535	52,958
LSTMs Only	0.229	0.303	0.261	491,421	112,535

Table 2: Performance of Different Models

Its	Prev	Slur Match	LSTMs
1	8,866	422	3,490
2	12,776	4,890	13,970
3	27,274	6,299	21,579
4	50,721	9,895	22,768

Table 3: Number of Labeled Tweets in Each Iteration

Intersection	LSTM Only	Slur Only
234,584	248,714	26,599

Table 4: Number of Hateful Tweets in Each Segment

In order to understand how necessary it is to maintain two learning paths for online hate speech detection, we also ran two experiments with one learning component removed from the loop each time. Therefore, the reduced bootstrapping systems can only repeatedly learn explicit hate speech (with the slur learner) or implicit hateful expressions (with the LSTM classifier).

The third section of Table 2 shows the evaluation results of the two single-path variants of the weakly supervised system. We can see that both the estimated precision, recall, F score and the estimated number of truly hateful tweets by the two systems are significantly lower than the complete two-path bootstrapping system, which suggests that our two-path learning system can effectively capture diverse descriptions of online hate speech, maintain learning momentums as well as effectively combat with noise in online texts.

5 Analysis

5.1 Analysis of the Learned Hate Indicators

berk	chavs	degenerates	douches
facist	hag	heretics	jihadists
lesbo	pendejo	paedo	pinche
retards	satanist	scum	scumbag
slutty	tards	unamerican	wench

Table 5: New slurs learned by our model

We have learned 306 unigram phrases using the slur term learning component. Among them, only 45 phrases were seen in existing hate slur databases while the other terms, 261 phrases in total, were only identified in real-world tweets. Table 5 shows some of the newly discovered hate indicating phrases. Our analysis shows that 86 of the newly discovered hate indicators are strong hate slur terms and the remaining 175 indicators are related to discussions of identity and politics such as 'supremacist' and 'Zionism'.

5.2 Analysis of LSTM Identified Hateful Tweets

The LSTM labeled 483,298 tweets as hateful, and 172,137 of them do not contain any of the original seed slurs or our learned indicator phrases. The following are example hateful tweets that have no explicit hate indicator phrase:

(1) @janh2h *The issue is that internationalists keep telling outsiders that they're just as entitled to the privileges of the tribe as insiders.*

(2) *This is disgusting! Christians are very tolerant people but Muslims are looking to wipe us out and dominate us! Sen <https://t.co/7DMTIrOLyw>*

We can see that the hatefulness of these tweets is determined by their overall compositional meanings rather than a hate-indicating slur.

5.3 Error Analysis

The error of our model comes from semantic drift in bootstrapping learning, which partially results from the complexity and dynamics of language. Specifically, we found dynamic word sense of slurs and natural drifting of word semantic. Many slur terms are ambiguous and have multiple word senses. For instance, “Chink”, an anti-Asian epithet, can also refer to a patch of light from a small aperture. Similarly, “Negro” is a toponym in addition to a racial slur. Further, certain communities have reclaimed slur words. Though the word “dyke” is derogatory towards lesbians, for example, some use it self-referentially to destigmatize it, a phenomenon we sometimes encountered.

5.4 Temporal Distributions of Tagged Hateful Tweets

By applying our co-training model on the 62 million tweets corpus, we found around 510 thousand tweets labeled as hateful in total.

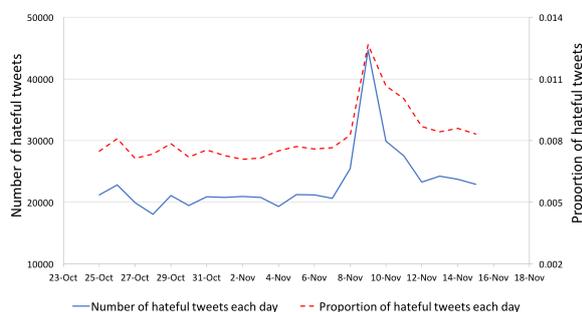

Figure 2: Temporal Distribution of Hateful Tweets

The figure 2 displays the temporal distribution of hateful tweets. There is a spike in hateful tweets from Nov.7th to Nov.12th in terms of both number of hateful tweets and ratio of hateful tweets to total tweets.

5.5 Most Frequent Mentions and Hashtags of Tagged Hateful Tweets

Table 6 and 7 show the top 30 most frequent mentions in hateful tweets. They are ranked by frequency from left to right and from top to bottom.

It is clear that the majority of mentions found in tweets tagged as hateful address polarizing political figures (i.e. @realDonaldTrump and

@HillaryClinton), indicating that hate speech is often fueled by partisan warfare. Other common mentions include news sources, such as Politico and MSNBC, which further support that “trigger” events in the news can generate inflammatory responses among Twitter users. Certain individual Twitter users also received a sizable number of mentions. @mitchellvii is a conservative activist whose tweets lend unyielding support to Donald Trump. Meanwhile, Twitter user @purplhaze42 is a self-proclaimed anti-racist and anti-Zionist. Both figured among the most popular recipients of inflammatory language.

Table 7 shows that the majority of hashtags also indicate the political impetus behind hate speech with hashtags such as #Trump and #MAGA (Make America Great Again, Trump’s campaign slogan) among the most frequent. The specific televised events also engender proportionally large amounts of hateful language as they can be commonly experienced by all television-owning Americans and therefore a widely available target for hateful messages.

@realDonaldTrump	@HillaryClinton	@megynkelly
@CNN	@FoxNews	@newtgingrich
@nytimes	@YouTube	@POTUS
@KelliannePolls	@MSNBC	@seanhannity

#hiring	#bbcqt	#USElection2016
#tcot	#TrumpProtest	#XFactor

Table 7: List of Top 30 Hashtags in Hateful Tweets During Election Days

6 Conclusions

Our work focuses on the need to capture both explicit and implicit hate speech from an unbiased

corpus. To address these issues, we proposed a weakly supervised two-path bootstrapping model to identify hateful language in randomly sampled tweets. Starting from 20 seed rules, we found 210 thousand hateful tweets from 62 million tweets collected during the election. Our analysis shows a strong correlation between temporal distributions of hateful tweets and the election time, as well as the partisan impetus behind large amounts of inflammatory language. In the future, we will look into linguistic phenomena that often occur in hate speech, such as sarcasm and humor, to further improve hate speech detection performance.

Estimating Reactions and Recommending Products with Generative Models of Reviews

Jianmo Ni and Zachary C. Lipton and Sharad Vikram and Julian McAuley

Department of Computer Science and Engineering

University of California San Diego

jin018, zlipton, svikram, jmcauley@ucsd.edu

Abstract

Traditional approaches to recommendation focus on learning from large volumes of historical feedback to estimate simple numerical quantities (Will a user click on a product? Make a purchase? etc.). Natural language approaches that model information like product reviews have proved to be incredibly useful in improving the performance of such methods, as reviews provide valuable auxiliary information that can be used to better estimate latent user preferences and item properties.

In this paper, rather than using reviews as an *inputs* to a recommender system, we focus on generating reviews as the model’s *output*. This requires us to efficiently model text (at the character level) to capture the preferences of the user, the properties of the item being consumed, and the interaction between them (i.e., the user’s preference). We show that this can model can be used to (a) generate plausible reviews and estimate nuanced reactions; (b) provide personalized rankings of existing reviews; and (c) recommend existing products more effectively.

1 Introduction

Review text has been extensively studied in modern recommender systems as a means of improving the performance on traditional recommendation tasks. Compared with conventional techniques that model simple numerical feedback (ratings, clicks, purchases, etc.), review text provides valuable information about user and item attributes, and more importantly the interaction between them. Recent systems have adapted ideas from topic modeling and sentiment analysis

to leverage the side-information contained in reviews; in essence, these approaches use language models as a form of ‘regularization,’ such that the model should explain user preferences and review text simultaneously (McAuley and Leskovec, 2013; Bao et al., 2014; Ling et al., 2014).

In parallel, recent advances in generative text modeling have demonstrated the effectiveness of recurrent neural networks in capturing content, structure, and style in natural language. As a result, several recent works have focused on learning generative models of product reviews, either to generate reviews *per se*, or as a means of learning user and item attributes (Lipton et al., 2015; Radford et al., 2017; Dong et al., 2017; Hu et al., 2017). In this paper, we address the problem of how to leverage both review text and implicit feedback simultaneously in order to provide richer user experiences and more meaningful recommendations. In particular, we focus on estimating latent user preferences through implicit feedback while simultaneously predicting the contents of the reviews themselves. Thus, given an item that a user hasn’t yet interacted with, our goals are to (a) generate a plausible review, in order to estimate the user’s nuanced reaction to the product; (b) estimate whether the user would be likely to interact with the product, based on their learned latent attributes; and (c) rank existing reviews using the language model, in order to surface ‘meaningful’ reviews to the user.

To solve the above problems, we propose a model—CF-GGN—that combines Collaborative Filtering (CF) with Generative Concatenative Networks (GCN) (Lipton et al., 2015) to simultaneously perform item recommendation and review generation. Given a large dataset of implicit feedback (e.g. purchases vs. non-purchases), we start by modeling user and item latent factors through collaborative filtering; we also adapt ideas from

text embeddings (e.g. word2vec), and use multi-layer perceptrons (MLP) to model complex interactions between embeddings and latent preference factors. Finally we build a generative concatenative model by stacking two LSTM layers; we adopt a simple replication strategy to concatenate latent factors with text input and jointly train the model in a supervised way. By sharing the same model parameters, the two tasks (recommendation and generation) mutually reinforce each other when all parameters are trained end-to-end.

To our knowledge, our work is the first to show that we can generate plausible reviews while simultaneously achieving substantial quantitative improvements on recommendation tasks. To summarize, our main contributions are as follows:

- We jointly perform recommendation and review generation by combining collaborative filtering with LSTM-based generative models. Our model captures latent information such as user preferences and item attributes, and learns to generate coherent, structured, and personalized reviews.
- We investigate the effect of sparsity in both reviews and implicit feedback data; a virtue of our joint training approach is that we can learn effective text models even for users with limited reviews at training time, i.e., we can learn to estimate likely reactions (in the form of reviews), on the basis of implicit feedback (e.g. purchases and clicks), even for users who write few reviews.
- We conduct extensive experiments on three real-world datasets in order to qualitatively and quantitatively demonstrate the effectiveness of our joint training approach.

2 Related Work

Review text provides valuable information about users' experiences and preferences toward the items they consume. Modeling the detailed information in reviews is especially important in sparse datasets, where a small amount of reviews carries substantially more information than is available in ratings alone. Several previous works have taken reviews into consideration to improve the performance of various recommendation tasks (McAuley and Leskovec, 2013; Ling et al., 2014; Bao et al., 2014; Wang et al., 2015).

Recently, neural-network-based models have been considered when modeling review text, in place of traditional topic modeling techniques. Zheng et al. (2017) leveraged Convolutional Neural Networks (CNN) to extract embeddings from reviews, which were used as features in a factorization machine (Rendle, 2010) to generate rating predictions. Catherine and Cohen (2017) proposed a model ('transNet') consisting of a source network and a target network; the former learns user and item embeddings from reviews while the latter performs sentiment analysis over the ground truth review. By minimizing the difference between the two networks' latent representation layers, the model learns more expressive latent factors. Wu et al. (2017) presented a neural network based model that jointly considers both ratings and reviews. Their approach models the temporal rating prediction task via a Recurrent Neural Network (RNN), and uses an additional LSTM network to model the review text as a regularization term in the loss function. Their experimental results show improvements on rating prediction tasks over state-of-the-art techniques, however they do not report results in terms of the model's ability to generate plausible reviews.

Given their expressive power when modeling sequential data, RNN-based methods have been widely studied for a variety of generation tasks (Graves, 2013; Zhang and LeCun, 2015; Sutskever et al., 2011). Recently, several works have focused on the task of learning language models to generate reviews. Generating coherent and personalized reviews still poses considerable challenges, due to their length, structure, and the sparsity of real datasets. Radford et al. (2017) trained a character-RNN language model based on the Amazon review dataset (McAuley et al., 2015); they consider a single multiplicative LSTM layer with 4096 hidden units and train the model for nearly a month. The authors find a sentiment unit among the hidden units which is highly correlated to review sentiment. They can then generate reviews by forcing this sentiment unit to be positive or negative. Lipton et al. (2015) proposed a generative concatenative network to supervise the training of a character-level language model; they concatenate auxiliary information in the form of one-hot representations of user/item IDs, categories and ratings. The model generates plausible reviews when conditioned on this auxiliary information, and demon-

strates the potential for RNNs to capture subjective user information and generate personalized text, though they do not consider recommendation problems. Dong et al. (2017) studied attribute-to-sequence generative models with stacked LSTMs; they encode attributes such as user/item IDs and ratings and use the encoded information to initialize the hidden states of the LSTM layer. They also make use of an attention mechanism in the decoder to improve the accuracy of predictions. Their model is based on word-level LSTMs and struggles when generating long sequences. Moreover, their network does not have the ability to predict user preferences toward items, which limits performance when given unseen (user,item) pairs.

The most relevant work to ours is perhaps Li et al. (2017). They addressed the problem of jointly learning rating prediction and ‘tip generation.’ They employ a standard latent factor model with MLP layers to predict ratings, following which they use the latent factors to initialize the LSTM model for tip generation. Experimental results show quantitative improvements at rating prediction and their word-level generative model produces tips that are consistent with users’ ratings. Compared with their task, we focus on review generation (rather than generating short tips), which requires the model to maintain generation quality over long sequences. Moreover, we consider review text as content during the training of our collaborative filtering model, which further enhances the prediction of user preferences.

3 Proposed Method

First we define our problem before introducing our CF-GCN model. Table 1 summarizes the notation used throughout this paper.

Given an implicit feedback dataset \mathcal{R} (i.e., a set of ‘positive’ instances such as clicks or purchases), and the corresponding set of reviews \mathcal{T} , we focus on two tasks: item recommendation and review generation. We want to recommend a list of items to a user while also generating plausible reviews that the user might write.

3.1 Collaborative Filtering with Reviews

For the task of item recommendation with implicit feedback, our goal is to estimate pairwise preferences of a user u toward an item i via a scoring function $\hat{y}_{u,i}$. Many state-of-the-art techniques define their predictor in terms of matrix factorization

Table 1: Notation

Notation	Description
\mathcal{R}, \mathcal{T}	feedback set, review set
\mathcal{U}, \mathcal{I}	user set, item set
I^+, I^-	set of observed and unobserved entries
\hat{y}_{ui}	predicted ‘score’ for user u and item i
γ_u, γ_i	latent factors of user u and item i ($K \times 1$)
θ_u, θ_i	text factors for user u and item i ($K \times 1$)
f_u, f_i	word2vec embeddings of u and i ($D \times 1$)
E_u	$K \times D$ embedding matrix of user u
E_i	$K \times D$ embedding matrix of item i
Θ	set of neural network parameters
Φ	set of collaborative filtering parameters

(MF), i.e.,

$$\hat{y}_{ui} = \gamma_u^T \gamma_i, \quad (1)$$

where γ_u and γ_i represent K -dimensional user and item latent factors, whose inner product models the preference of u toward i .

There have been many extensions of standard MF methods by incorporating ‘side information’ such as categorical attributes, image features (He and McAuley, 2016), and text (Hu, 2017; Zheng et al., 2017). To fully take advantage of review text, we start by incorporating text embeddings from reviews into our predictor. Following this we use a single layer MLP to model the interactions between latent factors and text embeddings. The extended predictor is defined as

$$\hat{y}_{ui} = \sigma(\mathbf{W} \begin{bmatrix} \gamma_u^T \gamma_i \\ \theta_u^T E_i f_i \\ \theta_i^T E_u f_u \end{bmatrix} + \mathbf{b}), \quad (2)$$

where θ_u and θ_i are K -dimensional (latent) text factors that interact with the text embeddings of u and i . f_u and f_i are D -dimensional text features extracted from reviews written by user u or about item i . Only reviews in the training set are used (since reviews are not available at test time). Specifically, we first train a word2vec model on all reviews in the training set; then we aggregate reviews written by u or about i , and take an average over the representations. E_u and E_i are transform matrices that project D -dimensional text features into K -dimensional ‘preference space.’

Given the preference predictor, we can learn the model by minimizing the point-wise classification loss (He et al., 2017):

$$\mathcal{L} = - \sum_{(u,i) \in \mathcal{I}^- \cup \mathcal{I}^+} y_{ui} \log \hat{y}_{ui} + (1 - y_{ui}) \log(1 - \hat{y}_{ui}), \quad (3)$$

where I^+ and I^- represent the set of observed and unobserved entries in \mathcal{R} . With (eq. 3), the

item recommendation task becomes a classification problem of deciding whether i belongs to the positive or negative feedback set (I^+ or I^-).

3.2 Generative Concatenative Network

Recurrent neural networks with units such as long short term memory (LSTM) and gated recurrent units (GRU) have been widely used as generative models for tasks such as natural language generation, image captioning, dialogue generation, etc. (Józefowicz et al., 2016; Vinyals et al., 2015; Ghosh et al., 2017; Sutskever et al., 2014; Karpathy and Fei-Fei, 2017). In our model, we use a two-layer LSTM network to generate review text at the character level. We adopt the LSTM architecture from Zaremba et al. (2014). Updates of the LSTM layer are defined as:

$$\begin{pmatrix} \mathbf{g} \\ \mathbf{i} \\ \mathbf{f} \\ \mathbf{o} \end{pmatrix} = \begin{pmatrix} \tanh \\ \text{sigmoid} \\ \text{sigmoid} \\ \text{sigmoid} \end{pmatrix} W_l \begin{pmatrix} \mathbf{h}_{i-1}^t \\ \mathbf{h}_i^{t-1} \end{pmatrix} \quad (4)$$

$$\mathbf{s}_i^t = \mathbf{g}_i^t \odot \mathbf{i}_i^t + \mathbf{s}_i^{t-1} \odot \mathbf{f}_i^t$$

$$\mathbf{h}_i^t = \tanh(\mathbf{s}_i^t) \odot \mathbf{o}_i^t,$$

where \mathbf{s} is the internal state of the cell; \mathbf{g} represents the input node which has an activation function; \mathbf{i} , \mathbf{o} and \mathbf{f} are sigmoid gating units ('input,' 'output,' and 'forget,' respectively); and \mathbf{h} is the hidden state of the cell. \tanh and sigmoid are applied element-wise, as is the product \odot . W_l is the weight matrix for layer l .

Next we consider the text generation task using 'vanilla' LSTMs. For a character-LSTM model, each input x_t is a character of the original text. Given a text sequence $x^1 \dots x^T$, the LSTM-based network takes an input x^t for each step t and updates its hidden states \mathbf{h}^t based on both the current input x^t and the previous step's hidden state \mathbf{h}^{t-1} . The network predicts the input x^{t+1} at the next step, given all inputs $x^{\leq t}$ before $t + 1$. The output layer is connected to a softmax layer:

$$p(x^t | x^{\leq t}, \Theta) = \text{softmax}(W_s \mathbf{h}_L^t), \quad (5)$$

where W_s is the weight matrix of the softmax layer, \mathbf{h}_L^t is the hidden state at step t of the last hidden layer L , and Θ is the complete set of neural network parameters. Given the output probability distribution over all characters, we can predict the output by taking the character that maximizes the probability.

So far, the above method samples text from a 'background' distribution, but lacks the ability to generate personalized and item-specific text. We aim to address this by providing the network with auxiliary inputs x_{aux} . Here we hope that the same user and item latent factors γ_u and γ_i can also be effective as input to the generative model; this expectation is based on the notion that these factors describe the 'aspects' of user preferences and item properties that contribute to the user's overall opinion, and therefore the language in their review. Furthermore the use of low-dimensional latent factors means that the method can straightforwardly scale to large populations of users and items, which is not possible for methods based on one-hot encodings. Following Lipton et al. (2015) we adopt a simple replication strategy to concatenate the latent factors with the character input, so that the input to the model at each step becomes $x^{tt} = [x_{char}^t; \gamma_u; \gamma_i]$.

By concatenating the latent factors together with the character input, the auxiliary signal is preserved through hundreds of steps, allowing long and coherent sequences to be generated. If we were instead to treat latent factors as inputs to the hidden cell, the signal would quickly vanish or explode. In practice we found that a dimensionality of around $K = 8$ to 50 leads to acceptable performance when modeling users and items. This is a relatively small number compared with the hidden unit size (typically 256-1024), requiring only a modest computational overhead.

By sharing the same user and item latent factors, the tasks of item recommendation and review generation are learned jointly. The complete network structure is shown in Figure 1. We train the model in an end-to-end manner by optimizing the joint loss function:

$$\begin{aligned} \mathcal{L} = & - \sum_{(u,i) \in \mathcal{I}^- \cup \mathcal{I}^+} y_{ui} \log \hat{y}_{ui} + (1 - y_{ui}) \log(1 - \hat{y}_{ui}) \\ & - w \sum_{(u,i) \in \mathcal{I}} \sum_{t=1}^T \log p(x^t | x^{\leq t}, \Theta, \gamma_u, \gamma_i) \\ & + \lambda (\|\Theta\|_2^2 + \|\Phi\|_2^2), \end{aligned} \quad (6)$$

where w is a hyperparameter that trades off between the two tasks, $\Phi = \{\gamma_u, \gamma_i, \theta_u, \theta_i, E_u, E_i\}$ is the set of collaborative filtering parameters, and λ is a regularization hyperparameter.

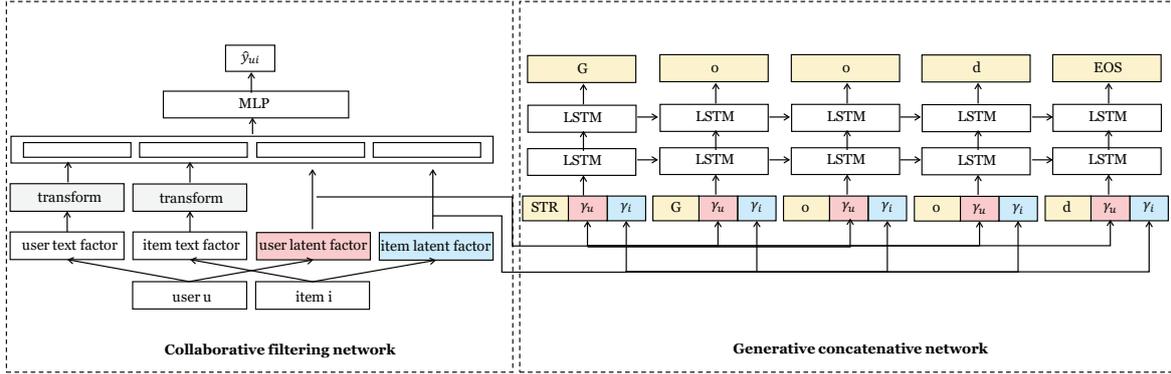

Figure 1: CF-GCN network structure

Table 2: Statistics after pre-processing.

Dataset	#users	#items	#reviews
BeerAdvocate	7,354	8,832	1,270,650
Electronics	20,247	11,589	306,899
Yelp	15,806	12,824	740,984

4 Experiments

We conduct experiments on multiple real-world datasets to investigate the following questions:

- **RQ1:** What can the model learn from review text? Does our joint training framework improve item recommendation performance?
- **RQ2:** What is the fidelity of the generative model? Does it successfully capture user/item attributes, sentiment, and writing style?
- **RQ3:** Can the model be used for personalized review ranking? How does performance improve as more reviews are available during training?

4.1 Datasets

We focus on three real-world datasets: BeerAdvocate,¹ Amazon Electronics,² and Yelp.³ We discard users and items with few actions by extracting the k-core, with $k = 20$ for BeerAdvocate and Yelp, and $k = 10$ for Amazon Electronics (which is substantially sparser). The statistics of the datasets after pre-processing are shown in Table 2.

¹<https://snap.stanford.edu/data/>

²<http://jmcauley.ucsd.edu/data/amazon/>

³https://www.yelp.com/dataset_challenge

4.2 Experimental Setting

We consider two experimental settings for sampling implicit feedback instances and reviews. In one (‘subset’) we consider a subset of implicit feedback instances in \mathcal{R} such that each is associated with exactly one review in \mathcal{T} ; in the second (‘wholeset’) we consider *all* implicit feedback instances in \mathcal{R} , but only a subset of the reviews. In other words, the two settings have the same subset of reviews, but differ in the amount of implicit feedback used. Our reasons for considering the latter setting are twofold: First, training LSTM models with review data is time-consuming, but it is relatively inexpensive to add additional implicit feedback instances during training, meaning that we can achieve a boost in performance with only a modest increase in running time. And second, in real recommendation scenarios, most users do not write reviews, while all provide implicit feedback through their actions; thus this setup allows us to train on both types of feedback simultaneously, and even to model likely reviews for users who have written very few (or none!).

We randomly sample 10%/50%/20% of instances from BeerAdvocate/Electronics/Yelp, respectively. We use a different sample ratio so that the subset maintains around 100,000 reviews for each review model. Then we use a skip-gram model to train word2vec on the training set for each dataset so as to reduce noise and learn better representations for those words that are dataset-specific. We choose an embedding size of 64 and keep the most frequent 20,000 words in each training corpus.

We implemented the proposed method using Keras. For all datasets, we randomly withhold two

Table 3: Comparisons of Hit Rate, NDCG and AUC on three datasets. CF-GCN improves all metrics over BPR and GMF for all settings (higher is better for all metrics).

Dataset	Setting	Hit Rate			NDCG			AUC		
		BPR	GMF	CF-GCN	BPR	GMF	CF-GCN	BPR	GMF	CF-GCN
BeerAdvocate	subset	0.583	0.584	0.613	0.351	0.334	0.371	0.826	0.847	0.861
	wholeset	0.752	0.763	0.773	0.476	0.487	0.501	0.925	0.925	0.928
Electronics	subset	0.375	0.428	0.459	0.224	0.254	0.275	0.690	0.746	0.779
	wholeset	0.494	0.521	0.529	0.295	0.317	0.324	0.665	0.824	0.826
Yelp	subset	0.641	0.660	0.679	0.378	0.392	0.412	0.899	0.895	0.902
	wholeset	0.811	0.830	0.847	0.514	0.530	0.553	0.946	0.946	0.952

interactions per user as our validation/test set, and use all other interactions for training, (i.e., leave-one-out evaluation (Rendle et al., 2009)). All results are reported on the test set, for the hyperparameters resulting in the best performance on the validation set. The dimensionality of the latent factors is set to $K = 8$. Parameters of the user and item latent factors and text embeddings are initialized from a Gaussian distribution with $\mu = 0$ and $\sigma = 0.01$. For the review model, we stacked two LSTM layers with 256 hidden units per layer. We first train a conventional character-LSTM model then load the pre-trained parameters as initialization to speed up training. During training, we concatenate all reviews in the training set and add start and end tokens (e.g. STR, EOS) as delimiters. Then we split the concatenated string into sequences of length 200.

The model is trained in min-batches with batch-size 256. We adopt the Adam Optimizer (Kingma and Ba, 2014) to update weights. We consider learning rates in $\{0.01, 0.001, 0.0001\}$ and $\lambda \in \{0, 0.001, 0.0001, 0.00001, 0.000001\}$, selecting the optimal values on the validation set using grid search. We also tune the weight w between 0 to 1 to trade off item recommendation vs. review generation in (eq. 6).

4.3 Item Recommendation (RQ1)

We first demonstrate that our model can learn user preferences through both implicit feedback and review text. We focus on the item recommendation task and compare the proposed model with two state-of-the-art methods: Bayesian Personalized Ranking (BPR) (Rendle et al., 2009) and Generalized Matrix Factorization (GMF) (He et al., 2017). Both BPR and GMF use the predictor as eq. 1. We consider three metrics: Hit Rate, NDCG, and AUC. At test time, given a user and item pair from the held-out data, we return a truncated ranked list

of items with size 10. Then the Hit Rate at the top 10 (HR@10) represents the ratio of ground truth items existing in the ranked list, while the NDCG measures the position of the hits (He et al., 2017, 2016). The AUC (*Area Under the ROC curve*) is evaluated as:

$$\text{AUC} = \frac{1}{|\mathcal{U}|} \sum_u \frac{1}{|\mathcal{S}(u)|} \sum_{(i,j) \in \mathcal{S}(u)} \delta(\hat{y}_{ui} > \hat{y}_{uj}),$$

where δ is an indicator (1 iff its argument is true), and the set of pairs of u is defined as:

$$\mathcal{S}(u) = \{(i, j) | i \in \mathcal{I}_{test}^+(u) \wedge j \notin \mathcal{I}_{train}^-(u) \cup \mathcal{I}_{valid}^-(u) \cup \mathcal{I}_{test}^-(u)\}.$$

As shown in Table 3, CF-GCN improves over BPR and GMF on the three metrics. Note that we only use a modest number of latent factors (8) and word2vec embedding dimensions (64). Moreover, we can see that CF-GCN achieves greater improvements in sparse settings, confirming the ability of review text to overcome the sparsity of implicit feedback datasets.

4.3.1 User Cold-Start

Real recommender systems often suffer from cold-start issues due to data sparsity. It is a critical task for the system to capture user preferences toward items given limited data. To explore the performance of CF-GCN, we further analyze the improvement on cold (or ‘cool’) users. Figure 2 shows the improvement (in Hit Rate and NDCG) for users with fewer than 5 reviews on BeerAdvocate. The largest improvement ratio happens for users with only a single review during training.

4.4 Review Generation Analysis (RQ2)

4.4.1 Perplexity

Perplexity is commonly used to measure the quality of generated text. It is defined as

$$\text{ppx} = e^{-\frac{1}{N} \sum_{(u,i)} \frac{1}{T} \sum_{c=1}^T \log p(c_t | c_{<t}, \Theta, \gamma_u, \gamma_i)},$$

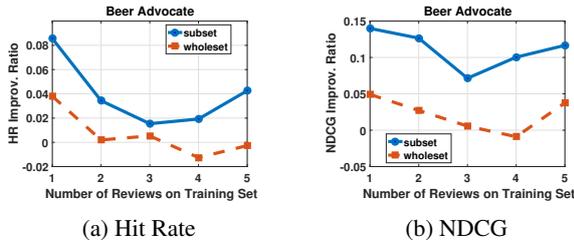

Figure 2: Improvement Ratio on Cold-Start Users

Table 4: Comparison of Perplexity on test set (lower is better).

Dataset	Character LSTM	CF-GCN (subset)	CF-GCN (wholeset)
BeerAdvocate	2.370	2.318	2.329
Electronics	3.033	2.998	2.959
Yelp	2.916	2.817	2.809

where (u, i) are pairs from the test set of reviews \mathcal{T}_{test} , N is the number of reviews on the test set, and T is the number of characters in each review.

We compare the test-set perplexity of CF-GCN to that of a standard character-LSTM. As shown in Table 4, CF-GCN achieves lower perplexity than an unsupervised character-LSTM, suggesting that the model is successfully able to leverage information encoded in the user and item representations.

4.4.2 Generated Examples

Figure 3 gives a representative example of a generated review, for a (user,item) pair that is not present in the training set. In other words, only the user and item IDs are provided to the model, from which it must synthesize a plausible review.

Qualitatively, CF-GCN appears to capture the user’s writing style, the item’s attributes, and the user’s sentiment, and more importantly maintains the overall flow and structure of the review in spite of its length and complexity. For example, the synthetic review captures idiosyncrasies of the real review, including the user’s tendency to use abbreviations to denote different sensory aspects (‘A:’ for Appearance, ‘S:’ for Smell, etc.) CF-GCN also provides descriptions of the item’s color, taste and category (“Pours a very dark brown,” “a slight sweetness,” “bitter,” “ale”) which approximately match those of the real review. Moreover, the synthetic review shares the same overall sentiment with the real review (3 stars, ‘not bad’).

Figure 4 presents synthetic review examples conditioned on users who have not written *any* reviews in the training set. We include the ground-

truth rating, which is a score between 1.0 and 5.0. The model appears to successfully generates plausible reviews that express sentiment matching the ground-truth rating.

Note here that we only use two LSTM layers with 256 hidden units. Performance could be further improved by increasing the number of hidden units and stacking more layers, at the cost of additional computational resources. For the current setting, it takes around 80 minutes to run 1 epoch for the BeerAdvocate dataset. Typically CF-GCN needs 5 to 10 epochs to converge.

4.5 Personalized review ranking (RQ3)

Besides synthesizing reviews, a more realistic application of our model is to recommend (or rank) existing reviews, by surfacing the review that is most consistent with a user’s preferences or writing style. As with our previous experiments, this can be done even for users who have never written a review before: that is, based on their past behavior we can surface the types of reviews written by users who behave similarly.

Since CF-GCN captures both the sentiment and writing style of users, it can also be used in a discriminative way to identify which existing review of an item a particular user is most likely to have written. Given a target item and a list of users, the personalized review ranking problem can be quantitatively evaluated in terms of our ability to rank the ‘true’ review (i.e., the one the user actually wrote) higher than others. This target captures whether the model can recommend the most relevant existing review to a potential user.

For a review written by user u on item i , we first calculate the perplexity when the generative model is given the latent factors of u and i . We then estimate the AUC by randomly sampling reviews (of the same item) by other users u' and calculating their perplexity when the model is again given the latent factors of u and i . We can then evaluate the model in terms of its ability to associate a lower perplexity to the review u actually wrote. The model generates reasonable results given only a modest number of reviews, and can identify authors with almost perfect accuracy once sufficiently many reviews are provided during training.

Figure 5 shows AUC results for the personalized review ranking task. As the number of reviews available during training increases, the AUC

Real review	Synthetic review
<p>12 oz. bottle, excited to see a new Victory product around, A: Pours a dark brown, much darker than I thought it would be, rich creamy head, with light lace. S: Dark cedar/pine nose with some dark bread/pumpernickel. T: This ale certainly has a lot of malt, bordering on Barleywine. Molasses, sweet maple with a clear bitter melon/white grapefruit hop flavour. Not a lot of complexity in the hops here for me. Booze is noticeable. M: Full-bodied, creamy, resinous, nicely done. D: A good beer, it isn't exactly what I was expecting. In the end above average, though I found it monotonous at times, hence the 3. A sipper for sure.</p>	<p>A: Pours a very dark brown with a nice finger of tan head that produces a small bubble and leaves decent lacing on the glass. S: Smells like a nut brown ale. It has a slight sweetness and a bit of a woody note and a little cocoa. The nose is rather malty with some chocolate and coffee. The taste is strong but not overwhelmingly sweet. The sweetness is overpowering, but not overwhelming and is a pretty strong bitter finish. M: Medium bodied with a slightly thin feel. D: A good tasting beer. Not bad.</p>

Figure 3: Real and synthetic reviews conditioned on the latent factor of user *Halcyondays* and item *Yakima Glory*. Colors added for emphasis. The model successfully captures the high-level structure of the review, as well as the fine-grained characteristics of their opinion.

<p>Synthetic review: user <i>BeerShirts</i>, item <i>Black Albert</i>, sentiment <i>5.0</i></p> <p>A - Pours a brownish-copper color with a thick tan head. S - Strong and smoky aroma, fruity and sweet. The alcohol is not very prominent on the nose. Smells like a stout and enjoyable. It's almost like a hefeweizen and the smell is dominated by a slight burnt sugar character and a slight chocolate smell to it. The taste is sweet and malty. The mouthfeel is very light and watery. Overall a very nice beer that I'd have again.</p>
<p>Synthetic review: user <i>Morbo</i>, item <i>Avalon Spiced Ale</i>, sentiment <i>1.5</i></p> <p>I don't like this beer. I was not a big fan of this beer. The aroma was pretty accessible and the taste was a bit sweet and fruity. There was a hint of sweetness that was overwhelmed by the rice and malt also a bit of the hops in the finish. The mouthfeel was medium bodied with a medium carbonation. This was a good beer to drink but I would not be able to get more of this.</p>

Figure 4: Synthetic reviews for users who have written *no* reviews in the training set. The model successfully predicts user preferences and generates plausible reviews.

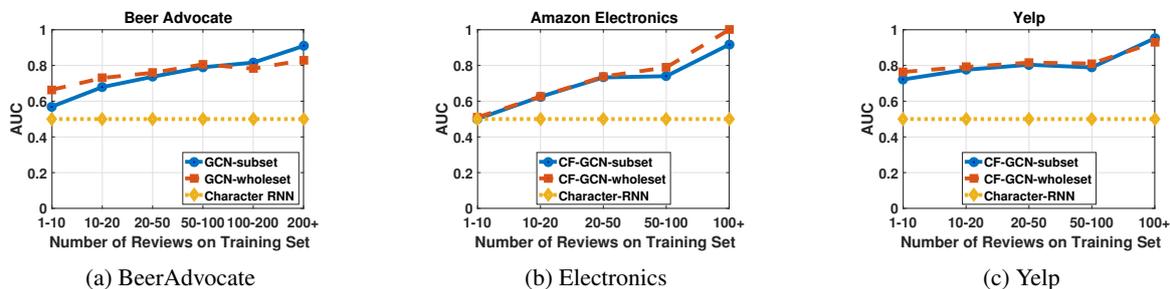

Figure 5: Comparisons of AUC for personalized review ranking for users with different number of reviews on the training set.

also increases, indicating that the method is better able to capture the characteristics of the user and item given more observations.

5 Conclusions

In this paper, we proposed to combine collaborative filtering with generative concatenative networks to jointly perform the tasks of item recommendation and review generation. We formulated the item recommendation task using matrix factorization, in order to capture low-dimensional user preferences and item properties, which we combined with a character-level LSTM model, so that

the latent factors are simultaneously responsible for explaining both language and preferences. We adopted a simple input replication strategy to allow the LSTM model to ‘remember’ the input on which it is conditioned, so that it is able to generate long reviews that capture high-level structure as well as fine-grained sentiment. In addition to using the model generatively, we showed that it can also improve recommendation performance, both in terms of predicting products that a user is likely to interact with, as well as personalized review ranking.

Summarizing Lengthy Questions

Tatsuya Ishigaki Hiroya Takamura Manabu Okumura

Tokyo Institute of Technology

ishigaki@lr.pi.titech.ac.jp, {takamura, oku}@pi.titech.ac.jp

Abstract

In this research, we propose the task of *question summarization*. We first analyzed question-summary pairs extracted from a Community Question Answering (CQA) site, and found that a proportion of questions cannot be summarized by extractive approaches but requires abstractive approaches. We created a dataset by regarding the question-title pairs posted on the CQA site as question-summary pairs. By using the data, we trained extractive and abstractive summarization models, and compared them based on ROUGE scores and manual evaluations. Our experimental results show an abstractive method using an encoder-decoder model with a copying mechanism achieves better scores for both ROUGE-2 F-measure and the evaluations by human judges.

1 Introduction

Questions are asked in many situations, such as conference sessions and email communications. However, questions can sometimes be lengthy and hard to understand, because they often contain peripheral information in addition to the main focus of the question. To address this issue, we propose the task of *question summarization*; summarizing a lengthy question into a simple question that concisely represents the original content.

As an example of an excerpt from a Community Question Answering (CQA) site, Yahoo Answers¹, is shown in Table 1. In this example, the gist of the question is whether the chlorine will stripe the questioner’s hair. However, the question also contains the additional information that the questioner swims five days a week and has black

¹<https://answers.yahoo.com/>

Table 1: Example of question-summary pair

Question Text:
I’m a swimmer for my school swim team and I practice two hours a day, five days a week. I would like to dye my hair black (it is dark brown now) but I am wondering whether the chlorine will stripe it. Will it or will it not ?
Summary:
Will the chlorine stripe my hair ?

hair. Although such information can sometimes be important for finding the exact answer, it is often peripheral when we want to grasp what is being asked.

Summarizing a question, which can often be lengthy, helps respondents understand the question. The task of question summarization has not been studied yet and is worth being explored. In this work, we focus on a CQA site and examine the characteristics of the question summarization task with a CQA dataset as a case study. Specifically, we first examine CQA data consisting of pairs of a question text and its title, which we refer to as “question-title” pairs. We then propose a method for creating pairs of a question and its summary, which we refer to as “question-summary” pairs, out of the CQA data. We also propose methods for question summarization and describe an empirical evaluation we conducted.

Approaches used in generic summarization tasks are often classified into two different types: extractive and abstractive. Extractive approaches select and order units, which are usually sentences or words, from the input text. Abstractive approaches, rather than selecting units, generate a summary using words not found in the input text.

However, existing summarization approaches, whether extractive or abstractive, do not assume

a question as an input. We therefore developed a number of methods designed for question summarization: extractive methods based on simple heuristic rules, extractive methods based on sentence classification/regression, and abstractive methods based on neural networks. We compared the performance of these methods through evaluations both by human judges and automatic scoring using Recall-Oriented Understudy for Gisting Evaluation (ROUGE) (Lin, 2004). The experimental results show that an abstractive approach using an encoder-decoder model with a copying mechanism achieves the highest score for both ROUGE and evaluations by human judges.

2 Related Work

Text summarization is one of the problems that have been studied for a long time in the field of natural language processing. In many of the existing summarization tasks including the shared tasks in Document Understanding Conference (DUC)², documents from newspapers or scientific articles are considered as an input. There are also other summarization tasks in which other types of input are assumed such as conversations or email threads (Duboue, 2012; Oya and Carenini, 2014; Oya et al., 2014). Unlike the researches, we assume a question as an input.

As a related attempt in Question Answering researches, Tamura et al. (2005) worked on classification of multiple-sentence questions into classes such as yes/no questions and definition questions, and attempted to extract the question sentence that was the most important in finding the correct class. However, the extracted question sentence is not always a summary of the question. Consider the last sentence “Will it or will it not?” for the aforementioned Table 1 question. This last sentence is important in finding the class of this question, which is a yes/no question, but is not appropriate as a summary, because it is impossible to understand what is being asked merely from “Will it or will it not?”

Many existing extractive approaches select the sentences to be included in the summary on the basis of calculated scores for each sentence. The scores are often calculated by the TF-IDF measure (Luhn, 1958), the similarity measure between sentences (Mihalcea and Tarau, 2004) and an approximation made by a regression model of the

²<http://duc.nist.gov>

ROUGE score or the bigram frequency included in a summary (Peyrard and Eckale-Kohler, 2016; Li et al., 2013). Other approaches consider summarization tasks as a classification problem. They adopt supervised machine learning techniques to solve them (Hirao et al., 2002; Shen et al., 2007).

Abstractive summarization approaches include methods based on syntactic transduction (Dorr et al., 2003; Zajic et al., 2004) or statistical machine translation models (Bank et al., 2010; Wubben et al., 2012; Cohn and Lapata, 2013) and templates (Oya et al., 2014). In addition, encoder-decoder approaches have been proposed in recent years. They were originally applied to machine translation tasks (Luong et al., 2015; Bahdanau et al., 2015; Cao et al., 2017), and have been actively applied to other sequence-to-sequence tasks including sentence summarization (Rush et al., 2015; Kikuchi et al., 2016; Gu et al., 2016).

3 Data Analysis

We first carried out an analysis on the dataset provided by Yahoo! Answers, “Yahoo! Answers Comprehensive Question and Answers version 1.0”³. The data contains 4,484,032 question-title pairs posted between June 28, 2005 and October 25, 2007. On the CQA site, users can freely write a question text and its title. Thus, some of the pairs in the data can be regarded as question-summary pairs, but some others cannot. To obtain a dataset that can be used for training, we need to filter out the pairs that are not suitable for our objective. Furthermore, it is not clear how questions are summarized, i.e., whether by extractive or abstractive methods. Therefore, in this study, we first analyzed the data to clarify the following issues:

1. What are the characteristics of the pairs that cannot be regarded as question-summary pairs?
2. Can an extractive approach generate a summary equivalent to the title, or are abstractive approaches required?

3.1 Question text length

To characterize the question-title pairs that could not be regarded as question-summary pairs, we first focus on the number of sentences in question text. We randomly extracted the question-title

³<https://webscope.sandbox.yahoo.com/>

Table 2: Number of sentences in question text and proportion of question-summary pairs

No. of sentences in question text	Proportion
1	3/20
2	8/20
3	14/20
4	15/20
5	15/20

Table 3: Number of titles generated by extractive and abstractive approaches

Not a question-summary pair	5/20
Extractive approach can summarize	8/20
Abstractive approach needed	7/20

pairs that contained 1-5 sentences in the question text, and manually classified them as to whether they could be regarded as a question-summary pair or not. Table 2 shows the number of question-title pairs that can be regarded as question-summary pairs for question text size measured by the number of sentences.

This analysis showed that if there are two or fewer sentences in the question text, the pairs are unlikely to be question-summary pairs because the question texts tend to contain only peripheral information to support the question presented in the title. In contrast, if there are three or more sentences, the proportion of the question-summary pairs becomes high and substantially constant. This suggests that the number of sentences in a question text is one of the clues to find question-summary pairs.

3.2 Nouns overlapping between question and title

We show here an example that cannot be regarded as a question-summary pair.

Title:

Why is there often a mirror in an elevator?

Question text:

I just realized this when I was in an elevator. Does anybody know the reason? What is the history behind it?

This is not a question-summary pair because the question text does not express the content of the title. In such cases, people cannot grasp the gist of

the question text when only the title is presented. Here we focus on the words “mirror” and “elevator”; they appear in the title, but not in the question text. We actually observed many similar instances. This suggests that noun overlapping between a question and its title can be considered an important clue to determine whether the pair can be regarded as a question-summary pair or not.

3.3 Extractive vs. abstractive

We next analyzed question-summary pairs in terms of whether the summaries can be generated by an extractive method or an abstractive method is required. Specifically, we randomly selected pairs whose question text had 3-5 sentences and manually classified them into one of the following 3 categories: 1) The pair cannot be regarded as a question-summary pair, 2) An extractive method can generate a summary that is equivalent to the title, and 3) Others (i.e., an abstractive method might be needed to generate a summary that is equivalent to the title).

The manual classification results are shown in Table 3. We also show representative examples of question-summary pairs in Table 4.

Five out of 20 cases cannot be regarded as question-summary pairs. In Example 1 of Table 4, the questioner accidentally spilled buttered popcorn and needs to know how to remove it. However, the title “Please help!” does not contain enough information to grasp the gist of the question. In some cases, pronouns in the titles refer to nouns in the question text.

In eight of the 20 pairs, an extractive approach can generate a summary that is almost equivalent to the title. Example 2 in Table 4 is such a case. In this example, a summary can be generated by extracting the last sentence in the original content. However, if one takes the actual title into consideration, the idiom “get rid of” in the original question can be replaced by the word “remove”. Even if a question text can be summarized by an extractive method, the actual titles are often generated by abstractive approaches.

In the remaining seven pairs, the question texts cannot be summarized by an extractive approach, and abstractive approaches might be required. The category is further split into two subcategories. In the first subcategory, pronoun resolution as well as sentence extraction is needed to generate a summary. In the second subcategory, a short question

Table 4: Representative examples of pairs in Yahoo! Answers dataset

<p>Example 1 (The title does not express the content of the question text): I accidentally spilled buttered popcorn on my leather hospital shoe. It has dark spots on it now and I don't know how i can get them off. ... Title: Please help!</p>
<p>Example 2 (Extractive approaches can be applied.): I keep getting annoying Winfixer Pop Ups . I have tried all sorts of ad removal programs to get rid of them but without success . How can I get rid of them ? Title: How can one remove annoying pop ups ?</p>
<p>Example 3 (Abstractive approaches are required.): "The Simpsons" is one of the funniest shows ever . It's one of my favorites . Do you like it ? Title: Do you like "The Simpsons" ?</p>
<p>Example 4 (Abstractive approaches are required.): I want my chocolate chip cookies to be thicker and kind of gooey-crispy outside, chewy inside. I've experimented with various recipes and various oven temperature, but my cookies always turn out thin and flat. Why? What am I doing wrong? Title: Why do my chocolate chip cookies always turn out thin and flat?</p>

follows a lengthy explanation.

In Example 3 in Table 4, the pronoun "it" in the main question "Do you like it?" refers to the program name "the simpsons", which appeared previously. Therefore, the summary does not contain enough information to grasp the gist if we naively apply any extractive approaches. The short main question "why" in Example 4 follows the explanation about baking cookies. In examples such as these, we cannot naively use extractive approaches to generate an understandable summary, because the title is generated by picking up the information from multiple sentences.

4 Dataset and Methodology

In this section, we describe how we created a dataset consisting of question-summary pairs, and a number of methods for question summarization.

4.1 Dataset

As training data for extractive and abstractive models, we use question-title pairs posted to a CQA site, namely, "Yahoo! Answers Comprehensive Question and Answers version 1.0". The original data contains 4,485,032 question-title pairs. However, not all of them are question-summary pairs. To filter out the pairs that are not question-summary pairs, we removed the pairs that match

at least one of the following conditions:

Multiple sentences in the title Comprising two or more sentences

Long Title The title consists of over 16 words.

Short Title The title consists of three or less words.

Overlap of nouns

No nouns in the title appear in the question text.

Short Question Text

The question text consists of two or less sentences.

Long Question Text

The question text consists of over five sentences.

After applying the filtering, we obtained 251,420 pairs⁴. We use the pairs for training extractive and abstractive models, and also for evaluations.

⁴Note that the data still contains non-English question-title pairs, since the language recognition is not perfect.

4.2 Extractive approaches

As extractive approaches, we adopted rule-based approaches and machine learning based approaches.

4.2.1 Rule-based approaches

As rule-based approaches, we used three rules to compare: “Lead Sentence”, “Lead Question”, and “Last Question”. The first sentence presented (Lead Sentence) is known as a strong baseline for generic summarization tasks. However, in the question summarization, the summaries should be also questions. Therefore, we adopted methods to select a question in the input by heuristic rules, choosing the first question (Lead Question) and the last question (Last Question). A sentence was determined to be a question if the last character is “?” or the first word is an interrogative word.

4.2.2 Machine learning-based approaches

We will here introduce two types of machine learning-based methods: a classification-based method and a regression-based method.

The regression-based model predicts the ROUGE-2 F-measure score for each sentence in the input question. After the prediction step finishes, the model outputs the sentence with the highest predicted ROUGE score. To train the regression model, we first calculated the ROUGE score for each sentence in the training set, regarding the title as a reference summary. After the calculation, we trained Support Vector Regression (SVR) (Basak et al., 2007).

The classification-based method predicts the sentence with the largest ROUGE-2 F-measure. In the training phase, we regarded the questions which had the highest ROUGE score and consisted of at least four words as positive instances. Other questions were used as negative instances. We adopted Support Vector Machine (SVM) (Suykens and Vandewalle, 1999) as a classifier. If the SVM classifies more than one sentence in a single input document as positive, then our method outputs the first question. In contrast, if the SVM classifies all questions in the input as negative, then the model outputs the first question. It outputs the first sentence if there is no question in the output. A sentence is regarded as a question if the last character is “?” or the first word is an interrogative word.

We trained the regression and classification models by using the following features:

- Word unigram
- Sentence length
- Whether the sentence is the initial sentence
- Whether the sentence is the first question
- Presence of other question sentences

All features are expressed as binary: i.e., 0 or 1. For unigram features, we adopted features that appeared at least five times in the training set. We used four sentence-lengthy features: the sentence had less than three, less than five, more than 10, and more than 15 unigrams.

4.3 Abstractive approaches

We adopted encoder-decoder based methods for abstractive approaches. Specifically, we trained three models: a vanilla encoder-decoder model, an encoder-decoder model with an attention mechanism and an encoder-decoder model with a copying mechanism.

Questions in the CQA site are usually composed of 3-5 sentences, which are longer than in the usual settings used in machine translations tasks. Therefore, in addition to the vanilla model, we trained a model with the attention mechanism (Luong et al., 2015). To reduce the model size, we replaced low-frequency words with the special token UNK, which is a well-known technique. After the preprocessing, the vocabulary size was reduced to approximately 136,000. In summarization tasks, the words in the input are often likely to appear in the summary. Therefore, we also adopted the encoder-decoder model with the copying mechanism (Gu et al., 2016), which can select words in the input as words in the output.

We briefly describe those models below.

4.3.1 Vanilla encoder-decoder

The encoder-decoder model is composed of two elements: an encoder and a decoder. The encoder receives the input question x_1, \dots, x_n , and converts it into the fixed-length continuous value vector h_τ :

$$h_\tau = f(x_\tau, h_{\tau-1}), \quad (1)$$

where f represents an activation function used in any Recurrent Neural Network (RNN). In this study, the vanilla encoder-decoder and the attention models use Long Short-Term Memory (Hochreiter and Schmidhuber, 1997), and Gated

Recurrent Unit (GRU) (Cho et al., 2014) is used in the model with the copying mechanism. All encoder-decoder models adopt bidirectional-RNNs as the encoder.

The decoder receives the last hidden state of the encoder and generates a sentence. Each node in the decoder receives the previously generated word and the hidden state generated in the previous time step to calculate the hidden state \mathbf{s}_t and the *softmax* function. The occurrence probability of y_t is calculated by using the hidden state \mathbf{s}_t and a *softmax* function:

$$\mathbf{s}_t = f(y_{t-1}, \mathbf{s}_{t-1}), \quad (2)$$

$$p(y_t|y_{<t}, \mathbf{x}) = \text{softmax}(g(\mathbf{s}_t)). \quad (3)$$

The conditional probability given the input sequence \mathbf{x} can be decomposed to the product of the probabilities of generating words as follows:

$$p(\mathbf{y}|\mathbf{x}) = \prod_{t=1}^m p(y_t|y_{<t}, \mathbf{x}). \quad (4)$$

In the training, we estimated the parameter values so that they maximize the log-likelihood of the training set:

$$\log p(\mathbf{y}|\mathbf{x}) = \log \sum_{j=1}^m p(y_j|y_{<j}, \mathbf{x}). \quad (5)$$

In the test phase, the model generates the output by beam-search.

4.3.2 Encoder-decoder with attention

In the vanilla encoder-decoder model, the input document is encoded into the hidden state \mathbf{h}_n . The decoder receives the hidden state as the initial state \mathbf{s}_0 of the decoder ($\mathbf{s}_0 = \mathbf{h}_n$). In contrast, the encoder-decoder model with the attention mechanism uses the context vector \mathbf{c}_t represented as a weighted sum of the hidden states of the encoder:

$$\mathbf{c}_t = \sum_{\tau=1}^n \alpha_{t\tau} \mathbf{h}_\tau, \quad (6)$$

where $\alpha_{t\tau}$ is the weight of the t -th word of the input at time step τ and can be calculated as

$$\alpha_{t\tau} = \frac{\exp(\mathbf{s}_t \cdot \mathbf{h}_\tau)}{\sum_{\mathbf{h}'} \exp(\mathbf{s}_t \cdot \mathbf{h}')}. \quad (7)$$

Finally, the conditional probability of the word y_t is calculated by the *softmax* function:

$$\tilde{\mathbf{h}} = \tanh(\mathbf{W}_c[\mathbf{c}_t; \mathbf{h}_t]), \quad (8)$$

$$p(y_t|y_{<t}, \mathbf{x}) = \text{softmax}(\mathbf{W}_s \tilde{\mathbf{h}}_t). \quad (9)$$

Table 5: Evaluation on ROUGE-2

	Recall	F-measure
Lead	39.4	27.0
Last-Q	42.6	33.9
Lead-Q	45.3	34.5
Classification	44.3	35.1
Regression	44.7	29.7
EncDec	3.5	2.6
EncDec+Attn	38.5	38.5
CopyNet	47.4	42.2

4.3.3 Encoder-decoder with copying mechanism

As the encoder-decoder model with the copying mechanism, we used the model proposed by Gu et al. (2016). In the model, the decoder calculates the probability of generating y_t at time step t by using a mixed probabilistic model of two modes: the generate-mode and the copy-mode:

$$p(y_t|y_{<t}, \mathbf{x}) = p_{gen}(y_t|\mathbf{s}_t, y_{t-1}, \mathbf{c}_t, \mathbf{x}) + p_{copy}(y_t|\mathbf{s}_t, y_{t-1}, \mathbf{c}_t, \mathbf{x}), \quad (10)$$

where p_{gen} is the probability calculated by the generate-mode using the same scoring function proposed by Bahdanau et al. (2015) and p_{copy} is the probability that the copy-mode will “copy” the word y_t from the input document if $y_t \in \mathbf{x}$. If $y_t \notin \mathbf{x}$, then p_{copy} is set to 0. Thus, the model increases the probability that words in the input will be generated. Refer to the original paper by Gu et al., (2016) for more detailed explanations.

5 Experiments and Evaluation

We adopted ROUGE-2 (Lin, 2004) as a metric for the automatic evaluation. Additionally, we carried out an evaluation on a 5-point scale scored by human judges. In this section, we will describe the details of model training, automatic and manual evaluations we conducted.

5.1 Experimental setting and training

The created dataset contained 251,420 pairs. We used 90% of the data for training. We separate the remaining equally for the development and the test set. Thus, we split the dataset into 18 (train):1 (development):1 (test).

As an implementation of SVM and SVR, we used Liblinear (Fan et al., 2008). The linear kernel was used as the kernel function for SVM and

SVR. We tuned the regularization parameter C on the development set.

For the encoder-decoder model, we adopted 256 dimensions for word embedding and hidden layers, setting the batch size to 64. The words that appeared at least twice in the training set were used in training, and other words were replaced by the special token UNK. The end of a sentence was represented by another special token, i.e., EOS. For testing, we used the model which achieves the minimum loss function in the development set. When the encoder-decoder model does not output the EOS token within 20 words in the decoding step, the model outputs the first question in the input text. If there is no question in the input, the first sentence is output.

5.2 Evaluation with ROUGE

In our task setting, the number of sentences in the output was limited to one. There was no length constraint in terms of the number of characters or words. However, we assumed that a better summary would contain more focused content in a shorter output. Therefore, as the evaluation metric, we adopted the ROUGE-2 F-measure in addition to Recall.

Table 5 shows ROUGE-2 scores for a number of methods. Lead method (Lead), Last Question (Last-Q) and Lead Question (Lead-Q) are rule-based methods. The classification-based model (Classification) and regression-based model (Regression) are non-neural machine-learning based methods. Vanilla encoder-decoder (EncDec), encoder-decoder with an attention mechanism (EncDec+Attn) and encoder-decoder with a copying mechanism (CopyNet) are neural-network based methods.

In rule-based extractive methods, the lead method, which simply outputs the first sentence, is known as a strong baseline. However, in question summarization, selecting questions such as Lead Question or Last Question increases the ROUGE score. Lead Question is a strong baseline in particular.

Classification was as good as Lead-Q, because most input texts contained only one to two question sentences; as a result, the two methods mostly output the same results. The encoder-decoder models with an attention and with a copying mechanism achieved a significantly higher ROUGE score than the extractive approaches. Note that

the vanilla encoder-decoder model yielded significantly low ROUGE score, because it generated mostly the same question for all input texts. The input sequences in this task were longer than those in machine translation. As Loung et al. (2015) mentioned, encoder-decoder models without an attention do not work well for long sentences. Therefore, the model failed to decode the sequence. On average, outputs of extractive methods are longer than those of abstractive methods. This accounts for the relatively low F-measure and competitive recall obtained with extractive methods.

5.3 Manual evaluation

Since our work is the first attempt to address the task, no other annotated data exists. To make up for this, we adopted manual evaluation in addition to the evaluation using ROUGE scores. The manual evaluation was performed using the “Crowdfloer”, which is a crowdsourcing service⁵.

The evaluators were presented with a question and four summaries from different models: Human, and the best model in each group, Lead-Q, Classification and CopyNet. They were asked to rate each summary on 1-5 scale: very poor(1), poor(2), acceptable(3), good(4) and very good(5). The evaluation criteria were “grammaticality” and “focus”, which are based on the criteria used in DUC. We asked the evaluators to give a higher score for the aspect of “focus” if a summary expressed the main focus of the input text. We also asked them to give a high “grammaticality” score to a grammatical summary. To control the quality of the evaluation, we randomly presented clearly ungrammatical and non-focused summaries as test to all evaluators, and excluded the evaluations by evaluators who failed the test questions. The data for the manual evaluation consists of 100 randomly selected instances from the test set for the automatic evaluation. Each instance was evaluated by 3 evaluators.

The results on “grammaticality” and “focus” are respectively shown in Tables 6 and 7. The tables show the number of times each method on a row was evaluated higher than another method on a column. Evaluations on both criteria showed a trend similar to that of the automatic evaluation: Human achieved the highest score, Lead-Q and Classification were competitive, and CopyNet got

⁵<https://www.crowdfloer.com>

Table 6: Human Evaluation-Focus-

	Human	Lead-Q	Classification	CopyNet
Human	-	135	135	103
Lead-Q	69	-	11	72
Classification	70	10	-	68
CopyNet	89	107	103	-

Table 7: Human Evaluation - Grammaticality -

	Human	Lead-Q	Classification	CopyNet
Human	-	85	86	63
Lead-Q	51	-	10	54
Classification	54	10	-	53
CopyNet	69	79	82	-

Table 8: Example outputs from each model.

Question Text
The Simpsons is one of the funniest shows ever . its one of my favorites . do you like it ?
Human : Do you like The Simpsons?
Lead-Q : Do you like it?
Classification : Do you like it?
EncDec+Attn: Do you like UNK?
CopyNet : Do you like The Simpsons?

the better score than Lead-Q and Classification.

CopyNet was judged better than Human in terms of focus in 89 cases, and in terms of grammaticality in 69 cases, because Human sometimes removes specific information. For example, CopyNet generated “How do you stop the itching after shaving?”, while Human summary omits “after shaving”. In terms of grammaticality, some Human summaries are not complete sentences such as “The best way to get money?”. Therefore, Human was sometimes judged lower than CopyNet.

5.4 Qualitative analysis

In this section, we review the outputs of each model. Table 8 shows examples of each model.

The outputs of Lead-Q and Classification, which are generated by extraction, include the unresolved pronoun “it”. This makes the summary not clearly focused. Such cases are often seen in lengthy questions that contain long supplementary explanations followed by a short question. These examples suggest that extractive approaches are intrinsically not suitable for cases where informa-

tion needs to be picked up from multiple sentences in the input. In contrast to extractive approaches, the output of CopyNet properly resolves this; “it” is resolved by “The Simpsons” even if the model needed to use information across sentences. The EncDec+Attn model faces the difficulty in generating low frequency words such as “The Simpsons”; its output includes the special token UNK. This problem was also reported in other papers on encoder-decoder models (Bahdanau et al., 2015). Adding the copying mechanism effectively solved the problem.

6 Conclusion

We proposed a novel task of summarizing lengthy questions into simple questions that clearly express the focus of the original content. We created a dataset by filtering out inappropriate instances from a dataset provided by a CQA site, and developed extractive/abstractive models. Our results show that abstractive approaches outperform extractive approaches both in automatic and human evaluations. Since all the methods were inferior to the Human method in terms of performance, we believe there is still room for improvement. As a subject for future work, we will extend the approach to cover question summarization tasks that have multiple focuses. We are also interested in how existing analyzers such as coreference resolvers can improve the performance.

Concept-Map-Based Multi-Document Summarization using Concept Coreference Resolution and Global Importance Optimization

Tobias Falke, Christian M. Meyer, Iryna Gurevych

Research Training Group AIPHES and UKP Lab
Department of Computer Science, Technische Universität Darmstadt
<https://www.aiphes.tu-darmstadt.de>

Abstract

Concept-map-based multi-document summarization is a variant of traditional summarization that produces structured summaries in the form of concept maps. In this work, we propose a new model¹ for the task that addresses several issues in previous methods. It learns to identify and merge coreferent concepts to reduce redundancy, determines their importance with a strong supervised model and finds an optimal summary concept map via integer linear programming. It is also computationally more efficient than previous methods, allowing us to summarize larger document sets. We evaluate the model on two datasets, finding that it outperforms several approaches from previous work.

1 Introduction

Concept-map-based multi-document summarization (MDS) is a variant of traditional MDS that produces structured summaries in the form of a concept map instead of a coherent text (Falke and Gurevych, 2017a). A *concept map*, introduced by Novak and Gowin (1984), is a labeled graph showing *concepts* as nodes and *relations* between them as edges. As an example, consider a document collection discussing treatments for ADHD. A (very) small concept map would be

in which *Caffeine* and *ADHD* are concepts, while *reduces* is a relation, forming the *proposition* “*Caffeine* – *reduces* – *ADHD*”.

A summary in this form has interesting applications, as it provides a concise overview of a

¹Source code available at <https://github.com/UKPLab/ijcnlp2017-cmaps>

document collection, structures it across document boundaries and can be used as a table-of-contents to navigate in the collection. Several studies report successful applications of concept maps in this direction (Carvalho et al., 2001; Briggs et al., 2004; Richardson and Fox, 2005; Villalon, 2012; Valerio et al., 2012; Falke and Gurevych, 2017b).

The task we consider in this work is defined as follows: *Given a set of documents on a certain topic, extract a concept map that represents the most important content on that topic, satisfies a specified size limit and is connected.*

Although work dealing with the automatic extraction of concept maps from text exists (§2), current methods have several limitations. First, most approaches do not attempt to detect coreferences between extracted concepts. For instance, if both *ADHD symptoms* and *symptoms of ADHD* are found, they treat them as separate concepts. In a concept map, such duplicate concepts are immediately visible to a user, waste valuable space and make it harder to look for relations of that concept, as they are spread among the duplicates.

Second, previous work mostly focused on the extraction of concepts and relations, largely ignoring the subsequent selection step necessary to produce a summary of manageable size. Existing studies suggested only a few unsupervised metrics to determine important elements, leaving it unclear whether the task can benefit from more sophisticated supervised approaches. In addition, no method has been suggested to find an optimal summary concept map under the constraints of the size limit and connectedness.

Third, most approaches for concept map extraction and also traditional summarization are typically evaluated on small document sets where the computational complexity of methods is less relevant. We work on a corpus with sets of around 40 documents that should be summarized, which,

while being a realistic real-world application scenario, is 10 to 15 times larger than traditional DUC² and TAC³ summarization corpora. This poses an additional challenge that requires the methods to scale to these sizes.

In this work, we propose a new model for concept-map-based MDS that overcomes the aforementioned issues. Building upon previous work in textual summarization, coreference resolution and semantic similarity, it learns to identify and merge coreferent concepts, scores them for importance and finds an optimal summary concept map via integer linear programming (ILP). We also present several optimizations that make it possible to apply our model to large document sets. Experiments on two datasets demonstrate the efficacy of the model, which outperforms several methods suggested in previous work.

2 Related Work

Previous approaches to construct concept maps from text, working with either single documents (Zubrinic et al., 2015; Villalon, 2012; Valerio and Leake, 2006; Kowata et al., 2010) or document clusters (Qasim et al., 2013; Zouaq and Nkambou, 2009; Rajaraman and Tan, 2002), all follow a similar pipeline: concept extraction, relation extraction, scoring and concept map construction.

During concept extraction, most approaches apply hand-written patterns to extract labels for concepts from syntactic representations, focusing on noun phrases-like structures. Similar approaches are used to extract relation labels for pairs of concepts. Alternatively, semantic representations have been suggested as a more easily accessible representation compared to syntax (Falke and Gurevych, 2017c; Olney et al., 2011).

Given these extractions, few attempts beyond string matching have been made to identify unique concepts. Valerio and Leake (2006) suggest to consider only certain part-of-speech during string matching, while the earlier approach of Rajaraman and Tan (2002) uses a clustering algorithm based on a vector space model. Our work proposes a more comprehensive approach, leveraging state-of-the-art semantic similarity measures and set partitioning to also detect coreferent concept labels that are paraphrases.

The selection of a summary-worthy subset of

all extracted concepts and relations was largely ignored in previous work, as many studies did not have a focus on summarization. However, when dealing with larger document clusters, this step becomes inevitable. Zubrinic et al. (2015) suggest a tf-idf metric on the level of concept labels, Villalon (2012) uses Latent Semantic Analysis and Valerio and Leake (2006) suggest simple concept frequencies. Our model goes a step further and combines these with other features in a supervised model, which works well for textual summarization (Cao et al., 2016; Yang et al., 2017).

For building a summary concept map that is connected, does not exceed the target size and contains as many important concepts as possible, we are only aware of a heuristic approach suggested by Zubrinic et al. (2015). It iteratively removes low-scoring concepts from all extractions until a connected graph of the target size remains. However, it is not guaranteed that the optimal subset is found. Integer Linear Programming (ILP) has been successfully used to solve the knapsack problem that arises in sentence-level extractive summarization (McDonald, 2007). In our task, the knapsack problem is not present, as both the scoring and size restriction are defined on the level of concepts, but the connectedness requirement poses a similar constraint that restricts the subset selection. ILP formulations for such a problem have been proposed for graph-based abstractive summarization (Li et al., 2016; Liu et al., 2015). In our work, we transfer these ideas to concept maps and evaluate their efficacy. This is important, as the methods were originally proposed for different kinds of graphs (event networks and AMR graphs) and introduced to generate abstractive textual summaries, while we use our concept map graphs directly as the final summaries.

3 Model

Given a document set D , topic t and size limit L , our model applies the three stage approach that is illustrated in Figure 1 to create a summary concept map: (1) Concept and Relation Extraction, (2) Concept Graph Construction, (3) Graph Summarization. We describe these steps in the following sections in detail.

3.1 Concept and Relation Extraction

The goal of the first step is to identify spans in the documents that can be used as labels for concepts

²<http://duc.nist.gov/>

³<https://tac.nist.gov/>

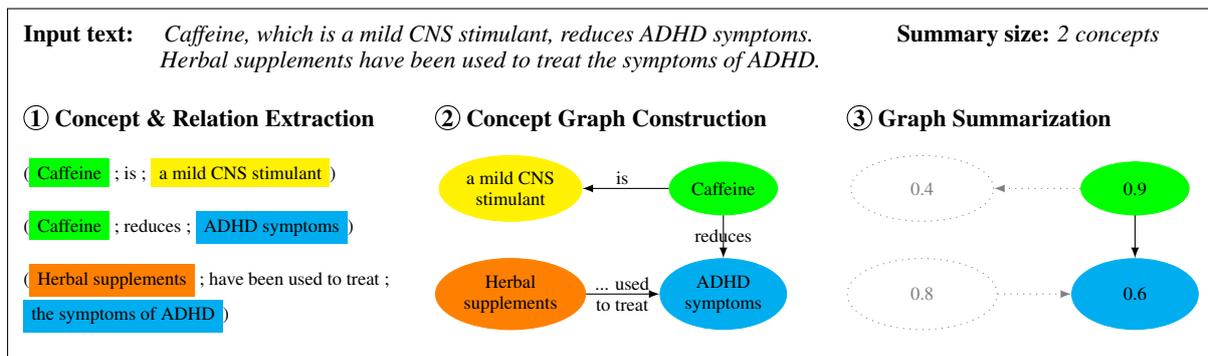

Figure 1: Conceptual illustration of the model: (1) Extracted propositions are (2) connected to a graph based on coreference and (3) the best subgraph, here of target size 2, is selected after scoring concepts.

and relations in the concept map.

Extraction For the extraction, we rely on Open Information Extraction (Banko et al., 2007), an approach that extracts binary *propositions* from text. Given a sentence such as

Caffeine, which is a mild CNS stimulant, reduces ADHD symptoms.

an Open IE system extracts the tuples:

(Caffeine ; is ; a mild CNS stimulant)
(Caffeine ; reduces ; ADHD symptoms)

This representation is particularly useful because it is very similar to propositions in a concept map, requiring only a few postprocessing steps. We use the extracted tuples (m_1, r, m_2) , after applying the postprocessing steps discussed below, and use their arguments m_1, m_2 as *concept mentions* and predicates r as *relations*.

Filtering To ensure that the arguments of the extractions are meaningful concept mentions, we filter the candidate set with two simple constraints: First, an argument has to contain at least one noun token, and second, it cannot be longer than ten tokens. This removes overly long arguments that are clauses rather than suitable labels for concepts.

Post-Processing In addition, we apply three rule-based post-processing steps that refine the extractions in order to increase the recall of the candidate sets. First, using off-the-shelf coreference resolution, we try to resolve pronominal anaphora in arguments of the propositions.

Second, if an argument is a conjoining construction, as indicated by *conj*-edges in a dependency parse, we break it down into its conjuncts and in-

troduce separate extractions for each of them:

(Caffeine ; works with ; young children and teens)

would be split into two extractions

(Caffeine ; works with ; young children)
(Caffeine ; works with ; teens)

And third, if the second argument starts with a verb, as in the following example,

(Herbal supplements ; have been used to ; treat the symptoms of ADHD)

we move that verb and subsequent prepositions to the predicate. In the example, the predicate is extended to *have been used to treat*, reducing the second argument to *the symptoms of ADHD*.

3.2 Concept Graph Construction

Given the concept mentions extracted in the previous step, several of these mentions may refer to the same concept. While this is obvious if the mentions are identical (e.g. *Caffeine* in the first two extractions of Figure 1), they could also differ slightly (e.g. *ADHD symptoms* and *the symptoms of ADHD*) or be synonyms or paraphrases without any lexical overlap. In this step, we connect all extracted propositions (m_1, r, m_2) to a concept graph by grouping coreferent mentions to a set of unique, non-redundant concepts (see Figure 1). As this special form of concept-specific and cross-document coreference goes beyond the capabilities of off-the-shelf coreference resolution systems, we propose a solution based on pairwise classification and set partitioning.

3.2.1 Pairwise Mention Classification

Given the set M of concept mentions, we want to determine whether a pair $(m_1, m_2) \in M^2$ refers to the same concept or not. We model this as a binary classification problem using a log-linear model

$$P(y = 1 | m_1, m_2, \theta) = \sigma(\theta^T \phi(m_1, m_2))$$

where a positive classification, $y = 1$, means that the mentions are coreferent, $\phi(m_1, m_2)$ are features for a pair of mentions, σ is the sigmoid function and θ are the learned parameters.

As features we use different similarity measures that indicate if both terms have the same meaning. Lexical features are normalized Levenshtein distance and the overlap (Jaccard coefficient) between stemmed content words. To capture similarity on a semantic level, we use cosine similarity between concept embeddings⁴ and two measures using word-level similarity based on Latent Semantic Analysis (Deerwester et al., 1990) and WordNet (Resnik, 1995) together with a word alignment method, both implemented in Semilar (Rus et al., 2013). The selection of these features is driven by practical reasons: Since the number of pairs is in $\mathcal{O}(|M|^2)$, the feature set has to be small and restricted to fast-to-compute metrics to make the approach computationally feasible.

3.2.2 Mention Partitioning

The task of grouping mentions to concepts can be seen as finding a partition of M based on the pairwise classifications. However, this is non-trivial, as single predictions might conflict: Both (a, b) and (b, c) could be classified as coreferent, but not (a, c) . Formally, the relation of all coreferent pairs $S \subseteq M^2$ has to be an equivalence relation, i.e. reflexive, symmetric and transitive, to represent a consistent partitioning.

For a similar problem, Barzilay and Lapata (2006) propose to use ILP to find a valid partitioning that maximally agrees with the pairwise classifications. Let $x_p \in \{0, 1\}$ indicate the coreference of mentions $p = (m_1, m_2)$ and be $c(p) = P(y = 1 | m_1, m_2)$. Then they optimize the assignments x_p to maximize

$$\sum_{p \in M^2} c(p) x_p + (1 - c(p)) (1 - x_p) \quad (1)$$

⁴Using the sum of vectors for all tokens; 300-dimensional word2vec Google News embeddings (Mikolov et al., 2013).

Algorithm 1 Greedy Local Partitioning Search

Input: pairwise predictions $c(p)$ for $p \in M^2$

Output: coreferent pairs $S \subseteq M^2$

```

1: function SEARCH( $x, y$ )
2:    $S \leftarrow \{ p \mid c(p) \geq 0.5 \}$ 
3:    $b \leftarrow \text{SCORE}(S)$ 
4:    $S_m \leftarrow \text{SHUFFLE}(\text{TRANSREDUCTION}(S))$ 
5:   for  $p \in S_m$  do
6:      $S' \leftarrow S \setminus \{p\}$ 
7:     if  $b < \text{SCORE}(S')$  then
8:        $b \leftarrow \text{SCORE}(S')$ ,  $S \leftarrow S'$ 
9:   return  $\text{TRANCLOSURE}(S)$ 
10: function SCORE( $S$ )
11:    $S^+ \leftarrow \text{TRANCLOSURE}(S)$ 
12:   return Compute Equation 1 for  $S^+$ 

```

under the transitivity constraints

$$x_{p_i} \geq x_{p_j} + x_{p_k} - 1 \quad (2)$$

for all $p_i, p_j, p_k \in M^2$ where $i \neq j \neq k$. Unfortunately, this ILP needs $\mathcal{O}(|M|^2)$ variables and $\mathcal{O}(|M|^3)$ constraints, which makes it difficult to solve for our problem (where $|M|$ is up to 20k and we thus have up to 400 million variables and 8 trillion constraints). As an alternative approach, we use an approximate optimization algorithm.

Algorithm 1 shows our greedy local search algorithm. It creates the transitive closure over all positive classifications as the initial solution and computes the objective function (lines 2-3). This solution is a very aggressive grouping that joins as many mentions as possible, ignoring all negative classifications. The algorithm then tries to iteratively improve this solution by removing one positive classification at a time (line 6) if that improves the objective (lines 7-8). Removals are only tested for pairs in the transitive reduction of the initial solution (lines 4-5), as removing others would not change the partitioning. This approach still runs for several hours on large problem instances due to the expensive calculation of SCORE (lines 11-12), making more complete local searches, using best-first or beam search, impractical.

As a result, we obtain a relation S that partitions M into a set of sets $C = \{C_1, \dots, C_n\}$ where each C_i is a set of mentions representing a concept.

3.2.3 Graph Construction

Using the partitioning, we can now connect the extracted propositions to a graph $G = (C, R)$ in

which the nodes are concepts C and an edge with label r exists for every proposition (m_1, r, m_2) between the nodes of the concepts of m_1 and m_2 . For each concept C_i , we select one mention $m_l \in C_i$ as its label. We experimentally found that using the most frequent mention, breaking ties by choosing the shortest, is a good heuristic to choose the most generic and representative label.

3.3 Graph Summarization

With the concept graph $G = (C, R)$ built from the documents, we can cast the selection of a summary concept map as a subgraph selection problem:

Given G , find a subgraph $G' = (C', R')$ with $C' \subseteq C$ and $R' \subseteq R$ that maximizes

$$\sum_{C_i \in C'} s(C_i) \quad (3)$$

such that the subgraph is connected and satisfies the size constraint $|C'| \leq L$. With $s(C_i)$, we denote the importance of concept C_i .

3.3.1 Subgraph Selection

The selection of a subgraph that maximizes Equation 3 can be formulated as an ILP. Let x_i be a binary decision variable that represents whether concept C_i is part of the subgraph. Then, the objective can be written as

$$\max \sum_{i=1}^{|C|} x_i s(C_i) \quad (4)$$

subject to⁵

$$x_i \in \{0, 1\} \quad \forall i \in C \quad (5)$$

$$\sum_{i=1}^{|C|} x_i \leq L. \quad (6)$$

To ensure that the selected subgraph is connected, we introduce flow variables following previous work (Li et al., 2016; Liu et al., 2015). Let f_{ij} be a non-negative integer variable capturing the flow from concept C_i to C_j . We only introduce flow variables for concept pairs that have a relation in R . The constraints

$$f_{ij} \leq x_i \cdot |C| \quad \forall (i, j) \in R \quad (7)$$

$$f_{ij} \leq x_j \cdot |C| \quad \forall (i, j) \in R \quad (8)$$

$$\sum_i f_{ij} - \sum_k f_{jk} - x_j = 0 \quad \forall j \in C \quad (9)$$

$$f_{ij} \in \mathbb{N} \quad \forall (i, j) \in R \quad (10)$$

⁵To simplify the notation, we write $i \in C$ instead of $i \in \{1, \dots, |C|\}$ and correspondingly for R .

enforce that flow can only move between concepts that are selected (7,8) and a selected concept consumes one unit of flow (9). Further, let $i = 0$ be a virtual root node and e_{0i} a virtual edge from the root to each concept. The additional constraints

$$|C| \cdot e_{0i} - f_{0i} \geq 0 \quad \forall i \in C \quad (11)$$

$$\sum_{i=1}^{|C|} e_{0i} = 1 \quad (12)$$

$$\sum_{i=1}^{|C|} f_{0i} - \sum_{i=1}^{|C|} x_i = 0 \quad (13)$$

$$e_{0i} \in \{0, 1\} \quad \forall i \in C \quad (14)$$

$$f_{0i} \in \mathbb{N}_0 \quad \forall i \in C \quad (15)$$

ensure that only one virtual edge can be active (12), that the virtual node can only send flow over this active edge (11) and that the total amount of flow sent from the root cannot exceed the size of the selected subgraph (13). As a consequence, if n concepts are selected, n units of flow are sent from the root over the edges of the graph and each selected concept consumes one of them. This is only possible if the subgraph is connected.

The above ILP formulation has the advantage that it only requires $\mathcal{O}(|C| + |R|)$ variables and constraints as opposed to $\mathcal{O}(|C|^2)$ with the flow constraints used by Li et al. (2016). For sparse graphs, where $|R| \ll |C|^2$, this leads to much smaller ILPs. We further leverage the fact that G is typically disconnected and solve separate ILPs for each connected component. Only with these measures, the ILP approach can be solved for the real-world problem sizes in our evaluation dataset.

3.3.2 Score Prediction

The subgraph selection introduced above relies on estimates $s(C_i)$ of a concept's importance. These scores are estimated with a linear model

$$s(C_i) = \vartheta^T \psi(C_i, t)$$

where $\psi(C_i, t)$ are features for a concept C_i in a document cluster on topic t . Parameters ϑ are learned with *SVM^{rank}* (Joachims, 2002). We use a rich set of features that are commonly used in summarization and keyphrase extraction and briefly describe them in the following section:

Frequency Concept frequency and document frequency based on the partitioned mentions. In addition, frequencies re-weighted with background inverse document frequencies from Google N-Grams (Klein and Nelson, 2009).

Position First, average and last position of a concept and the distance between first and last.

Topic Relatedness Relatedness of the concept to the topic, measured as the semantic similarity between the concept label and the document cluster’s topic description t . As similarities, we use the measures introduced in Section 3.2.1.

Length Length of shortest, average and longest mention measured in tokens and in characters.

Label Several features describing the concept label, including the number of stopwords, capitalization, part-of-speech and named entities.

Word Categories As suggested in recent work by Yang et al. (2017), dictionary-based features that capture general properties of words such as concreteness, familiarity or imagery, using the MRC Psycholinguistic Database (Coltheart, 1981), the LIWC dictionary and an additional list of concreteness values (Brysbaert et al., 2014).

In addition, we derive several features from the concept’s position in the concept graph G :

Centrality Measures Measures such as degree, closeness and betweenness centrality as well as PageRank scores that indicate the centrality of the node C_i in the graph G .

Concept Map HARD and CRD scores suggested by Reichherzer and Leake (2006) and their underlying metrics. They are slight variations or extensions of common graph metrics that were specifically developed to describe concept maps.

Graph Degeneracy Following Tixier et al. (2016) who show that graph degeneracy is helpful to identify keyphrases, we use the graph core number and core rank suggested by them.

All numeric features are discretized into bins, such that the final feature set has only binary features.

3.3.3 Finalization

After predicting scores for every concept and selecting the highest scoring subgraph with the ILP, we use this subgraph as the summary concept map. However, this graph might contain multiple edges between certain concepts. Because this is rare and the number of available relations is low, we use a simple heuristic and select the relation that was

Table 1: Benchmark datasets used in experiments. Values are averages per topic. Compression = tokens in concept map / tokens in documents.

extracted with the highest confidence in the first step. The resulting graph is the final summary.

4 Experimental Setup

4.1 Data

We evaluate our approach using two benchmark datasets and compare the generated concept maps against reference maps. As the first dataset, we use a recently published corpus by Falke and Gurevych (2017a) that provides summary concept maps for document clusters on educational topics. They were manually created using crowdsourcing and expert annotators. As the second dataset, we use a corpus in which the introductions of featured Wikipedia articles are used as summaries for web documents (Zopf et al., 2016). This property allows us to make use of the links to other Wikipedia pages in the summaries as annotations of concepts. In combination with Open Information Extraction, we can therefore automatically derive concepts and relations from the Wikipedia summaries to obtain a second corpus of summary concept maps.

We refer to these datasets as **EDUC** and **WIKI**. Table 1 shows their characteristics. Note that in both datasets the summaries are much smaller than the document sets, posing a challenging summarization task. In addition, the document clusters of EDUC are very large, constituting a challenging but real-world evaluation setting regarding computational efficiency. We randomly split both datasets into equally sized training and test sets.

4.2 Evaluation Metrics

As input, our model receives the documents to summarize, the corresponding topic description and the number of concepts in the reference concept map as the size limit. To compare a system-generated concept map with a reference concept

map we represent both as sets of propositions P , i.e. a set in which each element is the concatenation of a relation label with its two concept labels. We then calculate the overlap between the set P_S for the system map and the set P_R for the reference map. As the number of relations and thus propositions of the generated map can differ, we report precision, recall and F1-scores.

Our first metric based on **METEOR** (Denkowski and Lavie, 2014) has the advantage that it takes synonyms and paraphrases into account and does not solely rely on lexical matches. For each pair of propositions $p_s \in P_S$ and $p_r \in P_R$ we calculate the match score $meteor(p_s, p_r) \in [0, 1]$. Then, precision and recall per map are computed as:

$$Pr = \frac{1}{|P_S|} \sum_{p \in P_S} \max\{meteor(p, p_r) \mid p_r \in P_R\}$$

$$Re = \frac{1}{|P_R|} \sum_{p \in P_R} \max\{meteor(p, p_s) \mid p_s \in P_S\}$$

The F1-score is the equally weighted harmonic mean of precision and recall. Scores per map are macro-averaged over all topics.

As a second metric, we compute **ROUGE** (Lin, 2004), the standard metric for textual summarization. We concatenate all propositions of a map into a single string, s_S and s_R , and separate propositions with a dot to ensure that no bigrams span across propositions and the metric is therefore order-independent. We run ROUGE 1.5.5⁶ with s_S as the peer summary and s_R as a single model summary to compute ROUGE-2.

4.3 Implementation and Training

All source documents are preprocessed with Stanford CoreNLP 3.7.0 (Manning et al., 2014) to obtain tokenization, sentence splitting, part-of-speech tags, named entities, dependency parses and coreference chains. For Open Information Extraction, we use OpenIE-4⁷, a system developed at the University of Washington that is currently state-of-the-art according to a recent comparison (Stanovsky and Dagan, 2016). ILPs are solved with the IBM CPLEX optimizer.⁸

The concept coreference model is implemented using the logistic regression model of Weka (Hall

⁶Parameter: -n 2 -x -m -c 95 -r 1000 -f A -p 0.5 -t 0 -d -a

⁷<https://github.com/knowitall/openie>

⁸<https://ibm.com/software/commerce/optimization/cplex-optimizer/>

et al., 2009). For EDUC, we trained it on 17,500 pairs of mentions, and for WIKI, on 4,500 pairs of mentions, which were in both cases derived from the reference concept maps of the training part of the respective dataset.

The SVM^{rank} model for importance scoring is trained with Dlib⁹. We use the set of all extracted concepts from all topics in the training set and assign binary labels if these concepts also occur in the reference concept maps. The SVM then learns weights for all features such that the positive instances per topic are ranked higher than the negative instances. We tuned the regularization parameter C of the SVM by testing values from 0.1 to 100 with leave-one-out cross-validation on the training topics. The final models are trained on the full training set with the best parameter. We did this separately for all ablations of our model that produce different training data, obtaining best parameters of $C = 10$ for *coref=lem* on EDUC and all models on WIKI as well as $C = 30$ for *coref=doc* and *our model* on EDUC (see Table 2).

5 Results and Analysis

5.1 Evaluation Results

We compare our model against several previously suggested methods. As unsupervised methods, we include concept selection based on frequency (Valerio and Leake, 2006), denoted as *Valerio 06*, selection with idf-corrected frequencies (Zubrinic et al., 2015), *Zubrinic 15*, and using the popular *PageRank* algorithm (Page et al., 1999). For a fair comparison, we run all methods on the same extracted concepts and relations and with our ILP-based subgraph selection. In addition, we include the baseline method *Falke 17* published along with the EDUC corpus (Falke and Gurevych, 2017a), which includes a supervised importance scoring model based on a binary classifier. To the best of our knowledge, this is all existing work for this task to which we can compare the proposed model.

Table 2 shows METEOR and ROUGE-2 scores for all methods on both datasets. Our model outperforms all three unsupervised approaches significantly on both datasets, demonstrating the superiority of the supervised scoring model. With regard to *Falke 17*, which is supervised to a similar extent, the results are twofold: While our model improves in ROUGE-2, it has a lower METEOR score. We looked into these results in de-

tail and found that the high scores of *Falke 17* are due to heavy overgeneration during relation extraction, introducing many rather meaningless relations into the concept map.¹⁰ Hence, the method only obtains higher scores by sacrificing the quality of the extracted propositions.

To verify this observation, we carried out an additional human evaluation between the two systems, capturing aspects beyond the content-oriented automatic metrics. For each topic, the concept maps generated by both approaches were shown to five crowdworkers on Mechanical Turk and they were asked for their preference with regard to different quality dimensions.¹¹ Table 3 shows that our concept maps tend to have more meaningful and topic-focused propositions and are especially more grammatical and less redundant.

5.2 Analysis

Concept Coreference To analyze the contribution of our concept coreference detection and partitioning (§3.2.1, §3.2.2), we replaced it with two simpler baselines: merging concepts based on string matches after lemmatization (*coref=lem*), as done in previous work, and using per-document coreference chains detected by CoreNLP and merging them across documents by lemmatized string matching (*coref=doc*). Both alternatives cause a drop in both metrics on EDUC and WIKI, showing that our approach is important for the model’s performance. The baselines merge much less mentions than necessary but also tend to lump

¹⁰Note that METEOR scores can be improved by incorrect relations if they are between a correct pair of concepts, leading to a partial match of the proposition.

¹¹To control for the influence of graph layouting quality, we showed the concept maps as simple lists of propositions.

Dimension	<i>Falke 2017</i>	<i>Our</i>
Meaning	44%	56%
Grammaticality	31%	69%
Focus	44%	56%
Non-Redundancy	21%	79%

Table 3: Human preference judgments between concept maps generated on EDUC ($n = 75$).

too many too different mentions together. In contrast, our model can make many more merges based on semantic similarity and at the same time manages to avoid lumping effects by relying on the global partitioning approach.

Subgraph Selection To analyze the effectiveness of the subgraph selection (§3.3.1), we replaced the ILP approach with a greedy heuristic similar to Zubrinic et al. (2015): Given the graph of scored concepts, start with the most important one and select the best neighbor (by score, breaking ties by node degree) until the size limit is reached. While the ILP will always find the optimal solution and hence the best subgraph, this heuristic approach does not have such a guarantee. In fact, it found the optimal subgraph for only 35% of the topics, selecting a subgraph with an on average 0.63% (EDUC) and 1.30% (WIKI) lower objective function score in the other cases.

Row *w/o ILP* in Table 2 shows the effect on the summary concept map. While it is rather small for EDUC, the differences on WIKI are bigger – in line with the observation that the selected subgraphs are less optimal. A problem for this analysis are errors in the preceding scoring step: The optimal

¹²Approximate randomization test with $N = 10000$.

Method	Var.	Const.	Time (s)
(Li et al., 2016)	37M	75M	2670.61
by component	26M	52M	999.25
Our ILP	22k	31k	7.31
by component	18k	26k	5.61

Table 4: Comparison of average ILP size and runtime per topic for subgraph selection on EDUC.

subgraph according to the estimated scores might not be the best with regard to the gold standard, explaining the slightly higher METEOR scores on EDUC without the ILP. To control for this effect, we also tested the selection using gold scores $s^*(C_i)$ for all concepts C_i , demonstrating that the optimal subgraphs selected by the ILP are clearly superior (last two rows in Table 2).

Score Prediction The contribution of our supervised scoring model based on ranking SVMs (§3.3.2) can be seen in Table 2 when comparing it to the unsupervised approaches *PageRank*, *Vale-rio 06* and *Zubrinic 15*. Note that all models use the same concepts and relations as input and the same ILP-based subgraph selection. Our model clearly outperforms all of them. Looking into the learned weights for our set of features, we observed that the most helpful features are frequencies, in particular document frequency and idf-weighted concept frequency, and topic relatedness as well as page rank. To identify unimportant concepts (i.e. assigning low scores), the model makes use of concreteness values and the label’s length.

Runtime As mentioned earlier, the size of the document sets in EDUC resembles an interesting real-world setting that required us to pay special attention to complexity. Table 4 compares our subgraph selection ILP with the ILP formulation by Li et al. (2016). For the extracted graphs, with on average 4022 nodes and 5613 edges between them, our formulation leads to ILPs that are orders of magnitude smaller and can be solved in a fraction of the time.¹³ For both formulations, solving separate ILPs for each connected component in the graph further improves the runtime.

Error Analysis Table 5 shows the number of concepts and their recall at different steps in our model, which is a good indicator of bottlenecks.

¹³Times for running CPLEX multi-threaded on 24 cores. Direct comparison with the same data on the same machine.

Step	EDUC		WIKI	
	Count	Recall	Count	Recall
Mentions	8630	73.87	2549	88.93
Concepts	4022	60.27	1315	82.38
Subgraph	25	16.53	11	30.71

Table 5: Average number of concepts and recall per topic at different steps in our model.

The recall of mentions shows that performance is already lost during extraction, suggesting that better approaches would be beneficial. We observed that the problem is mainly the identification of correct spans rather than missing some concepts completely. A custom extraction model instead of relying on Open IE could resolve this.

With regard to concept coreference, we found that even more coreferent mentions could be grouped together. However, while the current model only accidentally merged mentions of different gold concepts in two cases across all topics, a stronger grouping could introduce more of these errors. Please also note that the drop in recall in Table 5 is due to exact string matching of the recall metric used here, missing concepts for which the selected cluster label is not exactly the gold concept. As the METEOR and ROUGE evaluations show, this is not a problem for the final result.

Finally, Table 5 reveals that one of the main bottlenecks is to determine the important concepts. On both datasets, but especially on the bigger document sets of EDUC, a substantial amount of recall is lost during this challenging step.

6 Conclusion

We proposed a new model for concept-map-based MDS and showed that it outperforms several methods from previous work. All of our contributions, including concept coreference resolution, the supervised scoring model and the global optimization approach contribute to its efficacy. In addition, it is able to scale to large document sets, which makes it much faster than previous methods in realistic scenarios with such documents sets.

Abstract

Existing work for abstractive multi-document summarization utilise existing phrase structures directly extracted from input documents to generate summary sentences. These methods can suffer from lack of consistence and coherence in merging phrases. We introduce a novel approach for abstractive multi-document summarization through partial dependency tree extraction, recombination and linearization. The method entrusts the summarizer to generate its own topically coherent sequential structures from scratch for effective communication. Results on TAC 2011, DUC- 2004 and 2005 show that our system gives competitive results compared with state-of-the-art abstractive summarization approaches in the literature. We also achieve competitive results in linguistic quality assessed by human evaluators.

1 Introduction

Multi-document summarization generates a textual summary from a corpus of documents dealing with a set of related topics. An optimum generated summary should encompass the most relevant and topically diverse content, which can represent the input corpus in stipulated summary space. Extractive multi-document summarization approaches pick out a subset of sentences to constitute the summary, which can be noisy and incoherent, as all the portions of a sentence may not be relevant for summary generation (Lin and Bilmes, 2011).

An abstractive multi-document summarizer, in contrast, infers the most relevant information and generates summary sentences exhibiting coher-

ence and fluency. There has been relatively little existing work on abstractive multi-document summarization. Bing et al. (2015) merge phrases that are extracted from input documents into a coherent summary. Banerjee et al. (2015) utilize multi-sentence compression for summarization. Both of the above approaches rely on sequential arrangement of phrasal or subsentential structures existing in the input corpus to generate summary. However, an ideal abstractive multi-document summarizer should enjoy the freedom to exhibit its own writing style and to generate the sentences from scratch.

We build a model to this end by leveraging syntactic dependencies. Input for our model is the set of syntactic dependency trees obtained by parsing sentences in the corpus to be summarized. Relevant and noise pruned partial tree structures are extracted from the set of dependency trees and different subsets of maximally relevant partial dependency structures are identified. Partial trees in different subsets are linearized to generate individual summary sentences. In this work, we utilize transition-based syntactic linearization approach proposed by Puduppully et al. (2016) to linearize a combination of partial trees and to generate a noise free summary sentence. The combinability of a set of partial trees to form a full dependency tree of a valid sentence is estimated using a generative model of syntactic dependency trees (Zhang et al., 2016). As a result, the model is allowed to exhibit its own learnt writing style while generating summary sentences.

The summaries generated by our system are evaluated on the DUC 2004, DUC 2007 and TAC 2011 multi-document summarization data-sets. In addition, we relied on human evaluation to evaluate factual accuracy and linguistic quality of generated summary sentences. To our knowledge this is the first work on multi-document abstrac-

tive summarization with syntactic dependency trees, which entrust the summarization model to generate summary sentences without exploiting any kind of subsentential or phrasal sequential structures originally present in the input corpus. Our code is released at https://bitbucket.org/litton_kurisinkel/tree_sum

2 Related Work

Text summarization can be achieved using extractive (Takamura and Okumura, 2009; Lin and Bilmes, 2011; Wang et al., 2008) and abstractive methods (Bing et al., 2015; Li, 2015). Extractive summarization has the advantage of output fluency due to direct use of human-written texts. However, extractive summarization cannot ensure a noise free and coherent summary. It can also result in a wrong inference to the reader due to out of context sentence usage. In contrast, abstractive summarization techniques can generate a noise-free summary out of most relevant information in the input corpus.

A subset of previous extractive summarization approaches utilized parsed sentence structures to execute noise pruning while extracting content for summary (Morita et al., 2013; Berg-Kirkpatrick et al., 2011). As a first step towards abstracting content for summary generation, sentence compression techniques were introduced (Lin, 2003; Zajic et al., 2006; Martins and Smith, 2009; Woodsend and Lapata, 2010; Almeida and Martins, 2013), but these techniques can merely prune noise, and cannot combine related facts from different sentences to generate new ones. (Banerjee et al., 2015) suggests a better way of doing sentence compression without harming linguistic quality.

Recent work attempts to solve the problem of abstractive multi-document summarization (Bing et al., 2015; Li, 2015), claiming that the method has the advantage of generating new sentences. Bing et al. (2015) extracts relevant noun phrases and verb phrases and recombines them to generate new sentences while Li (2015) system make use of semantic link network on basic semantic units (BSUs) to generate summary. Neither of these methods employ a learnt model to generate summary sentences. Instead, they make use sequential structures in the source text itself to construct the summary sentences. Cheng and Lapata (2016) propose a fully data driven approach using neu-

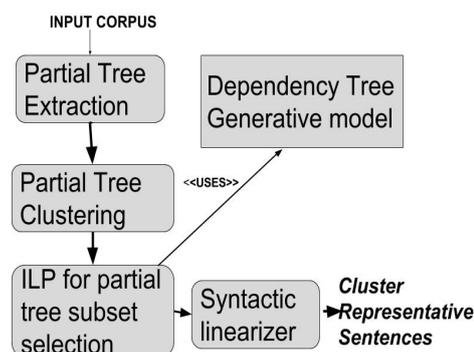

Figure 1: Overall approach

ral network for single document summarization by extracting words. They have treated highlighted text in news articles consisting of very short bulleted lines on the web as summary of the corresponding article.

A major challenge of using a fully data driven approach for multi-document abstractive summarization using neural network is the expensive task of creating dataset which can be used to jointly model extraction of relevant content and generation good quality summary sentences. But multi-document abstractive summarization becomes an achievable task, by disintegrating the extraction of knowledge granules from the input corpus and using a separate language generation model trained in a sophisticated dataset which can take a subset of extracted knowledge granules and generate a summary sentence of high linguistic quality. To this end, we leverage partial tree linearization (Zhang, 2013) synthesizing summaries from extracted treelets.

3 Approach

The overall approach (Figure 1) for abstractive multi-document summarization detailed in the current work starts with extracting the most relevant set of partial trees of varying sizes from the set of all syntactic dependency trees in the corpus using maximum density sub-graph cut algorithm (Su et al., 2008). In parallel, generative model for syntactic dependency trees is trained (Zhang et al., 2016) so that it can be leveraged for estimating the combinability of a set of partial trees for constructing a whole or part of a full dependency tree of a valid sentence during summary generation. Also, the transition based syntactic linearization model Puduppully et al. (2016) is trained using

a dataset, consisting of dependency trees of sentences in Penn-tree bank and corresponding sentence.

The set of extracted partial dependency trees are clustered to ensure topical diversity. We identify a subset of partial trees from each cluster, which can be linearized to a single sentence which represents the cluster in the final summary. Integer linear programming is used for locating the most accurate subset of partial trees out of which representative sentence can be generated.

The objective function consists of linear components for maximising *total relevance* and *total combinability* of the subset of partial trees selected. *total combinability* is measured using the generative model Zhang et al. (2016). Here we try to jointly model the human summarizers method of collecting relevant knowledge granules and deciding the combinable set of information. Cluster representative sentence are generated using the linearization model of Puduppully et al. (2016) from the subset of partial trees identified earlier. The following sections explain how the system achieves each one of the tasks listed above in detail.

3.1 Extracting Relevant Partial Trees

For each dependency tree in the input corpus, there is a subtree rooted at every node. Each subtree do not necessarily contain extractable information to generate a summary. The method used to create a noise pruned subset of subtrees containing cognizable information from the set of all subtrees in the corpus can be split into two steps.

- Identify the roots of valid subtrees containing cognizable information in all the syntactic dependency trees in the input corpus.
- Prune the identified subtrees so that it contains nodes relevant for generating summary.

3.1.1 Identify Subtree Roots

The level of granularity at which syntactic elements chosen to generate summary sentence considerably decides factual accuracy of a generated sentence. As extracted set of subtrees are basic building units for summary sentence generation, the structure of subtrees extracted should be suitable for generating factually correct summary sentences with respect to the corpus to be summarized. We observe that a node containing *subject*

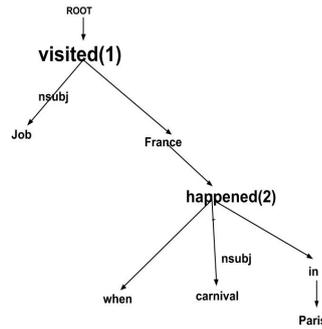

Figure 2: Marking relevant subtree roots

relationship with its child node is a valid candidate. Consequently any node in a dependency tree sharing dependency relations such as *nsubj*, *csubj*, *nsubjpass* or *xsubj* with any of its child node is treated as the root node of a subtree which contains extractable and cognizable information. In Figure 2, for example, subtrees rooted at words *visited* and *happened* are valid subtrees to contribute for summary generation as per the linguistic criteria discussed above.

3.1.2 Pruning Subtrees

Identified subtrees are dissected out from their original dependency trees after pruning away their noisy portions which are irrelevant for summary generation. Su et al. (2008) introduced a dynamic programming approach to find a length-constrained maximum-density subtree containing the root r , from a tree rooted at r for which weight and length is preset for all edges. The density of a tree T is defined as follows.

$$density = \frac{\sum_{e \in E} W(e)}{\sum_{e \in E} Len(e)} \quad (1)$$

where E is the set of all edges in T , $W(e)$ is the weight of edge e and $Len(e)$ is the length of edge e . The constraint on length implies that total length of all edges in the resultant maximum density subtree should be between lower bound L and upper bound U which are taken arguments by the algorithm. We leverage multi density subtree extraction algorithm for dissecting out a noise pruned subtree from an identified valid subtree in a dependency tree after setting values for edge weights, edge lengths, L and U .

The weight of an edge in a syntactic dependency in the input corpus should represent its topical relevance for summary generation. Consequently the

weight depends on the frequency of *bigram* constituted by words on either side of the dependency edge (D_{bigram}). We set the weight of edge e as,

$$W(e) = \frac{\log(1 + fd_{bigram})}{depth(e)^2}, \quad (2)$$

where fd_{bigram} is the frequency of the D_{bigram} of e in the corpus and $depth(e)$ is the depth of dependent node of e in the tree. Summary should prefer general information over context specific information. The specificity of the information contained increases with depth in dependency tree and the denominator term in Equation 2 penalizes deeper edges.

The length of the edge is set as the size of the word in the dependent node in bytes so that length of all edges in the tree equals the total size of all words in the tree. Length constraint U is the total length of all edges in the tree and L is calculated as follows

$$L = \alpha * \tanh(\beta * twe - \sigma) * TL,$$

where twe is the total weight of all edges in the subtree, TL is the total length of all edges in the subtree and σ , α and β are constants optimized empirically. σ sets the universal upper bound for all subtrees minimum length while α and β set the slope and position of tanh curve. The value of L ensures that subtrees containing more relevant information are pruned lesser. We enforce a rule to retain the tree nodes to maintain grammaticality while pruning. If the grammatical relation pointing to a node from its parent is *nsubj*, *csubj*, *nsubjpass*, *xsubj*, *aux*, *xcomp*, *pobj*, *acompl*, *dobj*, *case*, *det*, *poss*, *possessive*, *auxpass*, *ccomp*, *neg*, *expl*, *cop*, *prt*, *mwe*, *pcomp*, *iobj*, *number*, *quantmod*, *predet*, *dep* or *mark*, then the node cannot be removed without also removing its parent to maintain grammatical and factual correctness.

For the rest of this paper, we refer to a noise-pruned subtree extracted out of a dependency tree as a *partial tree*. The partial trees pruned out of subtrees sharing ancestor-descendant relationship may contain overlapping information (eg: subtrees rooted at ‘visited’ and ‘happened’ in Figure 2). So ancestor-descendant relationship between corresponding partial trees is recorded to avoid redundant information during summary sentence generation.

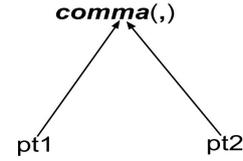

Figure 3: $Combine(pt_1, pt_2)$

3.2 Estimation of Combinability of Partial trees using Generative Model of Dependency Trees

During the final stage of summary sentence generation, each of the summary sentence is generated from a precisely identified subset of relevant partial trees. To arrive at such a precise subset, along with information regarding topical relevance, due consideration should be given to the combinability of partial trees in the subset to form a full dependency tree of a valid sentence w.r.t to the syntactic and semantic information contained in them. As a primitive measure upon which total combinability of a set of partial trees can be built upon, we estimate the combinability of any two partial trees to form whole or a part of a valid dependency tree as follows

$$DepTree \rightarrow Combine(pt_1, pt_2) \quad (3)$$

$$C(pt_1, pt_2) \rightarrow P_{depgen}(DepTree), \quad (4)$$

where $Combine(pt_1, pt_2)$ combines two partial trees pt_1 and pt_2 as represented in Figure 3 by adding a dummy root containing ‘,’ with ‘comma’ as the dependency relation of edges and pt_1 comes before pt_2 in breadth first order. $C(pt_1, pt_2)$ is the *Combinability* of any two partial trees and P_{depgen} represents a generative distribution of syntactic dependency trees trained with a large set of dependency trees. $Combine(pt_1, pt_2)$ need not exactly represent a substep in the final process of combination and linearization of a set of selected partial trees to generate a summary sentence. But $P_{depgen}(DepTree)$ acts as an indicative measure on how much pt_1 and pt_2 can together participate in the construction of a full-dependency tree of a valid sentence with respect to the syntactic and semantic information contained in them.

3.2.1 Learning P_{depgen}

Zhang et al. (2016) introduced Tree Long Short-

Term Memory (TreeLSTM), a neural network model based on LSTM, which is designed to predict a tree rather than a linear sequence. They define probability of a sentence as the generation probability of its dependency tree. Under the assumption that each word w in a dependency tree is only conditioned on its dependency path, the probability of a sentence S given its dependency tree T is:

$$P(S|T) = \prod_{w \in BFS(T) \setminus ROOT} P(w|D(w)) \quad (5)$$

where $D(w)$ is the dependency path of w and how dependency path for each node is identified is detailed in the paper Zhang et al. (2016) and each word w is visited according to its breadth-first search order ($BFS(T)$). $P(S|T)$ can be restated as a generative probability $P_{depgen}(T')$ where T' is a restricted syntactic dependency tree structure in which, for all nodes, left and right dependants and breadth first order of its children are fixed. As the above mentioned structural restrictions can be fixed in parameter for partial trees for *Combine* in Equation 3, we can directly use TreeLSTM network to estimate P_{depgen} in Equation 4.

The sentence dataset shared by Zhang et al. (2016) is parsed using Stanford parser for training a TreeLSTM network. The negative log probability values produced by the network is normalized for partial tree pairs in the corpus.

3.3 Syntactic Linearization

We make use of the syntactic linearization model proposed by Puduppully et al. (2016) to linearize the input set of partial trees. Puduppully et al. (2016) and Liu et al. (2015) propose a transition-based word ordering model, which takes a bag of words, together with optional POS and dependency arcs on a subset of input words, yields a sentence together with its dependency parse tree that conforms to input syntactic constraints (Zhang, 2013). The system is flexible with respect to input constraints, performing abstract word ordering when no constraints are given, but gives increasingly confined outputs when more POS and dependency relations are specified. We retrain their model¹ using autoparsed data obtained using Stanford Dependency Parser.

¹<https://github.com/SUTDNLP/ZGen>

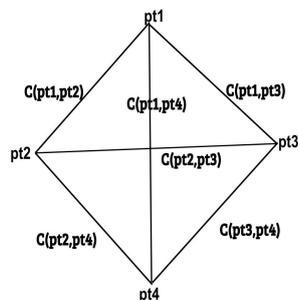

Figure 4: Cluster graph of partial trees

3.4 Clustering for Topical Diversity

To ensure topical diversity we apply K-means clustering in the set of partial trees with an aim of generating a sentence from each of the cluster as a topical representative of the respective cluster. Cosine similarity between D_{bigram} frequency vectors of partial trees is treated as the similarity metric during clustering. Number of clusters (K) is decided using the relation,

$$K = \lfloor q * ShannonEnt \rfloor \quad (6)$$

where $ShannonEnt$ is the Shannon entropy of unigram distribution of the corpus and q is a constant.

3.5 Generating Cluster Representative Sentence

Our system generates a single sentence from each of the partial tree clusters identified as described in section 3.4 to represent the cluster in final summary. Here we search for a subset of partial trees from each cluster which maximise the *total relevance* and *total combinability* of the partial trees in the selected subset. Relevance of a partial tree is defined as the total weight of all dependency edges calculated using the Equation 2.

A data structure which searchably organizes the relevance and combination probabilities of partial trees belonging to a cluster is essential for formulating the partial tree subset selection as an integer linear programming problem. For this purpose we visualize the entire partial tree information organized in a *cluster graph (CG)* as shown in Figure 4 in which *nodes* represent partial trees, and *edge weights* represent the combination probability of partial trees represented by the edge nodes calculated using the Equation 4. An *edge exists* between two nodes if the partial trees at the nodes contain mention about same named entity.

From cluster graph we try to extract a *connected subgraph (SG)* which maximizes the

objective function which takes a binary indicator vector representing a sub-graph of cluster graph as argument.

$$F(x_1, \dots, x_n, e_{1,1}, \dots, e_{n-1,n}) \rightarrow \sum_{i \in Nodes} R(x_i) * x_i + \lambda * \sum_{\{i,j\} \in Edges} W(\{i,j\}) * e_{ij} \quad (7)$$

subject to constraints,

$$x_i + x_j - 2 * e_{ij} \geq 0 \rightarrow C_1$$

$$x_i + x_j - 2 * e_{ij} \leq 1 \rightarrow C_2$$

$$e_{i,j} \leq I(x_i, x_j) \rightarrow C_3$$

$$\sum_i x_i * size(i) \leq MaxLen \rightarrow C_4$$

$$x_i + ancestor(i) < 1 \rightarrow C_5$$

where λ is a constant, $R(i)$ is the relevance of partial tree at node i , $W(\{i,j\})$ is the weight of the edge $\{i,j\}$ in CG, $Nodes$ is the set of all nodes in CG and $Edges$ is the set of all edges in CG.

$$x_i = \begin{cases} 1 & \text{if node } i \text{ is present in input SG} \\ 0 & \text{otherwise} \end{cases}$$

$$e_{ij} = \begin{cases} 1 & \text{if edge } \{i,j\} \text{ is present in input SG} \\ 0 & \text{otherwise} \end{cases}$$

$$I(x_i, x_j) = \begin{cases} 1 & \text{if edge } \{i,j\} \text{ is present in CG} \\ 0 & \text{otherwise} \end{cases}$$

$ancestor(i)$ indicator variable that represents a partial tree that is extracted from an ancestor subtree of the subtree from which i is extracted (Explained in section 3.1). $size(i)$ is the total size of all words in subtree i and $MaxLen$ is the maximum size of a sentence in the input corpus.

The constraints C_1 and C_2 ensure that an edge will be present if and only if the corresponding edge nodes in CG are present in the input vector, while C_3 ensures that the input vector represents a subgraph of CG. The constraint C_4 keeps an upper bound on the size of sentence that is generated from a single cluster, while C_5 ensures that partial trees with overlapping information are not present together in the selected subset of partial trees in a cluster.

The set of partial trees represented by the nodes of the subgraph that maximizes the objective function in Equation 7 functions as the syntactic ingredients to generate the cluster’s representative sentence. A selected subset of partial trees are linearized using the transition based syntactic linearization model detailed in Section 3.3 to generate cluster representative sentence.

4 Experiments

We evaluate our method using the test sets of DUC 2004, DUC-2007 and TAC-2011. In particular, the set of attributes of the summary including content coverage of summaries and linguistic quality and factuality of newly generated summary sentences are evaluated. The content coverage is evaluated using ROUGE (Lin, 2004) and we relied on human evaluation for evaluating linguistic quality and factuality.

4.1 Data

DUC 2004, DUC-2007 and TAC-2011 consist of several corpora, each of them consisting of 10 documents and four model summaries for those 10 documents. We have tuned our development parameters using DUC 2003 dataset.

4.2 Settings

The values of α , β , σ , q and λ are tuned on the development set for optimum content coverage and sentence quality. In order to objectively evaluate a summary sentence generated by linearizing a set of partial trees, we need a human written reference sentence of high linguistic quality which is written after carefully understanding the information contained in selected partial trees. As it is time-consuming to create such reference sentences for each of the combination constituted by the possible values of α , β , σ , q and λ , we choose to separate parameter tuning for optimal content coverage and sentence quality. Optimal values of α , β , σ and q contributes prominently for better content coverage while that of λ contributes for better sentence quality as it weights combinability of partial trees. In Subsections 4.2.1 and 4.2.2 we explain how we tune different development parameters for optimal content coverage and sentence quality.

4.2.1 Tuning α , β , σ and q for maximum content coverage

The values α , β , σ and q are optimised for maximum content coverage where pruned partial trees are extracted to fill the allotted summary space without any combination to generate summary sentences. Content coverage is measured as the sum of ROUGE-1 and ROUGE-2 scores with reference summaries on the DUC-2003 dataset. The values of α , β , σ and q optimized using grid search to give maximum average ROUGE score for corpora in DUC-2003 are 0.5, 0.15, 0.5 and 1 respectively.

42	0.403	0.54	70%
48	0.401	0.571	70%
75	0.373	0.579	77%
105	0.361	0.570	79%

Table 2: Optimizing λ for better topical coverage sentence quality

4.2.2 Tuning λ for optimum content coverage and sentence quality

The values of α , β , σ and q are preset to the optimum values identified in the section above. The value of λ is varied from 0 to 100 with an increment of 3 and set partial trees to form each of the summary sentences for all corpora in DUC 2003 is identified. We asked a human annotator to write a linear sentence out of each of the selected partial trees sets without using new words which are not present in partial tree nodes in the set and the BLEU score of generated summary sentences with respect to the human written sentences is estimated. For each value of λ we estimate the average ROUGE-1 and BLEU for the generated summaries and summary sentences respectively. The value at which total value of average BLEU and ROUGE-1 scores is maximum is set as the value of λ during testing. Table 2 reports BLEU and ROUGE-1 for different values of λ . Column NCS in the Table 2 represents the percentage of complex sentences generated by linearizing more than one partial tree.

4.3 Final Results

4.3.1 Content coverage

While evaluating the relevant content coverage of abstractive summarization system, we also have to evidently substantiate the effectiveness of noise pruning done using multi density partial tree extraction algorithm. For this purpose we have created extractive summarizer using maximum weighted word coverage algorithm Takamura and

Okumura (2009), which tries to extract sentences containing maximum weighted D_{bigram} s in their dependency trees.

Table 1 shows the results on DUC-2004, DUC-2007, TAC-2011 along with previous approaches. In the table R-1,R-2 and R-SU4 represents ROUGE-1, ROUGE-2 and ROUGE-SU4 (skip-bigrams with unigrams), respectively. *WordCoverage(D_{bigram})* summarizer using maximum weighted word coverage algorithm represents the word coverage algorithm using D_{bigram} weights while *PartTreeAbsum* abstractive summarization approach detailed in the paper. Results on DUC-2004 shows that noise-pruning using maximum weighted partial tree extraction was effective in terms of better content coverage. Despite rephrasing content in many contexts, *PartTreeAbsum* shows results comparable with previous approaches. CompAbsum (Banerjee et al., 2015) demands high syntactic overlap between source sentences to recombine and generate new sentences, otherwise resembles an extractive summarization system. Our system shows better ROUGE-1 and equal ROUGE-2 values in DUC-2004 test set. PhraseAbsum (Bing et al., 2015) which extracts phrases from the corpus and phrases can enjoy lower granularity in terms of information content when compared to partial trees by compromising topical coherence in summary sentence generation. Still our results are comparable with that of PhraseAbsum in TAC 2011. Our results show competitiveness with Semantic (Li, 2015) which generate summary content from a corpus level semantic network utilizing linear structures smaller than a partial tree and does not employ explicit means to ensure grammaticality.

4.3.2 Linguistic quality and factual accuracy

In order to fully evaluate the effectiveness of an abstractive summarization approach it is also useful to evaluate the linguistic quality and factual accuracy of generated sentences. Here linguistic quality refers to the quality of sentences in terms

Input Corpus Sentences
Hun Sen’s Cambodian People’s Party won 64 of the 122 parliamentary seats in July’s elections [1]
Sam Rainsy and a number of opposition figures have been under court investigation for a grenade attack on Hun Sen’s Phnom Penh residence on Sep. [2]
Hun Sen was not home at the time of the attack. [3]
Ranariddh and Sam Rainsy have charged that Hun Sen’s victory in the elections was achieved through widespread fraud. [4]
Sentence Generated by <i>PhraseAbSum</i> (Bing et al., 2015)
Sam Rainsy and a number of opposition figures, have been under court investigation for a grenade attack on Hun Sen’s Phnom Penh residence on Sep, charged that Hun Sen’s victory in the elections was achieved through widespread fraud (<i>source sentences [2] and [4]</i>)
Sentences Generated by <i>PartTreeSum</i> (Current Work)
Sam Rainsy and a number of opposition figures have been under court investigation for attack on Hun Sen residence, at the time of the attack Hun Sen (He) was not home (<i>source sentences [2] and [3]</i>)
Hun Sen’s party won 64 of the 122 parliamentary seats in elections, victory in the elections was achieved through widespread fraud, Ranariddh and Sam Rainsy have charged (<i>source sentences [1] and [4]</i>)

Table 3: Tree Combination vs Phrase Combination

	LQ	FA
Human Summary	4.5	4.3
PartTreeSum(WC)	2.1	2.32
PartTreeSum	3.15	3.09

Table 4: Human Evaluation on sentence quality

of grammaticality and readability, and factual accuracy refers to how much the information conveyed by the generated summary sentences are true with respect to what is contained in the input corpus. For this purpose we employed 4 manual evaluators who are post-graduate students in English literature. 10 random corpora were chosen for manual evaluation and we asked the evaluators to read the documents in each corpus and rate corresponding summary sentences for their linguistic quality and factual accuracy.

For each corpus the summaries participated in manual evaluation include a randomly chosen human summary for corpus, current approach for abstractive summarization (PartTreeSum), the current approach without combinability measure by setting λ to 0 (PartTreeSum(WC)). Human evaluation results shown in Table 4 proves that linguistic quality and factual accuracy have considerably increased with the introduction of combinability measure.

4.4 Discussions

Tree combination vs phrase combination: Table 3 contains the four input corpus sentences in one test example and sentences generated by

PhraseAbSum (Bing et al., 2015) and the current work (*PartTreeSum*), *PhraseAbSum* could generate only one sentence respectively, due to the hard constraint for verb phrases to coincidentally share same noun phrase in source sentences and the sentence exhibit poor topical coherence. In contrast, *PartTreeSum* is flexible to generate more sentences and the *Combinability* component in Equation 7 ensures that generated summary sentence contain topically related content. The original content is rephrased when required as observed in the second half of generated sentences. In Table 3, the summary sentences generated by *PartTreeSum* are more topically coherent compared to those generated by *PhraseAbSum*.

Error analysis : We have analysed the low-rated sentences from human evaluators with their corresponding set of partial trees. Though the partial trees contained information which can be combined in a single complex sentence, text aggregation during linearization should be more effective to improve the quality of sentences. For future work we plan to construct a neural generation model, which can aggregate and generate a sentence from a set of partial trees while maintaining factual accuracy with respect to the input documents. Also there should be a means to treat quotes separately apart from normal sentences.

5 Conclusion

We built a model for abstractive multi-document summarization by extracting partial dependency

trees to represent knowledge granules, and generating summary sentences using combinable granules utilizing syntactic linearization. Compared to existing methods for the task, our method has the advantages of generating new sequential sentential structures by rephrasing information if required as decided by the linearization model. On standard evaluation of using ROUGE metric and human evaluation for qualitative aspects of summary, this method showed competitive accuracies to the state-of-the-art methods for multi-document summarization.

(alex.judea|michael.strube)@h-its.org

Abstract

In this paper we investigate the performance of event argument identification. We show that the performance is tied to syntactic complexity. Based on this finding, we propose a novel and effective system for event argument identification. Recurrent Neural Networks learn to produce meaningful representations of long and short dependency paths. Convolutional Neural Networks learn to decompose the lexical context of argument candidates. They are combined into a simple system which outperforms a feature-based, state-of-the-art event argument identifier without any manual feature engineering.

1 Introduction

Event extraction is a difficult information extraction task. The 2005 Automatic Content Extraction evaluation (ACE 2005) defines three challenging sub-tasks: *Entity mention detection*, the task of finding mentions of predefined entity types like persons and organizations; *event trigger detection*, the task of finding words, mostly verbs or nominalizations, indicating an event from a set of predefined event types; and *event argument identification*, the identification of entity mentions¹ playing a role in the events, as well as the identification of the roles they play.

When we look at the evaluations in three of the most influential recent event extraction papers (Li et al., 2013, 2014; Chen et al., 2015; Nguyen et al., 2016) we note that argument identification performance is low, ranging from 52.7 to 55.4 F₁. There are multiple reasons for the low performance. First, argument identification suffers from

¹In this work we make no distinction between ‘entity’, ‘time’, and ‘place’ for the sake of simplicity.

error propagation. Missed or spurious event triggers or entity mentions may lead to missed or spurious event arguments. Second, event structure is complex. Multiple entities can play the same role in the same event. Additionally, one entity can play different roles across events (and thus cause multiple event arguments). Consider the following example.

A Palestinian **boy** as well as his **brother** and a **sister** were *wounded* late Wednesday by Israeli *gunfire*.

Here, the three entity mentions (in bold) are all Victims of the INJURE event triggered by ‘wounded’ as well as Targets of the ATTACK event triggered by ‘gunfire’. Such structures can become even more complex when more events and more entities are involved.

The third reason for low argument identification performance is syntactic complexity. Many arguments are syntactically far away from their triggers, making it hard to construct meaningful syntactic features. Section 3 shows that performance is tied to the length of the shortest dependency path connecting trigger and argument.

Error sources one and two were already targeted by systems which jointly infer triggers and their arguments. To the best of our knowledge, no previous work identified syntactic complexity as the third key problem for argument identification performance, and no previous system aimed to decompose syntactic structure in order to learn better classifiers for the task. The contributions of this paper are the following.

1. We observe that syntactic complexity is a crucial factor for argument identification. Argument identification performance highly correlates with dependency path length (Section 3.1).

2. We propose to represent dependency paths with bidirectional Long Short-term Memory networks (biLSTMs) in order to account for their sequential and compositional nature. Using LSTMs to learn dependency path representations proved effective in other areas like relation extraction (Xu et al., 2015) and semantic role labeling (Roth and Lapata, 2016). We investigate their use for argument identification.
3. We propose to represent lexical contexts of event arguments with Convolutional Neural Networks. Together with LSTMs, they form an effective and simple argument identifier which beats a state-of-the-art, feature-based system without any manual feature engineering, especially for long dependency paths.

2 Baseline

2.1 Baseline Argument Extraction

Our baseline is a re-implementation of Li et al. (2013). It is a state-of-the-art event extractor that predicts event triggers and arguments jointly. Because of this joint inference, it avoids error propagation and can draw features based on joint event extraction decisions, e.g., how many arguments of a specific type does a specific trigger have?

The system uses a structured perceptron with beam search. It processes a sentence from left to right and token by token. With each position it advances, it constructs new hypotheses containing event trigger and argument assignments. Then, it prunes the hypotheses spaces to the n best alternatives and processes the next token position. After the last token was processed, the hypothesis with highest score is selected as the final prediction. This hypothesis contains trigger and argument assignments for the entire sentence.

2.2 Baseline Argument Extraction Features

Our baseline system uses a rich, hand-engineered feature set. Feature templates can be divided into *local templates* and *global templates*. Local templates characterize single arguments, and they involve only the mentions and triggers of this argument. They capture, e.g., the trigger and entity types, the mention context, and the dependency path between trigger and mention.

Global templates on the other hand characterize multiple arguments, either in terms of shared mentions, or in terms of shared roles. Global templates

Argument type	Support _{train}	F ₁ _{dev}
Victim	578	79.0
Instrument	256	77.1
Artifact	605	75.6
Attacker	574	47.3
Target	438	42.6
Giver	94	32.9

Table 1: Training set support and development set baseline F₁ for the three best and three worst performing argument types.

can be divided into *segment level templates* and *sentence level templates*. Segment level templates capture characteristics of the mentions within one event, e.g., the words between two mentions sharing a role in one event, or the head and modifier of nominal modifications like ‘IBM CEO’. Sentence level templates capture characteristics of events sharing mentions, e.g., the roles such a mention fills, or the dependency path connecting the two triggers. The system uses two dozen feature templates, resulting in 150,000 features for argument identification.

3 Performance Analysis

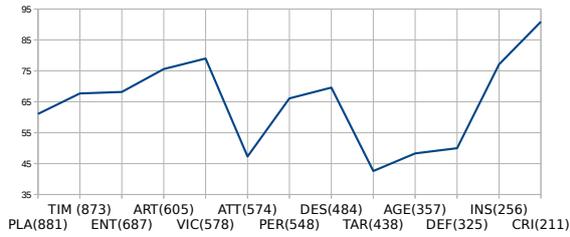

3.1 Analysis of Baseline Performance

We start the analysis of argument identification performance with the observation that despite the low overall performance, some argument types perform reasonably well. Table 1 reports development set precision, recall, and F₁ of our baseline for the three best and the three worst performing argument types in the development set.² As we can see, the difference between the best type (Victim) and the worst type (Giver) is 46.1 F₁ points. What is the reason for this big difference?

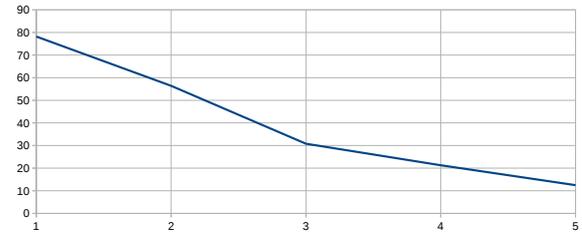

Our first assumption is that the best performing types have more training samples. Indeed, Victim has considerably more samples than Giver. Attacker however has nearly the same amount of training samples but a much lower performance (-31.7 F₁). Instrument on the other hand has only half the training samples of Attacker, but a better performance (+29.8 F₁).

To further investigate this, Figure 1a plots training set support in decreasing magnitude against development set F₁ for the 12 most frequent argument types. The plot is not conclusive: More

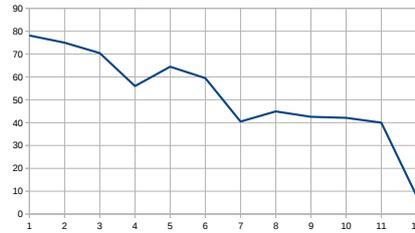

²We excluded types with less than 20 samples in the development set.

(a) Training set support in decreasing magnitude plotted against baseline devset F_1 .

(b) Increasing dependency path length plotted against baseline devset F_1 .

(c) Increasing lexical distance plotted against baseline devset F_1 .

Figure 1: Training set support, lexical distance of trigger and argument, and dependency path length plotted against development set performance.

training data does not automatically lead to better performance. The most frequent argument type `Place` with 881 training samples has an F_1 of 61.1, whereas `victim` with 34% less training samples has an F_1 of 79.0. `Instrument` has about 70% less training samples and an F_1 of 77.1. If the number of training samples is not an important factor for performance, what else could be?

One important factor is semantic variety: Some roles can only be filled by one or two entity types, and most of their mentions *are* role fillers. This is especially true for `Instrument` which can only be filled by vehicles and weapons in ACE 2005; in turn, most weapons are `Instruments`. This is reflected in the good performance of `Instrument` in Table 1 and Figure 1a.

However, most roles can be filled by more than two entity types, and their potential fillers are more frequent than vehicles and weapons: `Entity` for example can be filled by persons, organizations, and geopolitical entities. At the same time, most of the respective mentions are *not* `Entities`. Even if a role can only be filled by one entity type, it may be that most occurrences are not role fillers, making the task to correctly fill those roles harder. Consider `Time` for example, which can only be filled by *time* mentions, yet it has only a mediocre performance of 67.7 F_1 points on the development set. Semantic variety alone cannot explain the big performance differences between argument types.

Another important factor is syntactic complexity: How long and diverse are dependency paths connecting arguments and triggers? To investigate the effect of syntactic complexity, Figure 1b depicts length of dependency paths connecting triggers and arguments in decreasing magnitude against development set F_1 . In this plot, we see a much clearer trend: Shorter syntactic distance leads to better performance. Length-1 paths (direct trigger-argument dependency) have an F_1 of 78.2. Length-2 path F_1 drops to 56.4, and to 30.8 for length-3 paths. Length-4 and length-5 paths have an F_1 of 21.3 and 12.5, respectively.

This trend is also reflected in the performance of individual argument types. The most frequent type `Place` has a high average path length of 2.2 and a low F_1 of 61.1. `victim` on the other hand has considerably less training data, but an average path length of 1.5 and an F_1 of 79.0. For the three best performing types, the average path length is 1.7 vs. 2.3 for the three worst performing types.

Dependency path length is related to lexical distance – the longer a dependency path, the more words are usually between trigger and argument. To investigate the effect of lexical distance, Figure 1c depicts the number of words between trigger and argument against development set performance. Here, we see a somewhat less clearer trend: Increasing lexical distance leads to lower performance; however, with a

considerable increase between distances 4 and 5, and a performance plateau between 8 and 11. Word sequences are much more diverse than dependency paths. A dependency path like $\text{returning} \xrightarrow{\text{nmod:from}} \text{summit} \xrightarrow{\text{nmod:in}} \text{Ireland}$ abstracts from actual word sequences and ignores many words which are less relevant for argument identification, like adjectives and adverbs. This in turn alleviates data sparsity.

Syntactic complexity is a crucial factor for argument identification, both in terms of overall performance as well as and in terms of individual argument type performance. Therefore, it is inevitable to reduce or better handle syntactic complexity. Most systems incorporate dependency paths merely as strings, or rely on direct dependencies of triggers and arguments. They do not decompose or further analyze dependency paths in order to find relevant substructures, or to deal with data sparsity of long paths. In Section 4, we present a simple but efficient system which directly addresses syntactic complexity.

3.2 Dependency Paths

We now illustrate the benefits and difficulties of using dependency paths for argument identification. Our dependency paths are lexicalized; they always start with the trigger word and end with a mention word.³ We say that a path has length 1 if trigger and argument are directly related, length 2 if the path includes one intermediate dependency, etc.

Often, short dependency paths directly reflect event argument structure:

$$\begin{array}{l} \text{killed} \xrightarrow{\text{nsubj}} \text{father-in-law} \\ \text{killed} \xrightarrow{\text{dobj}} \text{him} \end{array}$$

The trigger (‘killed’, a DIE event) has two dependencies, ‘father-in-law’ being the subject and ‘him’ being the object. Even without looking at more context we can say with confidence that the subject must be the *Agent* of the event and the object must be the *Victim*. Even longer paths may be quite clear:

$$\text{returning} \xrightarrow{\text{nmod:from}} \text{summit} \xrightarrow{\text{nmod:in}} \text{Ireland}$$

Here, ‘returning’ indicates a TRANSPORT event. The path conveys the information that some entity

³For multiword expressions, the path connects trigger and entity mention head.

returns from a summit in Ireland, making ‘Ireland’ the *Origin* of the event.

Of course, not all dependency paths are as easy to interpret. The following examples show the necessity to decompose dependency paths in order to catch similarities between them.

$$\begin{array}{l} \text{war} \xleftarrow{\text{dobj}} \text{fight} \xrightarrow{\text{nsubj}} \text{U.S.} \\ \text{war} \xleftarrow{\text{nmod:to}} \text{go} \xrightarrow{\text{nsubj}} \text{we} \end{array}$$

These paths are more complex than previous ones because trigger and argument are governed by other words, namely by ‘fight’ and ‘go’. In both cases, ‘war’ triggers an ATTACK event and the subject is an *Attacker* argument. Humans can easily spot similarities in the two paths. The arguments are in both cases the subjects of the governing verbs: ‘U.S.’ is the entity fighting a war and ‘we’ is the entity going to war. However, the left sides of the paths look quite different: In one case, ‘war’ is the direct object of the governing verb, in the other it is the nominal modifier. Additionally, the governing verbs do not share meaning. In order to catch the similarities, a system needs the ability to decompose the paths and to learn the meaning of sequences of words and dependencies.

4 Approach

4.1 Problem Encoding

We cast argument identification as a classification task. For a trigger-mention pair (t, m) we make one instance for training/testing consisting of (a) event type, mention type, and text genre, (b) the shortest lexicalized dependency path $t \rightarrow m$ and (c) the sentence. Figure 2 depicts the pair (‘returning’, ‘Ireland’). Event type (TRANSPORT), entity type (*loc*) and genre (newswire, not depicted) constitute the first information layer. The second Information layer is the lexicalized dependency path ($\text{returning} \xrightarrow{\text{nmod:from}} \text{summit} \xrightarrow{\text{nmod:in}} \text{Ireland}$). The third information layer is the sentence.

The three layers correspond to the most valuable information sources for the baseline. However, the baseline draws only simple categorical features from them. Most notably, it relies on having seen dependency paths during training because it cannot decompose them into meaningful subpaths, which is crucial for better identification performance (Section 3.1). The neural network architecture we present in Section 4.2 is able to automatically construct more meaningful features.

Figure 2: A training/test instance. Depicted in red is given information, depicted in blue is requested information. The trigger is underlined, the entity mention is bold.

4.2 biLSTM/CNN: Architecture

Input to our system (called biLSTM/CNN) are instances as described in Section 4.1. Each instance has three information layers, each layer is processed by a separate component. Figure 3 depicts the system architecture. The figure is split in four (bottom, middle left/right, and top), each part visualizing one component, plus the final classification. We will now describe each part. In the following, \oplus means the concatenation of vectors.

Bias

The bias vector \mathbf{b} provides a representation of the event type, entity type, and genre. The intuition behind the bias vector is that arguments are expressed differently across event types, entity types, and genres. \mathbf{b} is input to the other two components and helps to learn better representations.

More formally, \mathbf{b} is the last layer of a fully-connected three layer neural network whose input is defined as follows: $\mathbf{b}_1 = en \oplus ev \oplus ge$, where en , ev , and ge are representations of the entity type, event type, and genre. They are randomly initialized and will receive standard backpropagation updates during training.

biLSTMs

Representing dependency paths with Long Short-term Memory networks (LSTMs, Hochreiter and Schmidhuber 1997) shows good results in fields like relation extraction (Xu et al., 2015) and semantic role labeling (Roth and Lapata, 2016). We investigate their use for argument identification.

Our LSTMs produce a representation of lexicalized dependency paths, such that similar paths have similar representations. LSTMs automatically learn meaningful patterns in arbitrarily long paths. For example, they learn that the paths attacked^{nsubj}→US and attacked^{nsubj}→Iraq have similar representations given that both indicate an Attacker and only differ in two closely related words. They also learn that attacked^{dobj}→Iraq has a different representation because the change

from nsubj to dobj often distinguishes between Target and Attacker.

Input to our LSTM is a lexicalized dependency path $\mathbf{P} = (w_1, d^{1:2}, w_2, \dots, d^{n-1:n}, w_n)$ where w_1 is the trigger word, w_n is the argument word, and $d^{a:b}$ is the dependency between w_a and w_b . The element at position i in \mathbf{P} is resolved by a vector $\mathbf{v}_i = \mathbf{e}_i \oplus \text{dist}_{\text{trigger}} \oplus \text{dist}_{\text{mention}} \oplus \mathbf{b}$. \mathbf{e}_i is either a pre-trained word embedding or a randomly-initialized dependency embedding, according to the element type at position i . $\text{dist}_{\text{trigger}}$ and $\text{dist}_{\text{mention}}$ refer to the lexical distance of a word to the trigger or the argument word, respectively.⁴ Finally, \mathbf{b} is our bias vector as defined above. We keep word embeddings fixed, but dependency embeddings receive backpropagation updates during training.

\mathbf{P} is processed by a bidirectional LSTM (biLSTM). For a path element i , the biLSTM produces two (so-called) hidden states h_i^f (from the forward LSTM) and h_i^b (from the backward LSTM). These vectors contain information about the respective input, i.e., \mathbf{v}_i , as well as the hidden states of previously processed elements, i.e. elements to the left of i for h_i^f and elements to the right for h_i^b . We average the hidden states belonging to the same input vector: $\mathbf{a}_i = 1/2(\mathbf{h}_i^f + \mathbf{h}_{n-i+1}^b)$. Instead of averaging one could combine the vectors differently, e.g., by concatenating them. However, none of the other possibilities worked better in our case.

Using biLSTMs has the advantage that each \mathbf{a}_i contains information from the entire sequence; using only a forward LSTM limits the representations at each position to the left context.

The middle-left part of Figure 3 depicts the biLSTM and its final output, the average vectors \mathbf{a} .

Convolutional Neural Networks

In contrast to LSTMs, which are designed to capture the meaning of sequences, Convolutional Neural Networks (CNNs) are often used to pro-

⁴Dependencies have the same distance as their governor.

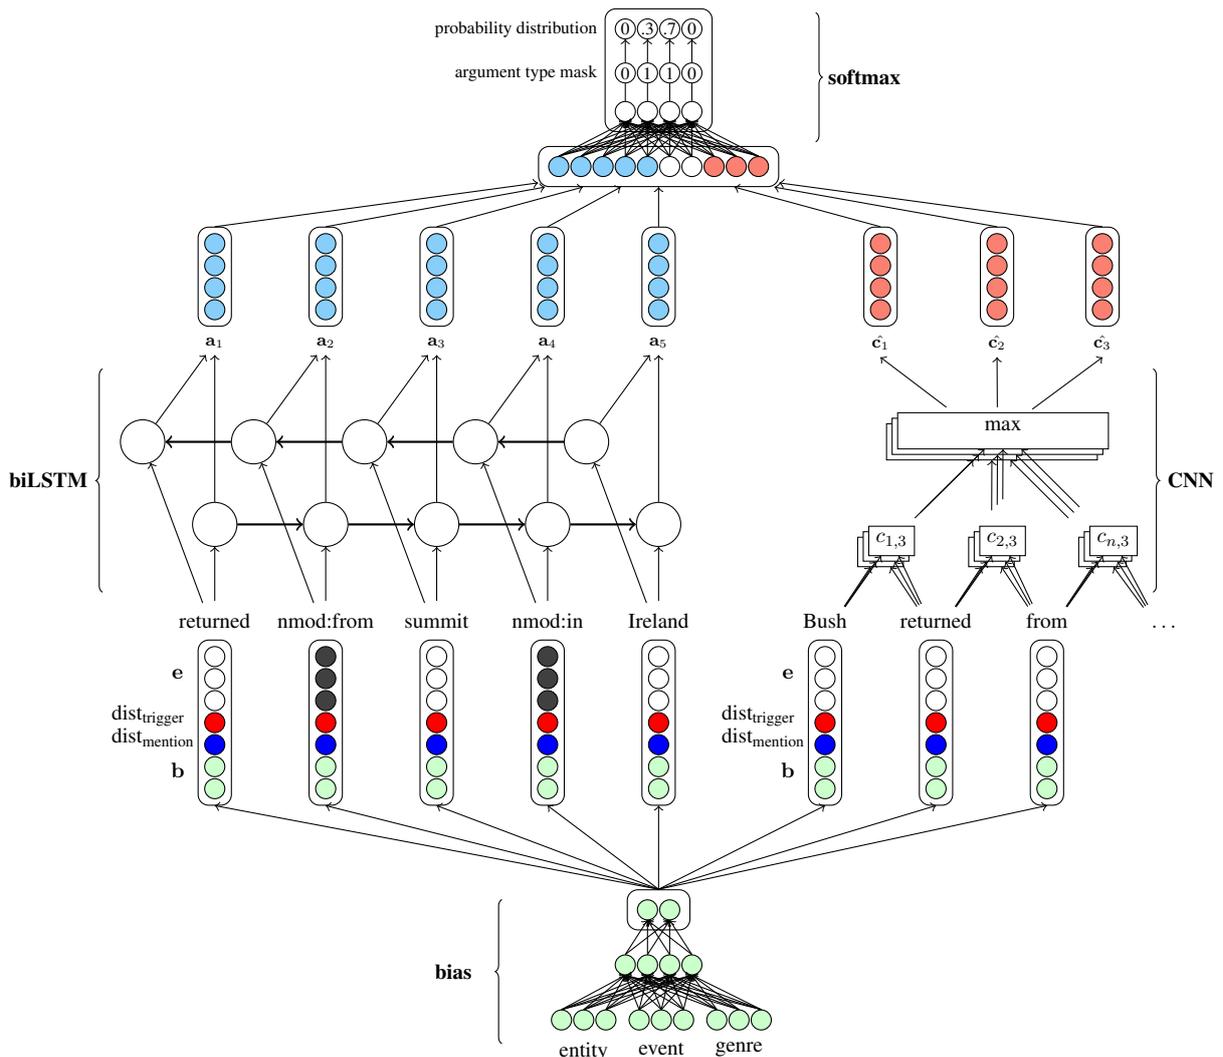

Figure 3: biLSTM/CNN architecture. Process flow is depicted from bottom to top. Embeddings e depicted in white are fixed, every other node receives backpropagation updates during training. Section 4.2 describes each component in detail.

duce bag-of-words-like representations. They were successfully applied to many NLP problems (Kim, 2014; Johnson and Zhang, 2015, inter alia).

Input to our CNN is a tokenized sentence where each word at position i is replaced by a vector \mathbf{x}_i which is almost identical to the definition of \mathbf{v}_i above. The only difference is that \mathbf{x}_i contains only word embeddings.

CNNs apply filters (also called kernels) to a fixed number of consecutive input vectors. Filters are then moved by a certain offset (also called a stride) and re-applied. In our case, one filter produces one feature for one position i : $c_i = \sigma(\mathbf{W} \cdot \mathbf{x}_{i:i+h-1} + s)$ where σ is a non-linearity (tanh in our case), \mathbf{W} is a weight matrix, $s \in \mathbb{R}$ is

a bias, and $\mathbf{x}_{i:i+h-1}$ is a concatenation of vectors $[\mathbf{x}_i \oplus \mathbf{x}_{i+1} \oplus \dots \oplus \mathbf{x}_{i+h-1}]$. h is the filter width. \mathbf{W} and s receive backpropagation updates during training, word embeddings are fixed.

We use CNNs to represent a sentence. The sentence is important because the lexical contexts of trigger and mention convey valuable information for argument identification. This means that in our case a filter of width h produces features for the entire sentence, $c = [c_1, c_2, \dots, c_{n-h+1}]$. We apply max-pooling afterwards, i.e., the final output of one CNN filter is given by $\hat{c} = \max(c)$. Our CNN uses 20 filters for filter widths 2,3,4. The middle-right part of Figure 3 exemplifies a CNN with 3 filters and filter width 2.

Final Classification

Finally, the averaged biLSTM hidden vectors for the dependency path and the max values for all CNN filters applied to the entire sentence serve as input to a softmax layer which produces a probability distribution over all argument types. We pick the class with the highest probability as our final result. However, choosing between *all* classes is unnecessary because not all combinations of event type, entity type and argument type are possible. For example, the argument type `Vehicle` can only be assigned to `TRANSPORT` events, and only mentions with entity type `veh` can be possible fillers. We modify softmax to assign zero probability to classes which are disallowed:

$$y_i = \frac{m_i e^{x_i}}{\sum_j m_j e^{x_j}}$$

The above equation gives the probability for a particular argument type, y_i , where x is the input vector to softmax, and m is a binary vector indicating allowed types. Note that $y_i > 0$ only if the respective argument type is allowed.

The top part of Figure 3 visualizes the softmax component. The input vector is first reduced to 29 dimensions (28 argument types and one ‘null’ type), multiplied with the restriction mask, and forwarded to our modified softmax.

Parameter Averaging

Inspired by the Averaged Perceptron (Freund and Shapire, 1999; Collins, 2002) we do not use the learned parameters directly for prediction. Instead, in each epoch we keep a moving average of the parameters:

$$\theta^V = \alpha \theta^T + (1 - \alpha) \theta^{V-1}$$

Here, θ^T is the current weight vector after training epoch T , θ^{V-1} is the averaged weight vector before the new update, and α is the fraction of how much θ^T influences θ^V . We set $\alpha = 0.1$. θ^V is then used during testing. Note that this procedure does not change the training in any way.

With the formulation above, older weight vectors have less influence on θ^V than more recent vectors. After every training epoch, we evaluate θ^V on the development set and keep the version with highest F_1 for the final evaluation.

Parameter averaging leads to better generalization of our system. Furthermore, performance fluctuation for different training runs is reduced.

5 Experiments

5.1 Data, Evaluation Metrics and Parameters

We evaluate on ACE 2005 and use the same data split as most previous approaches (Ji and Grishman, 2008; Nguyen et al., 2016, inter alia). We follow standard evaluation procedures: An event argument is correct, if its span and role match a reference argument (Ji and Grishman, 2008). Section 1 gives an overview over the annotations provided in ACE 2005.

Because we want to measure argument identification performance by itself, we must ensure that compared systems use the same entity mention and trigger predictions; the best way to ensure this is to set both to gold. Using gold entity mentions is a common setting in event extraction (Li et al., 2013; Chen et al., 2015; Nguyen et al., 2016, inter alia). Since we have evaluation numbers only for biLSTM/CNN and our baseline in this setting, *there is no direct comparability* with previous work other than Li et al. (2013).

Both systems were trained on the same training set, and hyperparameters were optimized on the same development set. We trained both systems using `enhanced++` dependencies (Schuster and Manning, 2016).

We optimize hyper parameters for biLSTM/CNN using Random Search (Bergstra and Bengio, 2012). We use a batch size of 450, 20 CNN filters, 150 LSTM dimensions, and 130 bias dimensions. In order to deal with class imbalance, we set the weight of non-null training samples to 2; this value is used to scale the loss accordingly. We used Keras (Chollet et al., 2015) version 2.0.2 with the TensorFlow backend as the learning framework. Training the network on an NVIDIA P40 GPU takes about 20 seconds per epoch.

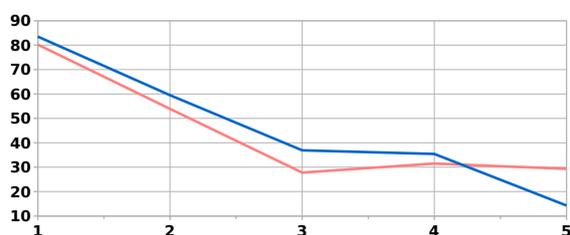

5.2 Experiments and Results

We report the results of four main experiments, namely measuring argument identification performance in general, grouped by argument type, grouped by dependency path length, and using only a dependency path biLSTM. We report precision, recall, and F_1 .

Training neural networks is usually a non-deterministic process. In order to increase reliability, training was performed five times and the evaluation on the test set was averaged across five evaluation runs, one run per trained model.

		Baseline			biLSTM/CNN			Support	ΔF_1
		P	R	F ₁	P	R	F ₁		
1	Micro	67.7	58.7	62.9	63.1	68.3	65.5[†]	916	2.6\pm0.5

12	Agent	64.7	34.3	44.9	55.9	40.6	46.8	32	1.9

Table 2: Test set precision, recall, and F₁ for the baseline and biLSTM/CNN, ordered by frequency. Reported are argument types with more than 30 instances. **Mirco** reports micro-averaged numbers, averaged across 5 training and testing rounds, ‘dep-path biLSTM’ reports numbers using only a dependency path biLSTM, the other rows report numbers per argument type. ‘Support’ reports the number of instances for the respective type. ‘ ΔF_1 ’ reports the difference in F₁ between biLSTM/CNN and the baseline, as well as the standard deviation of biLSTM/CNN F₁. [†] means statistically significant for every training and testing round at the $p < 0.05$ level.

(a) Test set F₁ performance plotted against dependency path length. The red curve depicts baseline F₁, the blue curve depicts biLSTM/CNN F₁.

Length	Baseline	biLSTM/CNN	Support	ΔF_1
	F ₁	F ₁		
1	80.2	83.5	432	3.3
2	53.9	59.5	248	5.6
3	27.8	36.9	123	9.1
4	31.5	35.4	59	3.9
5	29.3	14.3	26	-15.0

(b) Test set F₁ by dependency path length for the baseline and biLSTM/CNN. ‘Support’ reports the number of instances, ‘ ΔF_1 ’ reports the difference in F₁ between biLSTM/CNN and the baseline.

Figure 4: Test set F₁ by dependency path length for the baseline and biLSTM/CNN.

Table 2 reports micro-averaged evaluation numbers for the baseline and biLSTM/CNN (Line 1), a variant which uses only a dependency path biLSTM (without context CNNs, Line 2) as well as numbers per argument type (Lines 3-12). The column ‘Support’ gives the number of instances for the respective evaluation. Finally, the column ‘ ΔF_1 ’ reports the difference in F₁ between biLSTM/CNN and the baseline, positive numbers meaning better biLSTM/CNN performance, as well as the standard deviation of the biLSTM/CNN F₁ score.

As we can see in Table 2, Line 1, biLSTM/CNN has a lower precision and a considerably higher recall than the baseline, resulting in an increase of 2.6 points in micro-averaged F₁ (with a standard deviation of 0.5 F₁ points). This is statistically significant at the $p < 0.05$ level.⁵ Note

⁵We measured significance using approximate randomization (Noreen, 1989). Each of the 5 models we trained performed significantly better than the baseline.

that biLSTM/CNN does not use any manually engineered features, whereas the baseline uses two dozen feature templates, resulting in 150,000 features. Furthermore, biLSTM/CNN is a simple trigger-argument-pair classifier, whereas the baseline jointly predicts all arguments of all triggers in a sentence.

When we compare the performance using dependency paths alone (Line 2), recall drops by 4.3 points, while increasing precision slightly by 1.8 points, resulting in a decrease of 1.1 F₁ points. The main advantage of the CNN is that it makes the lexical context outside of the shortest dependency path available to the system, which reflects itself in the increased recall.

When we look at individual argument types, we note that biLSTM/CNN improves performance for all but three types. Destination has the highest performance improvement (7.1 F₁ points), Artifact the highest loss (-1.5 F₁ points).

Time as the most frequent type in the test data has a high improvement of 4.8 F_1 points.

Figure 4 reports micro-averaged numbers for the baseline and biLSTM/CNN per dependency path length. Figure 4a is a visualization of Table 4b. In total, 888 arguments (out of the 916 in the test set) were connected to their triggers by dependency paths of length 5 or less. biLSTM/CNN performs considerably better for lengths 1-4, especially for paths of length 2 (+5.6 F_1) and 4 (+9.1 F_1). Length-1 paths, which are nearly as frequent as all other path lengths together, have an increased performance of 3.3 F_1 points. Only length-5 paths (with a test set support of 26) lose 15 F_1 points, mainly because biLSTM/CNN produced some false positives for this class.

Most of biLSTM/CNN’s errors are either false positives (wrongly classified as an argument) or false negatives (missed an argument). When it confuses argument types, it usually confuses opposing types like *Seller* and *Buyer*.

6 Related Work

To the best of our knowledge, no other paper is targeting event argument identification directly. For this reason, we first summarize ‘neural’ event extractors, for which argument identification is one necessary step. Then, we report work on representing dependency paths with neural networks.

Chen et al. (2015) use a pipelined event extractor based on CNNs. The input is a sentence, and the output is, in phase one, all triggers in the sentence and, in phase two, a classification of the argument type of a trigger-argument candidate pair. The second phase is similar to the setting we analyze in this paper.

Nguyen et al. (2016) propose a joint and hybrid approach using a Gated Recurrent Unit network (Cho et al., 2014), a variant of an LSTM. Input to their network is the word embedding matrix of a sentence. In contrast to Chen et al. (2015), they predict triggers and arguments jointly. They concatenate a one-hot representation of dependencies to each word embedding. In contrast to this paper, they do not attempt to directly operate on syntactic structure. Instead, the GRU goes over the sentence and passes its hidden states on to higher levels of the network, which dynamically output triggers and arguments for the entire sentence. Their approach is hybrid because they additionally use the features from Li et al. (2013) We did not choose

this system as our baseline because it is considerably more complex and would heavily rely on the same features as our baseline in the setting we investigate in this paper.

Xu et al. (2015) use LSTMs for relation extraction. Similar to our work, they use LSTMs to compute a representation of the shortest dependency path connecting two related entities. While the general learning scheme is similar to our biLSTM component, they represent dependency paths differently. Instead of one lexicalized path, they construct four different representations, using only dependency labels, only words, only part-of-speech tags, and only WordNet categories. This results in four LSTMs whose output is concatenated.

Roth and Lapata (2016) use dependency path-encoding LSTMs for semantic role labeling (SRL). Event extraction and SRL are similar in terms of structures: SRL also involves finding ‘triggers’ and ‘arguments’. They differ however in the nature of these structures. For example, potential arguments in SRL may be assigned to every verb in a sentence, while in event extraction, potential arguments must be assigned only to event triggers. Similar to our work, Roth and Lapata (2016) use an LSTM which processes a dependency path connecting predicate and argument. Their dependency paths mix words, part-of-speech tags and dependency relations.

7 Conclusions

In this paper, we show that argument identification performance is tied to the length of dependency paths connecting triggers and arguments. We propose a novel and efficient neural network that targets syntactic complexity. Without manual feature engineering, it learns to produce meaningful representations of dependency paths and to extract relevant lexical context of arguments. We show that our system outperforms a state-of-the-art baseline which uses manually engineered features and predicts arguments jointly.

Abstract

Cross-lingual open information extraction is the task of distilling facts from the source language into representations in the target language. We propose a novel encoder-decoder model for this problem. It employs a novel selective decoding mechanism, which explicitly models the sequence labeling process as well as the sequence generation process on the decoder side. Compared to a standard encoder-decoder model, selective decoding significantly increases the performance on a Chinese-English cross-lingual open IE dataset by 3.87-4.49 BLEU and 1.91-5.92 F_1 . We also extend our approach to low-resource scenarios, and gain promising improvement.

1 Introduction

Cross-lingual open information extraction is defined as the task of extracting facts from the source language (e.g., Chinese text in Fig. 1(a)) and representing them in the target language (e.g. English predicate-argument information in Fig. 1(c))¹. It is a challenging task and of great importance to solve the cross-lingual portability issues of various NLP systems which are in the support of open information extraction (Sudo et al., 2004). Additionally, there is often a great demand for rapid access to information across languages, especially when a large-scale incident occurs (Lu et al., 2016).

Conventional solutions decompose the task as a pipeline of machine translation followed by

¹The predicate-argument information is normally represented by relation tuples. Here, we use a richer representation (i.e., a tree structure) adopted by PredPatt (White et al., 2016), a lightweight tool for identifying predicate-argument information, available at <https://github.com/hltcoe/PredPatt>.

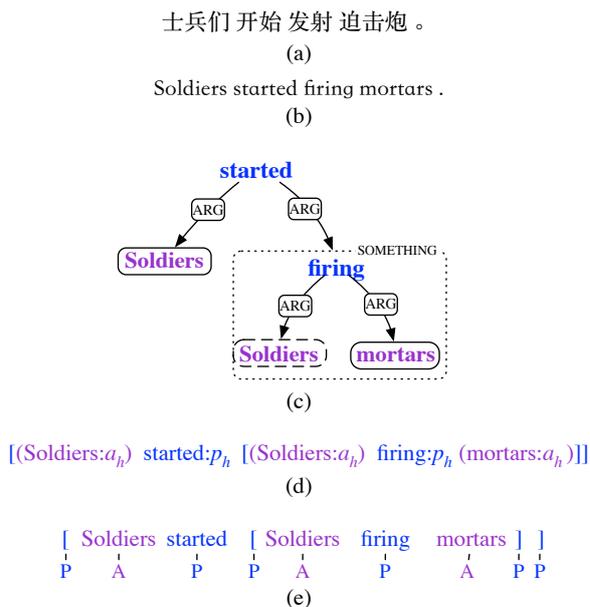

Figure 1: Example of cross-lingual open IE: Chinese input text (a), English translation (b), English predicate-argument information (c), linearized PredPatt output (d) and output with separated predicate and argument labels (e).

open information extraction (or vice versa), which causes a deviation since machine translation attaches equal importance to adequacy and fluency of the intermediate translation results (Snover et al., 2009), whereas the final goal focuses more on extracting correct predicates and arguments.

Recently Zhang et al. (2017a) proposes an end-to-end solution that outperforms the conventional pipeline solutions. They recast cross-lingual open IE as a sequence-to-sequence learning problem by converting the target facts in the tree structure (Fig. 1(c)) into a linear form called linearized PredPatt² (Fig. 1(d)), and employ a stan-

²Linearized PredPatt is converted from the PredPatt tree structure by taking an in-order traversal of every node in the tree. See Zhang et al. (2017a) for details.

standard encoder-decoder model to address the problem (from (a) to (d) in Fig. 1). In the linearized PredPatt (Fig. 1(d)), special labels are appended to tokens as type indications. Brackets and parentheses have to be inserted to delimit predicate and argument spans. Such a workaround inevitably expands the vocabulary space and increases the burdens on the decoder, which is not ideal for sparse data scenarios and limits the overall performance.

In this paper, we reformulate cross-lingual open IE as a sequence generation and labeling problem (from (a) to (e) in Fig. 1) by separating the predicate and argument labels from the target linearized PredPatt, and removing unnecessary parentheses. We propose a novel encoder-decoder model which employs a selective decoding mechanism to explicitly model the sequence labeling as well as the sequence generation process. The new model substantially reduces the vocabulary space, eases the burden on the decoder, and leads to a significant gain of performance. And the natural of the selective decoding mechanism enables a joint training strategy that optimizes sequence generation and labeling simultaneously. In addition, we introduce an adapted beam search algorithm to further improve the prediction quality.

Experimental results demonstrate that our model employing the selective decoding mechanism significantly outperforms the previous end-to-end solution not only on a Chinese-English dataset, but also in low-resource cross-lingual open IE scenarios.

2 Problem Formulation

Our goal is to learn a model which directly maps a sentence input X in the source language into a sentence Y in the target language, and simultaneously labels each token in Y with type information T . For cross-lingual open IE, the types are *predicate* and *argument*. It is important to label types because they are used to annotate predicates and arguments in the generated tokens. Formally, we regard the input as a sequence $X = x_1, \dots, x_{|X|}$, and the output as two sequences (Y, T) : (1) the sentence in target language $Y = y_1, \dots, y_{|Y|}$, and (2) the type information $T = t_1, \dots, t_{|Y|}$, where $t_i \in \mathcal{T}$ is the label for the token y_i , and $|X|$ and $|Y|$ are the length of the sequence X and Y respectively. Our model maps X into (Y, T) using a conditional probability which is decomposed as:

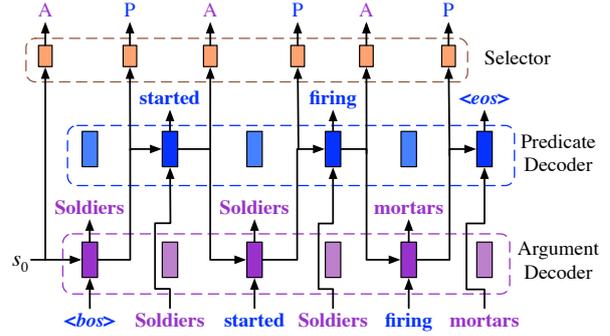

Figure 2: Selective decoding process. (Brackets and attention layers are omitted.)

$$P(Y, T | X) = \prod_{i=1}^{|Y|} P(y_i, t_i | y_{<i}, t_{<i}, X) \\ = \prod_{i=1}^{|Y|} P(y_i | y_{<i}, t_{<i}, X) P(t_i | y_{<i}, t_{<i}, X) \quad (1)$$

where $y_{<i} = y_1 \dots y_{i-1}$ and $t_{<i} = t_1 \dots t_{i-1}$.

Equation (1) can be interpreted as at each decoding time step, the model first decides which type (label) of tokens to generate, and then generates a token for that type.

3 Proposed Model

To learn the factored conditional probabilities as shown in Equation (1), we propose a novel encoder-decoder model with the selective decoding mechanism: on the encoder side, an input sentence X is encoded into vector representations; on the decoder side, the selective decoding mechanism employs multiple decoders each of which learns the conditional probability of decoding a specific type of token (i.e., $P(y_i | y_{<i}, t_{<i}, X)$), and a selector learning to decide which type of decoder to use (i.e., $P(t_i | y_{<i}, t_{<i}, X)$) at each decoding time step.

Fig. 2 illustrates the selective decoding process for the example shown in Fig. 1(e). s_0 is the initial decoder hidden state initialized by the last hidden state of the encoder. Special tokens $\langle bos \rangle$ and $\langle eos \rangle$ are added to the beginning and the end of the sequence to indicate the start and the finish of decoding. The connections at each decoding time step are dynamically changing according to the decision of the selector. Specifically, at the decoding time step i , firstly the selector on the top decides to use which type of decoder $D_{t_i} \in \{D_P, D_A\}$ ³, and

³ D_P stands for the predicate decoder, and D_A for the argument decoder.

then the decoder D_{t_i} decodes the token y_i which is naturally given the label t_i .

In addition to distinguish between labels, the multiple decoders used by the selective decoding mechanism has two prominent advantages over the single standard RNN decoder: (1) Multiple decoders learn different conditional probability distributions for predicate and argument generation respectively. For instance, given the same input token "wanted", the predicate decoder would like to next generate tokens such as "to" and "by" which starts a prepositional phrase, whereas the argument decoder would be in favor of tokens such as "a" and "him" which starts a direct object. (2) Multiple decoders reduce the decoder vocabulary size, which eases the burden of sequence generation. Moreover, we propose an efficient architecture that supports batch training of the model. The details of the architecture are described in the **Decoder with Selective Decoding** section.

3.1 Encoder

The encoder employs a bi-directional recurrent neural network (Schuster and Paliwal, 1997) to encode the input sequence $X = x_1, \dots, x_{|X|}$ into a sequence of hidden states $\mathbf{h} = h_1, \dots, h_{|X|}$. Each hidden state h_i in \mathbf{h} is a concatenation of a left-to-right hidden state $\overrightarrow{h}_i \in \mathbb{R}^n$ and a right-to-left hidden state $\overleftarrow{h}_i \in \mathbb{R}^n$,

$$h_i = \begin{bmatrix} \overleftarrow{h}_i \\ \overrightarrow{h}_i \end{bmatrix} = \begin{bmatrix} \overleftarrow{f}(x_i, \overleftarrow{h}_{i+1}) \\ \overrightarrow{f}(x_i, \overrightarrow{h}_{i-1}) \end{bmatrix},$$

where \overleftarrow{f} and \overrightarrow{f} are two L -layer stacked LSTM units (Hochreiter and Schmidhuber, 1997).

3.2 Decoder with Selective Decoding

Unlike the single standard RNN decoder (Bahdanau et al., 2014), which recurrently uses the same decoder to generate tokens, our model dynamically selects different decoders at each decoding time step to generate tokens (Fig. 2). However, since the decoding path may be different for each input sequence X , directly running the selective decoding process suffers from a key technical issue: it does not support batched computation, which makes them slow and unwieldy for large-scale NLP tasks (Bowman et al., 2016).

To address this issue, we introduce a general decoding architecture that is applicable to all selective decoding processes. The detailed connection

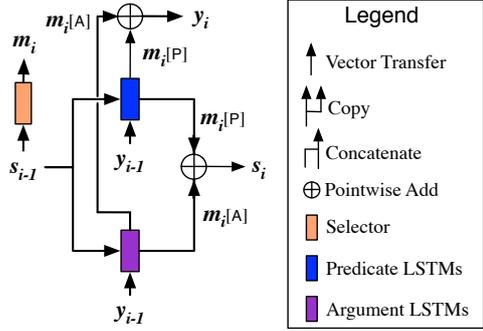

Figure 3: Detailed connection at a decoding step. (Attention layers are omitted.)

in the architecture is shown in Fig. 3. At each decoding time step, the model feeds the input token and the previous hidden state to all types of decoders, and use a mask vector created by the selector to select the decoder output to generate tokens and update the hidden state.

Formally, let $s_i \in \mathbb{R}^n$ denote the hidden state at decoding time step i . The last left-to-right hidden state $\overrightarrow{h}_{|X|}$ from the encoder is used to initialize the first hidden state s_0 in the decoder.

Selector: At the decoding time step i , given the sequence of encoder hidden states \mathbf{h} and the previous decoder hidden state s_{i-1} , the selector computes the conditional probability of t_i (i.e., the type of decoder to use) as:

$$P(t_i | y_{<i}, t_{<i}, X) = g(t_i, s_{i-1}, \mathbf{h}) = \text{softmax}(U_o s_{i-1} + C_o c_{i-1} + b_o)[t_i], \quad (2)$$

where $U_o \in \mathbb{R}^{|\mathcal{T}| \times n}$, $C_o \in \mathbb{R}^{|\mathcal{T}| \times n}$ and $b_o \in \mathbb{R}^{|\mathcal{T}|}$ are weight matrices and bias.⁴ $[t_i]$ indexes the element of a vector that corresponds to the type t_i .

Attention: The context vector c_{i-1} captures the attention to the encoder side (Bahdanau et al., 2014; Luong et al., 2015), computed as a weighted sum of encoder hidden states: $c_{i-1} = \sum_j^{|X|} a_{(i-1)j} h_j$. The weight $a_{(i-1)j}$ is computed by:

$$a_{(i-1)j} = \frac{\exp(\text{score}(s_{i-1}, h_j))}{\sum_{j'=1}^{|X|} \exp(\text{score}(s_{i-1}, h_{j'}))}, \quad (3)$$

where $\text{score}(s_{i-1}, h_j) = s_{i-1}^\top W_a h_j$, and $W_a \in \mathbb{R}^{n \times 2n}$ is a transform matrix.

Hidden State Update: According to the conditional probability $P(t_i | y_{<i}, t_{<i}, X)$, a mask vector \mathbf{m}_i is created, which is used to mask out the

⁴ $|\mathcal{T}|$ is the number of token types. In the example shown in Fig. 3, $\mathcal{T} = \{\text{P}, \text{A}\}$, and $|\mathcal{T}| = 2$.

decoders' hidden states,

$$\mathbf{m}_i[t_i] = \begin{cases} 1, & \text{if } t_i = \operatorname{argmax}_{t'_i \in \mathcal{T}} P(t'_i | y_{<i}, t_{<i}, X) \\ 0, & \text{otherwise} \end{cases}$$

Then the hidden state s_i for the decoding time step i is computed by:

$$s_i = \sum_{t_i \in \mathcal{T}} \mathbf{m}_i[t_i] f_{t_i}(y_{i-1}, s_{i-1}, c_i)$$

where c_i is the context vector capturing the *attention*, computed in the same way as Equation (3). f_{t_i} is L -layer stacked LSTMs for the type t_i . In Fig. 3, there is an L -layer stacked LSTMs for generating predicate tokens f_P , and another L -layer stacked LSTMs for generating argument tokens f_A . They have untied parameters.

Token Generation: The conditional probability of the token y_i with the type t_i is defined as:

$$P(y_i | y_{<i}, t_{\leq i}, X) = g'(y_{i-1}, s_{i-1}, \mathbf{h}, \mathbf{m}_i) \\ = \operatorname{softmax}(U'_o s_i + C'_o c_i + b'_o)[y_i], \quad (4)$$

where $U'_o \in \mathbb{R}^{|\mathcal{V}| \times n}$, $C'_o \in \mathbb{R}^{|\mathcal{V}| \times n}$ and $b'_o \in \mathbb{R}^{|\mathcal{V}|}$ are weight matrices and bias.⁵

3.3 Training

In the training procedure, our optimization objective is to minimize the negative log-likelihood of the sequence Y and its type information T given the input sequence X over the training data, defined as:

$$\operatorname{minimize} - \sum_{(X, Y, T) \in \mathcal{D}} \log P(Y, T | X)$$

According to Equation (1), the log-likelihood $\log P(Y, T | X)$ can be decomposed as:

$$\sum_{i=1}^{|Y|} [\log P(y_i | y_{<i}, t_{\leq i}, X) + \log P(t_i | y_{<i}, t_{<i}, X)],$$

where $P(y_i | y_{<i}, t_{\leq i}, X)$ models the sequence generation process, and $P(t_i | y_{<i}, t_{<i}, X)$ models the sequence labeling process. They are computed by Equations (4) and (2) respectively. The decomposition of the log-likelihood into these two parts enables a joint optimization for the sequence generation and labeling process simultaneously.

We use the Adam optimizer (Kingma and Ba, 2014) and mini-batch gradient to solve this optimization problem. To prevent overfitting, we apply dropout operators (Srivastava et al., 2014) to non-recurrent connections between LSTM layers.

⁵ $|\mathcal{V}|$ is the vocabulary size of the target language.

3.4 Inference

In the inference procedure, we predict the sequence Y and its type information T for an input sequence X according to:

$$(\hat{Y}, \hat{T}) = \operatorname{argmax}_{(Y', T') \in \mathcal{V}^{|\mathcal{Y}'|} \times \mathcal{T}^{|\mathcal{Y}'|}} P(Y', T' | X)$$

$\mathcal{V}^{|\mathcal{Y}'|} \times \mathcal{T}^{|\mathcal{Y}'|}$ is the set of all possible (Y', T') pairs. And (\hat{Y}, \hat{T}) can be directly converted to the form of linearized PredPatt which is used for evaluation.

However, it is impractical to iterate over all these (Y', T') pairs during inference: here, we use beam search to generate tokens and labels as shown in Algorithm 1.

Algorithm 1 Beam search for selective decoding

Input: X - sequence in the source language
Output: (Y, T) - sequence in the target language and its type information

```

1:  $step \leftarrow 0$ 
2:  $b \leftarrow$  beam size
3:  $l \leftarrow$  max decoder length
4:  $fw\_hid \leftarrow \operatorname{Encoder}(X)$ 
5:  $\text{TERMINATED\_STATES}.\operatorname{init}(\emptyset)$ 
6:  $start\_state \leftarrow \operatorname{State}(\langle bos \rangle, fw\_hid)$ 
7:  $\text{BEAM}.\operatorname{init}(\{start\_state\})$ 
8: while  $\text{BEAM} \neq \emptyset$  and  $step < l$  do
9:    $step \leftarrow step + 1$ 
10:   $\text{ACTIVE\_STATES}.\operatorname{init}(\emptyset)$ 
11:  for  $state$  in  $\text{BEAM}$  do
12:     $\triangleright$  Select the decoder.
13:     $t \leftarrow \operatorname{Selector}(state)$ 
14:     $\triangleright$  Generate the next token.
15:     $states \leftarrow \operatorname{Decoder}_t(state)$ 
16:     $\triangleright$  Update the active states.
17:     $\text{ACTIVE\_STATES}.\operatorname{update}(states)$ 
18:   $\text{BEAM}.\operatorname{clean}()$ 
19:   $\triangleright$  Get the top-k candidates.
20:  for  $state$  in  $\operatorname{top}(b, \text{ACTIVE\_STATES})$  do
21:    if  $state.\operatorname{decoded\_token} = \langle eos \rangle$  then
22:       $b \leftarrow b - 1$ 
23:       $\triangleright$  Move out the terminated states.
24:       $\text{TERMINATED\_STATES}.\operatorname{add}(state)$ 
25:    else
26:       $\triangleright$  Update the beam.
27:       $\text{BEAM}.\operatorname{add}(state)$ 
28:   $\text{TERMINATED\_STATES}.\operatorname{update}(\text{BEAM})$ 
29:   $state \leftarrow \operatorname{top}(1, \text{TERMINATED\_STATES})$ 
30: return  $(state.Y, state.T)$ 

```

The beam is used to increase the search space for the sequence Y in the target language. At each decoding time step, we first greedily select the type of decoder, and then generate candidate tokens from the selected decoder to update the beam. When the special token ($\langle eos \rangle$) is generated, we remove the candidate sequence from the beam.

4 Related Work

The model we propose in this paper is adapted from the RNN encoder-decoder architectures which have been successfully applied to a wide range of NLP tasks such as machine translation (Kalchbrenner and Blunsom, 2013; Cho et al., 2014; Bahdanau et al., 2014), image description generation (Karpathy and Fei-Fei, 2015; Vinyals et al., 2015b), syntactic parsing (Vinyals et al., 2015a), question answering (Hermann et al., 2015), summarization (Rush et al., 2015), and semantic parsing (Dong and Lapata, 2016).

As a novel variation of the encoder-decoder architecture, our model provides a general solution to tasks involving translation and labeling. cross-lingual open IE is an example of this kind of task. The end-to-end solution proposed by Zhang et al. (2017a) used a vanilla attention-based encoder-decoder model to achieve results which outperform the traditional pipeline solutions. Compared to the vanilla encoder-decoder model, our model splits the joint task into two concurrent tasks (i.e., labeling and translating), which are jointly learnt by a selector and multiple decoders. This eases the burden of the decoder by shifting the labeling task to the selector. As a result, our model requires a smaller vocabulary for the target language.

The selective decoding mechanism can be viewed as having different types of decoders stacking together and adding a hard gate to the RNN unit, through which the bit of information will be either totally kept or dropped. It may seem redundant since the RNN gated unit already has the sophisticated gating mechanism such as the GRU unit (Cho et al., 2014) and the LSTM unit (Hochreiter and Schmidhuber, 1997). However, we think that the selective decoding mechanism is a complement to the gated unit: rather than having a soft pointwise control, the selective decoding mechanism adopts a hard vectorwise control to explicitly select a certain type of information which corresponds to the predicate or the argument by keeping one and dropping the others,

whereas the GRU/LSTM gated unit itself learns to memorize long short-term dependencies. Similar mechanisms have been used in neural machine translating (Tu et al., 2016) and image caption generation (Xu et al., 2015) to explicitly control the influence from source or target contexts. The experiments in § 5 also confirms our point: our model using the selective decoding mechanism significantly improves the performance, compared to the standard encoder-decoder model.

Regarding to open IE systems for generating training data, PredPatt has shown promising performance on large-scale open IE benchmarks (Zhang et al., 2017c). Compared to other existing open IE systems (Banko et al., 2007; Fader et al., 2011; Angeli et al., 2015), PredPatt uses manual language-agnostic patterns on UD, which makes it a well-founded component across languages. Additionally, the underlying structure constructed by PredPatt has been shown to be a well-formed syntax-semantics interface (Zhang et al., 2017b).

5 Experiments

We describe the hyper-parameters setting for experiments, evaluate our approach in two kinds of scenarios, and compare the results of our approach and the other comparing approaches.

5.1 Hyper-parameters

On the encoder side, both the forward RNN and the backward RNN have 2-layer stacked LSTMs with 500 hidden units. On the decoder side, all types of decoders are 2-layer stacked LSTMs with 500 hidden units. All LSTM parameters are sampled from $\mathcal{U}(-0.1, 0.1)$. The dropout rate is set to 0.3. The word embedding size is 300 for input tokens on both the encoder side and the decoder side. We use open-source GloVe vectors (Pennington et al., 2014) trained on Common Crawl 840B with 300 dimensions⁶ to initialize the word embeddings on the decoder side. The mini-batch size is set to 64 and the step size set to 50. Gradients are clipped when their norms are greater than 5 (Pascanu et al., 2013). For simplicity, we use vanilla softmax over the decoder vocabulary as opposed to more efficient alternatives such as sampled softmax (Jean et al., 2015). The vocabulary size is set to 40,000. The number of epochs

⁶<https://nlp.stanford.edu/projects/glove/>

is 20. Early stopping is used to avoid overfitting. The beam size is 5. Before feeding into the encoder, we reverse the input sentences (Sutskever et al., 2014).

5.2 Chinese-English

5.2.1 Dataset

We first evaluate our approach on the Chinese-English dataset (Zhang et al., 2017a), which contains pairs of Chinese sentences and English linearized PredPatt. Table 1 shows the number of data for training, validation and test.

#Train	#Valid	#Test
941,040	10,000	39,626

Table 1: Number of data used for Chinese-English cross-lingual open IE.

5.2.2 Comparisons

Our approach (**Selective Decoding**) is compared against four other approaches: (1) **Joint Seq2Seq**, which trains a standard encoder-decoder model on the Chinese-English dataset described in Table 1; (2) **Joint Moses**, which trains a phrase-based machine translation system, Moses (Koehn et al., 2007), directly on the same data; (3) **Pipeline-S** which consists of a Moses system that translates Chinese sentence to English *sentence*, followed by SyntaxNet Parser (Andor et al., 2016) for Universal Dependency parsing on English, and PredPatt (White et al., 2016) for predicate-argument identification; and (4) **Pipeline-N** is the same as Pipeline-S except that the Moses system is replaced by OpenNMT (Klein et al., 2017), a neural machine translation system.

5.2.3 Evaluation Metrics

For evaluation, we directly convert the output by our approach (e.g. Fig. 1(e)) to the form of linearized PredPatt (e.g., Fig. 1(d)), and follow the same manner in Zhang et al. (2017a), using the cased BLEU score and the token-level F_1 score to evaluate the results, since the generation of linearized PredPatt involves translation and information extraction. We also compute the recoverability: the number of outputs can not be recovered to the tree structure (e.g., Fig. 1(c)).

5.2.4 Evaluation using BLEU

Table 2 shows the cased BLEU scores of linearized PredPatt and linearized predicates⁷ on the test set. Selective Decoding significantly improves the performance on both of them. Compared to the previous best approach (Joint Seq2Seq), Selective Decoding improves the BLEU score of linearized PredPatt to 23.88, and the score of linearized predicates to 25.42.

Approach	Linearized PredPatt	Linearized Predicate
Pipeline-S	17.19	17.24
Pipeline-N	18.03	18.59
Joint Moses	18.34	16.43
Joint Seq2Seq	18.94	21.55
Selective Decoding	23.88	24.81
- pretrained embeddings	23.67	25.42
- beam search	22.07	23.94

Table 2: Evaluation results (BLEU) of linearized PredPatt and linearized predicates on the test set.

We also report two ablation variants of Selective Decoding, i.e., without the pretrained word embeddings for parameter initialization (-pretrained embeddings), and without beam search, only using greedy search during inference (-beam search). As shown in Table 2, while the pretrained word embeddings moderately improve the BLEU score of linearized PredPatt, they have slightly negative impact on linearized predicates. Beam search helps improve the BLEU score of both.

Selective Decoding explicitly models sequence generation and sequence labeling, which enables a standalone evaluation of the sequence generation process (i.e., the final output without predicate and argument labels). To make a baseline comparison, we train an OpenNMT system (Klein et al., 2017) directly on the same data ignoring the labels.

OpenNMT	Selective Decoding
24.92	25.16

Table 3: Evaluation results (BLEU) of sequence generation on the test set.

Table 3 shows the BLEU score of sequence generation on the test set. Selective Decoding achieves higher BLEU than OpenNMT. It demonstrates that the selective decoding mechanism

⁷In linearized predicates, arguments are replaced by placeholders. For example, the linearized PredPatt in Fig. 1(d) becomes “[?arg started: p_h Sth:= [?arg firing: p_h ?arg]]” after replacement.

learning with extra labels helps improve the quality of sequence generation. We also notice that the BLEU score (25.16 in Table 2) of the final linearized PredPatt from Selective Decoding is even higher than OpenNMT (24.92 in Table 3). Hence, we can draw a conclusion that simply placing a labeler atop the OpenNMT system to tackle the cross-lingual open IE problem will not narrow the gap in BLEU between itself and our Selective Decoding approach.

5.2.5 Evaluation using F_1

Approach	Predicate	Argument
Pipeline-S	24.24	33.54
Pipeline-N	24.41	33.51
Joint Moses	25.11	38.90
Joint Seq2Seq	25.79	34.44
Selective Decoding	31.71	40.81
- pretrained embeddings	31.56	40.81
- beam search	30.06	39.06

Table 4: Evaluation results (F_1) of predicates and arguments on the test set.

We compute the token-level F_1 score (Liu et al., 2015) of predicates and arguments. As shown in Table 4, Selective Decoding substantially improves the F_1 score of both predicates and arguments. In the ablation test, pretrained word embeddings slightly improve F_1 of predicates, but have no improvement on F_1 of arguments. Beam search helps improve the score of both.

5.2.6 Recoverability

We compute the number of the linearized PredPatt outputs from which the tree structure representation can not be recovered, including the empty outputs and the outputs which have unmatched brackets, or have zero or multiple heads for an argument or a predicate. As shown in Table 5, compared to the previous best Joint Seq2Seq approach, Selective Decoding further reduces the number of unrecoverable outputs by one order of magnitude.

Pipeline-S	Pipeline-N	Joint Moses	Joint Seq2Seq	Selective Decoding
5,965	6,014	33,178	557	53

Table 5: Number of unrecoverable outputs.

5.2.7 Analysis

To analyze the difference between Selective Decoding and the previous best approach Joint

Seq2Seq, we plot the BLEU scores of the linearized PredPatt on the test set with respect to the lengths of the reference. As shown in Fig. 4, when the reference length is greater than 20, the linearized PredPatt generated by Selective Decoding gets notably better BLEU scores, especially for the reference length around 30. However, when the reference length is shorter than 11, the performance of Selective Decoding drops below the Joint Seq2Seq approach.

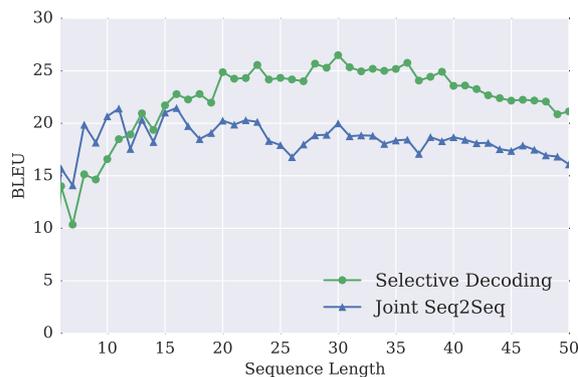

Figure 4: BLEU scores of the linearized PredPatt on the test set w.r.t. the lengths of the references.

To explain this performance drop, we randomly sample an example from the test set, where the reference length is shorter than 11, and the BLEU score of the linearized PredPatt generated by Joint Seq2Seq is higher than Selective Decoding. The example is shown in Table 6.

Input sentence and its English translation:

我哪怕有千分之一的希望呢,我死活都要给他做最后的
(Even if there was only a one thousandth of a hope, er, live or die I would give him my all.)

Reference⁸:

(1) (I) would give (him) (my all)

Selective Decoding:

(1) Even if (we) have (a .UNK per cent hope)
(2) uh, (I) would have SOMETHING⁹
(3) SOMETHING := (I) give (him) (the final thing)

Joint Seq2Seq:

(1) (I) wish (everyone) (last hope)

Table 6: Example outputs with the reference length shorter than 11.

In this example (Table 6), the Chinese input sentence has a grammatical error: the object modified by “最后的” is missing. Additionally, the reference linearized PredPatt output in this example is incomplete: the fact related to the concessive clause is missing. Although here Joint Seq2Seq gets the better BLEU score against the incomplete reference, Selective Decoding is able to better generalize over the train data: the facts it generates are much closer to the original input sentence, and even better than the reference.

Input sentence and its English translation:
 结果, 民主党失去了列举布什“罪状”的良机,
 (As a result, the Democratic party lost a good opportunity to list the ‘charges’ against Bush.

Reference:

- (1) As (a result), (the Democratic party) lost (a good opportunity)
- (2) (a good opportunity) list (the ‘charges’ against Bush)

Selective Decoding:

- (1) As (a result), (the Democratic Party) lost (the good opportunity)
- (2) (the good opportunity) cite (Bush)

Joint Seq2Seq:

- (1) (The result) is SOMETHING
- (2) SOMETHING := (the Democratic Party) lost (his opportunity)
- (3) (his opportunity) give (him) (good opportunity)

Table 7: Example outputs with the reference length longer than 20.

Another example where the reference length is greater than 20 is shown in Table 7. In this example, Selective Decoding generates the same number of facts as the reference, and the meaning of the facts is closer to the reference than Joint Seq2Seq: though not perfect, Selective Decoding captures “列举 布什 ‘罪状’ ” (“list the ‘charges’ against Bush”) by generating “cite (Bush)”, whereas Joint Seq2Seq fails to generate anything related.

⁸The predicate tokens are colored blue, and the argument tokens are colored purple. Head tokens are underlined in bold. Token labels and brackets are omitted.

⁹“SOMETHING” is a special argument used to indicate that the argument is a proposition.

5.3 Low-resource Scenarios

One of the goals of cross-lingual open IE is to extract facts from languages for which few NLP resources and tools are available, and represent the facts in the language for which plenty of resources and tools can be used. Therefore, we extend the experiments to cross-lingual open IE from 5 languages to English in a low-resource setting.

5.3.1 Datasets

Task	#Train	#Valid	#Test
uzb-eng	31,581	1,373	1,373
tur-eng	20,774	903	903
amh-eng	12,140	527	527
som-eng	10,702	465	465
yor-eng	5,787	251	251

Table 8: Number of data used for cross-lingual open IE in low-resource scenarios.

To prepare the experiment datasets, we first collect bitexts from DARPA LORELEI language packs (Strassel and Tracey, 2016). The source languages of the bitexts are Uzbek, Turkish, Amharic, Somali, and Yoruba.¹⁰

We then run a process similar to Zhang et al. (2017a) to generate pairs of source-language sentences and English linearized PredPatt: first, we employ SyntaxNet Parser (Andor et al., 2016) to generate Universal Dependency parses for the English sentences, and then run PredPatt (White et al., 2016) to generate English linearized PredPatt from the Universal Dependency parses. We remove empty sequences and very long sequences (length>50) in the pairs, and randomly split them into training, validation and test sets in the ratio of 23:1:1. The detailed number of pairs for each experiment is shown in Table 8.

5.3.2 Baseline

To compare with Selective Decoding, we implement the Joint Seq2Seq approach which uses a standard encoder-decoder model as the baseline.

5.3.3 Evaluation Results

We train the models of Selective Decoding and Joint Seq2Seq respectively using the same hyper-

¹⁰These bitexts are from LDC2016E29 (uzb-eng); LDC2014E115 (tur-eng); LDC2016E86 and LDC2016E87 (amh-eng); LDC2016E90 and LDC2016E91 (som-eng); LDC2016E104 and LDC2016E105 (yor-eng).

parameters setting described in § 5.1, and evaluate the results on the test set by computing the cased BLEU score of the linearized PredPatt, and the token-level F_1 scores.

Task	Joint S2S	Selective Decoding
uzb-eng	8.66	10.76
tur-eng	7.18	7.47
amh-eng	7.18	8.37
som-eng	10.61	13.06
yor-eng	11.31	12.19

Table 9: Evaluation results in low-resource cross-lingual open IE scenarios: BLEU of linearized PredPatt.

Table 9 shows the evaluation results using BBLEU. Selective Decoding outperforms the Joint Seq2Seq approach by 0.29-2.45, which is expected since Selective Decoding employs the decoder solely for sequence generation and the selector solely for sequence labeling.

Task	Predicate		Argument	
	Joint S2S	Selective Decoding	Joint S2S	Selective Decoding
uzb-eng	12.50	12.46	19.57	24.08
tur-eng	9.89	6.49	17.39	17.76
amh-eng	8.44	8.82	17.31	18.58
som-eng	13.64	13.91	22.81	25.38
yor-eng	11.97	10.74	22.61	25.57

Table 10: Evaluation results in low-resource cross-lingual open IE scenarios: the token-level F_1 of predicates and arguments.

The F_1 score measure is shown in Table 10 where both the F_1 scores of predicates and arguments are computed separately. For predicates, Selective Decoding shows no advantage to the Joint Seq2Seq approach. In the tur-eng task, its F_1 score is obviously worse than the baseline. However, Selective Decoding in general shows promising results in the argument F_1 scores.

6 Conclusions

In this paper, we recast cross-lingual open IE as a more general problem, which involves sequence generation and sequence labeling. We propose a novel encoder-decoder model which employs the selective decoding mechanism to explicitly model the sequence generation and sequence labeling process. Experimental results show our approach achieves consistent and significant improvements in a variety of cross-lingual open IE scenarios.

Since the selective decoding mechanism is not limited to cross-lingual open IE, we believe that it will also benefit other NLP tasks which can be generalized as jointly doing sequence generation and sequence labeling. In the future, we plan to investigate its effectiveness to tasks such as cross-lingual information retrieval.

Abstract

This paper improves on several aspects of a sieve-based event ordering architecture, CAEVO (Chambers et al., 2014), which creates globally consistent temporal relations between events and time expressions. First, we examine the usage of word embeddings and semantic role features. With the incorporation of these new features, we demonstrate a 5% relative F1 gain over our replicated version of CAEVO. Second, we reformulate the architecture’s sieve-based inference algorithm as a *prediction reranking* method that approximately optimizes a scoring function computed using classifier precisions. Within this prediction reranking framework, we propose an alternative scoring function, showing an 8.8% relative gain over the original CAEVO. We further include an in-depth analysis of one of the main datasets that is used to evaluate temporal classifiers, and we show that in spite of the density of this corpus, there is still a danger of overfitting. While this paper focuses on temporal ordering, its results are applicable to other areas that use sieve-based architectures.

1 Introduction

Narratives that describe a series of events rarely do so in order. Basic rules of journalism dictate that important information leads a news report, and accordingly, algorithms that re-order events chronologically need to combine a wealth of contextual, rhetorical, and commonsense information.

Most research on event ordering aims to produce only partial orderings of event mentions

and time expressions (Bethard and Martin, 2007; Cheng et al., 2007; UzZaman and Allen, 2010; Llorens et al., 2010; Bethard, 2013). In the past, labeled corpora used for training and evaluation contained only small subsets of pairs of events and times. Some of these corpora, like *Timebank*, have annotations restricted to salient, easily labeled pairs within the same document. Other more recent data sets contain annotations that form timelines of events that involve common entities (Pustejovsky et al., 2003; Minard et al., 2015). Due to the lack of consistency of annotations across event pairs, it is difficult to use these corpora in accurately measuring the practical performance of event ordering algorithms.

Richer datasets are becoming available that provide more complete event orderings which include logically implied relations that are less evident from local text features. In particular, the *TimeBank-Dense* corpus provides a significantly more dense and complete set of annotations, allowing for the evaluation of methods that make use of broad contextual information across many event pairs (Cassidy et al., 2014). One method that has been developed to leverage such information is CAEVO—a sieve-based architecture that made the first effort toward dense event ordering (Chambers et al., 2014). This method maintains transitivity constraints across independent predictions from several specialized classifiers. More specifically, the architecture runs a series of “sieve” classifiers with their predictions ranked in order by precision using a held-out dataset. The higher precision classifiers are ranked more highly in the series, and predictions are expanded by transitivity rules (e.g. if event e_1 is before e_2 , and e_2 is before e_3 , then e_1 is before e_3) after each individual classifier generates its predictions. The high den-

sity of the constructed prediction graph allows the transitivity rules to generate accurate predictions for links that would otherwise be difficult to predict from the text.

This paper proposes improvements to CAEVO with respect to (1) feature engineering within machine learned sieves, (2) generalization of the sieve-based architecture to facilitate higher performing sieve prediction rerankings, and (3) the leveraging of unlabeled data. First, for our feature engineering improvements, we are motivated by the fact that TimeBank-Dense contains a relatively small training sample, and so we extend the feature sets for the architecture’s machine learned classifiers to include features that encode lexical information about events in relatively low dimensional spaces based on word embeddings (Mikolov et al., 2013) and semantic role labeling (SRL) annotations (Gildea and Jurafsky, 2002). Second, our generalization of the sieve-based architecture allows us to experiment with alternative methods for establishing the precedence ranking of sieve predictions. Furthermore, we identify an approximate upper bound on any ranking method’s performance. Lastly, in our experiments with unlabeled data, we analyze the effect of changing the density of the architecture’s prediction graph. Our hypothesis is that increasing the number of predictions on unlabeled data will increase performance on labeled data through the application of CAEVO’s transitivity constraints.

Our extensions produce new state-of-the-art results on the original test split of TimeBank-Dense (8.8% F1 increase). Beyond this, we describe alternative evaluations on other splits of the data in order to analyze the effect of the common small sizes of temporal corpora like TimeBank-Dense. This analysis is critical for future work in temporal ordering, and sheds further light on previous work’s results.

2 Related Work

Early work on event ordering focused on developing machine-learned classifiers that label the temporal relations between small subsets of pairs of events within documents using lexical and syntactical features (Bethard and Martin, 2007; Cheng et al., 2007; UzZaman and Allen, 2010; Llorens et al., 2010; Bethard, 2013). Later work leveraged information across pairwise predictions by imposing transitivity constraints using techniques

like integer linear programming and Markov logic networks (Bramsen et al., 2006; Chambers and Jurafsky, 2008; Tatu and Srikanth, 2008; Yoshikawa et al., 2009). CAEVO followed these and other hybrid rule-based approaches (D’Souza and Ng, 2013), but with the transitivity constraints yielding larger gains in performance for the more complete temporal graph constructed on the TimeBank-Dense corpus (Cassidy et al., 2014; Chambers et al., 2014).

The *TimeBank-Dense* corpus provides a significantly more dense and complete set of annotations compared to previous corpora.¹ TimeBank-Dense extends a subset of the original TimeBank corpus with annotations for (almost) *all* event-time, time-time, and event-time pairs across consecutive sentences, as well as relations to the document creation time. This dense corpus facilitated the evaluation of CAEVO—a sieve-based architecture which maintains transitivity constraints across independent predictions from several specialized classifiers.

Recent work has focused on the construction of timelines of related events, using SRL annotations to determine which events are related through common actors (Laparra et al., 2015). In addition, other work has outperformed the original CAEVO with a 2.2% relative F1 gain on TimeBank-Dense using word embedding features within a stacked ensemble of event-event, event-time, and event-creation-time logistic regression classifiers (Mirza and Tonelli, 2016). We draw inspiration from this recent work by incorporating SRL and word embedding features into the machine-learned CAEVO sieves.

The CAEVO architecture is itself inspired by the sieve-based architectures that have been successfully applied to event and entity coreference as well as spatial relation extraction tasks (Lee et al., 2012, 2013; D’Souza and Ng, 2015). Years since CAEVO’s introduction, a coreference sieve architecture still achieves top performance (Lee et al., 2017). The key idea behind these architectures is to combine information from several classifiers by assigning precedence to predictions according to the reliability of the classifier from which they originate. A precision-ranked series of

¹The new corpus is the result of several TempEval competitions (Verhagen et al., 2007, 2010; UzZaman et al., 2012) which prompted efforts to develop more complete event ordering annotations (Bramsen et al., 2006; Kolomiyets et al., 2012; Do et al., 2012).

“sieve” classifiers generate predictions, and predictions from the more reliable sieves earlier in the series inform the predictions of the less reliable sieves later in the series. Generally, the predictions from a highly-ranked sieve can inform a low-ranked sieve in several ways, but within CAEVO, predictions from early classifiers are coupled via transitive inference rules to generate an expanding set of predictions that override output from less reliable classifiers later on in the series. In the next section, we describe a more generic view of this architecture which will motivate alternative methods for assigning precedence to predictions from the collection of classifiers.

3 Generalizing Sieve Architectures

Sieve architectures are used in many areas such as entity coreference, relation extraction, and temporal ordering. A core contribution of this paper is a generalization of how these models score and rank their decisions. Like other sieve models, CAEVO uses a precision-ranked series of classifiers (i.e. “sieves”) coupled with transitivity constraints to provide a solution to the event ordering task. However, prior work has not investigated alternatives to the coarse-grained precision-based rankings provided by the architecture. This section gives a generalized formal view on this precision-ranked setup, and Section 4.3.1 describes our experiments with new alternatives to traditional sieve architectures that are available within our generalized view.

Informally speaking, a sieve architecture applies a sequence of classifiers that each make their own independent labeling decisions, and the architecture resolves conflicts between these decisions by assigning precedence to those which have higher estimated precision. The architecture estimates the precision for each sieve on a development set of data, and associates all predictions from a given sieve with this precision estimate. These precision scores determine an overall ranking to predictions within the final system. When labeling a new test document, the architecture chooses predictions from all higher precision sieves over predictions from lower precision sieves. But this common ranking of predictions is coarse-grained, so this paper proposes other ways of ordering the classifier predictions. Figure 1 illustrates the difference between prediction rankings from traditional sieve architectures and our

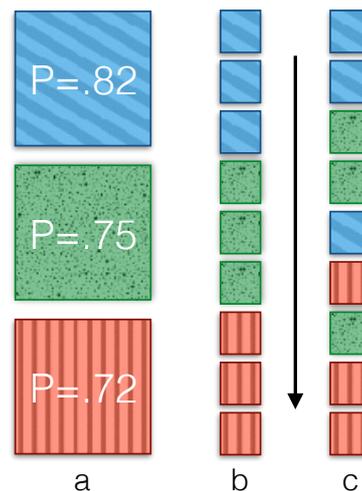

Figure 1: Sieve classifier decisions as ranked in a sieve architecture: (a) three sieves with their precisions, (b) each sieve’s decisions ranked as in a traditional system, (c) a potential ranking influenced by precision, but not strictly bound to it.

alternatives. The middle column shows the strict prediction ordering given by traditional sieve systems, but the fuzzy ordering in the right column is possible within our proposed alternative architectures. Section 4.3.1 explores this in depth.

We now formally define a typical sieve architecture (in terms of the temporal ordering domain). Consider the set of event mentions E , time expressions T , and temporal relation types $L = \{\text{BEFORE, AFTER, INCLUDES, INCLUDED, SIMULTANEOUS, VAGUE}\}$. We desire an architecture that encodes functions $f_{ee} : E \times E \rightarrow L$, $f_{et} : E \times T \rightarrow L$, and $f_{tt} : T \times T \rightarrow L$ which accurately classify relations between event-event, event-time, and time-time pairs, respectively. The gold-standard annotations within our corpora are logically consistent, so we can assume that the true event orderings induced by the functions f_{ee} , f_{et} , and f_{tt} conform to the transitivity constraints given in Table 1.

Algorithm 1 depicts a generalized view of the CAEVO architecture which encodes approximations to the desired f_{ee} , f_{et} , and f_{tt} labeling functions (and this view also applies to other typical sieve systems). The algorithm combines predictions from a set of sieve classifiers \hat{F} that provide partial approximations to f_{ee} , f_{et} , and f_{tt} within restricted syntactic contexts. As described by Chambers et al. (2014), \hat{F} contains both rule based and machine-learned classifiers. In this pa-

Table 1: Transitivity and symmetry constraints in C from Equation 1 and Algorithm 1. In this list, every constraint applies to events and/or times o_1, o_2 and o_3 . We abbreviate ‘‘SIMULTANEOUS’’ with ‘‘SIMULTAN’’ due to space constraints.

per, our experiments focus on the machine learned sieves that give within-sentence event-event predictions (EEWS), within-sentence event-time predictions (ETWS), within-syntactic dominance relation event-event predictions (EED), and event to document creation time relations (EDCT).

Given a set of unlabeled data points $D \subseteq (E \cup T) \times (E \cup T)$, Algorithm 1 uses the sieves in \hat{F} to construct a set of predictions $\hat{F}_D = \{(d, \hat{f}(d), \hat{f}) \mid d \in D, \hat{f} \in \hat{F}\}$ where each prediction is indexed with its associated sieve \hat{f} . The algorithm then sorts and partitions \hat{F}_D according to a prediction scoring function $s : (D \times L \times \hat{F}) \rightarrow \mathbb{R}$. Finally, the returned set of predictions R is constructed by iteratively adding predictions from \hat{F}_D in descending order (with respect to s) while applying constraints C . C consists of the transitive rules (depicted in Table 1) along with the constraint that prior predictions in R cannot be overwritten by

later predictions. The rules C are applied at each iteration by extending the current predictions with those implied by transitivity.

return  $R$ 

```

One of the weaknesses of CAEVO (and other sieve-based systems) addressed in this paper is that its scoring function, $s(d, \hat{f}(d), \hat{f})$, is simply the precision of \hat{f} as measured on held-out data. All predictions made by \hat{f} must have the same ranking score (see Figure 1 again). This coarse-ranking is likely to be sub-optimal relative to rankings based on other scoring functions.

We can motivate improvements to Algorithm 1 by viewing it as a greedy approximation to the optimization problem which chooses a set of scored predictions according to:

$$R = \arg \max_{S \subseteq \hat{F}_D} \left(\sum_{p \in S} s(p) \right) \text{ subject to } C \quad (1)$$

Given the view that CAEVO is providing a solution to the objective in Equation 1 using Algorithm 1, it is straightforward to see possible directions for improvement. Namely, the architecture can be improved through changes to the sieves \hat{F} , the scoring methods s , the constraints C , the data D , and the underlying greedy approximation algorithm. Intuitively, if we want Equation 1 to give a highly accurate set of predictions, then we should pick an \hat{F} to contain more accurate classifiers², an s which ranks correct predictions above incorrect predictions, and a large set D which enables C to propagate precise labels from easy-to-classify data samples onto hard-to-classify data samples. Notably, CAEVO’s rigid choice of scoring function s to be the precision of \hat{f} only allows s to give a coarse-grained scoring, which can score incorrect predictions higher than correct predictions.

²This includes possibility that one or more $\hat{f} \in \hat{F}$ could be parameterized by more complex function approximators, such as neural networks (LeCun et al., 2015).

Furthermore, CAEVO’s sieve-inference in Algorithm 1 is greedy, and other methods like integer linear programming (ILP) which provide better solutions to Equation 1 might yield more accurate predictions. Lastly, CAEVO limits D to only contain *labeled* evaluation data without taking advantage of constraints imposed across *unlabeled* event pairs. These observations motivate several of the extensions we describe and experiment with below.

4 Models and Experiments

In our experiments, we replicate CAEVO, add new features to the sieves, modify the scoring function, and include larger amounts of related unlabeled data to further constrain the predictions. Unless otherwise noted, results are computed using the original train-dev-test split of the TimeBank-Dense and original CAEVO experiments (Chambers et al., 2014; Cassidy et al., 2014).

4.1 Replication

We replicate the CAEVO architecture within a more generic framework with the aim of substantiating and extending the CAEVO results from Chambers et al. (2014). The replication process allows us to validate the robustness of the originally published results while determining their sensitivity to various parameter settings.

We reconstruct features within an alternative feature engineering pipeline, and ensure that the feature matrices match those from the original system. During this process, we observed two issues in the original system. First, features based on gold-standard event “tense”, “aspect”, and “class” were not included in the machine-learned models that produced the reported results even though they were described in the original paper (they appear to have been inadvertently configured off). In light of this, we leave these features out of our replicated architecture, but add them into the revised architecture in our feature engineering experiments. Second, the EEWS, EED, and ETWS sieves in CAEVO used a minimum feature occurrence cutoff of 2 across training data whereas EDCT used a cutoff of 1. We experiment with different settings of these values in the next section. Other minor bugs and the details of replication are described in the appendix.

The **R** column of Table 2 gives micro-averaged

accuracies³ for the four machine-learned sieves and the full replicated architecture. These accuracies reproduce the original CAEVO results up to less than 1% discrepancy in accuracy due to version differences between the machine-learning libraries and minor bugs in the original system.⁴

4.2 Rich Feature Engineering

We extend our CAEVO replication with additional knowledge of event attributes, word embeddings, and SRL labels for each of the machine learned sieves.

4.2.1 Event Attributes

As noted above, the original CAEVO paper had reported the use of gold-standard TimeML tense, aspect, class, polarity, and modality event attribute features, but close inspection of the architecture suggests that these features had been left out when computing the final results. We experimented with adding features computed from these attributes into each of the machine-learned classifiers. For each event in a given event-event or event-time pair, we extend the feature vector with indicators for possible values of each event attribute. Also, for each event-event pair, we extend the feature vector with indicators of whether the event attributes are equal for the source and target (e.g. equal tense), as well as features representing the conjunction of each attribute across source and target (e.g. for the tense attribute, one of the indicators is *PAST-FUTURE*, which is for a pair containing a past tensed event and a future tensed event).

The F1 scores computed on the TimeBank-Dense test-set with the additional event attribute features are given in the **Ev** column of Table 2. Each machine-learned sieve increases in F1, but the overall architecture *decreases* slightly. This highlights the non-monotonic relationship between the performance of individual sieves and the performance of the overall architecture.

4.2.2 Semantic Role Labeling

We compute additional features from annotations generated using the *mate-tools* SRL system (Björkelund et al., 2009). Specifically, for a given pair, we compute features representing SRL predicates of the events as well as their conjunction.

³The micro-averaged accuracies are equivalent to micro-averaged F1 scores computed on data for which some label is output by a classifier.

⁴The results for the rule-based sieves are not shown, but they match the original system exactly.

Sieve	R	Ev	SRL	W2V	R+	F+
EDCT	.524	.547	.511	.524	.553	.553
ETWS	.414	.450	.414	.450	.443	.480

Full	.502	.495	.493	.504	.520	.527

Table 2: Micro-averaged accuracies on the TimeBank-Dense test-set for machine-learned sieves and the fully replicated architecture with various feature extensions. Results are given for our baseline CAEVO replication (**R**) and extensions with gold-standard event attribute features (**Ev**), SRL features (**SRL**), word embedding features (**W2V**), all new features (**R+**), and all new features with new feature count cutoffs (**F+**).

Also, we compute the shortest path between a pair within the undirected graph formed by the SRL predicates and arguments (i.e. where there are nodes for predicate spans and argument spans, and there is an edge between two spans if one is the argument of the other). As shown in Table 2 under the **SRL** column, these features only give a minor improvement in micro-averaged F1 for the EED sieve, but hurt performance of the other sieves and the architecture on the TimeBank-Dense test set. However, we believe this may be due to overfitting, as we observe 3% and 4% gains for the ETWS and EED sieves with these features on the development set.

4.2.3 Word Embeddings

Given that recent work has shown improvements using word embeddings (using log-linear neural language models such as the Skip-Gram architecture), we extend feature vectors with the word vectors representing events and their similarity. Following Mirza and Tonelli (2016), we use the three million 300-dimensional *word2vec* vectors⁵ pre-trained on part of the Google News dataset (Mikolov et al., 2013). For each token span corresponding to either an event mention or time expression in a given pair datum, we extend the feature vector with normalized sums of word vectors computed from tokens of the span. In addition, we include the cosine similarity between the vectors for the events in a pair, as well as a vector representing the normalized difference between the pair’s vectors. Micro-averaged F1 scores on the TimeBank-Dense test set with these word embed-

⁵Pre-trained word vectors can be retrieved from <https://code.google.com/archive/p/word2vec/>.

ding features are given in the **W2V** column of Table 2. The ETWS and EED sieves show improvements of more than 3%, and the EEWS shows a gain of about 1%. However, the F1 score for the overall architecture remains nearly the same.

4.2.4 Full Extension

We extend the machine learned sieves with the full set of event attributes, SRL, and word embedding features as described above. As shown under the **R+** column of Table 2, this yields a 2% gain in micro-averaged F1 for the overall architecture as well as gains for each individual sieve. Also, Section 4.1 mentioned that the feature count cutoffs in **R** and **R+** are set to 1 for EDCT and 2 for all remaining machine-learned sieves. For simplicity, we set the cutoff to 1 across all sieves in **F+**, yielding a 4% improvement in ETWS and minor gains in EEWS and the full system over **R+**. Overall, our feature engineering efforts give **F+** a 5% relative gain (2.5% absolute) over the replicated CAEVO architecture (**R**).

4.3 Modifying Sieve Inference

This section proposes new inference methods for sieve architectures by varying the scoring function s and adding unlabeled data to D from Algorithm 1 and Equation 1 in Section 3. This is a core contribution that can benefit not just temporal ordering, but also other sieve systems applied to other NLP tasks.

4.3.1 Alternative Scoring Methods

In the original CAEVO architecture’s implementation of Algorithm 1 from Section 3, the score $s(d, \hat{f}(d), \hat{f})$ is computed as the precision of the sieve \hat{f} on the development set. This greedy scorer s gives a coarse-grain ranking of sieve predictions, assigning equal precedence to all predictions from a given sieve \hat{f} . Intuitively, if we want to produce a higher accuracy architecture, then we should adjust the scoring function s to score all correct predictions more highly than all incorrect predictions⁶. CAEVO’s use of \hat{f} precision in computing s is a coarse-grained heuristic in line with this goal, but there are better choices.

Ideal Scorer In the best case, the **F+*** column of Table 3 shows the micro-averaged F1 (equivalent to accuracy) when s scores a prediction as

⁶Note that while such a choice of s should produce good performance, this performance is not necessarily optimal under the transitivity constraints.

Data	V	CAEVO (R)	F+	F+L	F+S	F+LU	F+*
Dev	.378	.481	.485	.490	.481	.491	.585
Test	.403	.502	.527	.546	.521	.541	.642

Table 3: Micro-averaged F1 scores on the original TimeBank-Dense train-dev-test split for several versions of the sieve architecture. Results are given for the VAGUE majority baseline (V), the CAEVO replication (R), the architecture with the extended feature set (F+), and varying inference methods under the extended feature set. The varying inference methods include an alternative prediction scoring function s computed by precision of each sieve on each relation label (F+L), s computed by precision multiplied by classifier probability estimates (F+S), s computed by precision on each label with extra unlabeled data (F+LU), and s computed to produce near-optimal ordering (F+*).

$s(d, \hat{f}(d), \hat{f}) = 1$ if $\hat{f}(d)$ is the correct label for datum d , and 0 otherwise. This near-optimal choice of s in F+* gives a 10% gain over F+, suggesting a large room for improvement by re-ranking sieve predictions rather than improving the accuracy of the individual sieves. This suggests that architecture performance will increase by improving the estimates of the prediction *confidence* encoded by s , rather than improving the predictions themselves.

New Scorers We thus consider several alternatives for s . First, we attempted estimating s by training a reranking logistic regression model to predict whether $\hat{f}(d)$ is the correct label for d within prediction $(d, \hat{f}(d), \hat{f})$. This approach did not improve performance over other simpler approaches (possibly due to the small size of reranking training data), and so we only report results for the simpler approaches. In one approach, motivated by the observation that precision varies across relation labels, we compute $s(d, \hat{f}(d), \hat{f})$ as the precision of \hat{f} for predictions with label $\hat{f}(d)$ on the dev data. This sieve-label precision approach improves F1 over F+ as shown in the F+L column of Table 3. In a second approach, we compute $s(d, \hat{f}(d), \hat{f})$ as the precision of \hat{f} multiplied by the probability assigned to $\hat{f}(d)$ by the logistic regression model employed by \hat{f} . According to the F+S column of Table 3, this approach does not show improvement over F+.

4.3.2 Leveraging Unlabeled Data

CAEVO uses Algorithm 1 to draw inferences about a data set D . In the original implementation, this set contained only the gold-standard labeled evaluation pairs within two sentence windows. However, if D were expanded with other unlabeled data points outside of two sentence windows (for which it is easy to predict labels with

high precision), the transitivity constraints in C might generate further high precision predictions on the labeled data. Interestingly, this gives the architecture the property that making a larger number of predictions on a logically connected set of data can lead to higher overall performance on subsets of that data. Given this observation, we apply the F+L version of the architecture to all pairs of events and times within a document. The resulting F1 scores given this expansion of D with the unlabeled TimeBank-Dense pairs are shown under column F+LU of Table 3. Unfortunately, these scores show no improvement over the scores under column F+L which suggests that the architecture did not draw high precision inferences from the unlabeled data to labeled data. This may be due to the lack of sieves tuned specifically to make between-sentence unlabeled data predictions, or it may be due to an inherent difficulty in making these predictions over the labeled within-sentence and consecutive sentence predictions.

5 Deep Dive into the Data

One of the difficulties facing the temporal ordering community is sparse data. This has been an issue since the original TimeBank Corpus, and the TimeBank-Dense Corpus had data expansion as one of its core goals. However, we argue that data sparsity is still a problem, and previous work tends not to explore different test sets, potentially misidentifying positive and negative results specific to particular splits of the data. This issue seems especially relevant due to the small size of the TimeBank-Dense data (only 5 documents in dev and 9 documents in test for the original split (Chambers et al., 2014)).

The underlying question is whether new results present a significant improvement upon older ones. We consider multiple cross-validation splits

of the data to get some sense about the answer to this question. We chose this approach over null-hypothesis significance testing due to limitations induced by small sample size in conjunction with the dependencies between predictions arising through the transitivity constraints. These two issues render it difficult to make a hard determination of significance in a way that does not violate hypothesis testing assumptions. Instead, our cross-validation splits give a weak qualitative sense of the generalizability of our methods.

Our cross validation setup consisted of four splits of the 36 documents with 5 documents per test set and 4 documents per development set for each split. Table 4 shows the micro-averaged F1 scores of the architectures described in the previous sections on each of these splits. Unsurprisingly, the results show that some architecture scores were boosted while others lessened on these alternative splits. Notably, the added features in **F+** still make consistent gains over the CAEVO replication **R**, and the ideal scorer **F+*** makes consistent large gains (as high as 18% on Fold 3, and a low of 6% on Fold 1). However, **F+L** performs well on the development sets but does not improve performance on the test sets. We hypothesize that **F+L** overfits to the development sets due to their small size and the small number of predictions available to compute sieve-label precisions. The consistently large gains of **F+L** on the dev sets suggest that the method will achieve high performance as long as the precision estimates in s are accurate, but the method requires more development data than **F+** to compute accurate estimates without overfitting due to the large number of sparsely distributed sieve-label combinations.

This extra analysis helps to highlight the potential for overfitting. We hope this encourages future work to bear this in mind, and to also present results across multiple tests. Extra evaluations like those in this section are often unexciting, but **we argue that it is of utmost importance that they are conducted**. This paper could have ended at the previous section’s top test set results, but we hope the reader sees extra value in the deep analysis of one’s results.

6 Discussion

In the above experiments, we successfully replicated the CAEVO system from Chambers et al. (2014), and then proposed a generalization of the

sieve-based architecture that enabled several new extensions and improvements. With the injection of new features, we improve the overall system with a **5%** relative gain in F1. Furthermore, our generalized version of CAEVO’s sieve architecture allowed us to score and rank predictions based on both label and sieve precision, raising the F1 results to an **8.8%** relative improvement over our replicated CAEVO (under **F+L** in Table 3). We consider these results a new state-of-the-art on the TimeBank-Dense corpus. In addition, the large gains using a near-optimal scoring function (under **F+*** in Table 3) suggest that future work might make substantial progress by building further alternative prediction scoring methods.

We also perform an in-depth analysis of our improvements on alternative splits of the data. Through this analysis, we find that our feature engineering results are robust. More interestingly, while the **F+L** scoring method gives increased F1 on the original TimeBank-Dense split and all cross-validation dev sets, it does not yield improved performance on our alternative cross-validation test sets. This analysis suggests significant improvement for **F+L** over the original architecture, but with possible overfitting label-specific precision estimates on our small amount of development data.

Finally, we presented the first experiments that leveraged unlabeled data. These experiments gave negative results, but we believe future research might see improvements through inference over unlabeled data by (1) improving the precision of unlabeled data predictions (through the incorporation of precise between-sentence prediction sieves), (2) increasing the density of the unlabeled data (e.g. by including easy-to-predict cross-document links between related events), (3) increasing the number of constraints across the data through the incorporation of sieves for additional tasks like event and entity coreference (coref), or (4) increasing the size of the data for more reliable evaluation and training. With respect to (4), we hypothesize that although Timebank-Dense contains more temporal relations than other temporal corpora, it is still small in size. Our hope for future work is to extend the data set with more dense annotations, but spread across a larger number of document contexts, such that different scoring and inference methods may be robustly trained and evaluated.

Split	Data	V	CAEVO (R)	F+	F+L	F+S	F+LU	F+*
Fold 0	Dev	.385	.574	.571	.596	.593	.596	.676
	Test	.400	.503	.535	.534	.530	.534	.632
Fold 1	Dev	.435	.519	.537	.592	.543	.592	.663
	Test	.312	.443	.503	.501	.506	.501	.558
Fold 2	Dev	.450	.522	.542	.555	.521	.516	.684
	Test	.462	.528	.540	.507	.541	.506	.706
Fold 3	Dev	.436	.536	.562	.575	.535	.573	.664
	Test	.470	.484	.497	.500	.500	.497	.682

Table 4: Micro-averaged F1 scores on four cross-fold validation train-dev-test splits of TimeBank-Dense for the sieve architectures defined in Table 3. The new features in **F+** make consistent gains across folds, and the ideal scorer **F+*** demonstrates consistently large room for improvement using alternative scoring methods. The **F+L** model still performs well on the dev sets, but it gives no performance gains on test sets. This suggests the danger of overfitting the scoring functions s within sieve architectures, as the sieve-label precision scores use in **F+L** were computed over a small, four document dev set in each fold.

In sum, we present a new state-of-the-art event ordering model. Furthermore, we propose a generalized approach to classifier ranking that is applicable to all sieve architectures (not just temporal ordering). Instead of producing coarse-grained ranking of classifier predictions, our proposal selects more fine-grained, higher performing prediction rerankings. In addition, we show temporal ordering gains using SRL and word embedding features. The code for our event-ordering architectures and experiments is publicly available⁷. We hope that this work will encourage further efforts in dense event ordering research.

Acknowledgments

We thank Jesse Dodge and Noah Smith for advising and support with preliminary experiments that gave several negative results prior to the work in this paper, helping to prune likely dead-end research directions. We also thank the RTW group at CMU for allowing us to use their library repositories. The work of authors BM and DR was funded under NSF grant SES-1528409. NC was partially supported by a grant from the Office of Naval Research.

A Replication Details

While replicating CAEVO, we did not find any major issues that significantly change the results reported in the original paper. However, we found the following minor bugs: (1) bias features are included in the EEWS, EED, and ETWS machine-learned sieves but not in EDCT, (2) the computation of dependency path features does not always compute the shortest paths, and (3) code that computes token paths is specified to only compute for paths with length less than 4, but does not do this correctly. In our replicated version, we remove each of these bugs.

We also noticed the following quirks in the original system:

- Features based on gold-standard event tense, aspect, and class were not included in the machine-learned models that produced the reported results even though they were described in the original CAEVO paper.
- The EEWS, EED, and ETWS sieves were trained using feature matrices with a minimum feature occurrence count of 2 across training data whereas EDCT has a minimum feature occurrence count of 1. We know of no motivation for setting this parameter differently for the EDCT sieve, but resetting it to 2 within EDCT drops its performance to below the “All Vague” baseline sieve, resulting in it being effectively removed from the system, and yielding a 5% drop in performance. The sensitivity of the overall system’s performance to this parameter setting highlights the importance of using enough data to acquire accurate precision estimates to determine the prediction scoring.
- The EED sieve had a lower precision estimate than EEWS, but EEWS makes predictions on a superset of the event pairs for which EED makes predictions. This means that EED has no functional relevance with respect to the performance of the original architecture.

The replication process also revealed the sensitivity of the results to the details of feature engineering and feature selection. Overall, the process confirmed that minor flaws and oddities will likely remain in complicated architectures like CAEVO after they have been documented, and it

can be worthwhile to repeatedly inspect and replicate these systems to ensure that they function as specified.

Open Relation Extraction and Grounding

Abstract

Previous open Relation Extraction (open RE) approaches mainly rely on linguistic patterns and constraints to extract important relational triples from large-scale corpora. However, they lack of abilities to cover diverse relation expressions or measure the relative importance of candidate triples within a sentence. It is also challenging to name the relation type of a relational triple merely based on context words, which could limit the usefulness of open RE in downstream applications. We propose a novel importance-based open RE approach by exploiting the global structure of a dependency tree to extract salient triples. We design an unsupervised method to name relation types by grounding relational triples to a large-scale Knowledge Base (KB) schema, leveraging KB triples and weighted context words associated with relational triples. Experiments on the English Slot Filling 2013 dataset demonstrate that our approach achieves 8.1% higher F-score over state-of-the-art open RE methods.

1 Introduction

Open Relation Extraction (open RE) (Banko and Etzioni, 2008) aims at extracting relational triples from an open-domain corpus. Each triple contains two arguments and a phrase which denotes the relation between them. In this paper, we focus on discovering relations between *entities*.

Most successful open RE approaches (Fader et al., 2011; Xu et al., 2013; Bovi et al., 2015; Bhutani et al., 2016) extract salient relational triples based on lexical or syntactic patterns. However, such handcrafted or automatically learned

patterns are incapable of covering diverse relation expressions (Soderland et al., 2013). Subsequently, the shortest path between arguments derived from a dependency tree has been widely applied to generate patterns to capture long-distance and complex relations. However, additional heuristic rules are usually needed to filter out the resulting large number of meaningless patterns (Wu and Weld, 2010; Mausam et al., 2012; Bovi et al., 2015). Besides, such flat syntactic structures lack the ability to measure the relative importance of candidate triples in a sentence. For example, the sentence in *E1* places particular emphasis on the relation between “*Lucille Clifton*” and “*1936*” which therefore should be retained.

E1 “*Lucille Clifton, whom he married in 1958, was born in 1936.*”

We notice that a candidate relational triple is likely to be salient if its two arguments are strongly connected in a dependency tree. Instead of relying on patterns to capture important triples, we use an importance-based strategy by exploring the entire dependency tree structure to automatically measure the connection strength of candidate argument pairs. Specifically, we assume that a relational triple is important if there is a relatively short random walk-based distance between two relatively important arguments, measured against the entire dependency tree of a given sentence. For each argument pair, we apply an effective random-walk based method to assign weights to context words in the sentence (Section 2).

How to assign a meaningful relation type name to a relational triple is also a primary challenge for open RE. Previous methods use relevant context words in the associated sentence as relation phrases (type names) (Del Corro and Gemulla, 2013; Bhutani et al., 2016). However, there is still no generally accepted guideline for relation phrase extraction. Multiple relation phrases can corre-

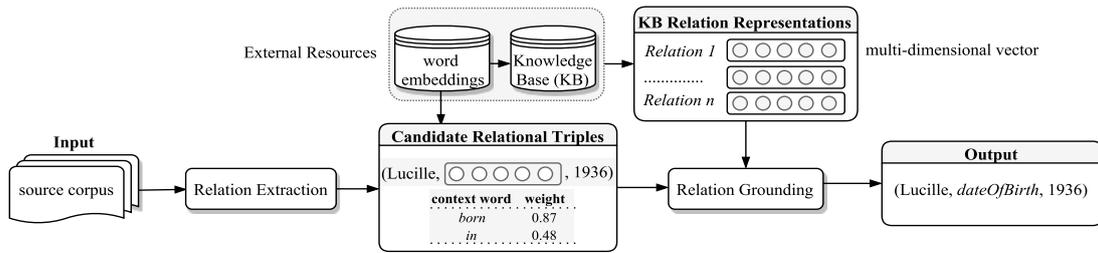

Figure 1: Framework overview.

spond to the same relation type. Besides, overly-specific or implicit relation phrases are incapable of providing adequate information for downstream applications. For example, the relation between “Patricia” and “Gary Cooper” cannot be clearly expressed by a set of words in the following sentence *E2*. Therefore, previous studies heavily rely on resources such as patterns (Soderland et al., 2013), training data (Weston et al., 2013), or distantly-labeled corpora (Angeli et al., 2015b) to map open RE triples to a known relation schema.

E2 “Patricia later described her relation with Gary Cooper as one of the most beautiful things that ever happened to her in her life.”

Compared with a small number of predefined relation types such as those defined in Automatic Content Extraction (ACE)¹, the relation schema in a large-scale Knowledge Base (KB) such as DBpedia (Auer et al., 2007) covers a much wider range of informative relations along with their type signatures. Considering the open-domain nature shared by open RE and a large-scale KB, we propose an unsupervised grounding method to name the relation type between two arguments as either a KB relation or NONE, by leveraging KB triples and weighted context information associated with each argument pair based on pre-trained word embeddings (Section 3). Compared with previous methods (e.g., (Riedel et al., 2013; Weston et al., 2013)), we regard intra-sentence context words as intermediate results for the subsequent grounding process, and we do not require any aligned training corpora or relation phrases for KB triples. The proposed framework is illustrated in Figure 1.

To the best of our knowledge, this is the first open RE method which exploits the global structure of a dependency tree to extract salient relational triples. This is also the first unsupervised relation grounding method to name relation

types for open RE based on KB triples and intra-sentence context information. Experiments on the English Slot Filling (SF) (Ji et al., 2010, 2011) 2013 dataset demonstrate that our approach outperforms state-of-the-art open RE approaches.

2 Relation Extraction

In this section, we introduce a graph-based method to extract argument pairs of salient relational triples. We first present the extended dependency tree construction for each sentence (Section 2.1). Then we show the computation of the relation strength between two arguments (Section 2.4) considering both their random-walk based distance (Section 2.2) and the relative importance of each argument in the tree (Section 2.3).

2.1 Extended Dependency Tree Construction

Given a sentence containing N words, we construct a weighted directed graph $G = (\mathcal{V}, \mathcal{E})$, where $\mathcal{V} = \{v_1, \dots, v_N\}$ represents words, and \mathcal{E} is a directed edge set, associated with each directed edge $v_i \rightarrow v_j$ representing a dependency relation originating from v_i to v_j . We assign a weight $w_{ij} = 1$ to $v_i \rightarrow v_j$ and add its reverse edge $v_j \rightarrow v_i$ with $w_{ji} = 0.5$. By adding lower-weighted reverse edges, we can analyze the relation between two nodes which are not connected by directed dependency links while maintaining our preferences toward the original directions.

We first apply a dependency parser to generate basic uncollapsed dependencies.² We annotate an entity or time mention node with its type. For example in *E1*, “Lucille Clifton” is annotated as a person, and “1936” is annotated as a date. Finally we perform coreference resolution which introduces coreference links between nodes that refer to the same entity within a document. We replace any nominal or pronominal entity mention with its coreferential name mention. For example, “he” is

¹www ldc.upenn.edu/collaborations/past-projects/ace.

²All the tools we used are introduced in Section 4.

replaced by “Fred James Clifton”. Formally, an extended dependency tree is an annotated tree of entity mentions and their links. By adding the reverse edges, we generate the final extended dependency tree in Figure 2. We regard any two entities as a candidate argument pair. $E1$ contains 4 entities and therefore we can extract $\binom{4}{2} = 6$ argument pairs (e.g., (“Lucille Clifton”, “1936”).

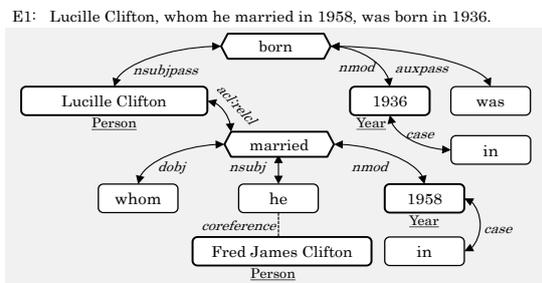

Figure 2: Extended dependency tree of E1.

2.2 Distance Computation

As mentioned previously, a shorter distance between two strongly connected nodes is more likely to indicate the existence of an important relation. We compute the distance between two nodes based on a Markov-chain model of random walk. We define a random walk through G by assigning a transition probability to each directed edge. Thus, a random walker can jump from node v_i to v_j and represent a state of the Markov chain. For a node v_i , we denote $\mathcal{N}(i)$ as the set of its neighbors. The probability of transitioning from node v_j to node v_i is defined as $p_{ji} = w_{ji} / \sum_{k \in \mathcal{N}(j)} w_{jk}$ for nodes v_i that have an edge from v_j to v_i , and 0 otherwise. We define the transition probability matrix of the Markov chain associated with random walks on G as P .

The **mean first-passage time** m_{ji} (Aldous and Fill, 2002) is the average number of steps needed by a random walker for reaching state i for the first time, when starting from state j . We call $c_{ij} = m_{ij} + m_{ji}$ as the **average commute time** (Lovász, 1993). The fact that c_{ij} can be regarded as a distance in G between nodes v_i and v_j is proven by Klein and Randić (1993). Compared with the shortest path between v_i and v_j , the value of c_{ij} will decrease when the number of paths connecting v_i and v_j increases and when the length of any path decreases (Fouss et al., 2007).

The fundamental matrix Z plays an essential role in computing various quantities related to ran-

dom walks. For a weighted and directed graph, Li and Zhang (2010) demonstrate that Z can be computed directly using the following equation:

$$Z = (I - P + ED)^{-1} - ED \quad (1)$$

where I is the identity matrix, E is a matrix containing all 1s, and D is the diagonal matrix with elements $d_{kk} = \pi(k)$ where $\pi(k)$ is the stationary distribution of node v_k in the Markov chain.

We can directly compute a mean first-passage $|\mathcal{V}| \times |\mathcal{V}|$ matrix and a symmetric average commute time matrix C based on Z as follows:

$$m_{ij} = \frac{z_{jj} - z_{ij}}{\pi_j} \quad (2)$$

$$c_{ij} = \frac{z_{jj} - z_{ij}}{\pi_j} + \frac{z_{ii} - z_{ji}}{\pi_i} \quad (3)$$

Using the example in Figure 2, we can obtain a 10×10 matrix M based on the above steps (10 nodes in total). We list the result involving only entity nodes in Table 1.

$m(row, col)$	Lucille	1958	he	1936
Lucille	0.0	64.2	24.7	74.7
1958	24.3	0.0	17.3	90.2
he	22.6	32.1	0.0	87.7
1936	20.2	101.3	37.1	0.0

Table 1: Mean first-passage time matrix M for E1.

Argument Role Identification: We notice that argument roles can be identified based on the mean first-passage time. In a weighted directed graph, m_{ij} and m_{ji} are not necessarily similar. Actually in many cases nodes that lie on the boundaries have shorter mean first-passage time to the central nodes in the graph while there exists longer mean first-passage time from a central node to a node close to the boundary. A central node is more likely to be the central argument. We define the first argument as the more important argument. Therefore, we can regard v_i as the first argument of the argument pair (v_i, v_j) if m_{ij} is larger than m_{ji} . If m_{ij} and m_{ji} are equal, v_i and v_j have similar argument roles. For example, the boundary node “1936” in Figure 2 has shorter first-passage time to the central node “Lucille Clifton” (i.e., the first argument) compared with the reverse direction.

2.3 Node Importance Computation

As we mentioned earlier, a candidate relational triple is more likely to be salient if it involves important entities of the sentence. In this section, we illustrate the node importance computation based on the extended dependency tree of a sentence.

TextRank (Mihalcea and Tarau, 2004) can be used to compute the importance of each node within G . Similarly, suppose a random walker keeps visiting adjacent nodes in G at random. The expected percentage of walkers visiting each node converges to the TextRank score.

We define a set of preferred nodes \mathcal{R} which correspond to entities in a sentence. We assign higher preferences toward these nodes when computing the importance scores since entities are more informative for relation extraction (Björkelund and Farkas, 2012). We extend TextRank by introducing a new measure called “back probability” $d \in [0, 1]$ to determine how often walkers jump back to the nodes in \mathcal{R} so that the converged score can be used to estimate the relative probability of visiting these preferred nodes. We define a preference vector $\mathbf{p}_{\mathcal{R}} = \{p_1, \dots, p_{|\mathcal{V}|}\}$ such that the probabilities sum to 1, and p_k denotes the relative importance attached to v_k . p_k is set to $1/|\mathcal{R}|$ for $v_k \in \mathcal{R}$, otherwise 0. Let I be the $1 \times |\mathcal{V}|$ importance vector to be computed over all nodes as follows.

$$I(i) = (1 - d) \sum_{j \in \mathcal{N}(i)} \frac{w_{ji}}{\sum_{k \in \mathcal{N}(j)} w_{jk}} I(j) + d \cdot p_i \quad (4)$$

ENTITY i	Lucille	he	1958	1936
$I(i)$	0.28	0.12	0.06	0.01

Table 2: Importance score of each entity in $E1$.

2.4 Combination and Filtering

Given the average commute time c_{ij} between nodes v_i and v_j (Section 2.2) and their relative importance scores $I(i)$ and $I(j)$ in G (Section 2.3), we will discuss how to combine them and generate the final score which can be used to measure the relation strength between two nodes. Intuitively, there exists a strong relation when there is a shorter distance between two relatively important nodes.

Previous approaches (Spagnola and Lagoze, 2011; Guo et al., 2011) consider the distance between two nodes and the influence of each node

modeled by its weighted frequency to measure the strength of links in networks. Similarly, in our setting we can regard c_{ij} as the distance between v_i and v_j and use the relative importance score to measure the influence of each node in G . Therefore, we obtain Equation 5 to compute the relation strength $F(i, j)$ between nodes v_i and v_j . We are more confident in predicting the existence of a salient relation with stronger relation strength.

$$F(i, j) = \frac{I(i) \times I(j)}{c_{ij}^2} \quad (5)$$

Relation Filtering: We get a complete entity graph since we analyze the connection between any two entities in a sentence. In this work, we focus on identifying the most significant structures among entities based on the connection strength we have obtained. Since the entity graph is undirected, we can simply apply the maximum spanning tree algorithm to keep those relatively important pairs. For $E1$, we obtain three argument pairs resulting after filtering: (“Lucille”, “1936”), (“Fred”, “1958”), and (“Lucille”, “Fred”). In comparison, the relations between argument pairs such as (“1958”, “1936”) and (“he”, “1936”) are less important.

3 Relation Grounding

We have presented how to extract candidate argument pairs in Section 2. In this section, we first introduce how to rank the context words given a pair of arguments (Section 3.1). Then we describe methods of learning KB relation representations from existing KB triples based on pretrained word embeddings. Finally we ground each relational triple to a KB relation or assign NONE (Section 3.2).

3.1 Context Word Selection and Weighting

In this section, we introduce how to extract informative context words and their associated weights given an argument pair (v_i, v_j) in a sentence based on the average commute time matrix \mathbf{C} introduced in Section 2.2. Previous work (Yu and Ji, 2016) regards this problem as finding important nodes in G relative to given arguments. However, they need to run the algorithm repeatedly to analyze the same graph for each argument pair. Here we discuss an efficient method to extract weighted context words.

We only keep nouns, verbs, adjectives, prepositions, and particles as indicative context words \mathcal{X} . We assume that a context word $v_k \in \mathcal{X}$ is more important relative to (v_i, v_j) if $c_{ik} + c_{kj}$ is close to c_{ij} . Actually if the relation between v_i and v_j does not rely on any indicative words, c_{ij} will be much smaller than $c_{ik} + c_{kj}$ considering other nodes in the same sentence. We denote Λ as the weight set for all the context words of a given argument pair (v_i, v_j) as follows. The higher λ_k is, the more important the context word v_k is relative to (v_i, v_j) .

$$\lambda_k = \frac{c_{ij}}{c_{ik} + c_{kj}} \quad (6)$$

In *E1*, given the argument pair (*Lucille Clifton*, *Fred James Clifton*), we generate the following weighted context words: $\{\text{married} : 0.60, \text{in}^1 : 0.36, \text{born} : 0.29, \text{in}^2 : 0.24\}$.

3.2 Grounding

The associated weighted context words of each candidate argument pair are not sufficiently informative and flexible to clearly express the relation between two arguments. Thus, we aim to name the relation between a pair of arguments as one of the KB relations or NONE by comparing the semantic representations of context words and KB relations based on word embeddings. We also learn argument type signatures from KB triples.

For each word we obtain its pretrained word embedding $e \in \mathbb{R}^k$ where k is the embedding dimensionality. For a phrase which contains multiple words, we simply average the vectors of all the single words in the phrase as its embedding.

Given a KB triple (h, l, t) composed of two entities h, t and a KB relation $l \in \mathcal{L}$ (the set of KB relations), we leverage a large-scale KB to learn the representation for each KB relation motivated by the basic idea behind previous studies (Bordes et al., 2013; Mikolov et al., 2013) that relation patterns can be represented as linear translations. We use $\mathcal{S}_l = \{(h_i, l, t_i), i = 1, \dots, |\mathcal{S}_l|\}$ to represent all the KB triples with the KB relation l .

KB relation type names can also provide important semantic information for relation representation and disambiguation especially when multiple relations co-occur in the same sentence, such as family relations (e.g., *spouse*, *parents*, and *other family*). We segment a compound name of a KB relation type into a set of words. For example, we

separate a DBpedia relation type name *political-Groups* into $\{\text{political}, \text{groups}\}$. Similarly, we average the vectors of all the words in a relation type name as its embedding $\tilde{e}_l \in \mathbb{R}^k$. Incorporating both implicit semantics from KB tuples and explicit semantics from KB relation names, we represent the relation embedding of each KB relation l as follows.

$$e_l = \frac{1}{|\mathcal{S}_l|} \sum_{i=1}^{|\mathcal{S}_l|} (e_{h_i} - e_{t_i} + \tilde{e}_l) \quad (7)$$

Both of the involved embeddings are obtained from the linear combination of pretrained word embeddings, which guarantees that they are in the same space.

Given a single KB relation type l , an argument pair (v_i, v_j) and a single context word x , we can compute the cosine similarity between any candidate open RE triple and any KB relation. We calculate the absolute value since we have already captured the direction of arguments in Section 2.2. Therefore, we can regard similarity scores -1 and 1 equally and 0 as the lowest score.

$$S(l, (i, j, x)) = \frac{|e_x \cdot e_l|}{\|e_x\| \|e_l\|} \quad (8)$$

When there are multiple context words $x \in \mathcal{X}$, we can compute the weighted cosine similarity between them as follows based on the squared weights of context words described in Section 3.1.

$$S(l, (i, j, \mathcal{X})) = \max_{x \in \mathcal{X}} S(l, (i, j, x)) \times \lambda_x^2 \quad (9)$$

Since we have multiple KB relations $l \in \mathcal{L}$, we can ground a candidate relational triple (i, j, \mathcal{X}) and obtain its relation $\hat{l}_{i,j,\mathcal{X}}$ considering all the possible relations. The predicted relation can either be assigned a valid KB relation or NONE. We use a marker to denote the relation between v_i and v_j which cannot be grounded to any KB relation.

$$\hat{l}_{i,j,\mathcal{X}} = \arg \max_{l \in \mathcal{L}} S(l, (i, j, \mathcal{X})) \quad (10)$$

Relation Argument Type Constraints

For each KB relation, we can obtain its type constraints for its two arguments. Take the relation *birthPlace* as an example: the entity types of two arguments should be person and location.

Given all the KB triples, we can estimate the probability of one of the arguments belonging to a certain entity type $z \in \mathcal{Z}$, where \mathcal{Z} represents the set of all the KB concept types. For a given KB relation l , we define $c(k \rightsquigarrow z | l)$ to be the number of times the k_{th} argument is seen paired with the entity type z where $k \in \{1, 2\}$ since there are two arguments. Given the above definitions, the maximum likelihood estimate is as follows.

$$p(k, z | l) = \frac{c(k \rightsquigarrow z | l)}{\sum_{z \in \mathcal{Z}} c(k \rightsquigarrow z | l)} \quad (11)$$

Therefore, given a candidate argument pair (v_i, v_j) and their entity types z_i and z_j , we can compute the probability of its being labeled as the relation l by considering both $p(1, z_i | l)$ and $p(2, z_j | l)$. We set $S(l, (i, j, \mathcal{X}))$ to 0 if the harmonic mean of $p(1, z_i | l)$ and $p(2, z_j | l)$ is smaller than a given threshold which will be introduced later in Section 4.4. We will not consider a candidate KB relation for comparison if the argument type of i or j fails to satisfy its type constraints. In this way, we can filter out some candidate triples and reduce the number of similarity computations. For example, given a KB relation *placeOfBurial*, the concept type *Species* is less likely to be the correct second argument type compared with other entity types such as *City* and *Location*. Remind that the order of arguments in the candidate triple has been introduced in Section 2.2.

4 Experiments

4.1 Knowledge Base and Word Embeddings

We use the April 2016 dump of DBpedia as our KB which contains 2,060 relation types and 30,024,093 relation triples in total. We use the 300-dimensional GloVe vectors (Pennington et al., 2014) pretrained on 6 billion tokens from the English Gigaword Fifth Edition and a 2014 Wikipedia dump.

4.2 Evaluation based on Slot Filling

There are several benchmarks developed for open RE (e.g., (Fader et al., 2011; Stanovsky and Dagan, 2016)). However, we mainly focus on relations between entities and therefore we cannot directly compare with state-of-the-art open RE methods on those datasets. To evaluate the effectiveness of our approach, we choose the TAC-KBP SF (McNamee and Dang, 2009; Ji et al.,

2010, 2011; Surdeanu and Ji, 2014) task as our evaluation platform which has been widely used by open RE methods (Soderland et al., 2013; Angeli et al., 2015b) since 2009. The goal of SF is to extract the values (*slot fillers*) of specific attributes (*slot types*) for a given entity (*query*) from a large-scale corpus which includes news documents, web blogs, and discussion forum posts. Justification sentences should be provided to support slot fillers. SF defines 25 slot types for person queries and 16 slots for organization queries.

We use the SF 2013 dataset for which we can compare with the ground truth and state-of-the-art open RE results reported in SF. We obtain 1,701 relevant documents from the official evaluation assessment for 50 person queries and 50 organization queries. We manually map KB relations to slot types based on TAC-KBP slot descriptions.³ Note that a single KB relation can be mapped to multiple slot types. For example, *birthPlace* can be mapped to *per:city_of_birth*, *per:stateofprovince_of_birth*, and *per:country_of_birth*. We assign a subtype (e.g., country, province, or city) to a location entity based on gazetteer matching.

DBpedia Relations	Slot Types
founder	org:founded_by
keyPeople	org:top_members_employees
education	per:schools_attended
workInstitution	per:employee_or_member_of
birthDate	per:date_of_birth

Table 3: Example Mappings from DBpedia relations to slot types.

We ignore all the slot types which require nominal phrases as fillers (e.g., *per:cause_of_death*) and slot types *per/org:alternate_names* which depend on cross-document coreference resolution. We apply Stanford CoreNLP (Manning et al., 2014) for English part-of-speech tagging, name tagging, time expression extraction, dependency parsing, and coreference resolution. We use the official Slot Filling evaluation scoring metrics: Precision (P), Recall (R), and F-measure (F_1).

As shown in Table 4, our method outperforms the KBP2013 SF submission from the University of Washington (Soderland et al., 2013) which applies Open IE V4.0, which is an extension of SRL-based IE (Christensen et al., 2011) and noun

Table 4: Performance (%) on KBP2013 English SF based on different relation representations.

phrase processing (Pal and Mausam, 2016), to generate relation triples. This is their latest published approach which uses Open IE for Regular Slot Filling. Their approach achieves very high precision but comparatively low recall (12.2%). In our experiments, we keep all the candidate triples which could be mapped to a slot type without tuning thresholds. On the same dataset, we also compare with an approach (Singh et al., 2013) which extracts relations with matrix factorization and *universal schemas* (Riedel et al., 2013) consisted of textual patterns and all the slot types. We do not directly compare with the work of Angeli et al. (2015b) because of the lack of access to their SF output.⁴

The importance-based strategy is effective at extracting more salient information. For example, previous methods only extract one argument pair (“*the top Egyptian cleric*”, “*Wednesday*”) from the sentence “*Sheikh Tantawi, the top Egyptian cleric who died on Wednesday on a visit to ...*” while omitting the person name. Our method extracts both (“*Sheikh Tantawi*”, “*Egyptian*”) and (“*Sheikh Tantawi*”, “*Wednesday*”) with their associated top-weighted context words “*cleric*” and “*died*” respectively, since the connection between “*Egyptian*” and “*Wednesday*” is much weaker.

Compared with relation phrases, the word embeddings of weighted context words are more flexible for comparison when we map relational triples to a known schema. For example, it is impossible for previous methods (e.g., (Soderland et al., 2013)) to summarize all the related mentions (e.g., “*appointed*” and “*CEO*”) and manually map them to the relation *employment*. Therefore previous approaches missed the slot filler “*Al-Azhar University*” of the query “*Mohammed Sayed Tantawi*” from the following sentence “*Tayeb, the president of Al-Azhar University since 2003, succeeds Mohammed Sayed*

⁴The highest recall they achieve is around 13% on all the slot types including nominal relations on the same dataset.

Tantawi” as “*succeeds*” was not included into the related terms. Our approach extracts it based on their semantic representations.

In addition, we obtain more generalized relation type names based from the KB schema. For example, we ground the relation in *E2* between “*Patricia*” and “*Gary*” to *influencedBy*. Similarly, in the sentence “*Ginzburg shared the Nobel Physics Prize with US physicists Alexei Abrikosov and Anthony Leggett for their contributions to the theory of superconductors ...*”, the relation phrase “*shared the Nobel Physics Prize with*” between “*Ginzburg*” and “*Alexei*” is too specific compared with the grounded KB relation *alongside* by our approach for subsequent applications.

4.3 Impact of Relation Representations

In Section 3.2, we use KB tuples and their relation type names to learn KB relation representations. As shown in Table 4, our approach can already achieve promising performance based on the relation representations learned from KB relation names. However, sometimes relations are implicitly expressed. It is likely that the context words of a relation triple and its corresponding KB relation name are not semantically similar. In this case, we need more general relation representations with the help of millions of KB tuples. For example, we can ground the relation *school* between “*McGregor*” and “*Colorado State University*” successfully by comparing the representation of context words “*tight*” and “*end*” with the joint relation representations from the following sentence: “*McGregor was a two-time All-America tight end at Colorado State University*” even though this relation is not explicitly described.

4.4 Impact of Argument Type Constraints

As mentioned in Section 3.2, we aim to filter out some candidate relation triples if the entity types of the arguments are not popular for a given KB relation. By tuning thresholds, there are no significant differences in performance when the threshold falls in the range 0.05–0.2. On the other hand, if the threshold is set too high (e.g., greater than 0.35%), we will mistakenly discard correct candidates which satisfy type constraints.

We implement Jenks optimization (Wikipedia, 2017) to automatically split the frequency values of all entity types into two tiers given a certain argument position and a KB relation. This is done by minimizing each tier’s average deviation from

the tier mean, while maximizing each tier’s deviation from the means of other groups (McMaster and McMaster, 2002). We set the threshold automatically using the obtained natural breaks for two arguments respectively to compute the harmonic mean of them. This approach achieves 28.9% F₁ which is comparable to the highest F₁ (29.2%) obtained by threshold tuning.

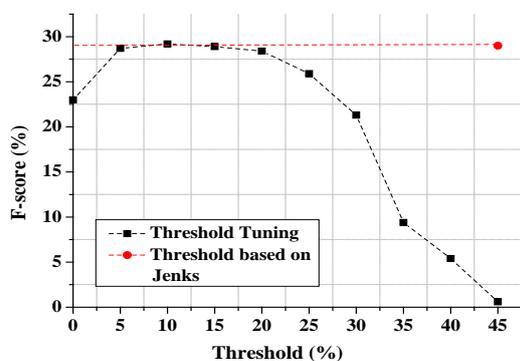

Figure 3: Performance (%) based on different thresholds for argument type constraints.

5 Related Work

5.1 Open Information Extraction

Lexical or syntactic features and patterns have been widely used to extract relational triples (Suchanek et al., 2009; Poon and Domingos, 2009; Wu and Weld, 2010; Nakashole et al., 2011; Fader et al., 2011; Nakashole et al., 2012; Mausam et al., 2012; Bovi et al., 2015; Angeli et al., 2015b; Grycner and Weikum, 2016). Our work explores the global structure of a dependency tree to identify salient triples within a sentence. Some open IE approaches have the capability to extract relations between concepts or phrases (Kok and Domingos, 2008; Min et al., 2012; Del Corro and Gemulla, 2013). Currently we focus on relations between two entities.

Given the SF schema, Soderland et al. (2013) manually design rules to map relational triples to slot types within hours. Researchers also use distantly labeled corpora to compute the PMI² value between open IE and SF relation pairs (Angeli et al., 2015b). Instead, we propose a novel grounding approach which facilitates building a mapping table between KB relations and slot types. We do not compare with RE methods specifically designed for SF (Sun et al., 2011; Li et al., 2012; Angeli et al., 2015a) since these methods actively search for candidate fillers of the given queries

based on slot-specific training resources while ignoring the salient relations which are irrelevant to the queries or the predefined slot types.

5.2 Relation Grounding

Besides textual features, large-scale knowledge bases are widely used for distant supervised relation extraction (Mintz et al., 2009; Riedel et al., 2010) to deal with the challenges caused by insufficient training data. Weston et al. (2013) combine two relation representations trained from KB triples and context words independently for relation extraction. Recent studies such as (Toutanova et al., 2015) train relation representations of KB and textual relations jointly. Another kind of representations combining matrix factorization (Riedel et al., 2013) with first-order logic information is learned by Rocktäschel et al. (2015). Compared with these previous efforts, our unsupervised grounding method does not need the aligned training corpus or relation mentions for KB tuples. Wijaya and Mitchell (2016) introduce an approach to map words to KB relations based on web text, but they only focus on verb phrases.

5.3 Node Importance Computation

Graph-based algorithms such as PageRank (Page et al., 1999) and TextRank (Mihalcea and Tarau, 2004) are useful in keyword extraction. The way we rank nodes is most similar to the work of White and Smyth (2003) and Yu and Ji (2016) which generate the relative importance score of each node toward a set of preferred nodes. However, they only deal with unweighted undirected graphs.

6 Conclusions and Future Work

We propose an unsupervised open relation extraction method by exploring the global structure of dependency tree and show its effectiveness in extracting salient candidate relation triples. We also leverage the knowledge from the large-scale KB relation triples and weighted context words based on general embeddings to enhance the quality of our relation grounding technique. Experiments on English Slot Filling demonstrate that our approach outperforms state-of-the-art open RE approaches. In the future, we aim to extend our framework for multilingual open RE based on the KB schema.

Abstract

Genetic information in the literature has been extensively looked into for the purpose of discovering the etiology of a disease. As the gene-disease relation is sensitive to external factors, their identification is important to study a disease. Environmental influences, which are usually called Gene-Environment interaction (GxE), have been considered as important factors and have extensively been researched in biology. Nevertheless, there is still a lack of systems for automatic GxE extraction from the biomedical literature due to new challenges: (1) there are no preprocessing tools and corpora for GxE, (2) expressions of GxE are often quite implicit, and (3) document-level comprehension is usually required. We propose to overcome these challenges with neural network models and show that a modified sequence-to-sequence model with a static RNN decoder produces a good performance in GxE recognition.¹

1 Introduction

Identifying genetic information related to a disease is an effective method for discovering the etiology of the disease. Many researchers in biology have attempted to identify the relationship between different types of genetic information, such as genes, gene mutations or other biological events, and diseases.

One of the difficult aspects in the research is that it is necessary to consider various external factors, because they can affect whether such biological relationships hold or not. For example, it has

been shown that there is no association of NAT2 gene and breast cancer (Zgheib et al., 2013), but after three years, other researchers made a conflicting claim that NAT2 gene is associated with breast cancer (Kasajova et al., 2016). There may be many factors causing this difference, but investigating the environmental factors has been one of the important research topics. Kasajova et al. (2016) found that NAT2 gene is associated with breast cancer when women with NAT2 gene polymorphisms have been exposed to long-period active smoking. As a result, active smoking has been considered as a crucial factor that determines the relation between NAT2 gene and breast cancer, which biologists called gene and environment interaction (GxE).

Since the importance of studying GxE is recognized, the amount of related work has steadily been increasing (Hunter, 2005). Nonetheless, there is still a lack of systems and databases that deal with this information (Simonds et al., 2016). For the purpose of addressing this situation, we present an automatic system that extracts environment terms indicating a change of gene-disease relations from the biomedical literature.

There are three major challenges that make it difficult to perform GxE recognition using existing systems in the biomedical domain. First, in contrast to general biomedical natural language processing (BioNLP) tasks, there are no preprocessing tools and corpora for GxE, though there are some resources for chemical-disease relations, such as named entity recognition systems specialized for chemical and disease names and corpora that annotate chemical and disease relations in abstracts (Wei et al., 2015b). Second, research on discovering biomedical relations usually specifies environmental information in the literature in various ways, using not only expressions that explicitly refer to certain biomedical concepts such as

*Corresponding author

¹Our source code and gold standard corpus are available at <http://biopathway.org/GxE>

pregnancy and smoking, but also statistical terms that refer to a comparison between two control groups, such as p-value and odds ratio, which are quite difficult to capture using conventional tools. Since the literature for GxE also tends to report experiment results in similar ways, the system needs to understand such implicit information to determine whether the result is meaningful or not. Third, information of this kind indicating GxE is usually not reported in a single sentence, requiring document-level comprehension of text.

To address this situation, we build an annotated corpus for GxE and develop an end-to-end system that recognizes environment information for gene-disease pairs given in single document. We exploit high-dimensional models based on neural networks to enable document-level understanding of text and to deal with the issues above. We also perform experiments with different neural network models to investigate which models are most suitable to GxE recognition.

2 Related work

One of the related areas that have been actively researched in BioNLP is biomedical event extraction. For example, a system was proposed in the recent shared tasks (Kim et al., 2013), attempting to extract ten biological events, with the best performance under a 0.6 F1-score. This score, however, was extremely skewed to particular event types. While all the systems showed good performance, with nearly a 0.8 F1-score, in extracting simple events such as gene expression and transcription, they showed quite poor performance for complex events such as binding and regulation. This is because, in contrast to simple events, complex events consist of more than two elements or another event. In particular, the task of extracting binding events is usually treated as finding ternary relations, where a system is supposed to recognize two biological entities together with a particular site where their binding takes place. This task is similar to our task as the relation between two entities can be changed according to the third entity. The best system for binding event extraction achieved a 0.49 F1-score.

Another recent work on dealing with complex relations in BioNLP is reading comprehension (RC), where the system is to find proper answers to given questions about a biological process within single document. For example, the

system in (Berant et al., 2014) attempts to find answers through comparisons between two graphs constructed from given documents and questions. Although the system explicitly combines biological events extracted from sentences to construct a long biological process, possibly leading to the propagation of errors, they reported fairly good performance and meaningful results, considering that it is the first attempt for document-level biological information extraction.

On the other hand, there are quite a few systems and corpora for document-level comprehension from a similar perspective in other domains, such as news articles (Hermann et al., 2015) and children’s books (Hill et al., 2016). One of the recent studies, (Hermann et al., 2015), addresses the reading comprehension task for which proposed models infer missing entities. From the perspective of evaluating how well such models understand documents for answering given questions, the task is similar to the present work. In this task, neural network models were shown to be effective for processing document-level information. More specifically, they demonstrated that a variant of neural network, RNN with attention mechanism, achieved the state-of-the-art performance (Chen et al., 2016).

WikiReading is most similar to our task as it deals with inference over entities based on a sequence of tokens (Hewlett et al., 2016). The authors were inspired from the QA task, treating given properties as questions and developing models to find proper entities that could be answers to the questions. There are two types of properties in WikiReading: (1) the categorical property that requires selection among a relatively small number of possible answers and (2) the relational property that requires extraction of rare or unique answers from the document. The authors compared various types of models from simple word embedding models to sequence-to-sequence models and showed that the sequence-to-sequence model gives rise to outstanding performance in both types of properties.

3 Task definition

3.1 GxE extraction

We formulate the GxE recognition task as extracting terms indicating a particular environment that is involved in a change of gene-disease relations. Figure 1 illustrates an example abstract that con-

Melatonin pathway genes and breast cancer risk among Chinese women. [PMID: 22138747]

Previous studies suggest that melatonin may act on cancer growth through a variety of mechanisms, most notably by direct anti-proliferative effects on breast cancer cells and via interactions with the estrogen pathway. Three genes are largely responsible for mediating the downstream effects of melatonin: melatonin receptors 1a and 1b (MTNR1a and MTNR1b), and arylalkylamine N-acetyltransferase (AANAT). It is hypothesized that genetic variation in these genes may lead to altered protein production or function. To address this question, we conducted a comprehensive evaluation of the association between common single nucleotide polymorphisms (SNPs) in the MTNR1a, MTNR1b, and AANAT genes and breast cancer risk among 2,073 cases and 2,083 controls, using a two-stage analysis of genome-wide association data among women of the Shanghai Breast Cancer Study. Results demonstrate two SNPs were consistently associated with breast cancer risk across both study stages. Compared with MTNR1b rs10765576 major allele carriers (GG or GA), a decreased risk of breast cancer was associated with the AA genotype (OR = 0.78, 95% CI = 0.62-0.97, P = 0.0281). Although no overall association was seen in the combined analysis, the effect of MTNR1a rs7665392 was found to vary by menopausal status (P-value for interaction = 0.001). Premenopausal women with the GG genotype were at increased risk for breast cancer compared with major allele carriers (TT or TG) (OR = 1.57, 95% CI = 1.07-2.31, P = 0.020), while postmenopausal women were at decreased risk (OR = 0.58, 95% CI = 0.36-0.95, P = 0.030). No significant breast cancer associations were found for variants in the AANAT gene. These results suggest that common genetic variation in the MTNR1a and 1b genes may contribute to breast cancer susceptibility, and that associations may vary by menopausal status. Given that multiple variants in high linkage disequilibrium with MTNR1b rs76653292 have been associated with altered function or expression of insulin and glucose family members, further research may focus on clarifying this relationship.

Figure 1: An illustrated abstract describing GxE for lung cancer. In this figure, gene and disease are shown in blue and red, respectively. Expressions in bold-face are targeted environment terms. Sentences highlighted in gray are the evidence supporting the claim that an association between MTNR1a and breast cancer is changed by menopausal status.

Environment type	Example
Energy balance	dietary factors, physical activity
Lifestyle	smoking, alcohol, breastfeeding
Exogenous hormones	HRT, OC use
Endogenous hormones	menopausal status, age of menarche
Chemical environment	grilled foods/meats, heterocyclic amines
Drugs/treatment	statin, NSAIDS
Infection and inflammation	helicobacter pylori, autoimmune disease
Physical environment	x-rays, sun exposure

Table 1: The list of biological environment types (Simonds et al., 2016)

tains information about GxE for breast cancer, where gene and disease names are shown in blue and red, respectively (Wei et al., 2015a; Lee et al., 2016). There are four types of genes (MTNR1a, MTNR1b, AANAT, insulin) and two types of diseases (breast cancer, cancer). Therefore, we consider twelve gene-disease combinations for which our system attempts to find environment terms from the abstract. As an example of environment terms, it is claimed in the abstract that the association between MTNR1a and 1b genes and breast cancer may vary to *menopausal status*. Sentences highlighted in gray are the evidence supporting the

claim. Expressions in bold-face are targeted environment terms to be extracted by our system.

Our model is given the abstract marked with genes and diseases, and considers each unique gene-disease combination, one at a time, to find its environment terms. For example, if we want to consider the combination of MTNR1a and breast cancer, the input is the abstract marked only with these two entities, without other entities marked such as MTNR1b or AANAT. We used two state-of-the-art named entity recognizers (Wei et al., 2015a; Lee et al., 2016) to identify gene and disease names from a given abstract. For each combination, we consider the following four cases: (1) the combination consists of an unassociated gene-disease pair, not affected by an environment; (2) although the combination consists of a pair that is basically unassociated, it becomes associated due to a particular environment; (3) the combination consists of an associated pair but it is not affected by an environment; and (4) the combination consists of an associated pair and the degree of its association is changed by an environment. Our system is trained to choose the most proper environment term for a given combination in cases (2) and (4), but not to choose any term in cases (1) and (3).

3.2 Corpus

For experimental data, we collected 253 raw abstracts that are taken from review papers on GxE for diverse diseases (Simonds et al., 2016; Dunn et al., 2011; DiGangi et al., 2013; Iyegbe et al., 2014; Hunter, 2005). To establish the gold stan-

standard data to train and test the system, we manually annotated the biological environments that should be extracted. For the clear definition of an environment, we only annotated the terms that can be categorized into one of the types in Table 1 and that are clearly reported as associated with gene-disease relations in the abstract.

Annotation was conducted by two experts in bioinformatics, who were given abstracts marked with gene and disease names. They did not annotate combinations consisting of entities that are incorrectly recognized by the named entity recognizer (i.e., entities that are neither gene nor disease). For each abstract, one annotator read the entire body of its text and annotated terms referring to an environment that is involved in a given combination of gene and disease, and then another annotator validated its correctness, in a way similar to other annotation tasks in BioNLP (e.g., [Berant et al. 2014](#)). The agreement on annotated environment terms between the two annotators is 0.81. If they did not agree on a certain annotation, they had a discussion on the disagreement and resolved it afterwards. The corpus contains a total of 1,429 combinations of unique genes and diseases. Among them, 341 combinations are annotated as being affected by environment, i.e., they are linked to some environment terms annotated in the same abstract.

4 Method

We use two types of models, a feature-based model and a neural-based model, that could be applied to document-level understanding of relations between entities in order to investigate which models are suitable to GxE recognition and whether or not there are important issues particularly in this new task. There are three variants based on the neural-based model: (1) an attentive reader ([Hermann et al., 2015](#)), (2) a sequence-to-sequence model ([Sutskever et al., 2014](#)), and (3) a static RNN decoder. We envision that different characteristics of these models would lead to different performance, according to the types of task.

In our experiment, the three models relied neither on any prior knowledge nor on external tools for collecting candidate environment terms. Even though such words as ‘smoking’ or ‘alcohol’ can be considered to have a higher probability to be a biological environment than other words, we did not use such information to prevent error propaga-

tion and to investigate the possibility of handling newly introduced terms.

4.1 A feature-based model

We combined two models proposed by [Chen et al. \(2016\)](#) and [Xu et al. \(2016\)](#): a model that adapts an entity-centric approach to the RC task, and a feature-based model that extracts chemical-disease relations on a document level.

Inspired by these two models, we use the following feature sets that we expect are suitable to our task. We describe each feature in detail below, where g , d , and e indicate gene terms, disease terms, and candidate environment terms, respectively: (1) shortest distance from e to g and d in the abstract, (2) whether e and g pair in the same sentence, (3) whether e and d pair in the same sentence, (4) whether e , d , and g pair in the same sentence, (5) whether e is included in MeSH (Medical Subject Headings) terms, (6) the frequency of e in an abstract, (7) the frequency of e in all abstracts, (8) whether e and g are connected by the dependency parser ([De Marneffe et al., 2006](#)), and (9) whether e and d are connected by the dependency parser ([De Marneffe et al., 2006](#)).

Using these features, the model tried to classify all terms that are present in the abstract. If the model assigns 1 to a term, we regard it as an environment. If the model classifies all terms for a particular gene-disease combination as 0, we assume that there is no environment for this combination in the abstract.

4.2 An neural-based model

We propose three neural-based models; 1) an attentive reader, 2) a sequence-to-sequence model, and 3) a static RNN decoder. The three models comprise two parts: converting text to vector representation, called encoding, and predicting the vector to answer, called decoding. The encoding is the same in all the three models. We look over the encoding and then compare each decoding part of the three models.

4.2.1 Encoding

Our encoding with attention is based on the model proposed by [Chen et al. \(2016\)](#), which shows better performance than any other encoders. The model runs in two steps, **text encoding** and **attention**, described in detail as follows.

Text encoding: All words are mapped to d -dimensional vectors using the PubMed/PMC word

embedding model (Pyysalo et al., 2013) with a limited dictionary size (V). We include special tokens, ‘<NOE>’, that stands for no environment terms for the combination and ‘<UNK>’, that stands for terms that are not included in the dictionary. The sequence of words in an abstract excluding stop words and special characters is encoded as $\mathbf{p}_1, \dots, \mathbf{p}_m \in \mathbb{R}^d$ where m is the number of words in the abstract. Then, we pass the sequence $\mathbf{p}_1, \dots, \mathbf{p}_m$ to bi-directional RNN:

$$\vec{\mathbf{h}}_i = RNN(\vec{\mathbf{h}}_{i-1}, \mathbf{p}_i) \in \mathbb{R}^h, i = 1, \dots, m$$

$$\overleftarrow{\mathbf{h}}_i = RNN(\overleftarrow{\mathbf{h}}_{i+1}, \mathbf{p}_i) \in \mathbb{R}^h, i = m, \dots, 1$$

$$\tilde{\mathbf{p}}_i = \text{concat}(\vec{\mathbf{h}}_i, \overleftarrow{\mathbf{h}}_i) = \begin{bmatrix} \vec{\mathbf{h}}_i \\ \overleftarrow{\mathbf{h}}_i \end{bmatrix} \in \mathbb{R}^{2h}, i = 1, \dots, m$$

where h is the dimension of hidden units of RNN.

From $\mathbf{p}_1, \dots, \mathbf{p}_m$, the model extracts marked gene and disease names. Let the set of gene names be $\{\mathbf{g}_1, \dots, \mathbf{g}_n\}$ where n is the number of gene names in the abstract. Let the set of disease names be $\{\mathbf{d}_1, \dots, \mathbf{d}_l\}$ where l is the number of disease names in the abstract. Then, we make the gene-disease combination vector \mathbf{c} by element-wise summation of concatenated vectors:

$$\mathbf{c} = \mathbf{W}_c^T \left(\begin{bmatrix} \mathbf{g}_1 \\ \mathbf{d}_1 \end{bmatrix} \oplus \begin{bmatrix} \mathbf{g}_2 \\ \mathbf{d}_2 \end{bmatrix} \dots \oplus \begin{bmatrix} \mathbf{g}_n \\ \mathbf{d}_l \end{bmatrix} \right)$$

where $\mathbf{W}_c \in \mathbb{R}^{2d \times 2h}$ is the weight vector for gene and disease.

Attention: In order to enable the model to focus more on evidence for identifying environment terms in the abstract, we used the attention mechanism. In the QA task, the vector of questions is projected to a document for calculating the probability of relevance degree between a question and a document. Likewise, we project the gene-disease combination vector (\mathbf{c}) to the sequence of word vectors ($\tilde{\mathbf{p}}_1, \dots, \tilde{\mathbf{p}}_m$). We applied a bilinear term, a variant of attention mechanism, to combine the combination vector and the sequence of vectors:

$$\mathbf{a} = \text{softmax}(\mathbf{c}^T \mathbf{W}_b \tilde{\mathbf{p}}_i), i = 1, \dots, m$$

where $\mathbf{W}_b \in \mathbb{R}^{2h \times 2h}$.

And then, we generated an attention vector by summation of projecting the bilinear term to the sequence of vectors:

$$\tilde{\mathbf{a}} = \sum_i \mathbf{a} \tilde{\mathbf{p}}_i, i = 1, \dots, m$$

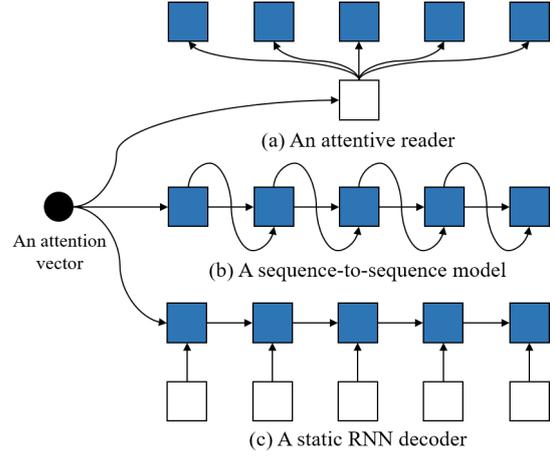

Figure 2: An overview of each decoding part in three models

4.2.2 Decoding

In this section, we describe each decoding of the three models. Figure 2 illustrates an overview of three models.

(a) An attentive reader

By mapping the attention vector ($\tilde{\mathbf{a}}$) to vocabulary, we compute output vector (\mathbf{o}_a) as follows,

$$\mathbf{o}_a = \mathbf{W}_a^T \tilde{\mathbf{a}}$$

where $\mathbf{W}_a \in \mathbb{R}^{2h \times V}$:

We choose terms that come from their conjunction showing the top values of the output vector and that are represented in the abstract, and consider them as environment. However, if the top value of the output vector indicates ‘<NOE>’, we conclude that there is no environment.

(b) A sequence-to-sequence model

A decoder in the sequence-to-sequence model dynamically generates tokens from ‘<SOE>’ (start of token) to ‘<EOE>’ (end of token). The model is based on a previous hidden vector, a previous token vector and an encoding vector that is an output vector of the encoding. The previous token vector is computed by projecting a token generated in previous time step to an embedding layer. We try to set the attention vector ($\tilde{\mathbf{a}}$) to the encoding vector as we expect that the attention vector is more properly tuned to extract terms depending on the gene-disease combinations than the original encoding vector:

$$\mathbf{t}_{i-1} = \mathbf{W}_e^T \mathbf{o}_{i-1}$$

$$\mathbf{y}_i = RNN(\vec{\mathbf{h}}_{i-1}, \mathbf{t}_{i-1}, \tilde{\mathbf{a}}) \in \mathbb{R}^{2h}, i = 1, \dots, e$$

where e is the number of environment terms and \mathbf{W}_e^T is an embedding layer.

$$o_i = \operatorname{argmax}(\mathbf{W}_s^T \mathbf{y}_i), i = 1, \dots, e$$

where $\mathbf{W}_s^T \in \mathbb{R}^{2h \times V}$. The o_i is the index of the vocabulary and a sequence of tokens, (o_1, \dots, o_e) , is regarded as environment terms predicted by the model.

If the first decoding token indicates ‘<NOE>’ in the output sequence, we assume that there is no environment.

(c) A static RNN decoder

As a modification to the sequence-to-sequence model, we suggest that the model uses a static RNN decoder, which does not use a previous token vector (\mathbf{t}_{i-1}). In particular, the model used randomly normalized token vectors. Because the model is needed to set the length of the decoder in advance, it seems to statically generate environment terms, which is an outstanding feature in comparison to the sequence-to-sequence model. Because our answer tokens are usually atomic and spread over the abstract, the previous output state, which is usually used when making a long sequence of tokens, is not useful for our task.

$$\mathbf{y}_i = \operatorname{RNN}(\vec{\mathbf{h}}_{i-1}, \mathbf{t}'_i, \tilde{\mathbf{a}}) \in \mathbb{R}^{2h}, i = 1, \dots, e'$$

where e' is the number of environment tokens that is set in advance.

$$o_i = \operatorname{argmax}(\mathbf{W}_r^T \mathbf{y}_i), i = 1, \dots, e'$$

where $\mathbf{W}_r^T \in \mathbb{R}^{2h \times V}$. The o_i is the index of the vocabulary and a sequence of tokens, $(o_1, \dots, o_{e'})$, is regarded as environment terms predicted by the model.

Similar to the sequence-to-sequence model, if the first decoding token indicates ‘<NOE>’ in the output sequence, we assume that there is no environment.

5 Experiments

5.1 Corpus statistics

In the 253 abstracts that report the presence of GxE, 341 out of 1429 gene-disease combinations show a relationship and are considered affected by environment. Table 2 provides some statistics of the dataset. There are a total of 247 types of gene and 106 types of disease. In an abstract,

Category	#
Types of genes	267
Types of diseases	106
Avg. # of tokens	304.1
Avg. # of sentences	10.4
Avg. # of environment tokens	2.7
Min. # of environment tokens	1
Max. # of environment tokens	15
Avg. # of environments per combination	1.4
Min. # of environments per combination	1
Max. # of environments per combination	8

Table 2: Data statistics of the GxE dataset. All values are based on the statistics from the entire dataset.

there are about 304 tokens and 10 lines on average. Also, the average number of environment tokens is about 3 and the maximum number is 15. Assuming that the combination shows GxE in an abstract, the average number of unique environments per combination is 1.4. From the statistics, we see that the environment is made of just one or two words and that the combinations showing GxE appear rarely.

In order to balance positive and negative values, we randomly sampled 146 combinations from almost 1000 redundant combinations that do not show GxE, and abstracts with a total of 487 combinations were given as input to the system. The input is already marked with gene and disease, and the annotated gold standard environment term was used as the target answer. We randomly selected 80% of the dataset (389) and used them for training, 10% for validation (49), and 10% for test (49).

5.2 Setup

For training the proposed model, we set common parameters empirically as follows. According to a given embedding model, the dimension of word vectors is 200. We built a dictionary using the most frequent 2.5K words. And we split sentences using the tool (Kazama and Tsujii, 2003) and tokenized the sentences using the supporting tool in BioNLP Shared Task 2011², where both tools are specialized to BioNLP.

Model	P	R	F1
Baseline model (DT)	0.157	0.172	0.152
Baseline model (SVM)	0.279	0.274	0.275
Baseline model (RF)	0.204	0.196	0.196
Baseline model (GB)	0.1	0.123	0.095
Baseline model (AB)	0.168	0.155	0.153
RNN reader (top-5)	0.321	0.359	0.338
Attentive reader (top-5)	0.362	0.373	0.366
Attentive reader (top-10)	0.290	0.542	0.378
Attentive reader (top-15)	0.283	0.639	0.390
Attentive reader (top-20)	0.214	0.670	0.324
Seq2seq model (basic encoding)	0.305	0.298	0.301
Seq2seq model (attention encoding)	0.322	0.319	0.320
Static RNN decoder (basic encoding)	0.484	0.389	0.426
Static RNN decoder (attention encoding)	0.450	0.380	0.409

Table 3: The performances of different models on GxE recognition. P and R stand for precision and recall, respectively. DT, SVM, RF, GB and AB stand for Decision Tree, Support Vector Machine, Random Forest, Gradient Boosting, and AdaBoost, respectively. The RNN reader indicates attentive reader without attention encoding.

The baseline models followed the initial parameter setting of a machine learning framework, *sklearn*³. We tried to change the parameter setting, without any significant difference in performance.

In the attentive reader and the static RNN decoder, we used LSTM (Hochreiter and Schmidhuber, 1997), a variant of the RNN model, and set the hidden size and dropout rate of RNN to 64 and 0.5, respectively. On the other hand, the sequence-to-sequence model used GRU (Cho et al., 2014), another variant of the RNN model, and we set the hidden size of 64 and dropout rate of 0.5. In the case of the static RNN decoder, it is necessary to set the length of the model due to a static attribute. Therefore, we evaluated the performance of the model according to the length, and we found that the model with a length of 25 performs best.

All weights of three models are initialized from Gaussian distribution with 0 mean and 0.01 STD. At each update, we randomly sampled a mini-batch of 16, and the attentive reader, sequence-to-sequence model, and static RNN decoder used the Adam algorithm (Kingma and Ba, 2015) with 0.0001, 0.001, and 0.01 learning rates for optimization, respectively. Except for the attentive reader, we additionally used 12 regularizations. And we clipped the gradients when the norm of

the gradients exceeds 10. We ran all neural network models up to 100 epochs.

We implemented the proposed neural network models using *TensorFlow*⁴.

5.3 Results

The overall performance of our proposed models is shown in Table 3. We ran each model 10 times independently, and reported average scores in the table. Among others, it shows that it is hard to detect environment terms with feature-based models and that it is necessary to use high-dimensional models such as deep neural network. It also shows that the static RNN decoders outperform other models. It is an interesting result because, contrary to our result, the sequence-to-sequence model showed outstanding performance in WikiReading, which is the most similar task to ours. The fact that the static RNN decoder shows best performance is probably due to the characteristics of our corpus where environment tokens are more widespread and atomic.

If the reader model and the sequence-to-sequence model use attention as demonstrated in other studies, it shows higher performance than the model without attention. On the other hand, the static RNN decoders show a different case, in that our proposed attention seems to hamper the model in exactly extracting the environment.

In order to monitor how performance varies to the choice of top- k values, we evaluated the attention model with different top- k values ($k = 5, 10, 15, 20$). When we increase k values, recall increases and precision decreases. Overall, precision of the static RNN decoder is found better than that of the other models. On the other hand, the attentive reader model shows outstanding performance in extracting all relevant environment tokens.

5.4 Analysis

The baseline models mainly show F1-scores under 30, which are worse than we expected. Among them, SVM outputs skewed results, failing to find any environment terms, and classifying all test data to ‘<NOE>’. As a result, its performance depends on the number of input data showing no environment terms, which explains why the model shows even precision and recall. In contrast to SVM, the other two models can detect environ-

Table 4: Results of experiment with four proposed models. Words in red and blue indicate disease and gene names, respectively, and the words in bold-face indicate environment terms.

ment terms, but they also identify irrelevant tokens as environment terms in most cases.

In order to analyze how differently the proposed models output, we select three proposed models showing the best performance, the attentive reader, the sequence-to-sequence model (attention encoding), and the static RNN decoder (basic encoding) among them, and show the result of experiments for two abstracts. In Table 4, the first row represents a partial content of the abstract and the second row represents the results. We show a sequence of tokens in the attentive reader as much as possible, and the sequence is ordered by scores. On the other hand, a sequence of tokens in the sequence-to-sequence model and static RNN decoder is ordered in which they were made in the decoding part.

The first example in Table 4 provides GxE for two genes, where we ask our models to extract environment tokens for *serotonin transport* and *depressive symptoms*. Although the three models failed to identify all answer tokens, the static RNN decoder shows better performance than the others. In tokens extracted by the attentive reader, there are not only answer tokens but also error tokens, which results in decreasing the performance. These weaknesses sometimes work as an advantage for the cases with many environment terms as shown in the abstract in the second example.

In the second example, the number of tokens is bigger than that in the first example. Interestingly, the performance of the attentive reader and that of the static RNN decoder are reversed. Although there are many answer tokens, the static RNN decoder seems to extract minimal tokens. On the other hand, the majority of tokens extracted by the

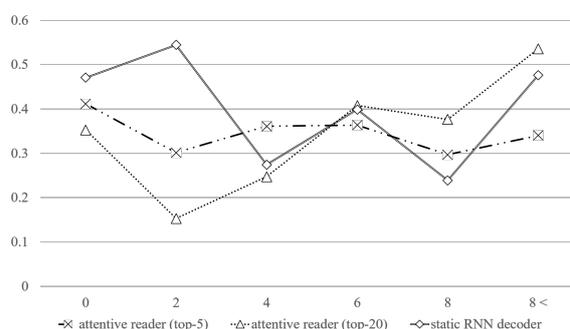

Figure 3: Performance of the two models, the attentive reader and the static RNN decoder model, according to the number of environment tokens. X-axis and Y-axis represent the number and F1 score, respectively.

attentive reader are included in answer tokens.

As shown in Table 4, the static RNN decoder models work better in extracting a small number of tokens. On the other hand, the attentive reader is suitable to the data with a large number of tokens. And the choice of k seems an important factor to affect the performance of the attentive reader. In order to see that the observations are common, we compared F1-scores of three models, the attentive reader (top-5 and top-20) and the static RNN decoder, according to the number of environment tokens.

Figure 3 presents the change of F1-score when the number of environment tokens varies. When the number is smaller than 2, the static RNN decoder works best. While the static RNN decoder is sensitive to the number, the attentive reader (top-5) shows stable performance. Therefore, the attentive reader (top-5) shows better performance than the static RNN reader at both 4 and 8 points. The per-

basic encoding	attention encoding
<NOE>	obstetric serious complications

Table 5: An example showing the benefits of using attention model: the words in bold-face indicate environment terms.

formance of the attentive reader (top-20), however, increases steadily according to the number. As a result, the attentive reader (top-20) works best at 6 points afterwards.

At 6 points, the performance of the static RNN decoder and that of attentive reader (top-20) are reversed, so it seems that there is not much performance difference among them in the graph. But, the overall difference in performance is much bigger because the average of the numbers in the corpus is nearly 5. As a result, the static RNN decoder outperforms other models. From this observation, we anticipate that if we address the GxE task focusing on the number by combining the two models, the performance will exceed the current best score, 0.426.

In the static RNN decoder, the attention encoding did not seem to work well, which is in contrast to our assumption that it would be better to consider combinations for our task. However, there is a special case showing the benefits of attention encoding as shown in Table 5. Table 5 shows part of an abstract where there are 39 combinations (13 genes and 3 diseases) and four genes associated with schizophrenia among them have the same environment terms (*serious obstetric complications*). Unless considering the combination, it seems hard to identify environment terms due to many negative examples. As a result, given a combination, (*RGS4* and *fetal hypoxia*), without an environment term such as the example in Table 5, the static RNN decoder using a basic encoding seems to regard the majority of combinations including the combination with environment as a negative example, as shown in the first column of Table 5. However, interestingly, the static RNN decoder using attention encoding identified three tokens that are correct environment terms when the four combinations with environment are given. This incor-

rect result may be due to the lack of training examples like this case. So, if we are given many cases as shown in Table 5, we envision that attention encoding will help improve performance.

6 Conclusion

In this paper, we proposed various methods for GxE recognition and showed that our models achieved good performance, despite the inherent difficulty of the task. Unlike general approaches, such as CNN, RNN, and attention mechanism, in order to extract targeted relations or infer the correct answer, we used an RNN decoder as a sequence-to-sequence model with a static decoder, and demonstrated that it is suitable to the task in extracting terms from documents. It is necessary to identify conditional information that creates the contradiction of gene-disease relations to develop advanced systems for understanding the full etiology of a disease or the full genetic network. We anticipate that the model will help researchers not only to identify correct gene-disease relations but also to apply them to other tasks, such as extracting location information that indicates where events occur.

Abstract

Massive Open Online Courses (MOOCs), offering a new way to study online, are revolutionizing education. One challenging issue in MOOCs is how to design effective and fine-grained course concepts such that students with different backgrounds can grasp the essence of the course. In this paper, we conduct a systematic investigation of the problem of course concept extraction for MOOCs. We propose to learn latent representations for candidate concepts via an embedding-based method. Moreover, we develop a graph-based propagation algorithm to rank the candidate concepts based on the learned representations. We evaluate the proposed method using different courses from XuetangX and Coursera. Experimental results show that our method significantly outperforms all the alternative methods (+0.013-0.318 in terms of R-precision; $p \ll 0.01$, t -test).

1 Introduction

In contrast with traditional courses that have limited numbers of students, each online course in a MOOC platform may draw more than 100,000 registrants (Seaton et al., 2014). The students have very diverse backgrounds; and knowledge presented in MOOCs is well understood by certain students, but might be difficult to others. In MOOCs, we use *course concepts* to refer to the knowledge concepts taught in the course videos, and related topics that help students better understand course videos. Identifying course concepts at a fine level is very important, as students with different backgrounds have totally different requirements. Figure 1 shows an example to illustrate the

You might learn how to write a **bubble sort** and learn why a **bubble sort** is not as good as a **heapsort**. Next, we are going to talk about the **quick sort** algorithm. **Quicksort** is an algorithm invented in the 1960s by doctor Tony Hoare. It is also called the **partition exchange sort**, and is a typical algorithm based on **divide-and-conquer**.
.....
Now we have the first version of **Q sort**. After we make an analysis on its performance, performance, we will find that **quicksort** is an **unstable sorting algorithm**. Fortunately, the **quick sort** has an average **time complexity** of $n \log n$, and in most cases, it can achieve its optimal performance. We first estimate its performance under **independent uniform distribution**.

Figure 1: Example of a video clip and its course concepts

problem addressed in this work. It is a clip (about ten minutes long) of video captions from the *data structure* course in XuetangX¹, one of the largest MOOCs in China. The related course concepts are marked in red and blue. We see that there are a dozen concepts mentioned in this clip. The major concept is “quick sort” (marked in red), but the content is related to many other prerequisite concepts such as “divide-and-conquer”, “bubble sort”, and “unstable sorting algorithm” (marked in blue). For students with a computer science background, those concepts would be easy; however, for students from other discipline areas, the concepts may be completely new. With the identified course concepts, we can build an interactive learning environment to help individual students better grasp the knowledge in a course. For example, for a non-science student, the system may display the definition of “unstable sorting” and “uniform distribution”; while for a science student, the system could recommend advanced concepts or potential applications of “quick sort”.

Course concepts were previously provided by the teacher, but only at a coarse level—it is time-consuming and tedious to annotate all fine-grained concepts in all videos of a course. Our goal is to automatically identify all course concepts from each video clip. Despite quite a few studies on related research topics, including keyphrase extraction (Salton and Buckley, 1988; Mihalcea and Tarau, 2004; Liu et al., 2010) and term extrac-

¹<http://www.xuetangx.com/>

tion (Hisamitsu et al., 2000; Li et al., 2013), the problem of course concept extraction in MOOCs is far from solved. The most challenging issue in the MOOC context is the **low-frequency problem**. Course video captions often contain many course concepts with low frequency, primarily for three reasons: (1) course video captions are relatively short documents, containing small numbers of words; (2) many infrequent course concepts are from other prerequisite or related courses (e.g., “uniform distribution” is from mathematical courses and “divide-and-conquer” is from courses about algorithms); (3) a disambiguated course concept tends to be expressed in various ways, which produces many scattered infrequent terms. For example, “Q sort” is a colloquial expression referring to quick sort, and “partition exchange sort” is another name for quick sort. They both have infrequent presence in course videos.

Handling infrequency errors remains an open challenge for state-of-the-art keyphrase extractors (Hasan and Ng, 2014). In MOOCs, the low-frequency problem makes it difficult for video captions to provide reliable statistical information (e.g., *tf-idf*, *c-value*, and co-occurrence) for extracting and ranking terms, and results in the ignoring of many course-relevant yet infrequent concepts. For example, in Figure 1, we can correctly extract the frequent concept “quick sort” using *tf-idf*, but fail to extract “partition exchange sort” due to its infrequent presence, even if these two concepts have the same meaning. The above problem can be addressed if we know the semantic relationship between “quick sort” and “partition exchange sort”. Such an “understanding” can be facilitated by the incorporation of background knowledge from external data sources. There exist quite a few attempts (Vivaldi and Rodriguez, 2010; Rospocher et al., 2012) that utilize external knowledge sources such as Wikipedia categories and WordNet to incorporate semantic relations (e.g. synonymy, is-a) into keyphrase extraction. However, these methods are not suitable in the MOOC context, because many highly technical course concepts are not covered by generic semantic resources, including Wikipedia and WordNet.

Recently, distributed representations of words, namely word embeddings (Mikolov et al., 2013b,a), provides us with powerful tools to represent semantic relations between words. In our

work, to address the low-frequency problem, we incorporate online encyclopedias to learn the latent representations for candidate course concepts. Moreover, we present a novel graph-based propagation algorithm to rank the candidates based on the learned representations. We evaluate the proposed method using real courses from XuetangX and Coursera² with different domains and different languages, and compare our method with state-of-the-art keyphrase extractors. In summary, our contributions include: a) the first attempt, to the best of our knowledge, to systematically investigate the problem of course concept extraction in MOOCs; b) proposal of an efficient model for course concept extraction via semantic representation learning, and ranking candidates through graph-based propagation; c) design of four novel datasets using real courses of different disciplines from XuetangX and Coursera to evaluate our proposed method.

2 Problem Formulation & Framework

In this section, we first give some necessary definitions and then formulate the problem of course concept extraction.

A **course corpus** is composed of n courses in the same subject area, denoted as $\mathcal{D} = \{\mathcal{C}_j\}_{j=1,\dots,n}$, where \mathcal{C}_j is one course. We assume that course $\mathcal{C}_j = \{v_{ij}\}_{i=1,\dots,m_j}$ consists of m_j course videos, where v_{ij} stands for the i -th video. Each video v_{ij} is composed of its video title t_{ij} and its video texts (video subtitles or speech transcripts) d_{ij} .

Course concepts are subjects taught in the course. Formally, a course concept c can be defined as a k -gram in \mathcal{D} with the following properties: a) *phraseness*: c should be a semantically and syntactically correct phrase; b) *informativeness*: c should represent a scientific or technical concept related to courses in \mathcal{D} .

Course concept extraction is formally defined as follows. Given the course corpus \mathcal{D} , the objective is to extract candidate course concepts from \mathcal{D} , denoted as $\mathcal{T} = \{c_1, \dots, c_M\}$, and output the confidence score s_i for each candidate $c_i \in \mathcal{T}$. s_i indicates the likelihood of c_i to be a course concept in \mathcal{D} .

The fundamental challenge for course concept extraction is how to capture the phraseness and informativeness of course concepts. The general

²<https://www.coursera.org/>

architecture of our model consists of three parts: (1) **candidate concepts extraction**, (2) **candidate concepts ranking**, and (3) **postprocessing**.

Candidate concepts extraction pre-processes the input corpus and extracts candidate course concepts. Considering that most concepts are noun phrases consisting of nouns, adjectives and some variants of verbs, and end with a noun word (Liu et al., 2010; Hulth, 2003; Li et al., 2013), we obtain candidate course concepts by extracting all noun phrases in the course corpus. The input text is first tokenized and annotated with part-of-speech (POS) tags. Next, we employ the linguistic pattern $((A|N)^+|(A|N)^*(NP)?(A|N)^*)N$, introduced by Justeson and Katz (1995), to extract all k -gram noun phrases as our candidates, where A , N , and P denote the adjectives, nouns, and prepositions, respectively.

Candidate concepts ranking, which is the most important part of our method, involves ranking the extracted candidates based on their phraseness and informativeness. In our model, we utilize local mutual frequencies to measure the phraseness of the extracted candidates. The informativeness of a candidate is largely dependent on its semantic meaning. Due to the low-frequency problem, local statistical features do not provide sufficient information for capturing the semantic meaning carried by each candidate concept. In our method, we propose an embedding-based method, which incorporates external knowledge from online encyclopedias, to provide semantic representations for candidate concepts. Based on the learned phraseness and informativeness information, we construct a weighted undirected graph, namely a *course concept graph* (CCG), where each vertex represents a candidate course concept. We then rank the vertices in the graph via a novel iterative graph-based propagation algorithm, namely *course concept propagation* (CCP).

In the *postprocessing* step, by choosing an appropriate cut-off value for the ranking list, we can easily annotate course concepts in video texts via string matching.

3 Course Concept Graph

We combine the phraseness and informativeness information of candidate course concepts synergistically to construct the course concept graph, formally defined as follows.

The **course concept graph** (CCG) of \mathcal{D} is a

weighted undirected fully-connected graph denoted as $\mathcal{G} = (V, E)$, where V is the vertex set of \mathcal{G} and E is the edge set of \mathcal{G} . Each vertex in V represents a candidate course concept $c_i \in \mathcal{T}$ and is associated with a *phraseness score* $ph(c_i)$, indicating the phraseness of c_i . For an edge $(c_i, c_j) \in E$, its edge weight $e(c_i, c_j) = SR(c_i, c_j)$, where $SR(c_i, c_j)$ indicates the *semantic relatedness* (SR) between c_i and c_j , i.e., the likeness of their meaning or semantic content.

A fully-connected CCG stores the SR between any candidate pair. But in practice, we introduce a parameter θ for pruning the graph. An edge (c_i, c_j) exists in a CCG only if $SR(c_i, c_j) > \theta$. The reason for pruning is: (1) the propagation on a fully connected CCG is computationally challenging, and (2) low-SR candidate pairs may introduce noise during propagation. In the following subsections, we introduce the essential building blocks of CCG, i.e., the calculation of phraseness and the representation of semantic relatedness.

3.1 Phraseness Measurement

Phraseness examines the likelihood of a multi-word term to be a semantically and syntactically correct phrase. There exists several mechanisms such as Log-likelihood (LL) (Dunning, 1993) and Pointwise Mutual Information (PMI) (Church and Hanks, 1990) to measure the phraseness of a term. These methods are mostly based on the assumption that if the constituents of a multi-word candidate term form a collocation, rather than co-occurring by chance, it is more likely to be considered as a phrase (Korkontzelos et al., 2008). In our paper, we propose a simple PMI-based approach, which utilizes local mutual frequencies in the course corpus, to calculate the phraseness score for each candidate. Specifically, for a k -gram candidate $c = \{w_1, \dots, w_k\} \in \mathcal{T}$, where $k > 1$, we split c into $f_i = \{w_1, \dots, w_i\}$ (prefix) and $b_i = \{w_{i+1}, \dots, w_k\}$ (suffix), where $i = 1, \dots, k-1$. Then, the phraseness score $ph(c)$ is defined as follows.

$$ph(c) = \max\{pmi(f_i, b_i) \mid i = 1, \dots, k-1\} \quad (1)$$

where $pmi(f_i, b_i)$ is the PMI of the prefix f_i and the suffix b_i , defined as follows.

$$pmi(f_i, b_i) = \frac{2 \times freq(c)}{freq(f_i) + freq(b_i)} \quad (2)$$

where $freq(c)$, $freq(f_i)$, $freq(b_i)$ are the occurrence frequencies of terms c , f_i and b_i in the cor-

pus, respectively. Due to the low-frequency problem in the MOOC corpus, the phraseness scores for infrequent candidates may be statistically unreliable. Thus, the final phraseness of a candidate is estimated on both the MOOC corpus and the online encyclopedia corpus as follows.

$$ph(c) = \alpha \cdot F[ph^D(c)] + (1 - \alpha) \cdot F[ph^E(c)] \quad (3)$$

where $ph^D(c)$ and $ph^E(c)$ are the phraseness calculated on the course corpus and the encyclopedia corpus, respectively. α ranges between 0 and 1, controlling the phraseness contribution of each corpus. $F[\cdot]$ is a filter for the value of $ph(c)$. If the frequency of c is lower than a pre-defined threshold $minc$, or c is an unigram, the filter simply assigns a priori value of 0.5 to the term, i.e., $F[ph(c)] = 0.5$.

3.2 Semantic Relatedness Learning

As mentioned in Section 2, statistical information in the course corpus cannot adequately capture the informativeness of concepts because of the low-frequency problem. In our method, we use word embeddings (Mikolov et al., 2013b,a) based on the online encyclopedia corpus to provide semantic representations for candidate concepts. Word embeddings represents each word as a low-dimensional, real-valued vector, and the semantic similarity between two words can be reflected by the cosine distance of their vectors. Our method for calculating semantic relatedness between candidate concepts consists of three steps: (1) corpus annotation, (2) representation learning, and (3) relatedness calculation.

Corpus Annotation. An online encyclopedia corpus is a set of articles, and can be represented as a sequence of words $\mathcal{W} = \langle w_1 \cdots w_i \cdots w_m \rangle$, where w_i denotes a word and m is the length of the word sequence. In \mathcal{W} , we replace any adjacent words which literally matches a candidate in \mathcal{T} as an unique token. After this step, we obtain a concept-annotated corpus $\mathcal{W}' = \langle x_1 \cdots x_i \cdots x_{m'} \rangle$, where x_i corresponds to a word $w \in \mathcal{W}$ or a concept $c \in \mathcal{T}$. Note that the length m' of \mathcal{W}' is less than the length m of \mathcal{W} because multiple adjacent words are labeled as one token.

Representation Learning. We then learn word embeddings on \mathcal{W}' to obtain vector representations for all annotated candidates and words in \mathcal{W}' . For any unannotated candidate concept in \mathcal{T} , we

obtain its semantic representations via the vector addition of its individual word vectors.

Relatedness Calculation. When vector representations of candidate concepts are learned, we define the **semantic relatedness** between two candidates c_1 and c_2 as the cosine similarity of their vectors, denoted as $SR(c_1, c_2)$.

With this method, a candidate course concept has no corresponding vector only if any of its constituent word is absent in the whole encyclopedia corpus. This case is unusual because a large online encyclopedia corpus can easily cover almost all individual words of the vocabulary. Our experimental results verify that over 98% of the candidates have vector representations in this way.

4 Graph Propagation-Based Ranking

After the construction of a course concept graph, we propose an algorithm to rank the candidate course concepts, based on the following assumption about CCG. *In CCG, a course concept is likely to connect with other course concepts with high semantic relatedness.* We make this assumption based on two reasons. First, course concepts are usually scientific concepts. Scientific concepts in the same domain usually have strong semantic relations. Second, the main ideas of a document can be captured by a group or groups of words with strong semantic relationships. Course concepts are strongly related to the course corpus, which makes them more likely to connect with each other with high semantic relatedness.

For a vertex c in CCG, we denote $conf(c)$ as its **confidence score** of being a course concept. Following the above assumption, the confidence score of a candidate course concept is evidenced by its semantic relations with other course concepts. In other words, high-confidence course concepts in CCG could propagate their confidence scores to their neighbor nodes that have high semantic relatedness with them, to discover other potential course concepts. Therefore, we propose an iterative graph-based algorithm, namely course concept propagation (CCP), which first assigns each vertex of CCG an initial confidence score, and iteratively updates the score for each vertex through propagation. The initial confidence score of each candidate course concept is determined by a **seed set** \mathcal{S} , which contains a list of known course concepts in \mathcal{D} . Specifically, let us denote the confidence score of the vertex c in the k -th iteration as

$conf^k(c)$, and the initial confidence score of c as $conf^0(c)$. We set $conf^0(c) = 1$ if $c \in \mathcal{S}$ and $conf^0(c) = 0$, otherwise. In the following subsections, we first introduce the construction of a seed set, and then present the propagation process in detail.

4.1 Seed Set Construction

In our method, the seed set can be constructed either manually or automatically. For some courses, key course concepts may already be included in course materials; however, this is not the case for most MOOC courses. For those courses in which key course concepts are not explicitly provided, we propose to extract them automatically from course outlines. A course in a MOOC usually contains hundreds of videos, each of which is associated with a video title. These video titles serve as an outline of a course and become a potential good resource for providing high-quality course concepts. Specifically, for each course \mathcal{C}_i , we first extract candidates from video titles of \mathcal{C}_i , following the same pattern-based procedure in the candidate extraction step. Then, candidates are ranked based on their *tf-idf* in \mathcal{C}_i . Finally, we select the top- N ranked candidates to form the seed set \mathcal{S} .

4.2 Propagation Process

To design the propagation process, we need to answer two crucial questions. First, a vertex should receive confidence scores from which vertexes in each iteration? Second, how much score should a vertex receives from another vertex in each iteration? Based on the above questions, we define two general functions as follows: a) **voting score** $vs^k(c_j, c_i)$: determines the confidence score c_j propagates to c_i in the k -th iteration; b) **voter-set** $A(c_i)$: it specifies the vertex set from which c_i receives the voting scores in each iteration. Therefore, a general propagation process can be defined as follows.

$$conf^{k+1}(c_i) = \frac{1}{Z} \left(\frac{\sum_{c_j \in A(c_i)} vs^k(c_j, c_i)}{|A(c_i)|} \right) \quad (4)$$

where Z a the normalization factor. The main idea of Equation 4 can be explained as a voting process. During each iteration, each vertex in $A(c_i)$ will vote for c_i . The score of c_i in the next iteration is dependent on the average voting score of vertexes in $A(c_i)$. We implement the voting score

function as follows.

$$vs^k(c_j, c_i) = ph(c_j) \cdot e(c_i, c_j) \cdot conf^k(c_j) \quad (5)$$

where $ph(c_j) \cdot e(c_i, c_j)$ determines the ‘‘authoritativeness’’ of the vote from c_j to c_i . If c_j has a higher phraseness (the voter is more credible) and c_j is more relevant to c_i (the voter knows more about the candidate), then c_j tends to propagate more of its score to c_i (the vote from c_j has a greater impact on determining whether c_i is a course concept than the votes from other voters). As for the implementation of $A(c_i)$, a natural way would be to set $A(c_i)$ as the neighbor vertexes of c_i in CCG. Because a course concept is likely to connect with other course concepts with high semantic relatedness, it tends to receive high voting scores from its course concept neighbors, compared with other vertexes, during propagation.

However, in practice, the propagation process is usually hampered by the **overlapping problem**. If two terms c_i and c_j contain one or more identical words, we say that c_i and c_j are *overlapping*. For example, ‘‘merge sort’’ and ‘‘bubble sort’’ are overlapping because they both have the word ‘‘sort.’’ Overlapping frequently occurs among course concepts because scientific terms often have background words such as ‘‘function,’’ ‘‘algorithm,’’ and ‘‘culture’’. We find that $vs(c_j, c_i)$ is less reliable if c_j and c_i overlap. For example, the term ‘‘same algorithm’’ is not a course concept, but it contains the word ‘‘algorithm,’’ which makes it to have a high SR with the course concepts including word ‘‘algorithm,’’ as in ‘‘bfs algorithm’’ and ‘‘kmp algorithm’’. Therefore, the score of the term ‘‘same algorithm’’ tends to be blindly increased by votes from these course concept neighbors. To solve this problem, we generalize the voting score by introducing a **penalty function** opf , which restricts the propagation of voting scores among overlapping terms. The **generalized voting score** (gvs) is defined as follows.

$$gvs^k(c_j, c_i) = opf(c_i, c_j) \cdot ph(c_j) \cdot e(c_i, c_j) \cdot conf^k(c_j) \quad (6)$$

where $opf(c_i, c_j) = 1$ when c_i and c_j is not overlapping, and $opf(c_i, c_j) = \lambda$ otherwise, where λ ranges from 0 to 1.

Termination Condition. To determine when the iteration process stops, we introduce a **termination set** \mathcal{F} , including S course concepts. Let us denote the average ranking of concepts in \mathcal{F} after the k -th iteration as $Ar^k(\mathcal{F})$. The propagation process terminates if $Ar^{k+1}(\mathcal{F}) > Ar^k(\mathcal{F})$.

Dataset	Domain	Language	#courses	#videos	#tokens	#candidates	#labeled	correlation
CSEN	Computer Science	English	8	690	1,242,156	59,050	4,096	0.734
EcoEN	Economics	English	5	381	401,192	27,571	3,652	0.696
CSZH	Computer Science	Chinese	18	2,849	2,291,258	79,009	5,309	0.721
EcoZH	Economics	Chinese	8	455	645,016	60,566	3,663	0.646

Table 1: Dataset Statistics

5 Experiments

5.1 Datasets

Because there is no publicly available dataset for course concept extraction in MOOCs, we construct four course corpuses with different domains and languages to evaluate our model. Specifically, we collect Computer Science and Economics courses from two famous MOOC platforms — Coursera and XuetangX — to construct our evaluation datasets.

Coursera is one of the first MOOC platforms in the world. We collect video captions from 8 Computer Science courses to form the **CSEN** dataset. Similarly, video captions from 5 Economics courses are picked to construct the **EcoEN** dataset. All video captions in CSEN and EcoEN are in English. XuetangX is one of the most popular MOOC websites in China. Video captions of 18 Computer Science courses and 8 Economics courses are collected to form the **CSZH** dataset and **EcoZH** dataset, respectively. All video captions in CSZH and EcoZH are in Chinese.

The statistics of the four datasets are listed in Table 1, where *#courses*, *#videos*, and *#tokens* are the total number of courses, videos, and tokens in each dataset. For each dataset, the video captions are preprocessed following the procedure of *Candidate concepts extraction* in Section 2. *#candidates* denotes the number of extracted candidates for each dataset. To create a gold standard for evaluation, candidates for each dataset are sent to two human annotators majoring in the corresponding domain. For each candidate, the annotator is asked to make a judgement about whether it is a course concept based on the course contents. Thus, each dataset is doubly annotated, and Pearson correlation coefficient is applied to assess inter-annotator agreement. A candidate is labeled as a course concept only if the two annotators are in agreement. The column *#labeled* presents the ground-truth number for each dataset. In each dataset, we use 10% of ground truth to form the termination set and others for evaluation.

The datasets will be publicly available later.

As for the online encyclopedia corpus, we employ the Baidu encyclopedia³, which is the largest web-based encyclopedia in China, for Chinese language. Our training corpus includes 6,223,649 web pages crawled from the latest Baidu encyclopedia. For the English language, we extract 9,834,664 articles from the latest publicly available Wikipedia dump.⁴

5.2 Evaluation Metrics

For our experiments, we select two evaluation metrics. The first metric is **R-precision** (R_p) (Zesch and Gurevych, 2009), which is an IR metric that focuses on ranking. Given a ranking list with n gold keyphrases, it computes the precision of a system over its n highest-ranked candidates. However, R-precision does not take the order of extracted keyphrases into account. To address the problem, we select the **Mean Average Precision** (MAP), which has been the preferred metric in information retrieval for evaluating ranked lists.

5.3 Influence of Parameters

We first investigate the parameters that may influence the performance including: (1) α in Equation 3, (2) the size of seed set N , and (3) the penalty factor λ .

The phraseness parameter α . The parameter α controls the contribution of a course corpus when calculating the phraseness score. If α is too large, the calculated phraseness may suffer from unreliable estimation; however, the calculated score may fail to reflect the real phraseness distribution in the course course when α is too small. We investigate the influence of α in Figure 2(a). This figure shows the R-precision of CCP when $\lambda = 0.3$, $N = 100$, and α ranges from 0 to 1. From this figure we find that, when α is set from 0.2 to 0.7, the performance is consistently good, and remains stable with the variations of α . When α is larger than 0.85, the R-precision drops in all

³<http://baike.baidu.com/>

⁴<https://dumps.wikimedia.org/enwiki/20170120/>

evaluation datasets. The results demonstrate that the large-scale encyclopedia data is conducive to making reliable estimations of the phraseness. In our experiment, α is set as 0.4 for all four datasets.

The size of seed set N . As mentioned in Section 4.1, we utilize the video titles to automatically construct the seed set for each dataset. We set the size of the seed set $N = 10, 50, 100, 200$ for each dataset and explore the influences of N on CCP. Figure 2(b) shows the R-precision of CCP with different N on CSEH ($\lambda = 0.3, \alpha = 0.4$). From the figures, we observe that the CCP reaches its best performance through 3 to 5 iterations. When N becomes larger, the algorithm tends to achieve the best performance faster, i.e., it terminates with fewer iterations. However, different settings of N all lead to a competitive best performance (around 0.43 on CSEH). We obtain similar observations on other datasets. In our experiments, we set $N = 100$ for all datasets.

The penalty factor λ . The parameter λ reconciles the influence of voting scores from overlapping terms. We demonstrate the influence of λ in Figure 2(c). This figure shows that the CCP achieves its best R-precision when λ ranges from 0.20 to 0.40 in all datasets. If we do not severely lower the voting scores from overlapping terms ($\lambda > 0.5$), or even have no penalty ($\lambda = 1.0$), the performance is consistently unsatisfactory. The experimental results verify that the voting score from a non-overlapping neighbor (e.g., “data mining” to “machine learning”) is relatively more reliable than an overlapping one (e.g., “difficult learning” to “machine learning”) in CCP. However, voting scores from overlapping terms still encode some useful semantics (e.g., “merge sort” to “quick sort”), ignoring them (λ close to 0.0) may cause a decline in performance. We set $\lambda = 0.3$ for all datasets.

5.4 Comparison with Baselines

After we explore the influences of parameters, we employ four baseline methods to compare with our proposed method, i.e., course concept propagation (CCP).

5.4.1 Baseline Approaches

First, we select two *statistics-based methods*, i.e., TF-IDF and PMI, as our baselines. **TF-IDF** ranks the candidate course concepts based on their *tf-idf* in the course corpus. For a candidate $c \in \mathcal{T}$, its *tfidf* $R(c) = tf_c \times \log(idf_c)$, where tf_c is the fre-

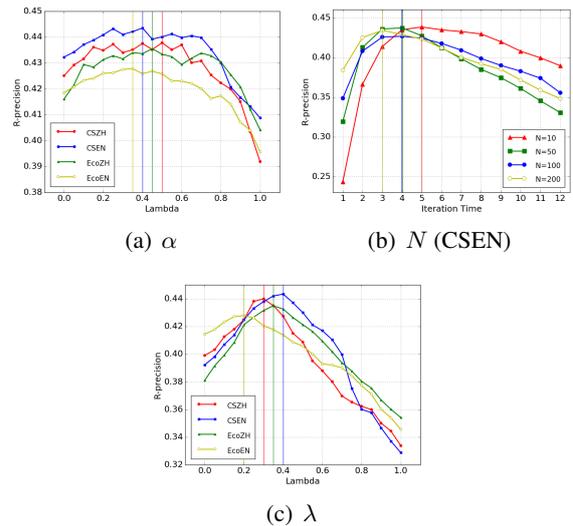

Figure 2: The Study of Parameter Influence on CCP

quency of c in \mathcal{D} , and idf_c is based on the number of videos in which c appears. In the **PMI** method, we directly rank candidates based on their phraseness, using the method described in Section 3.1. We use the same parameter α with CCP for a fair comparison. Second, we also employ two *graph-based methods*. **TextRank** (Mihalcea and Tarau, 2004) and **Topical PageRank** (TPR) (Liu et al., 2010) are two state-of-the-art graph-based keyphrase extraction approaches. They all construct a graph based on word co-occurrences within the corpus, and apply the PageRank algorithm (Brin and Page, 1998) to score the vertices. The score of a multi-word candidate is the average score of all words within the candidate. Different from TextRank, TPR decomposes traditional PageRank into multiple PageRanks specific to various topics using LDA (Blei et al., 2003). Topics in TPR are learned from external data sources, and we use the same encyclopedia corpus as ours to make a fair comparison.

5.4.2 Implementation Details

For pruning the CCG, we set $\theta = 0.3$ for all datasets. The *minc* is heuristically set as 5 in our experiments. The skip-gram model (Mikolov et al., 2013b) is applied to train word embeddings using the Python library *gensim*⁵ with default parameters. For TextRank and TPR, we use the THUTag⁶, a state-of-the-art keyphrase extraction package, which provides the implementations of these methods.

⁵<http://radimrehurek.com/gensim/>

⁶<https://github.com/YeDeming/THUTag>

Method		CSEN	EcoEN	CSZH	EcoZH
TF-IDF	R_p	0.125	0.303	0.118	0.198
	MAP	0.105	0.232	0.109	0.145
PMI	R_p	0.239	0.222	0.246	0.179
	MAP	0.141	0.197	0.187	0.121
TextRank	R_p	0.151	0.290	0.142	0.161
	MAP	0.137	0.263	0.131	0.115
TPR	R_p	0.284	0.414	0.305	0.303
	MAP	0.255	0.387	0.267	0.288
CCP	R_p	0.443	0.427	0.434	0.435
	MAP	0.432	0.365	0.416	0.423

Table 2: Performance of Different Methods on Different Datasets

5.4.3 Performance Comparison

In Table 2 we summarize the results of different methods across different datasets. From the table, we find that the proposed methods outperform all baselines on all datasets, which indicates the robustness and effectiveness of CCP⁷. Specifically, we have the following observations.

First, TF-IDF performs competitively with TextRank, but they both perform worse than TPR and CCP. TF-IDF and TextRank only use statistical information within the course corpus and have a strong reliance on term frequency, which hampers their performances. For example, both TF-IDF and TextRank correctly extract the concept “IP”, which appears 139 times in the Computer Network course, but failed to extract “Internet Protocol”, the full name of “IP”, due to its infrequent presence. Moreover, they also highly ranked many irrelevant yet frequent terms, such as “English language”. These errors are significantly reduced in CCP with the incorporation of semantic relations.

Second, TPR performs better than TextRank across all datasets (an average of +0.141 in terms of R-precision), but is worse than CCP. In MOOCs, a course usually contain multiple topics, but TextRank often falls into a single topic, and fails to cover other substantial topics of a course. For example, in the Data Structure course, TextRank highly ranked phrases with “tree”, but lower-ranked concepts related to “sort”. TPR alleviates this problem by incorporating topic information from online encyclopedias. However, TPR also favors frequent course concepts, because frequent words tend to have high connectivity in the co-occurrence graph, and thus receive high rankings using PageRank.

⁷The improvements are all statistically significant tested with bootstrap re-sampling with 95% confidence.

6 Related Works

Our work is relevant to automatic keyphrase extraction, which concerns the automatic extraction of important and topical phrases from the body of a document” (Turney, 2000). Generally, keyphrase extraction techniques can be classified into two groups: supervised approaches and unsupervised approaches. In supervised machine-learning approaches, the training phase usually includes a classification task: each phrase in the document is either a keyphrase or not (You et al., 2013). Different learning algorithms have been employed to train the classifier, including naïve bayes (Frank et al., 1999; Witten et al., 1999), decision trees (Turney, 2000), maximum entropy (Yih et al., 2006; Kim and Kan, 2009) and support vector machines (Lopez and Romary, 2010; Kim and Kan, 2009). Unsupervised approaches usually involve assigning a saliency score to each candidate phrase, by considering various features (Wan and Xiao, 2008). Generally speaking, the information such as *tf-idf*, co-occurrence, or neighbor documents are frequently used in unsupervised keyphrase extraction. For example, TextRank (Mihalcea and Tarau, 2004) is a well-known method that ranks keywords based on the co-occurrence graph. Huang et al. (2006) utilize co-occurrence information to construct a semantic network for each document and derive the importance of phrases by analyzing the network. The ExpandRank (Wan and Xiao, 2008) model uses a set of neighborhood documents to enhance single-document keyphrase extraction. Recently, Liu et al., (2015) proposed a new framework that extracts quality phrases from text corpora integrated with phrasal segmentation. This model also rely on local statistical information and requires a relatively large corpus.

However, extracting low-frequency keyphrases remains an open challenge for all these methods. To address this problem, many related works consider not only the document level information but also knowledge from external data sources, to improve the effectiveness of automatic keyphrase extraction. Representative examples include the KEA++ system (Medelyan and Witten, 2006) that obtains candidate phrases from a domain-specific thesaurus. The work of Gazendam et al. (2010) also use the thesaurus as a background corpus. Besides the thesaurus, knowledge bases are widely used to calculate semantic relations between

terms. For example, Rospocher et al. (2012) use the WordNet to detect synonym terms, and then rank a synonym term higher even if it is ranked lower by the statistical method. The work of Vivaldi and Rodríguez (2010) utilizes an ontology hierarchy extracted from Wikipedia categories to provide background knowledge. Similarly, Berend and Farkas (2010) invent features concerning the Wikipedia level to achieve enhancements in performance. All these methods make use of only the explicit semantic knowledge contained in the external source. Different from them, we use word embeddings to learn semantic representations for candidate concepts and rank them via a novel graph-based propagation process.

7 Conclusion and Future Work

In this paper, we study the problem of course concept extraction in MOOCs. We precisely define the problem and propose a graph-based propagation method to extract course concepts by incorporating external knowledge from online encyclopedias. Experimental results on evaluation datasets validate the effectiveness of the proposed method. Incorporating external knowledge of various kind to help extract course concepts is an intriguing direction for future research. A straightforward task is to incorporate structured information such as “is-a” relation into the proposed model.

Abstract

This paper addresses the task of detecting identity deception in language. Using a novel identity deception dataset, consisting of real and portrayed identities from 600 individuals, we show that we can build accurate identity detectors targeting both age and gender, with accuracies of up to 88%. We also perform an analysis of the linguistic patterns used in identity deception, which lead to interesting insights into identity portrayers.

1 Introduction

With the ever growing usage of social media and other online interactions, cyber-crimes such as identity thief, fraud, and sexual predation have become increasingly common. The availability of a wide variety of social platforms and apps further facilitates these kind of crimes, which are often characterized by the ease of deception and concealment of one's real identity. Moreover, the increased sense of security due to the spatial and temporal "distanciation" involved with online communications leads to a growing number of occurrences of identity deception.

Identity deception is defined as "pretending to be someone you are not" (Rowe, 2009). The intentions of identity deceivers differ between achieving monetary benefits, committing fraud, sexual predating, appearing more attractive in online dating, and so on. The risk is further increased with the massive number of children and teens using social media as well as the elderly who get involved in online interactions that they assume to be trustworthy by default due to their lack of experience. Multiple stories of teenagers who became victims of these activities, as well as elderly who lost hundreds of thousands of dollars are now

often encountered in the news. For instance, a recent study reported that 92% of teens go online on daily basis including 24% who are online "almost constantly".¹ The study additionally reported that females tend to use social media more than males.

Hence, due to the financial, social, physical, and psychological damages associated with cyber-crimes, there is a growing need to learn more about the patterns and behaviors of identity deceivers, in order to develop computational approaches that can aid in preventing such crimes.

In this work, we seek to identify linguistic differences in individuals' self-presentation when engaging in identity deception behaviors. We target the two most common behaviors related with online identity deception i.e., individuals portraying themselves as either younger and older, and individuals lying about their gender –also known as gender switching (Macwan and inz. Grzegorz Filcek, 2017; Herring and Martinson, 2004).

We perform a set of experiments to explore three main research questions. First, given a deceptive corpus consisting of written samples of gender switching, can we build fake identity detectors that predict gender deception? Second, given a deceptive corpus consisting of written samples of age deception, can we build fake identity detectors that predict age deception? Lastly, are there linguistic differences associated with individuals' gender and age in identity deception?

2 Related Work

Several approaches have been developed to detect and prevent identity deception (Tsikerdekis and Zeadally, 2015). Integration of latent textual features with spatial and temporal features has been suggested using probabilistic generative

¹<http://www.pewinternet.org/2015/04/09/teens-social-media-technology-2015/>

modelling to detect identity thieves (Wang et al., 2017). Another study analyzed the connection between time traces of stolen accounts and compared them to that of the original users using support vector machines (Villar-Rodriguez et al., 2016).

As linguistic patterns represent the main method for detecting identity theft, previous work used text mining techniques by extracting semi-structured information from online news stories and reports on the topic of identity theft, and identified behavioral and temporal patterns and resources used by identity thieves (Zaeem et al., 2017). An analysis of thieves' behavior in the Massive Multiuser Online Role Playing Game suggested a detection model based on specific sequences including item production, item sales, and acquisition of game money (Kim et al., 2015).

Focusing specifically on the patterns associated with impersonating the opposite gender, a research study using the Turing Game identified stereotypical content performed by the deceivers as well as stylistic cues to their real gender (Herring and Martinson, 2004). The study additionally suggested that linguistic cues referring to gender seem to be unconsciously generated.

One of the common practices of identity thieves is online sexual predation. To identify such behavior, word patterns and search engine query detection were suggested as means for detecting pedophilic activity (Macwan and inz. Grzegorz Filcek, 2017). Examples include the detection of predators using lexical and behavioral features and calculating the predator-hood score as a function of features weights (Dhouioui and Akaichi, 2016). A method was developed to identify sexual predation using phrase-matching and rule-based systems and reported the usefulness of statement lengths in chat lines for improving the identification process (Mcghee et al., 2011). A study (Bogdanova et al., 2012) analyzing a corpus of chats for detecting cyberpedophilia found that character n-grams are capable of discriminating pedophiles' chats. However, higher-level features that modeled behavior and emotion were required to detect conversations with cyberpedophiles from cybersex chat logs (Bogdanova et al., 2014).

An analysis of twenty chat rooms to detect sex offenders indicated eight recurrent themes, including 'implicit and explicit content of discourse', 'on-line solicitation', 'fixated discourse', 'use of colloquialisms', 'conscience', 'acknowledging il-

legal/immoral behavior', 'risk minimization', and 'preparing to meet offline' (Egan et al., 2011). Other work used automatic text categorization techniques with a support vector machine and distance weighted k-NN classifiers to distinguish between a sexual predator and a pseudo victim using data collected from volunteers posing as underage victims (Pendar, 2007). A language processing module was developed in order to successfully differentiate between porn titles and titles of encyclopedia articles using support vector machine and linear regression (Panchenko et al., 2012).

More recently, a conversational agent was developed by mimicking the behavior of a teenager and inferring its conversational rules from a real dialogue corpus in order to detect cyberpedophilia (Callejas-Rodríguez, 2016). The study reported a successful approach using a combination of the least frequent word and the most frequent bigram.

In summary, most of the previous work has focused on specific topics and in particular sexual predation and gaming, and relied primarily on limited text mining approaches. Instead, our approach uses a novel dataset where the participants are not restricted from discussing any topics, and hence we can identify general patterns of identity deception related to both gender and age. Moreover, an advantage of our dataset is the knowledge of the real identity and demographic information of the participants. Furthermore, we conduct multiple experiments using a wide variety of linguistic features in order to explore and analyze the textual clues that identify identity deceivers.

3 Data Collection

We seek to examine written samples of individuals presenting themselves with their real identity as well as a fake identity. To achieve this, we collect a corpus of writings from several participants, including responses to open-ended questions about their real identity, as well as about a pre-assigned fake identity. We target four fake identities: 1) 18-year-old female, 2) 18-year-old male, 3) 65-year-old female, 4) 65-year-old male. The choice of the fake identities was based on two practical considerations. First, the most prominent form of online identity deception is gender switching, thus we seek to collect samples of individuals portraying themselves as being from the opposite sex. Second, 18 and 65 years are extreme values on the age

FAKE IDENTITY	REAL IDENTITY
I'm Ashley, and I'm currently enrolled in a freshman in the nursing program at my university. My family is very important to me. I have two sisters, both of whom are younger than me. I do volunteer work in my free time through my church I enjoy hanging out with my friends, traveling (I get a lot of chances to do this through mission trips I go on). I want a husband and family, but my career comes first. I'm excited to see what new opportunities will appear on life's path.	I am a guy in his mid-30's. I have a cat and live with two roommates. I am self employed, selling various items on eBay as well as doing my Mechanical Turk work. I love music (alt and indie rock, electronica, and 80's especially), concerts, karaoke, video games, DC Comics, technology, reading, streaming TV and movies, camping and hiking, exploring the city, and good food and coffee. I'm currently involved in various projects to improve my life.
I am a male, aged 65 years old. I have a wife who is 59 years old and two grown children ages 30 and 32, both boys. I worked for Boeing making airplanes for thirty years before I was injured and needed shoulder surgery. I retired just recently and teach an after school class about airplanes and how they are built. I check the mail at 3 pm each day and go to the grocery store four times a week, my wife picks me up a 6 pack of Ice House nightly ...	I am a 35 year old female with bleached blonde hair and hazel eyes. I am a graduate in Public Admin and I enjoy bodybuilding. I have four children and a husband and we live in Seattle. I like to take hikes outside in the mountains but not when it is too hot outside. I am from Maine originally but lived in florida for ten years and hated it. The weather is too hot and there are too many snakes and lizards crawling all over your yard.

Table 1: Sample responses from our dataset. Top row: 35-year-old male acting as an 18-year-old female; bottom row: 35-year-old female acting as a 65-year-old male

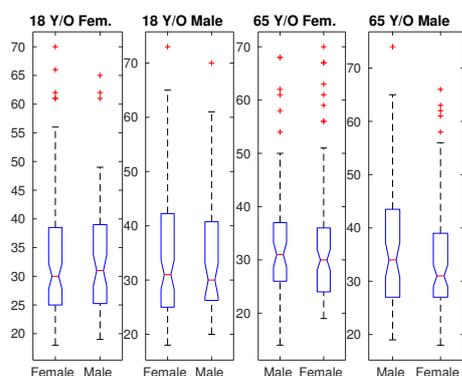

Figure 1: Participants' age clustered by gender when assuming four fake identities

distribution of Internet users, and this can allow us to explore deceptive behaviors in individuals portraying themselves as being younger or older than they actually are.

We designed four surveys using the Qualtrics survey software and distributed them via Mechanical Turk. In each survey, participants were asked to respond to the following prompt:

1. *Describe yourself.*
2. *Discuss any topic that comes to your mind.*
3. *Imagine you are trying to convince someone that you are a 18 | 65 year old male | female. Briefly describe yourself, pretending you are a 18 | 65 year old male | female.*
4. *Imagine you are trying to convince someone*

that you are a 18 | 65 year old male | female. Discuss any topic that comes to your mind as if pretending you are a 18 | 65 year old male | female.

Note that the participants are asked to respond to two open-ended questions when presenting themselves with their real and fake identity: one asking for a self-description, and another one asking for an essay on a topic of choice. Our motivation for this setup is to avoid stereotypical responses for each target identity, i.e., descriptions focusing on physical appearance and activities frequently associated to the target gender and age. Two sample responses (self-description only) from individuals posing as female and male are shown in Table 1.

We also collect demographic data from participants, including their gender, age, education, primary language, ethnicity, country of origin, and country of residence. During the data collection, participants self-reported their gender, using the male/female options. In the future, with larger-scale data collections, we will be able to work with an extended set of gender options. Also, note that individual's true identity is self-reported so we assume workers to provide accurate information – previous studies analyzing Mechanical Turk as a participant's pool show that this is often the case (Paolacci and Chandler, 2014).

In order to obtain responses with a reasonable amount of text, we constrain the response's length to be at least 400 characters. Additionally, we

Fake Identity	Respondents	Male	Female	Age (M,SD)
18 Y/O Fem.	151	41.7%	58.3%	(33.24, 10.82)
18 Y/O Male	154	35.7%	64.3%	(34.24, 11.62)
65 Y/O Fem.	150	38.0%	62.0%	(33.42, 12.03)
65 Y/O Male	149	42.3%	57.7%	(35.07, 11.96)

Table 2: Gender distribution and age statistics for four fake identities.

manually check for coherence and relevance to the prompt. We reject contributions that failed to follow the provided guidelines and did not pass the manual verification.

After this filtering, we obtained a total of 604 completed surveys, each of them containing descriptions of participants’ real and fake identities, as well as their corresponding demographic data. The data statistics are shown in Table 2.

Figure 1 shows the participants real age, clustered by gender, when assuming different fake identities. We observe that the average age of the respondents ranges between 33-35 year-old, thus suggesting a reasonable distance between their actual and fake age. In addition, the graph suggests differences in how deceivers portray themselves given their actual gender, which we further explore in section 5.

4 Features

In this section, we describe the sets of features extracted, which are used to build our classifiers.

Unigrams We extract unigrams and bigrams derived from the bag of words representation of each identity response.

POS These features consist of part-of-speech (POS) tags obtained with the Stanford Parser (Chen and Manning, 2014).

Semantic LIWC These features include the 74 semantic classes present in the LIWC lexicon 2015 (Pennebaker et al., 2015). Each feature represents the number of words in a response belonging to a specific semantic class, normalized with respect to the length of the response.

Semantic Word2Vec To obtain these features, we use the word2vec (Mikolov et al., 2013) implementation available in the Gensim toolkit (Řehůřek and Sojka, 2010) to obtain word vectors with dimension 300 for each word in the responses. The final identity vector is calculated by adding all the word vectors in the response.

Lexical diversity This set includes four lexical diversity metrics, including type/token ratio (McCarthy and Jarvis, 2010), mean word frequency, and the Yule’s I and K indexes (Oakes, 2000).

Readability We also extract features that indicate text understandability. These include readability metrics such as the Flesch-Kincaid, Flesch Reading Ease, Gunning Fog, and the Automatic Readability Index (ARI) (Kincaid et al., 1975; Senter and Smith, 1967)

5 Experimental Results

We conduct several experiments to answer the research questions formulated at the beginning of this paper. During our experiments, we perform the evaluations at individual level, by merging the two open-ended questions asked during the survey (i.e., the self-description and topic-of-choice essay), for both the real and the fake identities. Also, given the contributors’ age distribution shown in Figure 1, we opted to cluster the participants age into two groups: young (≤ 30 years) and old (>30 years).

The classifiers are built using the SVM algorithm² and the different sets of features described in section 4. We perform leave-one-out cross-validation in all our experiments. In all cases, we use the majority class baseline as a reference value.

5.1 Classification of Real and Fake Identities

Before focusing on our main research questions, we seek to evaluate whether deception detection can be conducted using our fake identity dataset. Thus, we focus on two main classification tasks. First, using our entire dataset, we explore whether we can discriminate between the portrayed identities and the real identities. Second, we once again attempt to discriminate between real and fake identities, but this time filtering by either age or gender.

²As implemented in the LIBLINEAR library, using (L2) SVM classification.

Features	All Identities	Gender		Age	
		Female	Male	Young	Old
Baseline	50.12	49.93	50.21	49.90	50.14
Ngrams	86.67	86.59	84.25	85.35	84.31
POS	66.61	68.39	68.93	68.97	67.30
LIWC	63.28	64.70	64.89	60.69	66.56
Word2Vec	77.51	77.70	72.34	77.26	75.51
LexDiv	49.45	50.47	46.38	46.62	48.09
Readability	54.55	52.25	51.16	51.55	54.45
All features	85.76	87.50	85.10	85.74	85.48

Table 3: Classification results for deception detection regardless of gender or age (All Identities); for people with a certain gender, according to their real identity (Gender); and people with a certain age according to their real identity (Age).

		Identity		
		Fake	Real	Total
Gender	Male	234	236	470
	Female	355	366	721
Age	Old	340	342	682
	Young	259	260	519
All identities		599	602	1201

Table 4: Class distribution for all identities, filtered by gender, and filtered by age.

To perform these experiments, we start by creating five subsets from all the data. The first one consists of all the real and fake identities that we collected; the second and third one consist of responses filtered by the individuals’ actual gender, i.e., male and female; and the last two consist of responses filtered by the individuals’ actual age, i.e., old and young. During this process, we discard those instances where the fake identity overlaps with the actual identity. The class distribution of the resulting subsets is shown in Table 4.

We then build classification models that attempt to discriminate between the real and fake identities under the following scenarios: a) having no previous knowledge of the actual individual’s age or gender, i.e., all data; b) knowing that the individual’s actual gender is female; c) knowing that the individual’s actual gender is male; d) knowing that the individual’s actual age is 30 years and under; and e) knowing that the individual’s actual age is over 30 years.

Classification results and the corresponding majority class baselines are shown in Table 3. For most of the prediction tasks, except for the first one, the best performing feature set is the combination of all features (*All features*), followed by *Ngrams*. The remaining sets of features achieve accuracy values ranging from 63% to 77%, which still represent a noticeable improvement over the majority class baseline (the only exception is the

Real Identity	Fake Identity	
	Male	Female
Male	185	181
Female	116	120
Total	301	301

Table 5: Class distribution for gender deceivers

lexical diversity feature set).

While the overall results are largely similar across the five experiments, note that the size of the datasets used in the gender and age-filtered experiments is much smaller than the one used in the All Identities experiment. This suggests that the gender (or age) of the writer plays an important role in this classification, and the gender (or age) characteristics can make up for the smaller data size.

5.2 Classification of Gender Deceivers

Motivated by our previous findings, we investigate our first research question. Can we build fake identity detectors that predict gender deception? This question focuses on the scenario in which we are interested in knowing if a text whose author claims to be of a certain gender is indeed authored by that particular gender. E.g., if the author claims to be a female, is the writer indeed a female or a male? This can be useful in the verification of user profiles in dating websites, where gender switching is a common form of deception.

For this classification task, we use only the data from the portrayed identities. That is, we use the responses from the 16 Y/O male, 65 Y/O male, 16 Y/O female, and 65 Y/O female identities. While we could have potentially also used the real identities, we chose to focus only on the portrayed ones so that we obtain a more consistent dataset. The distribution for this subsets is shown in Table 5.

For each portrayed gender, the classifier aims to

Features	Fake Identity		
	Female+Male	Female	Male
Baseline	50.00	60.00	61.00
Ngrams	86.20	82.72	87.04
LIWC	70.40	66.11	73.08
Word2Vec	75.90	63.78	65.11
POS	67.40	64.45	66.77
LexDiv	54.30	57.14	54.15
Readability	61.29	54.48	71.42
All features	86.04	83.05	87.70

Table 6: Classification results for gender deceivers, overall (Female+Male column) and broken down by portrayed gender.

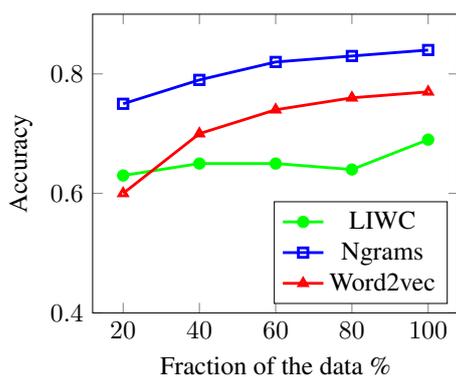

Figure 2: Learning curves on gender deceivers classification using three feature sets

predict the real gender. Classification accuracies for the resulting models are shown in Table 6. This table also shows the results of the models built using the portrayed male and female responses separately. In these experiments, the *Ngrams* features outperform all the other feature sets. The second best performing features are the ones based on the LIWC lexicon, followed by the part-of-speech features *POS*. Overall, the results suggest that it is easier to identify females portraying themselves as males (*Male* identity column) than males portraying themselves as females (*Female* identity column).

As an additional experiment, we investigate whether larger amounts of training data can improve the identification of gender deceivers. We plot the learning curves of the best performing sets of features using incremental amounts of data as shown in Figure 2. In this graph, the learning trends for the *LIWC* and *Word2Vec* features suggest that larger amounts of training data could improve the classification performance.

Real Identity	Fake Identity	
	Young	Old
Young	168	174
Old	137	123
Total	305	297

Table 7: Class distribution for age deceivers

Features	Fake Identity

LIWC	71.26	73.11	67.67
Word2Vec	77.24	73.77	65.99
POS	69.76	63.27	64.30
LexDiv	49.66	50.16	56.90
Readability	60.32	60.54	53.87
All features	82.72	87.21	81.81

Table 8: Classification results for age deceivers overall, and broken down by portrayed age.

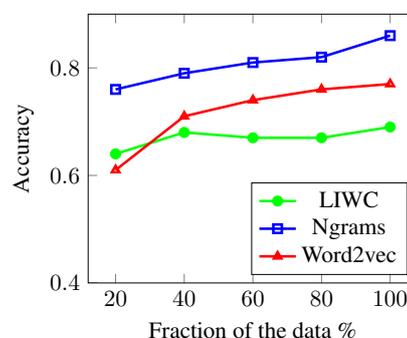

Figure 3: Learning curves on age deceivers classification using three feature sets

5.3 Classification of Age Deceivers

Next, we focus our attention on identifying age deceivers to answer our second research question: can we build fake identity detectors that predict age deception? This time we focus on the scenario where the author of a text claims to be either young or old (using our earlier definition of young/old), and we want to determine if the real age of the writer is indeed corresponding to their claims. This can be particularly useful in the identification of sexual predators who target younger people, or scammers who target elderly people.

For this classification task, we once again use only the data from the portrayed identities, i.e., we use only the responses corresponding to the portrayed 16 Y/O male, 65 Y/O male, 16 Y/O female, and 65 Y/O female identities. The distribution for this dataset is shown in Table 7.

For each portrayed age range (young or old), the classifier aims to predict the real age range. Clas-

Female as a Male		Real Female		Male as a Female		Real Male	
SWEAR	2.35	SEXUAL	2.03	FILLER	4.07	ACHIEV	1.57
FILLER	2.35	ANX	1.48	FEMALE	3.16	MONEY	1.51
ASSENT	2.15	INGEST	1.44	SWEAR	2.29	WORK	1.50
FRIEND	1.96	BIO	1.36	FAMILY	1.96	SEXUAL	1.36
INFORMAL	1.81	RISK	1.31	BODY	1.94	DEATH	1.34
YOU	1.75	HEALTH	1.28	NETSPEAK	1.91	RISK	1.29
DEATH	1.70	NUMBER	1.20	FRIEND	1.81	RELIG	1.27
NETSPEAK	1.61	RELIG	1.19	YOU	1.67	CAUSE	1.24
MOTION	1.50	INSIGHT	1.18	MALE	1.63	INSIGHT	1.23
FOCUSFUTURE	1.43	ADJ	1.17	INFORMAL	1.60	IPRON	1.18

Table 9: Top ranked semantic classes from the LIWC lexicon associated to gender impersonators and actual gender.

Younger as Older		Real Young		Older as Younger		Real Old	
YOU	2.02	ASSENT	1.76	NETSPEAK	5.43	RELIG	2.71
FAMILY	2.00	ANX	1.63	FILLER	4.48	INGEST	1.92
DEATH	1.86	ACHIEV	1.56	SWEAR	4.05	HEALTH	1.84
FILLER	1.79	NETSPEAK	1.47	FRIEND	3.05	SEXUAL	1.75
FEMALE	1.72	WORK	1.34	INFORMAL	2.82	RISK	1.73
THEY	1.66	HEAR	1.34	ASSENT	2.32	NUMBER	1.59
FOCUSPAST	1.63	LEISURE	1.25	FOCUSFUTURE	1.84	DEATH	1.56
TIME	1.42	ANGER	1.25	YOU	1.62	SAD	1.48
SEXUAL	1.39	NEGEMO	1.23	MOTION	1.51	BIO	1.48
HEALTH	1.33	POSEMO	1.18	HEAR	1.42	ANX	1.26

Table 10: Top ranked semantic classes from the LIWC lexicon associated to age impersonators and actual age.

sification accuracies for the resulting models are shown in Table 8. This table also shows the results of models built using the portrayed young or portrayed old responses separately. In these experiments, the *Ngrams* features also outperform all the other feature sets. The second best performing features are the ones based on the semantic vector obtained with *Word2vec*, followed by *LIWC* and part-of-speech *POS* features. Overall, the results suggest that it is easier to identify older individuals portraying themselves as being younger (*Young* identity column) than younger individuals portraying themselves as being older (*Old* identity column).

To explore whether more training data would be beneficial to improve classifiers performance, we plot the learning curves of the best sets of features using incremental amounts of data as shown in Figure 3. As observed, all feature sets show a positive learning trend suggesting that more training data might improve the performance in the age deception task.

5.4 Analysis of Linguistic Differences Associated to Gender and Age Deceivers

Seeking to answer our third research question: are there linguistic differences associated to individuals' gender and age in identity deception? we an-

alyze differences in word usage that might reveal the real identity of age and gender impersonators.

From the gender-based analysis, we use responses from actual females writing as males and responses from actual males writing as females as well as their truthful self-descriptions. Similarly, in the age-based analysis, we consider the responses from younger respondents writing as older and older respondents writing as younger as well as their truthful self-descriptions.

Our analyses are based on the semantic word classes from the LIWC lexicon and the semantic word-class scoring by (Mihalcea and Pulman, 2009). Tables 9 and 10 show the top classes for each deception group and their real identities.

The analyses reveal interesting word usage patterns among gender impersonators. On the one hand, when females pose as males they use more 'swear', 'fillers', and 'informal talk' words. On the other hand, males that impersonate females use more 'fillers', 'female', and 'family' words. When looking at the word associations for actual genders, it would seem that there is no clear relation with how males and females portray each other when faking their gender. We believe that this could be attributed to gender-related stereotypes and biases. In the age deceiver case, the younger individuals who portray themselves as older use

	Real Female	Male as Female	Real Male	Female as Male
Real Female	1			
Male as Female	0.670**	1		
Real Male	0.663**	0.994**	1	
Female as Male	0.668**	0.999**	0.995**	1

Table 11: Correlation of LIWC classes across real and fake gender identities. ** Correlation is significant at 0.001 level (2-tailed)

	Real Young	Old as Young	Real Old	Young as Old
Real Young	1			
Old as Young	0.973**	1		
Real Old	0.975**	0.996**	1	
Young as Old	0.976**	0.997**	0.994**	1

Table 12: Correlation of LIWC classes across real and fake age identities. ** Correlation is significant at 0.001 level (2-tailed)

more ‘you’, ‘family’, ‘death’ and ‘filler’ words. In contrast, older individuals who portray themselves as younger use more internet slang ‘net-speak’, ‘fillers’, and ‘swear’ words. Similar to the gender findings, age deception seems to be affected by stereotypes.

For further insights into the linguistic differences between gender and age impersonators, we also calculate the Pearson correlation of the LIWC class counts across actual and corresponding fake identities. We use word class counts normalized by the number of words in the sentence.

The correlation between *Real Female* and *Real Male* shown in Table 5.3 present an estimate of how similar the actual male and female writings are. We observe a positive mid-strength correlation as compared with the other correlation pairs. The *Real Male vs Female as Male* correlation suggests that females are good at emulating males’ writing. In contrast, the analysis shows that males are not as good emulating female language (see correlation of *Real Female vs Male*).

Surprisingly, the analysis of age deceivers in Table 5.3 shows a strong correlation trend between the different age-based identities. In particular, the correlation between *Real Old* and *Young* suggests high language similarity between the two groups. Furthermore, the correlation between the *Real Old vs Old as Young* and *Real Young vs Young as Old* indicates that in general, older people are good at imitating younger people and vice versa.

6 Conclusions

In this paper, we addressed the task of identity deception detection. We collected a novel identity deception dataset, consisting of individuals por-

traying themselves with four fake identities, targeting different ages and genders.

Through several experiments, we showed that we can build accurate identity detectors. Specifically, we focused on the prediction of gender and age impersonators. We were able to identify identity deceivers with accuracies up to 88%. Our main findings showed that it is easier to identify females posing as males and similarly, it is easier to identify older individuals posing as younger individuals.

Furthermore, we presented a statistical analysis of linguistic patterns that differentiate between fake and real identities based on age and gender.

The datasets introduced in this paper are publicly available under <http://lit.eecs.umich.edu/downloads.html>.

Abstract

Clinical diagnosis is a critical and non-trivial aspect of patient care which often requires significant medical research and investigation based on an underlying clinical scenario. This paper proposes a novel approach by formulating clinical diagnosis as a reinforcement learning problem. During training, the reinforcement learning agent mimics the clinician’s cognitive process and learns the optimal policy to obtain the most appropriate diagnoses for a clinical narrative. This is achieved through an iterative search for candidate diagnoses from external knowledge sources via a sentence-by-sentence analysis of the inherent clinical context. A deep Q-network architecture is trained to optimize a reward function that measures the accuracy of the candidate diagnoses. Experiments on the *TREC CDS* datasets demonstrate the effectiveness of our system over various non-reinforcement learning-based systems.

1 Introduction

Clinical diagnosis is a critical aspect of patient care requiring expert medical knowledge and intuition. Given a clinical case narrative such as a patient’s past medical history and current condition, a clinician performs complex cognitive processes to infer the probable diagnosis based on his/her experience or up-to-date knowledge obtained from relevant external resources (Norman et al., 2007). Table 1 shows an example clinical narrative with relevant external knowledge, which suggests that *Pulmonary Embolism* is the diagnosis for this clinical scenario.¹

¹The clinical narrative with corresponding diagnosis is obtained from the Text REtrieval Conference (TREC) Clin-

Clinical Narrative: An 87 yo woman with h/o osteoporosis, DM2, dementia, depression, and anxiety presents s/p fall with evidence of C2 fracture, chest pain, tachycardia, tachypnea, and low blood pressure.
External Knowledge (partially shown) From Wikipedia page for Pulmonary Embolism - “Signs and symptoms” Section: Symptoms of pulmonary embolism are typically sudden in onset and may include one or many of the following: dyspnea (shortness of breath), tachypnea (rapid breathing), chest pain of a “pleuritic” nature (worsened by breathing), cough and hemoptysis (coughing up blood).
From MayoClinic page for Pulmonary Embolism - “Symptoms” Section: Pulmonary embolism symptoms can vary greatly, depending on how much of your lung is involved, the size of the clots, and whether you have underlying lung or heart disease.
Diagnosis: Pulmonary Embolism

Table 1: An example clinical narrative with relevant external knowledge and diagnosis.

This paper considers the challenge of inferring the diagnoses of a patient condition based on available documentation in the Electronic Health Record (EHR), specifically free text clinical reports. Earlier work that builds Artificial Intelligence (AI) systems to support clinical decision making, mostly uses structured clinical data (e.g. physiological signals, vital signs, lab tests etc.) stored in the EHR (Lipton et al., 2015; Choi et al., 2015, 2016). They commonly formulate diagnosis inferring as a supervised classification task.

The efficacy of these models largely depends on the size of the annotated datasets used for training, which requires expert-derived annotations that are expensive to obtain. These models also tend to lack the ability to capture the underlying uncertainties related to generating differential diagnoses (Richardson et al., 1999) and linguistic complex-

ical Decision Support (CDS) track 2016 dataset (Roberts et al., 2016a).

ities (Seidel et al., 2015) of a clinical scenario as they consider medical codes and a finite number of diagnoses for prediction labels.

By contrast, we explore the discriminatory capability of the unstructured clinical narratives to infer the possible diagnoses. To overcome the sparsity in annotated data and adequate representation of ambiguities, we formulate the problem as a sequential decision-making process using deep reinforcement learning while leveraging external knowledge to infer the differential diagnoses.

Our proposed approach is novel as, unlike previous approaches, it focuses on the clinician’s cognitive process to infer the most probable diagnoses from clinical narratives. Given a clinical text scenario, a physician typically reviews the sentences sequentially, skipping those s/he deems irrelevant and focusing on those that would contribute to his/her understanding of the clinical scenario.

While assimilating the sentences (i.e. understanding partial information), s/he tries to recognize a logical pattern or clinical progression similar to one or more prior patient encounters towards arriving at a candidate diagnosis. Ultimately, the intuition of the clinician is guided by understanding of these sentences and s/he can make an overall assessment of the scenario based on the narrative and/or additional evidence obtained from relevant external knowledge sources.

Our system replicates this cognitive flow by using a deep reinforcement learning technique. During training, the agent learns the optimal policy to obtain the final diagnoses through iterative search for candidate diagnoses from external knowledge sources via a sentence-by-sentence analysis of the inherent clinical context.

A deep Q-network architecture (Mnih et al., 2015) is trained to optimize a reward function that measures the accuracy of the candidate diagnoses. Our model predicts the differential diagnoses by utilizing the optimum policy learned to maximize the overall possible reward for an action during training. Extensive experiments on the TREC CDS track (Roberts et al., 2015, 2016a) datasets demonstrate the effectiveness of our system over several non-reinforcement learning-based systems.

In recent TREC CDS tracks, clinical diagnosis inferencing from free text clinical narratives has been showcased as a significant milestone in clinical question answering and a path to improv-

ing the accuracy of relevant biomedical article retrieval (Roberts et al., 2015, 2016b; Goodwin and Harabagiu, 2016).

In addition to these established use cases, we envisage that our work can also lead to a busy clinician considering relevant differential diagnoses that could otherwise be ignored due to inadvertent diagnostic errors (Nendaz and Perrier, 2012; Graber et al., 2012; Berge and Mamede, 2013). Also, nurse practitioners can use the proposed system as a source of second opinion before contacting a physician towards accurately diagnosing and managing their patients.

2 Related Work

Addressing inference tasks generally requires significant contributions from domain experts and access to a variety of resources (Ferrucci et al., 2013; Lally et al., 2014) such as structured knowledge bases (KBs) (Yao and Van Durme, 2014; Bao et al., 2014; Dong et al., 2015). However, KBs are known to have limitations such as knowledge incompleteness, sparsity, and fixed schema (Socher et al., 2013; West et al., 2014; Bordes et al., 2014), which have motivated researchers to use unstructured textual resources like Wikipedia for various related tasks (Katz et al., 2005; Wu and Weld, 2010; Miller et al., 2016; Chen et al., 2017). In this paper, we also leverage the power of unstructured knowledge sources to address clinical diagnosis inferencing.

Previous clinical diagnosis inferencing works mostly utilized various bio-signals from patients (Lipton et al., 2015; Choi et al., 2015, 2016). EHRs typically store such structured clinical data (e.g. physiological signals, vital signs, lab tests etc.) along with unstructured text documents that contain a relatively more narrative picture of the associated clinical events.

Recently, diagnosis inferencing from unstructured clinical text has gained much attention among AI and Natural Language Processing researchers, with the advent of the *TREC CDS* tracks (Simpson et al., 2014; Roberts et al., 2015, 2016b; Goodwin and Harabagiu, 2016; Zheng and Wan, 2016; Balaneshin-kordan and Kotov, 2016; Prakash et al., 2017; Ling et al., 2017a). Although the main task in the CDS track was to retrieve relevant biomedical articles given a clinical scenario, researchers also explored diagnosis inferencing from clinical narratives as part of the pilot

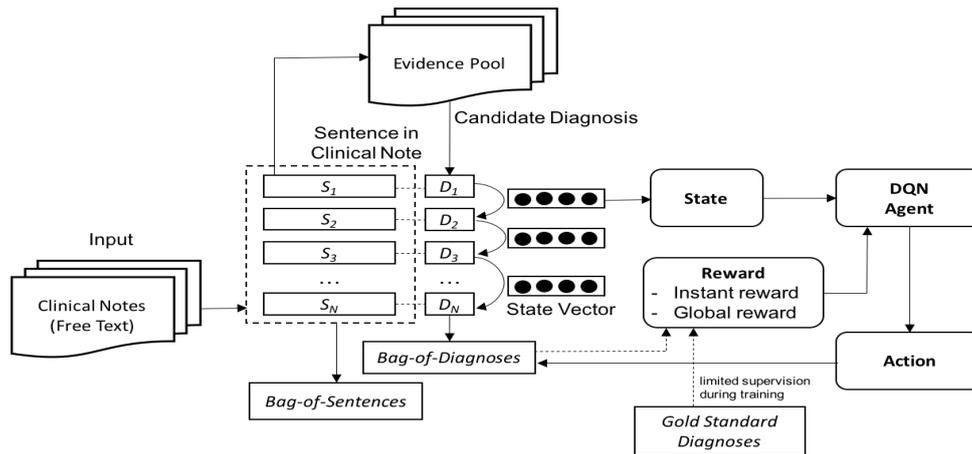

Figure 1: Overall architecture of the DBrain system.

task in 2015 that investigated the impact of diagnostic information on retrieving relevant biomedical articles (Roberts et al., 2015, 2016b).

Existing approaches for diagnosis inferencing mostly propose supervised classification models using various neural network architectures (Lipton et al., 2015; Choi et al., 2015; Prakash et al., 2017). However, such models heavily rely on large labeled data, and lack the ability to capture inherent ambiguities and complexities of a clinical scenario. Moreover, they are limited by the number of diagnosis labels and the use of medical codes to simplify the computational and linguistic difficulties of a clinical case. Other works have explored graph-based reasoning methods to incorporate relevant medical concepts and their associations (Shi et al., 2017; Geng and Zhang, 2014; Goodwin and Harabagiu, 2016; Zheng and Wan, 2016; Ling et al., 2017a).

These approaches do not focus on the intuitive and analytical processes of a clinician to infer the probable diagnoses from a clinical case narrative (Pelaccia et al., 2011; Kushniruk, 2001). By contrast, we propose a novel approach for clinical diagnosis inferencing that formulates the task as a reinforcement learning problem to mimic the clinician’s cognitive process for clinical reasoning.

Prior works that use reinforcement learning for clinical decision support tasks focused on other modalities e.g. medical imaging (Netto et al., 2008) or specific domain-dependent use cases, and clinical trials (Poolla, 2003; Shortreed et al., 2011; Zhao et al., 2011), but not for inferencing diagnosis. Recent works have shown the utility of deep reinforcement learning techniques for chal-

lenging tasks like playing games and entity extraction via utilizing external evidence (Mnih et al., 2015; Narasimhan et al., 2015, 2016). To the best of our knowledge, we are the first to explore deep-reinforcement learning for clinical diagnosis inference using text data from EHR.

3 Inferencing Diagnoses with Deep Reinforcement Learning

Our proposed approach, DBrain, uses a reinforcement learning formulation that leverages evidence from external resources to mimic the clinician’s complex reasoning. The overall architecture of our method is depicted in Figure 1.

DBrain takes free-text clinical narratives as input, and generates differential diagnoses as output. It scans the clinical narrative sentence-by-sentence and each sentence is used as a query to obtain a candidate diagnosis from external knowledge sources. We use a Markov Decision Process (MDP) to model this process. DBrain system creates two pools for each clinical narratives to keep the candidate sentences and the candidate diagnoses, namely: 1) bag-of-sentences, and 2) bag-of-diagnoses. Actions are taken at each step to decide which candidate sentence goes into the bag-of-sentences, and which candidate diagnosis goes into the bag-of-diagnoses.

3.1 MDP Framework

We model the integration of external knowledge sources for clinical diagnosis inferencing as a Markov Decision Process (MDP) (Bellman, 1957; Sutton and Barto, 1998). At each MDP step, the agent takes a sentence from the clinical narrative

and uses it as a query to obtain an external article from the evidence pool so that the sentence can be mapped to a candidate diagnosis. The evidence pool contains external knowledge sources, such as Wikipedia articles (details in Section 4.1).

For each sentence and the corresponding candidate diagnosis, a state vector s is created to encode their information. The state vector comprises information on the importance of the current sentence and the current candidate diagnosis with respect to inferring the most probable diagnoses for a clinical narrative. In a state s , the agent takes an action a to get to the next state, $s' = s + a$. A reward function $r(s, a)$ is used to estimate the reward at each state s after taking an action a .

We estimate a state-action value function $Q(s, a)$, which determines the optimal action a to take in a state s using the Q-learning technique (Watkins and Dayan, 1992). The Q -function is approximated using a deep Q -network (DQN) architecture (Mnih et al., 2015). The trained DQN agent takes state s and reward r as input, and outputs an action a .

Once the training is complete, the sentences in the bag-of-sentences represent the most important sentences, and the diagnoses in the bag-of-diagnoses denote the final predicated diagnoses for the clinical narrative. The overall MDP framework for clinical diagnosis inferencing is presented in Algorithm 1.

Algorithm 1: MDP framework

Input : clinical narrative $C = s_1, s_2, \dots, s_n$
Output: bag-of-diagnoses D , bag-of-sentences S

- 1 $D = \emptyset$ and $S = \emptyset$;
- 2 **for** each sentence s_i in C **do**
- 3 Use s_i as query, search in knowledge sources, get candidate diagnosis d ;
- 4 Generate state vector v for sentence-diagnosis pair (s_i, d) ;
- 5 Calculate reward value r ;
- 6 Send (v, r) to DQN agent, and get action value a_1 and a_2 from agent (where a_1 and a_2 denote actions for diagnoses and sentences, respectively);
- 7 **if** action == "stop" **then break**;
- 8 Update D according to a_1 ;
- 9 Update S according to a_2 ;
- 10 **end**
- 11 **return** D, S

For each clinical narrative, the output is a bag-of-diagnoses D and a bag-of-sentences S . For the training phase, the steps in Algorithm 1 for each clinical narrative are run for multiple epochs. During the testing stage, each clinical narrative is pro-

cessed only once in a single epoch. The next subsections provide details on the state, actions, and the reward function of the MDP framework.

3.1.1 State

The state s in our MDP comprises DBrain system's confidence on the current sentence and the corresponding candidate diagnosis. We represent state s as a continuous real-valued vector containing the following information: 1) $S1$: similarity between the current sentence and the bag-of-sentences, 2) $S2$: similarity between the current sentence and the context of the clinical narrative, 3) $S3$: similarity between the current sentence and the source article context of a candidate diagnosis, 4) $S4$: similarity between the bag-of-sentences and the source article context of a candidate diagnosis, 5) $S5$: similarity between a candidate diagnosis and the bag-of-diagnoses, and 6) number of words in the current sentence.

We compute the aforementioned similarities in two ways: 1) string similarity, which includes n-gram (unigram/bigram/trigram), and Levenshtein distance, 2) similarity/distance measures using one-hot vector representations including Jaccard similarity, cosine similarity, Manhattan distance, Euclidean distance, and fractional distance.

In addition to the above similarities, words in the current sentence are encoded into the state vector using a Long Short Term Memory (LSTM) network and mean pooling. In particular, we take the sequence of words in the current sentence as input, pass their one-hot vector embeddings to the LSTM cells, and output a corresponding vector representation, which combined with the similarities (described above) produces a state vector to serve as the input for the DQN module.

3.1.2 Actions

At each step, there are two kinds of actions for the agent: a_1 for updating the bag-of-diagnoses and a_2 for updating the bag-of-sentences, where a_1 includes: 1) accept the candidate diagnosis, 2) reject the candidate diagnosis, 3) reject all candidate diagnoses, and 4) stop; and, a_2 includes: 1) accept the current sentence, and 2) reject the current sentence.

3.1.3 Reward Function

The agent receives limited supervision from the ground truth diagnoses via a reward function during training. The reward function is chosen in

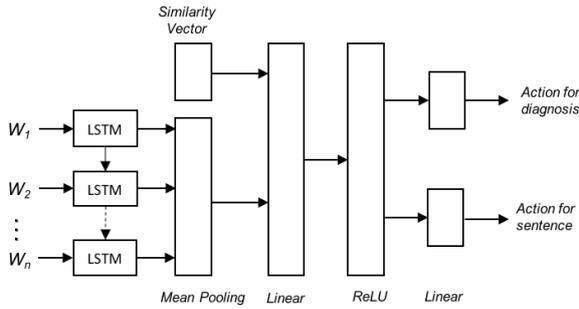

Figure 2: DQN architecture.

a way such that the accuracy of the final diagnoses prediction can be maximized. We consider two types of rewards: instant reward $r_{instant}$ and global reward r_{global} . The overall reward r is computed as:

$$r = r_{instant} + r_{global} \quad (1)$$

where $r_{instant}$ is calculated based on the match of a candidate diagnosis with gold standard diagnoses as:

$$r_{instant} = \begin{cases} 1, & \text{if candidate diagnosis matches} \\ 0, & \text{otherwise} \end{cases} \quad (2)$$

On the other hand, r_{global} is equal to the number of correct diagnoses minus the number of incorrect diagnoses in the bag-of-diagnoses.

3.2 DQN Architecture

In order to learn the Q -value, the iterative updates are derived from the Bellman equation (Sutton and Barto, 1998):

$$Q_{i+1}(s, a) = E[r + \gamma \max_{a'} Q_i(s', a') | s, a], \quad (3)$$

where γ is a discount factor for the future rewards and the expectation is over the whole training process.

It is impractical to maintain the Q -values for all possible state-action pairs. Mnih et al. (2015) proposed a deep Q -network (DQN) architecture, which approximates the Q -value function and predicts $Q(s, a)$ for all possible actions. We extended the DQN architecture in Narasimhan et al. (2015) to fit our problem formulation (Figure 2).

4 Experimental Setup

4.1 External Knowledge Sources

Our work relies on external knowledge sources to provide candidate diagnoses for the sentences

from a clinical narrative. We use two external knowledge sources: Wikipedia pages and MayoClinic pages. We index Wikipedia and MayoClinic using Elasticsearch². As an example, Wikipedia and MayoClinic pages for the diagnosis “pulmonary embolism” are partially displayed in Table 1.

4.1.1 Wikipedia

We select 37,245 Wikipedia pages under the “clinical medicine” category³. Each page title is used as the diagnosis name and the texts from the *Signs and symptoms* subsection are used as an evidence for mapping candidate diagnosis. As shown in Table 1, “*Sign and symptom*” section describes symptoms of “pulmonary embolism”. These symptoms have a higher chance of appearing in a clinical narrative if the documented diagnosis is “pulmonary embolism”.

4.1.2 MayoClinic

The MayoClinic⁴ disease corpus contains 1,117 pages, which include sections of *Symptoms*, *Causes*, *Risk Factors*, *Treatments and Drugs*, *Prevention*, etc. Each MayoClinic page title is regarded as one diagnosis. We select sentences from the “*Symptoms*” section as the external source of evidence for mapping candidate diagnoses.

4.2 Candidate Diagnosis Mapping

Each sentence from a clinical narrative is used as a query to search in both Wikipedia and MayoClinic corpora. Each search returns top 10 results per corpus. If there is any common diagnoses, we return the top ranked diagnosis as the candidate diagnosis. Otherwise, we consider the top ranked diagnosis from Wikipedia as the candidate diagnosis since Wikipedia has a higher coverage for ground truth diagnoses in both training and testing dataset. Table 2 presents the diagnoses coverage for Wikipedia and MayoClinic in our training and test set, where the test set numbers essentially denote the maximum possible recall of our systems.

	Wikipedia	MayoClinic
Training Set	93.33%	80.00%
Test Set	96.67%	86.67%

Table 2: Diagnoses coverage.

²<https://www.elastic.co/>

³https://en.wikipedia.org/wiki/Category:Clinical_medicine

⁴<http://www.mayoclinic.org/diseases-conditions>

4.3 Datasets of Clinical Narratives

We use the 2015 and 2016 *TREC CDS* track datasets (Roberts et al., 2015, 2016a) for our experiments. Each dataset contains 30 topics, where each topic is a medical case narrative that describes a patient scenario. A topic example is partially shown as the clinical narrative in Table 1 (see accompanied dataset for all topics).

Each topic contains “*description*”, “*summary*”, and “*diagnosis*” fields. “*description*” includes a comprehensive description of the patient’s situation, whereas “*summary*” contains an abridged version of the most important information. In addition, the 2016 dataset includes a “*note*” field for each topic, which resembles an actual clinical note in terms of linguistic complexity. We use “*description*”, “*summary*” and “*note*” fields separately to generate more samples with same/similar patient situations.

We use all fields from the 2016 dataset for training our systems, while “*description*” and “*summary*” fields from the 2015 dataset are used separately for testing (see dataset statistics in Table 3).

	Train	Test- <i>description</i>	Test- <i>summary</i>
# of Topics	30	30	30
# of Samples	90	30	30
Total # of Sent.	703	152	45
Avg. # of Sent.	7.8	5.1	1.5

Table 3: Dataset statistics.

4.4 Evaluation Metrics

We use precision, recall and F-score as the evaluation metrics. Precision is the fraction of correctly predicted diagnoses among all predicted diagnoses. Recall is the fraction of correctly predicted diagnoses among all gold standard diagnoses. F-score is calculated based on precision and recall as follows:

$$F = \frac{2 \times \text{precision} \times \text{recall}}{\text{precision} + \text{recall}} \quad (4)$$

Instead of using an exact match for comparing predicted diagnosis and gold diagnosis, we use paraphrases and disease synonyms based on the human disease network (Schriml et al., 2012) to compare two diagnosis terms.

4.5 Systems for Comparison

We explore a supervised method using Support Vector Machines (SVM), an information retrieval-

based method (*IR-based*), and two heuristic methods (*KG-based* and *Concept-based*) to systematically evaluate the performance of our DBrain system. In addition, we also compare the performance among different representational variations of the DQN architecture.

4.5.1 Supervised Method

We build a supervised method using SVM (Cortes and Vapnik, 1995). Each sentence s_i in a clinical narrative is used as a query to search in knowledge sources. We use the top retrieved Wiki page, p as the candidate diagnosis. For each sentence, we get a sentence-page pair (s_i, p) . If the page title indicates the correct diagnosis for a clinical narrative, we label the sentence-page pair (s_i, p) as a positive example, otherwise, the pair is labeled as a negative example.

The feature space for SVM contains 13 features⁵ denoting the similarity between a sentence from the clinical narrative and an external knowledge source page: cosine similarity, Damerau-Levenshtein distance, Jaccard similarity, Jaro-Winkler distance (Winkler, 1995), Levenshtein distance, weighted Levenshtein distance, longest common subsequence, metric longest common subsequence (Bakkellund, 2009), N-gram similarity (Kondrak, 2005), optimal string alignment, Q-gram distance (Ukkonen, 1992), Sorensen-Dice coefficient, and the relevance score returned from Elasticsearch. The similarity scores are concatenated to generate a vector. Finally, the similarity vector and positive/negative labels are used as input to train the SVM model. During testing, each clinical narrative generates multiple sentence-page pairs and the positive diagnoses predicted by the SVM model are considered as the final diagnoses.

4.5.2 IR-based Method

The IR-based method has the similar setting as the supervised method. Each sentence s_i is used as a query to obtain top 5 pages as candidate diagnoses. Each page is associated with a relevance score. We combine the results from each sentence in the narrative, and use the cumulative relevance scores to get top 5 ranked diagnoses pages per clinical narrative.

4.5.3 KG-based Method

We create a knowledge graph (KG)-based method, which uses Wikipedia pages under the “clinical

⁵<https://github.com/tdebatty/java-string-similarity>

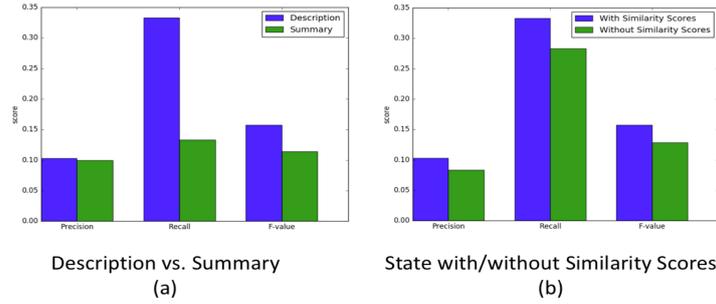

Figure 3: (a) Description vs. Summary. (b) State vectors with or without similarity scores.

medicine” category to build a knowledge graph. The hierarchy of each Wikipedia page is preserved to encode its distinguishing characteristics with respect to other pages. Each page consists of several sections and is related to other medical conditions. We build a directed graph (digraph) by using these relations, where each node is a medical condition, diagnosis, test, procedure, medication or any other clinical concept, and each edge is a relation between two nodes.

The constructed knowledge graph contains $\sim 100K$ nodes and $\sim 1M$ edges, where leaf nodes represent medical symptoms and are connected to relevant diseases and medical conditions. Based on this graph, we infer the clinical diagnoses given a list of signs and symptoms extracted from a clinical narrative using a clinical information extraction engine. This method produces a ranked list of diagnoses. We take the top 5 ranked results as the diagnoses.

4.5.4 Concept-based Method

We compare our system with the concept graph-based method proposed by Ling et al. (2017a). This method builds a concept graph by integrating knowledge from structured and unstructured sources to infer top 5 ranked diagnoses from a clinical narrative.

4.5.5 Representational Variations of DQN

As discussed in Section 3.1.1, we use LSTM and mean pooling to encode words in a sentence. We compare the DQN-LSTM model with two variations (Figure 6) (Narasimhan et al., 2015): 1) DQN-BOW, which uses a bag-of-words approach to represent words in a sentence, and 2) DQN-Rand, where instead of using the DQN agent to choose actions, we randomly choose an action in each step.

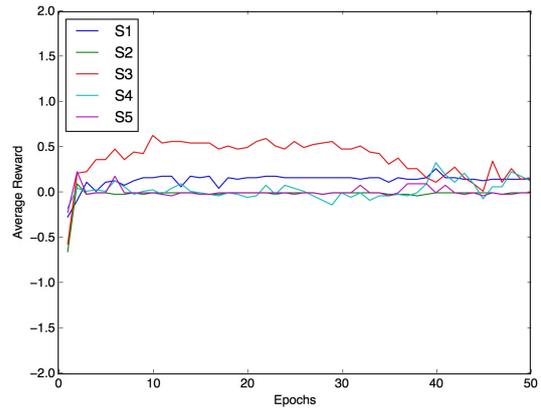

Figure 4: Evolution of reward with different similarities.

4.6 DQN Settings

For the DQN learning, we use a replay memory of size 50K, and a discount of 0.99. The embedding dimension is 300. All other settings are kept similar to Narasimhan et al. (2015).

5 Results and Discussion

5.1 Description vs. Summary

We use *Description* and *Summary* separately as clinical narratives for our experiments to evaluate their impact on the performance of our system. Figure 3 (a) shows Precision, Recall, and F-scores for *Description* and *Summary*. We can see that the results for *Description* is better than *Summary*. One reason is that *Description* has more average number of sentences than *Summary*. It is important for the reinforcement learning agent to infer candidate diagnoses from a sufficient number of sentences. Only one or two sentences may not be adequate for this purpose. Therefore, in the following experiments, we only use *Description* for system comparisons.

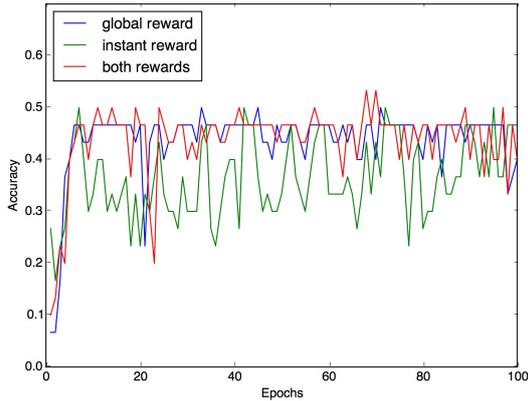

Figure 5: Evolution of accuracy.

5.2 State Vector Variations

In Figure 3 (b), we compare results for similarity scores in state vector to omitting similarity scores on state vector. We see that the inclusion of similarity vectors with the mean pooling of the context of a current sentence inside the DQN architecture provides better results for our model.

In Figure 4, we display the evolution of rewards by comparing with different similarities (used separately) as listed in Section 3.1.1. We see that S_3 , the similarity between the current sentence and the source article context of a candidate diagnosis, has better performance compared to other similarities.

5.3 Reward Functions

Figure 5 shows the learning curve of our DBrain system by measuring accuracy over epochs for different reward functions. By using instant reward only, the accuracy trend over epochs on training set is not stable. Global reward function becomes stable after ~ 10 epochs. By combining instant reward with global reward, the accuracy is slightly better than just using global reward. Therefore, we use the combined reward function in other experiments.

5.4 System Comparison Results

Table 4 presents the evaluation results of our system in comparison to other considered systems.

From these results we can see that the DBrain system achieves the best precision and F-value scores over other methods demonstrating the effectiveness of our reinforcement learning formulation. The concept-based approach shows an impressive recall score although with a loss in preci-

	Precision	Recall	F-Value
Supervised Method			
SVM	4.44	33.33	7.84
IR Method			
IR-based	7.33	36.67	12.22
Heuristic Methods			
KG-based	7.33	36.67	12.22
Concept-based	8.96	44.78	14.93
Our System			
DQN-BOW	11.94	20.00	14.11
DQN-LSTM	10.28	33.33	15.71

Table 4: Evaluation results (%).

sion. On the other hand, DQN-LSTM achieves the best F-Value, which is better than DQN-BOW, illustrating the importance of having a better representation of words as input. All the improvements of our system (DQN-LSTM) are statistically significant ($p < 0.05$) over SVM using the paired samples t-test (David and Gunnink, 1997) except for the methods that compute scores for the top 5 diagnoses as output (IR and heuristic-based).

Overall, the low F-measures demonstrate the difficulty of the task, as they are consistently low for all methods. We use exact sentences from a clinical narrative as queries to search for the diagnoses in the knowledge sources. Thus, sometimes our system is not able to identify the correct diagnosis due to noise in the query (see Table 6). This can be rectified with forming the query by extracting relevant clinical concepts from a sentence as shown in Ling et al. (2017b). Another reason for low F-scores is that some ground-truth diagnoses (from the training and test set) are missing in both MayoClinic and Wikipedia (Table 2). A knowledge source with a better coverage for diagnoses may offer additional room for improvements.

Figure 6 shows the evolution of average rewards for DQN-LSTM, DQN-BOW, and DQN-Rand. DQN-Rand performs poorly, which again demonstrates the importance of using a DQN agent to learn the best strategies for actions.

5.5 Example Outputs from DBrain System

We present two detailed examples to show how our DBrain system predicts the diagnoses for two test set topics. Table 5 shows that our system can correctly predict the diagnosis ‘‘Hypothyroidism’’ while Table 6 shows an example where the DBrain system failed to predict the correct diagnosis as the candidate diagnoses list mapped from the sentences of the clinical narrative did not contain the correct diagnosis.

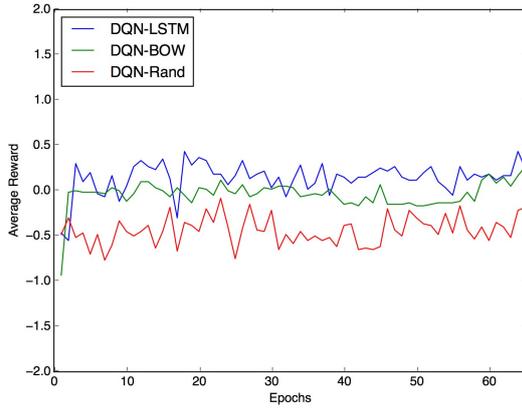

Figure 6: Evolution of reward with representational variations.

Example 1

Input:

Description: A 56-year old Caucasian female complains of being markedly more sensitive to the cold than most people. She also gets tired easily, has decreased appetite, and has recently tried home remedies for her constipation. Physical examination reveals hyporeflexia with delayed relaxation of knee and ankle reflexes, and very dry skin. She moves and talks slowly.

Ground-Truth Diagnosis: Hypothyroidism

Stage 1:

Sentence 1: A 56-year old Caucasian female complains of being markedly more sensitive to the cold than most people.

Candidate Diagnosis: Triple X syndrome

Action for the agent: reject the candidate diagnosis

Stage 2:

Sentence 2: She also gets tired easily, has decreased appetite, and has recently tried home remedies for her constipation.

Candidate Diagnosis: Colorectal cancer

Action for the agent: reject the candidate diagnosis

Stage 3:

Sentence 3: Physical examination reveals hyporeflexia with delayed relaxation of knee and ankle reflexes, and very dry skin.

Candidate Diagnosis: Hypothyroidism

Action for the agent: accept the candidate diagnosis

Stage 4:

Sentence 4: She moves and talks slowly.

Candidate Diagnosis: Conjugate gaze palsy

Action for the agent: reject the candidate diagnosis

Output:

Bag-of-Diagnoses: {Hypothyroidism}

Table 5: DBrain predicts the correct diagnosis.

6 Conclusion

We present a novel approach for clinical diagnosis inferencing that mimics the cognitive process of clinicians using deep reinforcement learning via leveraging evidence from external resources. Our experiments on the *TREC CDS* datasets demonstrate that the DBrain system learns to diagnose by digesting clinical narratives sentence by sentence and achieves better results than supervised, IR-based, and heuristic-based methods. Furthermore, our experiments using different variations such as *Description vs. Summary* for clinical narratives, *Instant vs. Global vs. Combined* for reward functions, *State Vector with/without Similarity Scores* as input to the DQN module along with various representational variations for the DQN architecture reveal that *Description*, *Combined* reward function, *State Vector with Similarity Score*, and *DQN-LSTM* provide the best results to infer the probable diagnoses, respectively.

Example 2

Input:

Description: A 31-year-old woman with no previous medical problems comes to the emergency room with a history of 2 weeks of joint pain and fatigue. Initially she had right ankle swelling and difficulty standing up and walking, all of which resolved after a few days. For the past several days she has had pain, swelling and stiffness in her knees, hips and right elbow. She also reports intermittent fevers ranging from 38.2 to 39.4 degrees Celsius and chest pain.

Ground-Truth Diagnosis: Rheumatic fever

Stage 1:

Sentence 1: A 31-year-old woman with no previous medical problems comes to the emergency room with a history of 2 weeks of joint pain and fatigue.

Candidate Diagnosis: Premenstrual syndrome

Action for the agent: reject the candidate diagnosis

Stage 2:

Sentence 2: Initially she had right ankle swelling and difficulty standing up and walking, all of which resolved after a few days.

Candidate Diagnosis: Caput succedaneum

Action for the agent: reject the candidate diagnosis

Stage 3:

Sentence 3: For the past several days she has had pain, swelling and stiffness in her knees, hips and right elbow.

Candidate Diagnosis: Synovial osteochondromatosis

Action for the agent: reject the candidate diagnosis

Stage 4:

Sentence 4: She also reports intermittent fevers ranging from 38.2 to 39.4 degrees Celsius and chest pain.

Candidate Diagnosis: Dientamoebiasis

Action for the agent: reject the candidate diagnosis

Output:

Bag-of-Diagnoses: {}

Table 6: DBrain fails to predict the correct diagnosis.

Abstract

Progress in natural language interfaces to databases (NLIDB) has been slow mainly due to linguistic issues (such as language ambiguity) and domain portability. Moreover, the lack of a large corpus to be used as a standard benchmark has made data-driven approaches difficult to develop and compare. In this paper, we revisit the problem of NLIDBs and recast it as a sequence translation problem. To this end, we introduce a large dataset extracted from the Stack Exchange Data Explorer website, which can be used for training neural natural language interfaces for databases. We also report encouraging baseline results on a smaller manually annotated test corpus, obtained using an attention-based sequence-to-sequence neural network.

1 Introduction

Natural language interfaces have received attention as tools for simplifying the interaction between users and computers. These interfaces often exclude or complement input devices, such as keyboard or touch screens, or even specific languages used for interacting with an application. A more focused area is composed of Natural Language Interface to Databases (NLIDB), which would allow a person to retrieve useful information from any database without knowledge of specific query languages such as structured query language (SQL) for relational databases.

Despite initial efforts into NLIDBs started decades ago, research has advanced slowly and at this moment there are no commercial solutions or widespread prototypes. The main difficulties in solving this problem stem from linguistic failures and the inability to develop general-purpose solu-

tions that are portable to different databases and schemas.

Due to the recent success of deep neural approaches in natural language processing, our aim is twofold. First, we hope to rejuvenate interest in the NLIDB problem by proposing a large dataset, called the Stack Exchange Natural Language Interface to Database (SENLIDB) corpus, for developing data-driven machine learning models and for reporting progress. The training set consists of 24,890 pairs (textual description, SQL snippet) crawled using the Stack Exchange API that we filtered and cleaned. A smaller test set consisting of 780 pairs that were manually created by two annotators is also available for comparing solutions.

Second, we report results on a neural baseline that uses an attention-enhanced sequence-to-sequence (SEQ2SEQ) architecture (Bahdanau et al., 2014) to model the conditional probability of an SQL query given a natural language description. This model is trained on the aforementioned dataset and its performance is computed both using cross-validation and on the manually labeled test set. Qualitative results reveal code that is syntactically correct most of the times and closely related to the user’s intention. Moreover, we report results on two smaller tasks, which we call the tables and columns identification tasks. These results suggest that our dataset is indeed valuable for training end-to-end neural natural language interfaces for databases (NNLIDB).

The paper continues with a short overview of related work in natural language interfaces for databases and in similar tasks where deep networks have been successfully employed. Section 3 contains a detailed description of the large SENLIDB dataset created for training, together with the smaller dataset used for testing and comparing various NLIDB systems. Preliminary results using a SEQ2SEQ neural model with attention trained

on the dataset proposed in this paper are presented in Section 4. We then propose alternative indicators for assessing the correctness of generated SQL queries in Section 5, while Section 6 concludes the paper by highlighting the key insights and future work.

2 Related Work

As all current NLIDB solutions are using mainly dependency and semantic parsing together with rule-based or constraint-based algorithms, we also present similar problems which inspired our approach, where deep networks have achieved state of the art results. In the last part of the section, we introduce the most frequently used corpora for evaluating the performance of NLIDB systems.

2.1 Current approaches for NLIDB

Natural language interfaces for databases have been studied for decades. Early solutions proposed using dictionaries, grammars and dialogue systems for guiding the user articulate the query in natural language on a step by step basis (Codd, 1974; Hendrix et al., 1978). Most systems developed until mid-90s used a mix of pattern matching, syntactic parsing, semantic grammar systems, and intermediate representation languages for generating the query from text (Androutsopoulos et al., 1995). The most important problems encountered by NLIDBs were related to ambiguity in semantics and pragmatics present in natural language: modifier attachment, understanding quantifiers, conjunction and disjunction, nominal compounds, anaphora, and elliptical sentences (Androutsopoulos et al., 1995).

In more recent studies, Popescu et al. (2004) combine syntactic parsing and semantic interpretation for natural language queries to change parse trees such that, by changing the order of some nodes in a tree, it will be correctly interpreted by the semantic analyzer. Then they use a maximum flow algorithm and dictionaries for semantic alignment between the text and several SQL candidates. One of their main contributions is that they introduce a subset of semantically tractable text queries, for which the proposed method generates correct SQL queries in most cases.

NaLIR (Li and Jagadish, 2014) uses dependency parse trees generated with CoreNLP (Manning et al., 2014) and several heuristics and rules to generate mappings from natural language to can-

didate SQL queries. Given the dependency tree, the database schema and associated semantic mappings, the system proceeds in building alternative query trees which can be easily translated to SQL. To determine the best query tree, the system combines a scoring mechanism and an interaction with the user to select the best choice (from a list of reformulations of the query tree into natural language). The scoring for each query tree takes into account the number of alterations performed on the dependency tree in order to generate it, the database similarity/proximity between nodes adjacent in the query tree, and the syntactic correctness of the generated SQL query.

The most promising results reported on several databases used for validating NLIDBs have been recently achieved by Sqlizer (Yaghamazadeh et al., 2017). Its main contributions are related to the fact that it uses a semantic parser to generate a query sketch, which is then completed using a rule based system, and iteratively refined and repaired using rules and heuristics until the score of the generated SQL query cannot be improved. Sqlizer is one of the few systems which employs machine learning and Word2Vec (Mikolov et al., 2013) for generating the query sketch - a general form of the query, including clauses, but which does not contain any specific database schema information (e.g. table and column names).

2.2 Deep learning solutions for NLIDB and related problems

Mou et al. (2015) introduced a case study for code generation from problem descriptions using recurrent neural networks (RNN). They trained a SEQ2SEQ architecture with a character-level decoder and produced program snippets that are syntactically correct most of the times and retain functionality. Moreover, they showed that the RNN generates novel code alternatives compared to the programs seen during training, thus ruling out the possibility that the network merely memorizes the input examples. Ling et al. (2016) combined the SEQ2SEQ approach with a pointing mechanism (Vinyals et al., 2015) in order to generate Python and Java code using textual descriptions automatically extracted from collectible trading card games.

More recently, Yin and Neubig (2017) proposed a syntax-aware neural model that generates Abstract Syntax Trees from natural language descrip-

tions, which then get mapped deterministically to the target source code. The decoder is guided by a predefined grammar, so their solution is agnostic of the target programming language. Using this syntax aware decoding mechanism, they show to improve the SEQ2SEQ baseline for code generation.

Another related topic is semantic parsing using deep neural networks. Semantic parsing focuses on converting natural language into logical forms which are used for querying knowledge bases (Berant et al., 2013). Neural approaches for semantic parsing use a SEQ2SEQ network to map natural language text to logical forms (Dong and Lapata, 2016; Herzig and Berant, 2017). Other solutions bypass the need for ground truth logical forms and instead train a supervised neural model from query-answer pairs (Yin et al., 2015; Nee-lakantan et al., 2016). Iyer et al. (2017) are the first to use a SEQ2SEQ network to map natural language directly to SQL language. They leverage feedback-based learning to continuously improve the parser accuracy.

2.3 Existing corpora for NLIDB evaluation

Solutions to the NLIDB problem have been traditionally evaluated against databases with few tables and on validation datasets with a small number of entries.

One of the most complex databases for NLIDB evaluation is ATIS (Air Travel Information Corpus) (Hemphill et al., 1990), which stores information about data flights and features 27 tables. However, it only has 2,886 natural language queries and no corresponding SQL statements, making it unsuitable for a data-driven approach. Most recent systems have moved to validation datasets which contain both the natural language query and the corresponding SQL snippet, such as MAS (Microsoft Academic Search), IMDB, and Yelp. For example, Sqlizer (Yaghmazadeh et al., 2017) achieves 80% accuracy on MAS, while NaLIR (Li and Jagadish, 2014) obtains only 32% accuracy on the same data. There also exist some slightly larger corpora for querying geolocation databases, the largest being NLmaps (Haas and Riezler, 2016) which contains 2,380 text queries but with no corresponding SQL code (instead they use machine readable language - MRL for expressing queries).

The training set (SENLIDB Train) proposed in

this paper is by far larger than any of the existing datasets, as can be seen from Table 1. This makes it extremely useful for training solutions using machine learning, including neural NLIDBs. More, the test set (SENLIDB Test), which has been manually annotated by two experts, is twice as large as current validation corpora and contains several text formulations for the same SQL query.

3 Dataset construction

A deep neural architecture, such as SEQ2SEQ, requires a large number of input-output pairs to produce qualitative results. The next subsections describe the steps taken to build the SENLIDB dataset, including our attempts to correct some of the problems inherent with crowdsourced data.

3.1 Data crawling and preprocessing

The Stack Exchange Data Explorer allows users to query the entire database of the well-known question-answering platform through a public API¹. The database uses Microsoft SQL Server, therefore users query it using the SQL extension developed by Microsoft, called Transact-SQL (T-SQL). For each query to the Stack Exchange database issued by a user, the web interface enforces the user to add a title and also an optional longer description. The main rationale for these two fields is for users to provide an accurate textual description for each query they make. However, there is no method to ensure that the title or the description entered for a query are actually relevant in describing it.

The list of all user queries is available online² and Stack Exchange offers various sorting and filtering capabilities including most upvoted or viewed queries. An important characteristic is that all available queries are correct, meaning that they do not throw any errors when querying the Stack Exchange database. Moreover, some of them are "interactive" - users can input values in the web interface for temporary variables enclosed by '##' or '#' in the SQL query.

In order to build the proposed dataset, we started by crawling all user queries from Stack Exchange, as they appear in the section 'Everything' in descending order by creation date.

¹<http://data.stackexchange.com/stackoverflow/query/new>

²<http://data.stackexchange.com/stackoverflow/queries>

Dataset	# Tables	# Columns	# Text queries	# SQL queries
ATIS	27	-	2,866	N/A
NLmaps	N/A	N/A	2,380	N/A
MAS	17	53	196	196
IMDB	16	65	131	131
Yelp	7	38	128	128
SENLIDB Train	29	204	24,890	24,890
SENLIDB Test	15	98	780	296

Table 1: Comparison of existing datasets and the SENLIDB corpora for NLIDB systems

First of all, we discarded SQL snippets longer than 2,000 characters as we considered them to be too complex. This step resulted in about 2,000,000 queries. The next step was to create pairs of textual description (which included the title and the actual description of a query) and corresponding SQL snippet. We then removed duplicate pairs (identical SQL code and description) and approximately 600,000 pairs were left. After this step, we removed items with SQL code in the description using simple empirical rules (descriptions starting with 'select' and containing 'from'). The remaining dataset was reduced to roughly 170,000 pairs.

Afterwards, we removed the comments from the SQL snippets and eliminated the entries that now had void snippets. Finally, we took away items with identical textual descriptions and different SQL snippets. For description d and corresponding SQL snippets s_1, \dots, s_n , we kept the code snippet s_i of median length, as we consider that an average length description is probably better than very long and very short ones which are probably outliers. This resulted in a dataset with 24,890 items, each having an unique textual description and an associated SQL query.

Although descriptions in this dataset are unique, there are 2,225 identical SQL queries with different descriptions.

3.2 Large dataset for training and validation

We consider that the previously described dataset can be used effectively for training machine learning models for NLIDB, including more data-hungry models such as neural NLIDBs. As this corpus was created by a large number of users from the Stack Exchange data portal, one might expect that the quality of the entries to be similar to other corpora created using various crowdsourcing mechanisms. To this extent, although this

dataset can also be used for validation (using either cross-validation or a hold-out set), the results will be impacted by the inherent biases, noise and errors collected through crowdsourcing. Some of the particularities of these data are addressed next.

First, most of the SQL snippets are relatively simple, containing at most 10 distinct tokens, as can be easily seen in Table 2. In contrast, textual descriptions are more evenly distributed, based on the number of tokens, with 2,003 of the entries in the dataset having more than 100 tokens. Thus although some queries might have an incomplete textual description, most of them are well explained.

Second, the Stack Exchange database schema available in the dataset contains 29 tables. Interestingly, their actual appearances in the dataset, judging by the number of occurrences in individual queries, follows Zipf's law (Zipf, 1949) as it can be observed in Table 3. We note that a large majority of queries refer to the 'Posts' and 'Users' tables, while other tables make almost no appearance in the dataset (e.g. 'PostNotices', 'PostNoticeTypes'). In Table 4 we present the most frequent SQL expressions in the datasets. Half of the queries contain ordering clauses and almost a third include multiple joined tables and group by clauses.

Third, the dataset contains samples of varied difficulty, from simple select operations to complex nested queries. We computed the Halstead complexity metrics (Halstead, 1977) to gain an insight into the difficulty of the SQL snippets in our datasets. To measure the difficulty of a snippet we used the formula (Halstead, 1977):

$$Difficulty = \frac{\eta_1}{2} \cdot \frac{N}{\eta_2} \quad (1)$$

where η_1 is the number of distinct operators, η_2 is the number of distinct operands and N is the total

# SQL query tokens \ # text tokens	1-10	11-25	26-50	51-100	100+	Total
2-4	2094	3321	2634	1536	605	10190

number of operands.

Finally, we used an off-the-shelf library³ to detect the language of the query descriptions. More than 95% were classified as English, followed at a great distance by French and Russian with less than 100 entries each. We remarked that some of the descriptions contain table and column names, which could affect the language identification performance (with a small bias towards English).

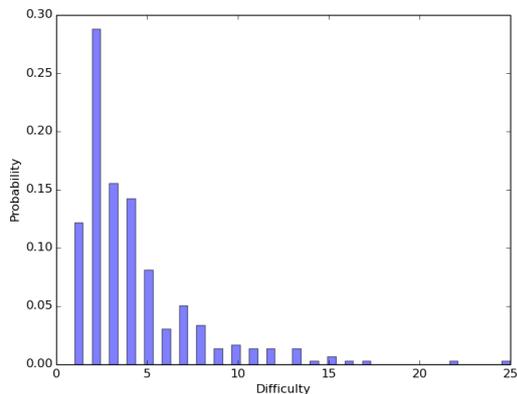

3.3 Manually annotated test dataset

In order to have a reliable test and validation dataset for the Stack Exchange database, we also developed a smaller corpus which was manually annotated by two senior undergraduate students in Computer Science. The SQL queries included in the test dataset are a subset of the data collected from the Stack Exchange Data Explorer as previously described. Each query has been labelled by at least one annotator using between 1 and 3 different textual descriptions that describe the respective SQL snippet in natural language (English). The annotators then ran the query in the interface and verified that the returned results are correct and correspond to the description. The total number of distinct queries is 296, while the number of tex-

(a) Training dataset difficulty

(b) Test dataset difficulty

Figure 1: Histograms of the Halstead difficulty measure for the training (a) and test (b) sets

tual annotations is 780, averaging to 2.63 textual reformulations per query.

In order to facilitate the annotation process, the annotators used an application which allowed the user to view a SQL query from the original dataset and add one or more possible descriptions. The SQL queries chosen for manual annotation were randomly selected from those with a very short textual description in the original corpus, consisting of only 1-2 tokens. These items were considered not informative enough to be included in the training set and were thus added to the human-annotated test set.

In order to achieve a better understanding of how similar or different the produced annotations are, for each sample we computed the BLEU score (Papineni et al., 2002), with the smoothing function proposed in Chen and Cherry (2014), between the descriptions of one annotator and those produced by the other annotator. The average of the scores obtained for each sample was 57.10, which

Dataset	Perplexity	BLEU
Validation	1.16	16.9
Test-original	1.24	13.5
Test-annotated	1.23	18.2

Table 5: Perplexity and BLEU score of the generated SQL statements on the validation set, original test set and annotated test set descriptions

is consistent with inter-translator BLEU scores observed in machine translation. It is important to notice that there are some differences between the train and test dataset. The most important one is highlighted in Figure 1 where the Halstead difficulty score for the test set is concentrated between 0-5 as opposed to the train dataset where the mode is at 8. This means that the queries in the test dataset are slightly less complex than the queries in the train dataset. There are also some other differences between the two datasets, such as the distribution of query and description sizes (see Table 2) and most frequent table names (see Table 3); these arise from how the test SQL queries were subsampled and annotated.

4 Model and experiments

We trained a SEQ2SEQ model with attention on the (description, SQL) pairs in the SENLIDB train set. We used the open-source neural machine translation toolkit OpenNMT (<http://opennmt.net/>) (Klein et al., 2017). This system implements a standard SEQ2SEQ model with global-general-attention (Luong et al., 2015). Both the encoder and the decoder are long short-term memory (LSTM) cells with two hidden layers and 500 neurons. The word embedding layer has 500 neurons. We used batches of maximum size 64. We trained the models with Stochastic Gradient Descent (SGD) for 25 epochs with a learning rate of 1.0 and a learning decay of 0.5 if perplexity did not decrease on the validation set. We generated SQL statement using a beam search of size 5.

Similarly to Ling et al. (2016), we report the BLEU score between the generated SQL queries and the ground truth SQL snippets in Table 5. While the BLEU score could penalize differently written, but otherwise correct, code snippets, it is still useful to measure the degree of token overlap. The results are reported for a validation set (hold-out of 4,000 random samples from the train set)

Natural language description	Predicted SQL query
top 50 users from india	select top 50 id , displayname , reputation , websiteurl , location from users where location like india order by reputation desc
top 100 users with no of gold badge	select top 100 b . userid , u . displayname , count (*) as gold from badges b inner join users u on u . id = b . userid group by b . userid , u . displayname order by count (b . name) desc
user rep	select reputation , count (*) from users group by reputation order by reputation
text of highest - scored comment	select top 100 id as [comment link] , score , text from comments order by score desc
questions with most view	select top 500 id as [post link] , viewcount from posts order by viewcount desc

Test-original	0.35	0.29	0.31
Test-annotated	0.55	0.47	0.50

Table 8: Precision, recall and F1 score for the columns identification task

and for the test set, using both the original and the manually annotated texts. We notice similar perplexities for SQL code generated from the original test titles and from the manually annotated ones, which means that both generate likely code. This is to be expected as the decoder is trained on SQL select statement therefore it will probably generate some sort of select statement even for short input texts given to the encoder. However, the original titles are much shorter compared to the annotated titles, and so the more informative natural language descriptions yield a SQL query that resembles more closely the ground truth SQL under a BLEU score. Thus, although both shorter (incomplete) and longer (and more descriptive) texts generate likely SQL statements, the manually annotated texts generate queries significantly more similar to the ground truth (BLEU score 18.2 vs

13.5, as reported in Table 5) than the original descriptions.

The initial vocabulary for the encoder (text descriptions) had 6,000 tokens, while the vocabulary of the decoder (SQL queries) consisted of 16,000 tokens. This resulted in a very large embedding matrix, thus we decided to restrict the number of tokens for both encoder and decoder to 500 and 2,000, respectively, by keeping only the most frequent tokens and replacing the others with the UNK token. Reducing the size of the vocabularies for both encoder and decoder resulted in a significant improvement for the performance of the model (BLEU score 18.2 vs 13.06 for the annotated test set).

From a qualitative perspective, Table 6 provides several examples of SQL queries generated for the validation set. The generated SQL statements are syntactically correct most of the time even when the textual description is incomplete or uses abbreviations (e.g. "no" for "number"). More, in the second example, we can also observe that the model learns to use table aliases correctly in complex queries with joined tables. On another hand, although the generated queries are syntactically correct, in most cases they fail to return the desired results when they are executed against the database. When the system fails to generate the correct SQL query for a description, it still generates a query related to the natural language description.

It is important to mention that, in order to correctly write an SQL statement, one needs to know the schema of the database. This is an aspect that we did not take into consideration when training

the baseline model. Thus the model is not explicitly provided with the database schema, however it can infer it from the training set. However, we believe that more complex approaches that integrate schema information and are syntax-aware can produce better results than a SEQ2SEQ model.

5 Discussion

Generating SQL queries from natural language can be broken down to a number of independent sub-problems. For example, in order to retrieve the desired information from a database, the appropriate table columns need to be instantiated in the SELECT clauses, and the correct tables need to be instantiated in the FROM clause. Breaking down the complex task of automatically generating SQL in multiple simpler tasks and working on each task separately can, in our opinion, yield significant improvements faster.

Apart from the BLEU score, we propose two new tasks that are easier than the NLIDB problem. This approach stemmed from the difficulty of the problem and the need for a more structured grasp of the performance of a certain system on this task. Therefore, we chose to also evaluate the ability of the proposed NNLIDB to correctly instantiate tables and columns from the database schema. For these two tasks, the most important metrics are precision and recall. For example, given a sample from the dataset, we compare the SQL query generated by the neural network architecture with the correct SQL statement and count existing and missing table and column names.

In Tables 7 and 8 we evaluate the performance of our baseline on the tables and columns identification tasks. We observe that on the validation and annotated test set, precision and recall scores are significantly higher, due to the fact that these are more informative than the original test set descriptions. Given the fact that the database schema contains a total of 29 entities (table names) and 204 attributes (column names), the precision and recall scores prove that the baseline model delivers decent performance on these tasks and moreover, that both tasks are representative for measuring the performance of a system on the NLIDB problem. It is important to mention that, for the sake of simplicity, for the columns identification task we ignored the fact that in different tables there may be columns with the same name (e.g. "id").

Both the tables and columns identification tasks

can be made more difficult using stricter evaluation. For example, for the table task, one could consider only the entities that are instantiated strictly in the FROM clause and the attributes that are instantiated in the SELECT clause.

6 Conclusions

In this paper we have introduced new datasets for training and validating natural language interfaces to databases. The SENLIDB train dataset is the first large corpus designed to develop data-driven NLIDB systems and it has been successfully used to train an end-to-end neural NLIDB (NNLIDB) using a SEQ2SEQ model with attention. Although the generated SQL output may sometimes be syntactically invalid and is rarely the desired SQL statement for the given textual query, we hope the dataset will prove valuable for future research.

The pursuit of a successful NNLIDB is still at the beginning and we hope that the current research will provide the first steps needed to investigate more complex solutions. Future research will investigate whether using a stacked decoder - one for generating a query sketch (e.g. subclauses) and one for the elements related to the database schema - will provide a better solution.

In comparison with existing approaches for NLIDB systems, our solution does not use any rules, heuristics or information about the underlying database schema or SQL syntax. On the other hand, the generated SQL queries are more often than not inaccurate and thus we have not compared the accuracy of the NNLIDB with existing solutions. However, we have focused on verifying how similar the generated SQL queries are to the annotated ones using measures from machine translation (BLEU) and also precision and recall for simpler tasks, such as generating the correct table and column names in a SQL statement.

Acknowledgments

We would like to thank Laurențiu Pantelimon and Alexandru-Robert Velcu for their help in annotating the test set. This work has been funded by the project Text2NeuralQL (PN-III-PTE-2016-0109).

Abstract

In a dialogue system, the dialogue manager selects one of several system actions and thereby determines the system's behaviour. Defining all possible system actions in a dialogue system by hand is a tedious work. While efforts have been made to automatically generate such system actions, those approaches are mostly focused on providing functional system behaviour. Adapting the system behaviour to the user becomes a difficult task due to the limited amount of system actions available. We aim to increase the adaptability of a dialogue system by automatically generating variants of system actions. In this work, we introduce an approach to automatically generate action variants for elaborateness and indirectness. Our proposed algorithm extracts RDF triplets from a knowledge base and rates their relevance to the original system action to find suitable content. We show that the results of our algorithm are mostly perceived similarly to human generated elaborateness and indirectness and can be used to adapt a conversation to the current user and situation. We also discuss where the results of our algorithm are still lacking and how this could be improved: Taking into account the conversation topic as well as the culture of the user is likely to have beneficial effect on the user's perception.

1 Introduction

In a dialogue system (DS), the dialogue manager (DM) is responsible for choosing the system's contribution to a conversation. Several studies (e.g. (Ultes et al., 2015; Bertrand et al., 2011;

Jaksic et al., 2006; Partala and Surakka, 2004)) show that adjusting the system's behaviour to the user can improve the user experience. To enable such adaptivity, the system needs several possible dialogue actions from which to choose. Often, those system actions are predefined manually. Hence, the amount of variants that the DM can choose from to adapt the system behaviour is limited by conversational skills, creativity and time of the person responsible for creating those actions. Foreseeing every possible situation the DS could find itself in and coming up with multiple viable system actions while considering possible types of users and their preferences in a conversation is demanding work. Approaches to the automatic generation of system actions, such as (Kadlec et al., 2015), have been presented to facilitate that process. However, those approaches often consider only system actions that are necessary from a functional point of view. There is no variety of system actions produced that would enable the DM to adapt to specific users characteristics or preferences. However, automatically generating variants of system actions can greatly increase the adaptability of a DM and thereby improve the user experience.

Studies (e.g. (Miehle et al., 2016; Pragst et al., 2017)) have shown that elaborateness and indirectness can be useful in adaptive DM. Here, elaborateness refers to the amount of additional information provided to the user and the level of indirectness describes how concretely information is addressed by a speaker. We have proposed the automatic generation of elaborateness and indirectness in (Pragst et al., 2016). In this work, we introduce an algorithm that, given a core statement on a semantic level, automatically creates more elaborated or indirect versions of that statement by retrieving semantic content from a knowledge base (KB) and assessing its relevance to the original

statement. Additionally, we ascertain that elaborateness and indirectness are suitable options for providing adaptability to the DM, and that our automatically generated system actions are mostly perceived similarly compared to human instances of elaborated and indirect statements. We further examine the circumstances under which the perception of automatically generated system actions deviates from human ones and discuss how to improve our algorithm based on those insights.

The remainder of the paper is structured as follows: In Section 2, we discuss related work. Section 3 gives an overview of the DS our approach is employed in. Our algorithm for the automatic generation of elaborateness and indirectness is presented in Section 4 and evaluated in Section 5. Finally, we draw a conclusion in Section 6.

2 Related Work

Adaptive DMs can be beneficial to the user experience (Ultes et al., 2015; Bertrand et al., 2011; Jaksic et al., 2006; Partala and Surakka, 2004) and has been implemented in a number of DMs (e.g. (Gnjatović and Rösner, 2008; Ultes and Minker, 2014; Rieser and Lemon, 2011)). Often, adaptive DMs consider user characteristics such as culture (Aylett and Paiva, 2012; Mascarenhas et al., 2013) or emotion (André et al., 2004; Gnjatović and Rösner, 2008; Pittermann and Pittermann, 2007). Komatani et al. (2005) use the amount of information presented as adaptation mechanism to the user’s knowledge and the degree of urgency. Such architectures provide the decision making process necessary for choosing the best suited system action. However, they depend on the availability of suitable system actions to perform optimally.

To facilitate the process of defining system actions, efforts have been made to model dialogues automatically, e.g (Beveridge and Fox, 2006; Kadlec et al., 2015; Zhai and Williams, 2014; Niraula et al., 2014). Those approaches are mostly focused on functional system behaviour. Only system actions that are necessary to solve a task are defined, limiting the possibilities for adaptation. Our goal is to generate variants of system actions that address the same functionality, and thereby increase the adaptability.

Our efforts to generate variants of system actions is paralleled by a number of tasks in the area of natural language generation. Natural language generators produce human-readable sen-

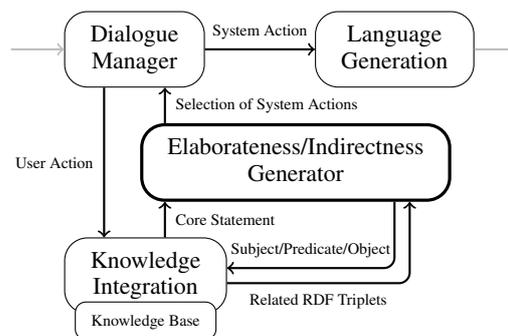

Figure 1: Partial architecture of the KRISTINA system, enhanced by the proposed algorithm.

tences from a more structured representation. With regard to surface realisation, one characteristic of good generators is their ability to provide variation in the generated sentences, which has been explored, among others, by Wen et al. (2015). With a similar goal, efforts towards the paraphrasing of sentences have been made (e.g. (Kozłowski et al., 2003; Langkilde and Knight, 1998)). Those approaches provide variation at the word level and preserve the semantic content of a sentence. They are complemented by our approach that focuses on variations of the semantic content of a system action. The content selection task is concerned with choosing relevant information that is to be communicated in the generated text, often with the goal of creating summaries (e.g. (Duboue and McKeown, 2003; Barzilay and Lapata, 2005)). While this research area certainly provides important insights to the generation of elaborateness, they need to be considered with respect to the peculiarities of dialogue. Instead of providing an overview over the most important information in a larger amount of data, the goal of our work is to augment an already determined piece of information with relevant further information. Hence, content selection is more concerned with filtering information, while our approach focuses on adding information.

3 System Architecture

We embed our approach to the generation of elaborateness and indirectness into an existing DS, the KRISTINA system (Wanner et al., 2016; Meditskos et al., 2016). It is employed in the health-care domain, with the overarching goal to support immigrants with health-care related issues in a socially competent manner. To enable a deeper understanding of the workings of the proposed algo-

rithm, this section presents the system architecture of KRISTINA. A graphic representation of the relevant parts can be found in Figure 1.

The KRISTINA system does not rely on predefined system actions. Instead, a knowledge integration component (KI) (Meditkos et al., 2017) is responsible for interpreting the user request and searching a KB for the required information. The information retrieved from the KB is represented as RDF triplets. RDF triplets consist of subject, predicate and object and are used to describe the relationship between objects, e.g. ($s:mother$, $p:is_from$, $o:Berlin$). As a result of this representation, system actions are given as a set of RDF triplets that represent the semantic content to be conveyed to the user. A language generation component (Bouayad-Agha et al., 2012) transfers those RDF triplets into sentences.

To enhance our system from a purely functionally oriented DS to a user oriented DS, our goal is to transform the RDF triplets retrieved by the KI in a way that makes them either more elaborated or more indirect, while preserving the original meaning. Thereby, the DM has more choices than just the functional answer to the user question. The KB employed by the KI is utilised to gather suitable RDF triplets for the new system action variants. Newly created system actions can be transformed to sentences by the language generation in the same manner as the output from the KI.

4 Generation of Elaborateness and Indirectness

The starting point for both the generation of elaborateness and indirectness is the set of RDF triplets that was selected to answer the user request by the KI. We call this set the *core statement*. To generate a more elaborated version of the core statement, further RDF triplets that are relevant to the core statement are added. To achieve a more indirect variant, the core statement is omitted from the system response and instead a set of RDF triplets that is closely related to it is used. This process is divided in two parts: the acquisition of relevant RDF triplets from the KB and the assessment of those triplets to find the ones most suitable with regard to the core statement. In the following, the procedure is described in more detail.

Algorithm 1: Pseudocode for the acquisition of RDF triplets from the KB.

Data: *coreStmt*, the set of RDF triplets selected by the KI
spo, a function that relates each triplet to the set of its subject, predicate and object
maxDist, the maximal number of iterations for the search of the KB
minDist, the minimal number of iterations after which triplets are included

4.1 Acquisition of Semantic Content

To avoid having to assess every RDF triplet stored in the KB with regard to its relevance to the core statement, triplets that are connected to the core statement are preselected. The pseudocode for this process is depicted in Algorithm 1. For every triplet in the core statement, the KB is searched for all further triplets that contain either its subject, predicate or object. Exemplary, if ($s:mother$, $p:is_from$, $o:Berlin$) is part of the core statement, the triplets ($s:Berlin$, $p:is_in$, $o:Germany$) and ($s:mother$, $p:has_age$, $o:42$) could be retrieved from the KB. This process is repeated for the newly gathered triplets to find further candidates. The number of iterations is determined by the desired level of elaborateness. The higher the targeted elaborateness, the more iterations are performed. A further parameter is used to adjust the level of indirectness. It determines the number of iterations that have to be performed before a triplet can be added to the final system action. If a triplet is encountered before sufficient iterations have been performed, it can be used to find further triplets, but is not allowed as part of the final system action. If an elaborated, but direct answer is desired, this parameter is set to 0. After gathering potential RDF triplets as candidates, the next step is to assess their relevance to the core statement.

```

4.2 Assessment of Semantic Content

The overall process to choose triplets for the final system action is depicted in Algorithm 2, with Algorithms 3, 4 and 5 contributing necessary functions. All gathered RDF triplets are ranked with regard to the core statement and those with the highest rank are included in the final system action. After the inclusion of each new RDF triplet, the ranking is repeated. It takes as reference the newly added triplets as well as the core statement. This improves the overall consistency. The number of triplets in the final system action is restricted by the targeted level of elaborateness.

The ranking function f takes into account several factors: p , the probability for the triplet to occur given the core statement, d , the mean distance between triplet and core statement in the KB, and i , the number of triplets in the core statement related to the triplet. It can be chosen freely to reflect the importance of the individual factors. In our experiments, we choose $f(p, d, i) = p + 2di$.

The probability for a triplet to occur given the core statement is derived from a corpus of dia-

return  $\frac{accDist}{|coreStmt|}$ 
```

logues between humans. An automated mapping of words to the semantic concepts that are used in the KB was performed and this data was used to calculate the probability that two concepts would appear in one dialogue turn as well as the overall probability that a concept would occur in a dialogue turn. From those probabilities, the conditioned probability that the concept of a new triplet will be in a turn if a concept of the core statement occurs in that turn can be calculated, as is shown in Algorithm 3. The mean of all conditioned probabilities between the concepts of the core statement and the triplet that is to be rated is used as input to the ranking.

Pseudocode for the calculation of the mean distance between a triplet and the core statement is given in Algorithm 4. The distance between two triplets in the KB refers to the number of iterations that have to be performed to find one triplet when starting from the other. If the triplet cannot be found due to the elaborateness restriction, a high number is assumed instead. The mean distance between a triplet and the core statement is used as a metric on how closely related they are.

The process to determine the number of triplets a triplet is related to can be found in Algorithm 5. A triplet is related to another triplet of the core statement if the triplet could be reached from it during the acquisition. It can be assumed that a

triplet that is related to the whole core statement is more relevant to the situation than one that is related to part of it.

5 Evaluation

Our approach has been evaluated in an online user study. Participants were asked to rate both human generated (HG) and computer generated (CG) variants of dialogue contributions with regard to the original statement. The research question of the study was twofold: First, to compare the variants produced by our algorithm to HG ones. Second, to show that elaborateness and indirectness have the potential to be used in adaptive DM. In the following, an overview of the participants of the user study, the study design as well as the results are presented. Finally, the findings and their implications for the proposed algorithm and adaptive DM in general are discussed.

5.1 Participants

The study included 21 Japanese and 21 German participants, most of which were between the age of 20 and 30. The 26 male participants slightly outweigh the female participants. The language of the study was English, so to identify potential influences of the individual English reading skill, participants were asked to rate their English skill using either the Common European Framework of Reference for Languages (CEFR), which is often used in Germany to assess language skills, or the Test of English for International Communication (TOEIC), which is more common in Japan. All

Statement 4

KRISTINA: Your mother is not originally from here? Does she miss Germany sometimes?

TOM (ORIG.): Yes, my mother misses Germany.

TOM (HG): I think my mother misses Germany because most of her relatives and friends are there and when she is there she is able to communicate much better.

TOM (CG): My mother misses Germany. She and my father married there. They immigrated, but they visit Germany. My father is happy.

Statement 6

TOM: Do you know how the weather is going to be?

KRISTINA (ORIG.): It is going to rain this afternoon.

KRISTINA (HG): It is going to rain this afternoon, but it's not going to be cold, still 20°C. But I would take an umbrella.

KRISTINA (CG): It is going to rain this afternoon. It is not going to be cold in the afternoon, 20°C by then. The temperature tomorrow is also going to be 20°C.

Figure 2: Examples for human and computer generated elaborated statements.

of the participants reported English reading skills above the beginner level (CEFR: A1/TOEIC reading: 115), with the majority even reporting skills at or above the upper intermediate level (CEFR: B2/TOEIC reading: 385 or better).

5.2 Study Design

The proposed algorithm was evaluated by comparing its results to actual human generated examples of elaborateness and indirectness. To this end, ten elaborated and ten indirect statements were extracted from natural conversations. The conversations take place between caregivers, caretakers and their relatives, with topics ranging from biographical information, eating preferences, health issues to recreational activities. For the extracted statements, the concise/direct version of the statement was determined manually, taking into consideration both previous and following parts of the conversation. Those concise/direct statements are referred to as the *original statements* for the remainder of the paper. The original statements were transformed into semantic representations of their content and the proposed algorithm was used to produce an altered semantic representation, either aiming to be more elaborated or more indirect. As the performance of our content acquisition and rating component was to be tested, not that of a language generation component, a human transformed the semantic representation of the content into sentences. They were instructed to create simple sentences and only include the information provided by the RDF triplets. Examples

Statement 1
TOM: My mother doesn't speak English very well.
KRISTINA (ORIG.): Can you translate for the nurses?
KRISTINA (HG): If the nurses need someone for translation can they contact you?
KRISTINA (CG): Can the nurses contact you to give them information about your mother?

Statement 6
KRISTINA: How much support does your father need? Can he walk on his own?
TOM (ORIG.): My father needs support walking.
TOM (HG): My father is unsteady and shaky if he has nothing to hold onto. He can do two, three steps if someone holds him.
TOM (CG): My father can do two, three steps if someone holds him.

Figure 3: Examples for human and computer generated indirect statements.

of the resulting sentence pairs can be found in Figure 2 and 3. A full list of the sentences pairs is provided in the additional material.

The study consisted of an online questionnaire, presenting pairs of an original statement and a HG or CG variant of it to the participants. The participants were not made aware that some of the statements were computer generated. Furthermore, the exchanges were presented as human-human instead of human-computer interaction. All participants assessed all HG and CG variants, resulting in 20 evaluated statements pairs for elaborateness and indirectness each. For elaborated variants, the participants were asked how relevant the additional information is. This question was rated on a five point scale from 1 - 'not at all' to 5 - 'very relevant'. For indirect statements, participants rated how easily they could derive the meaning of the original statement from the indirect statement on a five point scale from 1 - 'it is impossible' to 5 - 'it is obvious'. For all sentence pairs, participants were asked to rate which statement they preferred on a 5 point scale from 1 - 'the original one' to 5 - 'the elaborated/indirect variant'.

Apart from the comparison of the generation methods, differences between the nationalities and the individual original statements were also considered. Differing ratings in those areas suggest possible adaptations that may be employed by a DM to cater to different cultures or different situations.

The results for each research question were obtained using a three-way mixed ANOVA.

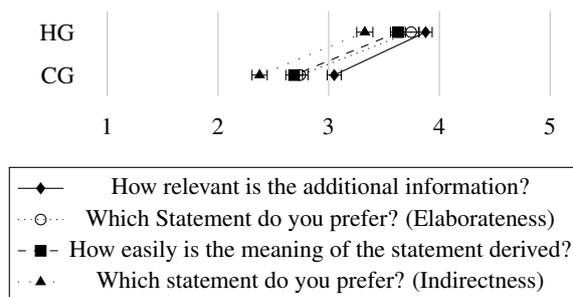

Figure 4: Comparison of the mean rating and standard error by the generation method used.

5.3 Results

Figure 4 depicts the mean and standard error of the rating for each of our research questions. Statistical tests show that HG and CG statements yield mostly similar results. No significant differences between the generation methods can be found for a significance level of 0.05, except for the ease with which indirect statements can be interpreted. Here, CG statements are harder to understand than HG ones. However, this does not significantly influence the preference of participants for either direct or indirect statements. Additionally, we find that nationality and situation influence the rating, suggesting that adapting to them by changing the level of elaborateness and indirectness is viable. Apart from the main factors generation method, nationality and original statement, we also tested for influences of age, gender or proficiency in English on the results of our study but found no significant effects.

In the following, a more detailed description of the results is presented. A complete list of mean ratings for each research question can be found in Tables 1, 2, 3 and 4.

5.3.1 Impact of Generation Method

The relevance of additional information as well as the user preference for either the original or the elaborated/indirect statement do not show significant differences regarding the generation method with a significance level of 0.05. Only the ease with which the meaning of an indirect statement can be derived is significantly influenced by the generation method ($F(1, 37) = 5.401, p = .026$). This indicates that overall participants perceived HG and CG statements to be similar, but had problems to interpret CG indirect statements. In addition to those results, several significant interaction effects can be found. Those interaction effects offer valuable information about potential improvements that can be made to the proposed algorithm. Hence, they are examined in closer detail in the following.

Significant interaction effects between generation method, nationality and original statement exist for both the relevance of additional information ($F(9, 333) = 2.731, p = .004$) as well as the user preference for either the original or the elaborated statement ($F(9, 333) = 2.486, p = .009$). For both question, several interaction patterns can be observed, depending on the original statement:

Statement	Japanese		German	
	HG	CG	HG	CG
1	3.57	3.05	4.19	2.57
2	3.05	2.38	2.95	1.43
3	2.62	2.14	2.24	1.38
4	1.95	1.52	2.00	1.38
5	3.90	2.57	3.90	2.57
6	3.86	3.29	3.76	3.19
7	4.33	3.00	3.10	2.38
8	3.81	3.67	3.71	2.76
9	3.95	2.29	2.71	1.52
10	3.29	3.10	3.62	1.33

Table 4: Mean ratings for the question ‘Which statement do you prefer?’ (Indirectness).

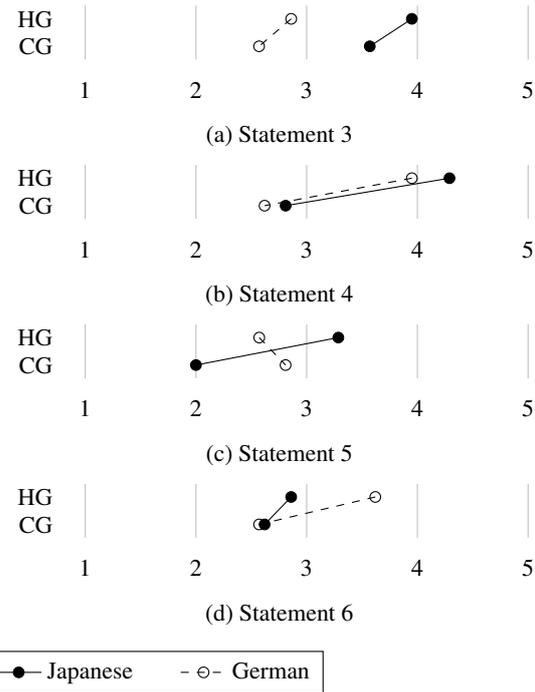

Figure 5: Interactions between nationality and generation method for the question ‘Which statement do you prefer?’ (Elaborateness). Different patterns can be found: Nearly no difference between HG and CG, a sharp decline for CG, a sharp decline only for Japanese and a sharp decline only for Germans.

The generation method can have almost no impact or lead to a declining rating from either Japanese, Germans or both, as can be seen exemplary in Figure 5. For some statements, one of the cultures rates the CG statement in a similar manner as the HG one, while the rating of the other culture shows a sharp decline for CG statements. As a consequence of the different perceptions across cultures, it might be beneficial to consider the target culture during the generation process and thereby improve

its performance. Furthermore, a few original statements receive a worse rating for CG variants than for HG variants by both cultures. This suggests that while the generation of elaborateness often works well, potential for improvements still exists in those cases.

The ease with which the meaning of an indirect statement can be derived depends significantly on the interaction between generation method and nationality ($F(1, 37) = 10.469, p = .003$). The corresponding interaction pattern is depicted in Figure 6. If the indirect statement is HG, Germans seem to have an easier time to derive the original meaning than Japanese ($F(1, 37) = 5.547, p = .024$), who mostly rate this question neutrally. This difference between cultures disappears for CG statements. It is possible that Germans have an advantage with the HG statements, as those statements were extracted from German dialogues and the original statements were derived by a German. Hence, the implicit connections between original and indirect statement could be more obvious to Germans due to a similar cultural imprint. This advantage disappears when the implicit connection between original statement and indirect one is made automatically by an algorithm and therefore foreign to both cultures. This would suggest that an effort should be made to better capture the human approach to generating indirectness and thereby reduce the difficulty of interpreting it. In this endeavour, the target culture needs to be taken into account.

The preference for either the original or the indirect statement is influenced significantly by the interaction between generation method, nationality and original statement ($F(9, 333) = 3.124, p = .001$). Here, patterns similar to the ones found for the preference regarding elaborated statements can be observed: The generation method can have almost no impact or lead to a declining rating from either Japanese, Germans or both, depending on the original statement. This affirms the potential for improvements regarding the adjustment to the target culture as well as the overall performance.

5.3.2 Potential for Adaptation

To ascertain the ability of elaborateness and indirectness to contribute to the adaptability of a DM, we assess the impact of nationality and original statement on user preferences.

A significant interaction effect of nationality and original statement on the preference for ei-

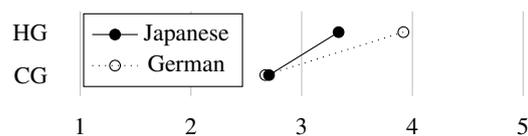

Figure 6: Interactions between nationality and generation method for the question ‘How easy is it to derive the original meaning?’.

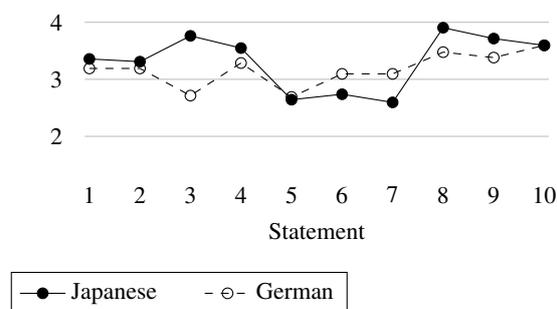

Figure 7: Interactions between nationality and original statement for the question ‘Which statement do you prefer?’ (Elaborateness).

ther the original or the elaborated statement can be found ($F(9, 333) = 2.578, p = .007$). As can be seen in Figure 7, Germans seem to be rather indifferent to the level of elaborateness. They mostly rate neutrally. In contrast, a clear distinction between topics can be found for Japanese. They tend to prefer concise statements if the topic of conversation is uncritical, such as the weather or day trips. This can be seen for Statements 5, 6 and 7. When talking about family members, more elaborated statements are preferred. Considering those findings, a culture and situation adaptive DM could utilise elaborateness as means to implement suitable adaptation.

As discussed in Section 5.3.1, there exist significant interactions of generation method, nationality and original statement on the preference of elaborateness/indirectness. If the generation methods are examined separately, the interaction of nationality and original statement still impacts the rating for both elaborateness (HG: $F(9, 333) = 2.197, p = .022$, CG: $F(9, 333) = 2.838, p = .003$) and indirectness (HG: $F(9, 333) = 2.143, p = .026$, CG: $F(9, 333) = 1.922, p = .048$). This implies that, while nationality and original statement always influence the user preference, the way they impact it is not the same for HG and CG statements. The different interac-

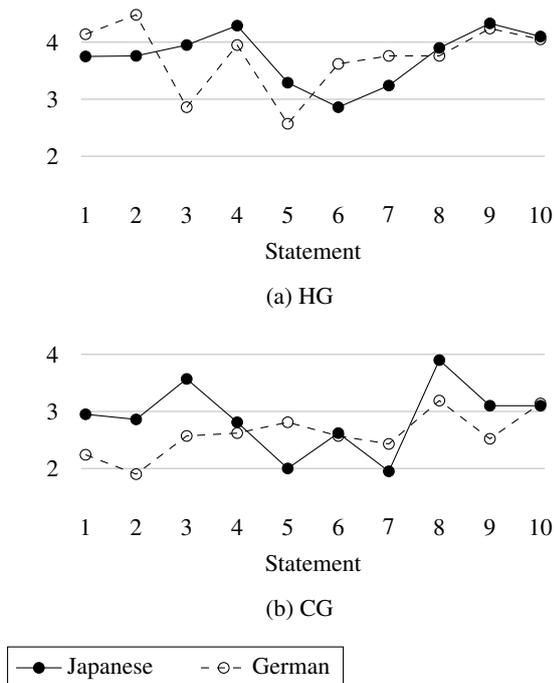

Figure 8: Comparison of the interaction pattern between nationality and original statement for the question ‘Which statement do you prefer?’ (Elaborateness) for HG and CG statements.

tion patterns are depicted exemplary in Figure 8. Those results suggests that an adaptive DM should not learn its dialogue strategy based on human-human dialogue containing examples of elaborateness/indirectness, as this can lead to wrong assumption about the user preferences. Instead, the dialogue strategy should be based on CG variants that reflect more accurately the elaborateness/indirectness variants that will be used.

5.4 Discussion

Overall, CG statements perform well compared to HG ones. However, there are cases when the rating of CG generated statements decreases for one or both of the considered cultures when compared to the HG statement. Therefore, it might be beneficial to consider both nationality as well as the topic of the original statement during the generation of system action variants. Another possibility would be to generate multiple elaborated/indirect variants and let the DM choose the most suitable with regard to the context and culture. Both approaches might improve the results of CG statements in cases where participants rated them worse than HG ones with the current approach.

In our study, the potential for adaptivity that is

provided by system actions with different levels elaborateness and indirectness was investigated. For elaborateness, we could show that different preferences exist depending on the culture and original statement. Therefore, it is feasible for an adaptive DM to choose either the elaborated or the concise variant depending on both the culture of the user as well as the current context of the conversation to improve the user satisfaction. Furthermore, our results show that the interaction between generation method, nationality and original statement has an impact on the user’s preference for elaborated/indirect statements. This implies that, while both elaborateness and indirectness can be used for adaptation, the DM should base its dialogue policy on experiences with CG statements instead of HG ones.

6 Conclusion

In this work, an approach to the automatic generation of more elaborated or indirect variants of a system action on the semantic level has been discussed. We proposed an algorithms for the acquisition of semantic data and the assessment of this data with regard to the dialogue contribution under consideration. Furthermore, a user study was performed to investigate the performance of our approach compared to humans and the applicability of elaborateness and indirectness for adaptiveness. The results show that, while the variants produced by the proposed algorithm are often perceived in a similar manner as human generated variants, complex interactions exist with both nationality and topic of the statement. Taking those into account can further improve the performance. Additionally, the study shows that differing preferences across cultures and statements exist and hence can be considered in adaptive DM.

In future work, the presented approach will be integrated into a fully functional DS, including the knowledge integration and language generation components that it relies on. Furthermore, the proposed algorithm will be further improved to better adjust to the user culture and the topic of the conversation.

Abstract

Most social media platforms grant users freedom of speech by allowing them to freely express their thoughts, beliefs, and opinions. Although this represents incredible and unique communication opportunities, it also presents important challenges. Online racism is such an example. In this study, we present a supervised learning strategy to detect racist language on Twitter based on word embeddings that incorporate demographic (Age, Gender, and Location) information. Our methodology achieves reasonable classification accuracy over a gold standard dataset ($F_1=76.3\%$) and significantly improves over the classification performance of demographic-agnostic models.

1 Introduction

The advent of microblogging services has impacted the way people think, communicate, behave, learn, and conduct their daily activities. In particular, the lack of regulation has made social media an attractive tool for people to express online their thoughts, beliefs, emotions and opinions. However, this transformative potential goes with the challenge of maintaining a complex balance between freedom of expression and the defense of human dignity (Silva et al., 2016). Indeed, some users misuse the medium to promote offensive and hateful language, which mars the experience of regular users, affects the business of online companies, and may even have severe real-life consequences (Djuric et al., 2015). In the latter case, (Priest et al., 2013; Tynes et al., 2008; Paradies, 2006b; Darity Jr., 2003) evidenced strong correlations between experiences of racial discrimination and negative mental health outcomes such as

depression, anxiety, and emotional stress as well as negative physical health outcomes such as high blood pressure and low infant birth weight.

As the information contained in social media often reflects the real-world experiences of their users, there is an increased expectation that the norms of society will also apply in social media settings. As such, there is an increasing demand for social media platforms to empower users with the tools to report offensive and hateful content (Oboler and Connelly, 2014).

Hateful content can be defined as "speech or expression which is capable of instilling or inciting hatred of, or prejudice towards, a person or group of people on a specified ground, including race, nationality, ethnicity, country of origin, ethno-religious identity, religion, sexuality, gender identity or gender" (Gelber and Stone, 2007). While there are many forms of hate speech, racism is the most general and prevalent form of hate speech in Twitter (Silva et al., 2016). Racist speech relates to a socially constructed idea about differences between social groups based on phenotype, ancestry, culture or religion (Paradies, 2006a) and covers the categories of race (e.g. black people), ethnicity (e.g. Chinese people), and religion (e.g. Jewish people) introduced in Silva et al. (2016).

Racism is often expressed through negative and inaccurate stereotypes with one-word epithets (e.g. tiny), phrases (e.g. big nose), concepts (e.g. head bangers), metaphors (e.g. coin slot), and juxtapositions (e.g. yellow cab) that convey hateful intents (Warner and Hirschberg, 2012). As such, its automatic identification is a challenging task. Moreover, the racist language is not uniform. First, it highly depends on contextual features of the targeted community. For example, anti-african-american messages often refer to unemployment or single parent upbringing whereas anti-semitic language predominantly makes refer-

ence to money, banking, and media (Warner and Hirschberg, 2012). Second, the demographic context of the speaker may greatly influence word choices, syntax, and even semantics (Hovy, 2015). For instance, a young female rapper from Australia may not use the exact same language as an elder male economist from South Africa to express her racist thoughts (Figure 1).

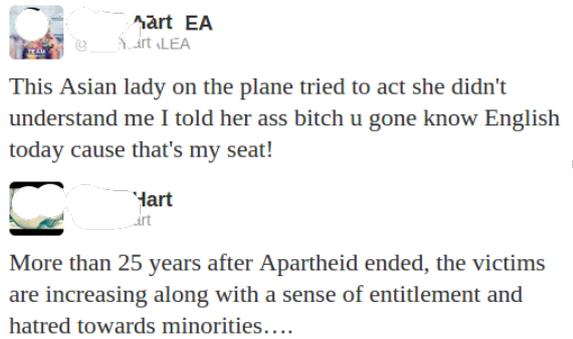

Figure 1: (Top) Tweet from a 25 years-old Australian rapper. (Bottom) Tweet from a senior South African economist.

To address these issues, we propose to focus on demographic features (age, gender, and location) of Twitter users to learn demographic word embeddings following the ideas of Bamman et al. (2014) for geographically situated language. The distributed representations learned from a large corpus containing a great proportion of racist tweets are then used to represent tweets in a straightforward way and serve as input to build an accurate supervised classification model for racist tweet detection. Different evaluations over a gold-standard dataset show that the demographic (age, gender, location) word embeddings methodology achieves F_1 score of 76.3 and significantly improves over the classification performance of demographic-agnostic models.

2 Related Work

Despite the prevalence and large impact of online hateful speech, there has been a lack of published works addressing this problem. The first studies on hateful speech detection are proposed by (Xu and Zhu, 2010; Kwok and Wang, 2013; Warner and Hirschberg, 2012) but with very limited scope and basic supervised machine learning techniques.

One of the very first attempts to propose a computational model that deals with offensive language in online communities is proposed by Xu and Zhu (2010). The authors pro-

pose a sentence-level rule-based semantic filtering approach, which utilizes grammatical relations among words to remove offensive contents in a sentence from Youtube comments. Although this may be a valuable work, its scope deviates from our specific goal, which aims at automatically detecting racist online messages.

The first identified studies that can directly match our objectives are proposed by Kwok and Wang (2013) and Warner and Hirschberg (2012). In Kwok and Wang (2013), the authors propose a naïve Bayes classifier based on unigram features to classify tweets as racist or non-racist. It is important to notice that the standard data sets of racist tweets were selected from Twitter accounts that were self-classified as racist or deemed racist through reputable news sources with regards to anti-Barack-Obama articles. Although this is the very first attempt to deal with Twitter posts, the final model is of very limited scope as it mainly deals with anti-black community racism. Similarly, (Warner and Hirschberg, 2012) propose a template-based strategy that exclusively focuses on the detection of anti-semitic posts from Yahoo!. In particular, some efforts were made to propose new feature sets, but with unsuccessful results.

In Warner and Hirschberg (2012), the authors propose a similar idea focusing on the specific manifestation of anti-semitic posts from Yahoo! and xenophobic urls identified by the American Jewish Congress. In particular, they use a template-based strategy to generate features from the part-of-speech tagged corpus augmented with Brown clusters. Then, a model is generated for each type of feature template strategy, resulting in six SVM classifiers. Surprisingly, the smallest feature set comprised of only positive unigrams performed better than bigram and trigram features. Similarly to Kwok and Wang (2013), this study focuses on a specific community and is of limited scope. However, efforts were made to propose new features, although with unsuccessful results.

Burnap and Williams (2016) is certainly the first study to propose a global understanding of hateful speech on Twitter including a wide range of protected characteristics such as race, disability, sexual orientation and religion. First, they build individual SVM classifiers for each of the four hateful-speech categories using combinations of feature types: ngrams (1 to 5), slur words and typed-dependencies. Overall, the highest F_1 scores are

achieved by combining ngrams and hateful terms, although the inclusion of typed dependencies reduces false positive rates. In a second step, the authors build a data-driven blended model where more than one protected characteristic is taken at a time and show that hateful speech is a domain dependent problem. The important finding of this work is the relevance of the simple dictionary lookup feature of slur words.

In Waseem and Hovy (2016), the authors study the importance of demographic features (gender and location) for hateful speech (racism, sexism and others) classification from Twitter as well as proposed to deal with data sparseness by substituting word ngrams with character ngram (1 to 4) features. 10-fold cross validation results with a logistic regression show that the demographic features (individually or combined) do to not lead to any improvement, while character-based classification outperforms by at least 5 points the F_1 score of word-based classification. Although non-conclusive results are obtained with demographic features, we deeply believe that these contextual features can lead to improvements.

While all these efforts are of great importance, most works point at the drawbacks of discrete representations of words and texts. This especially holds in the context of the racist language where offenders often use simple yet effective tricks to obfuscate their comments and make them more difficult for automatic detection (such as replacing or removing characters of offensive words), while still keeping the intent clear to a human reader. For that purpose, including continuous distributed representations of words and texts may lead to improved classification results.

Following this assumption, two studies have been proposed with different strategies. Tulkens et al. (2016) present a dictionary-based approach to racism detection in Dutch social media comments following the findings of Burnap and Williams (2016). In particular, they broaden the coverage of the categories in their dictionaries by performing a dictionary expansion strategy that uses a word embedding (skip-gram model) obtained from a general-purpose 3.9 billion words Dutch corpus. For instance, they show that the entry “mohammed”¹ can be expanded with “mohamed”, “mohammad” and “muhammed”. The SVM classification results show that the auto-

mated expansion of the dictionary slightly boosts the performance, but with no statistical significance. To our point of view, this may be due to the non-specificity of the corpus used to produce the word embeddings.

Indeed, more successful results are obtained by Djuric et al. (2015), who propose to build a specific paragraph embeddings for hateful speech. In particular, they show a two-step method. First, paragraph2vec (Le and Mikolov, 2014) is used for joint modeling of comments and words from Yahoo! comments with the bag-of-words neural language model. Then, these embeddings are used to train a binary classifier to distinguish between hateful and clean comments. The results of the logistic regression for 5-fold cross-validation show improved performance of the continuous representation when compared to discrete ngram features.

In this paper, we propose to study further the initial “unsuccessful” idea of Waseem and Hovy (2016) of taking into account demographic factors for racism classification in Twitter. Indeed, recent linguistic studies have shown that the racist language can differ from place to place (Chaudhry, 2015). Moreover, we deeply think that the specificity of racist language can be better modeled by continuous spaces as shown in Djuric et al. (2015).

As a consequence, we propose to build demographic word embeddings following the initial findings of Bamman et al. (2014) (location) and Hovy (2015) (age and gender) for discrete features. These embeddings are computed on a corpus specifically built for racism detection and obtained by massive gathering of tweets containing slur words listed in different referenced sources such as the racial slur database.² Then, the low-space distributed continuous representations are used as direct input of binary (racist vs. non racist) SVM classifiers, which are compared to concurrent approaches over a gold standard data set.

3 Data Sets

In this section, we first detail the process that consists in gathering a huge quantity of potentially racist and non-racist tweets from which the demographic word embeddings are computed. Then, we present the manual annotation process defined to create a gold standard data set and used to evaluate the proposed classification strategy.

¹The study specifically focuses on anti-Islamic racism.

²<http://www.rsdb.org/> Last accessed on 10-04-2017.

3.1 Unlabeled Data Set

The process starts by crawling English tweets using the Twitter streaming API³ for a period of three months (05/02/2015 to 05/05/2015). From this set, potentially racist tweets are collected by selecting all those that contain at least one racist candidate keyword from (1) a collection of 3000 plus racial and ethnic slurs or (2) a set of racially motivated phrases. In particular, the first list of keywords is compiled from the Wikipedia list of ethnic slurs⁴ and the racial slur database.⁵ The second list of racist phrases is produced by combining a general purpose insult with the name of a given ethnicity, giving rise to slurs such as “dirty jew” or “russian pig”. For that particular purpose, we collected 70 common insulting modifiers such as “dog”, “filthy”, “honky”, “redneck”, or “rat”. This process allowed to gather about 17.2 million potentially racist tweets from 1.8 million users.

In parallel, a random sample ($\approx 1\%$ of all retrieved tweets) of potentially clean (i.e. that do not contain racial and ethnic slurs) tweets is collected resulting in 41.3 million tweets from 4.6 million users all over the world.

In addition to the message conveyed in a given tweet, some information is stored for all tweets, such as location, time and user’s profile. However, this information is not accessible for most tweets. As a consequence, we propose different text processing methodologies to compute the three demographic variables: age, gender and location.

In particular, age and gender are predicted using the text-based models described in Sap et al. (2014). These models are trained on data from over 70,000 Facebook users and report an accuracy rate of 91.9% for gender (resp. 88.9% on Twitter data) and a Pearson correlation coefficient of 0.84 for age prediction. For location, we use the geo-coding scheme proposed in Chen and Neill (2014), which is based on three major rules with priorities.⁶ For each tweet, (1) we search for a location mention from GeoNames⁷ in the text message, then (2), we verify if the user enabled

⁵<http://www.rsd.org/>. Last accessed on 10-04-2017.

⁶This methodology is clearly prone to error. But, improving this pre-processing step is out of the scope of this paper.

⁷<http://www.geonames.org/>. Last accessed on 10-04-2017.

the geo-coding function of his/her device, and (3) we look for location information from the stored user’s profile. The first location information identified is then returned as the geographic location of the tweet. Note that the returned location information is at country-level.

Finally, similarly to Hovy (2015), we lowercase tweet texts, remove special characters, replace numbers with a 0, and join frequent bigrams with an underscore to form a single token.

Table 1 presents the distribution of the obtained corpus broken down by the contextual variables.

Country	Tweets	Users	Users Demographics			
			U. 35	O. 35	M	F
Potentially racist tweets						
USA	3.9M	124.2k	54.7k	69.5k	79.9k	44.3k
India	3.4M	132k	89.7k	42.3k	93.8k	38.2k

Canada	1.3M	96k	44.7k	51.3k	52.8k	43.2k
Japan	1.1M	98.4k	50.6k	44.8k	49.8k	45.6k
Potentially clean tweets						
USA	11.8M	259.4k	121.6k	137.8k	137.4k	121.9k
UK	8.3M	184.5k	98.3k	86.2k	94.1k	90.4k
India	6.4M	218.4k	136.2k	82.2k	145.6k	72.8k
Japan	2.3M	102.5k	54.8k	47.7k	57.3k	45.2k
Indon.	2.1M	109.4k	63.2k	46.2k	71.9k	37.5k

Table 1: Top five countries with most tweets in the unlabeled data sets. Tweet users are broken down by age - (i) Under 35 (U. 35); (ii) Over 35 (O. 35) - and gender - (i) Male (M); (ii) Female (F).

3.2 Classification Data Set

It is anticipated that recognizing racist tweets can be difficult. Certainly, the use of ethnic and racial slurs has been clearly not always hateful. A number of studies have examined how the slur “nigger” has been appropriated by African Americans as a way of actively rejecting the connotations it carries, e.g. for comedic purposes, a status symbol, a shorthand term expressing familiarity among friends, or even forgetting what the term ever denoted in the first place (Anderson and Lepore, 2013). Therefore, tweets that merely contain these slurs may not be always offensive.

In order to build a gold-standard data set that allows the evaluation of classifiers learned to detect “true” racist tweets, we adopt an approach, which depends on the assessments made by users of a crowdsourcing platform. For that purpose, we randomly sample 4 sub-collections from the collection of potentially racist tweets gathered in section 3.1, namely two for gender (Male and Female), and two for age (Under 35 and Over 35). The same strategy is followed to select 4 sub-

Japan	610	294	316	327	283

Table 3: Top five countries with most tweets in the classification data set. Tweets are broken down by age and gender.

collections from the set of potentially clean tweets.

The samples are equally distributed among male, female, and the two age groups, and the geographic distributions (at the country level) in the 8 sub-collections are in line with the distributions over the whole corpus of tweets.

Note that while the effect of age on language use is undisputed (Rickford and Price, 2013), providing a clear cut-off is hard. We therefore used age ranges that result in roughly equally sized data sets for both groups in the overall corpus.

Each sub-collection consists of 1000 tweets that are uploaded to the crowdsourcing service of the CrowdFlower platform⁸ for annotation. In particular, each tweet is represented by its text, location information, user’s age and gender, and a multiple choice question is asked to the annotators to decide whether the tweet has indeed a racist intent or not. The available answers are “Yes”, “No”, and “Unsure”. Each tweet is annotated by at least 3 annotators. Each annotator requires to be an English speaker and preferably in the same country as the origin of the tweet.

Out of the 8000 tweets that were judged, 7358 received a majority of “Yes” or “No” votes. The

⁸<http://www.crowdfLOWER.com/>. Last accessed on 10-04-2017.

remainder were less determinant with the addition of “Unsure” votes. Of these 7358 tweets, 3267 (44%) had a majority of votes confirming they were racist, with the remaining 4091 (56%) considered as not racially motivated tweets. Table 2 shows some examples of tweets with their annotations and Table 3 summarizes the classification data set by demographic variable.

This data set can be thought as a hard test for classifiers as non racist tweets may contain slurs unlike most works so far, which assess their models based on the hypothesis that non racist tweets usually contain general vocabulary and do not exhibit any critical content. In parallel, we acknowledge that some racist tweets may not contain any slur such as illustrated in Figure 1. Future work will definitely have to deal with the integration of racist tweets that do not present any direct racist mention, in the classification data set.

4 Methodology

Following the self-taught learning paradigm (Raina et al., 2007), we first construct demographic word embeddings from the unlabeled data described in section 3.1. Then, we obtained context-aware high-level low-dimensional features from a succinct input representation for the specific task of racist tweet detection.

4.1 Demographic Word Embeddings

Djuric et al. (2015) were the first to propose a self-taught learning strategy in the context of hateful speech detection, where they simultaneously learn low-dimension representations of documents and words in a common vector space. However, contextual/demographic characteristics were not taken into account.

A simple way to take demographic variables into account when building word embeddings is to train individual models on each variable value (e.g. a “male” model is obtained by using data

only from male users). This has been the strategy followed by Hovy (2015) for age and gender in the context of sentiment classification, topic identification, and author attributes identification.⁹

A more sophisticated model has been proposed in Bamman et al. (2014), which defines a joint parameterization over all variable values in the data. In this specific case, they study geographic variables. As such, information from data originating in some location can influence the representations learned for other locations. A joint model has three a priori advantages over independent models: (i) sharing data across variable values, encourages representations across those values to be similar; (ii) such sharing can mitigate data sparseness for less-witnessed variables; and (iii) all representations are guaranteed to be in the same vector space and can therefore be compared to each other.

In this work, we propose to follow the work of Bamman et al. (2014) and introduce a set of demographic features, namely Age (Under 35 and Over 35), Gender (Male and Female) and Location (top 20 countries in the unlabeled data set¹⁰).

This model corresponds to an extension of the skip-gram language model proposed in (Mikolov et al., 2013). Formally, given an input word w_i in a vocabulary V and a set of demographic variables A , the objective is to maximize the average data log-likelihood given in equation (1), where c is the length of the word context.

$$\mathcal{L} = \frac{1}{|V|} \sum_{i=1}^{|V|} \sum_{c \in \{-1,1\}} \log \Pr(w_{i+c}|w_i) + \quad (1)$$

$$\frac{1}{|A|} \sum_{a=1}^{|A|} \frac{1}{|V_a|} \sum_{i=1}^{|V_a|} \sum_{c \in \{-1,1\}} \log \Pr(w_{i+c}|w_i^a)$$

So, while any word has a common low-dimension representation that is invoked for every instance of its use (regardless of its demographic context), the word embedding specific to a given demographic variable indicates how that common representation should shift in the k -dimension space when used in this special context.

In terms of implementation, back-propagation functions as in the standard skip-gram language model, with gradient updates for each training ex-

ample and computation is speeded up using the hierarchical softmax function.

4.2 Racist Tweet Classification

For the classification process, we use linear Support Vector Machines (SVM) models that take as input a feature representation of tweets based on demographic word embeddings.

On the one hand, each word of a given tweet is represented by its joint embedding, which is the concatenation of its common low-dimension representation of dimension k and each low-dimension representation of its specific demographic embeddings, each one also of dimension k . For example, if a given word appears in a tweet issued by a male user of 45 years-old in the USA, its representation will be the concatenation of its common embedding with its 3 specific embeddings computed from the active variables Age=Over 35, Gender=Male and Location=USA. In this particular case, each word will be represented by a vector of $4k$ continuous values.

On the other hand, we need to represent tweets with variable lengths based only upon the concatenated embeddings of the words they contain. For that purpose, we follow the same strategy as proposed in Hovy (2015). For each learning instance (i.e. tweet), we collect 5 N -dimensional statistics (i.e. minimum, maximum, mean representation, as well as one standard deviation above and below the mean) over a $N \times t$ input matrix, where N is the dimensionality of the concatenated embeddings (i.e. $N = |A^*| \times k$, where $|A^*|$ is the number of active variables and k is the dimension of each individual embedding), and t is the sentence length in words. We then concatenate those 5 N -dimension vectors to a $(5N)$ -dimension vector to represent each learning instance in a single format and feed it to the SVM classifiers.

Note that taking the maximum and minimum across all embedding dimensions is equivalent to representing the exterior surface of the instance manifold (i.e. the volume in the embedding space within which all words in the instance reside). And adding the mean and standard deviation acts as the density per-dimension within the manifold.

We are aware that different tweet representations could have been tested, namely those based on neural sequence modeling. In particular, future work will aim to adapt models such as paragraph2vec (Le and Mikolov, 2014) or LSTM (Tai

⁹Thus, outside our application scope.

¹⁰Remaining countries did not have a reasonable amount of tweets to learn embeddings.

et al., 2015) to demographic embeddings.

5 Evaluation

5.1 Experimental Setups

The demographic word embeddings were computed based on the implementation provided by Bamman et al. (2014)¹¹ with $k = 100$ for the low representation dimension, while demographic-agnostic models were built using the word2vec¹² implementation for the same size of k . In particular, we built 8 different embeddings i.e. one demographic-agnostic embedding based on the unlabeled data set presented in section 3.1 without any demographic variable and 7 others with different demographic variables combinations such as Age, Gender, Location, Age+Gender, Age+Location, Gender+Location and Age+Gender+Location. With respect to the discrete representation of tweets, we proposed 6 different configurations using either word unigrams and/or bigrams, or character ngrams ($n=1$ to 4). In this context, the demographic information was included as binary variables for Gender and Age, and a n -ary variable for Location. One final model was proposed that joins demographic-agnostic word embeddings with demographic discrete variables. As a consequence, 15 different input settings were tested for classification as shown in the first column of Table 4, using the linear SVM model implemented in the Weka¹³ platform with standard parameters settings¹⁴.

As for evaluation, we proposed to split the gold-standard data set of 7358 tweets described in section 3.2 into a training data set of 5149 tweets (70%) and a test data set of 2209 tweets (30%). In particular, the test data set is equally distributed among male, female, the two age groups, and the top 20 countries with most tweets in our collected unlabeled data set. In order to evaluate the capacity of the classification models to generalize over the original data distribution, we also performed 10-fold cross-validation for all the settings. Moreover, we analyzed the effect of the training data size for the classification purposes.

Demo. W.2V. (Gen. + Loc.)	74.0	73.4	73.7
Demo. W.2V. (Age + Gen. + Loc.)	76.4	76.1	76.3

Table 4: Precision (Prec.), Recall (Rec.), and F_1 Score (F_1) for racist tweet detection over the test data set. Demographic variables Location and Gender are represented by Loc. and Gen., respectively. W.2V. stands for word2vec model learned over the racist data set.

The first finding is that demographic-aware models perform better than the demographic-agnostic ones across almost all configurations. This improvement raises at 5.3% of F_1 on average with a maximum increase of 9.5%. The only contradictory case is when character ngrams ($n=1$ to 4) are used as text representation. In that specific configuration, the inclusion of demographic variables has no impact on the results, confirming previous results of Waseem and Hovy (2016). However, using character ngrams improves over a word ngrams representation as noted by Waseem and Hovy (2016) but, it fails to benefit from the introduction of demographic variables, unlike the word ngrams representation which is boosted by the introduction of contextual variables. Note that this result was not reported in Waseem and Hovy (2016). Furthermore, we computed the exact same best configuration of Waseem and Hovy (2016), i.e. logistic regression over character ngrams with the Gender variable, and a F_1 score of 60.7% was achieved, which is comparable to our results with SVM reaching F_1 score of 61.0%.

The second important result is that the model learned over continuous feature representations of tweets from general embeddings in combina-

tion with features containing demographic information, namely Age, Gender, Location (row 8 in Table 4) outperforms all demographic-aware configurations based on discrete text representations (i.e. unigrams, bigrams or character ngrams) by a minimum (resp. maximum) margin of 9.5% (resp. 11.5%) of F_1 score. This result, particularly shows that word semantics is better captured by word embeddings than classical text representations.

The third result supports our initial hypothesis that demographic word embeddings can improve the task of racist tweet classification. Indeed, all demographic-aware embeddings improve over the demographic-agnostic embeddings, even boosted by discrete demographic variables, to the only exception of the gender-aware model (row 10 in Table 4). In particular, a maximum difference is obtained by the demographic word embedding that counts with Age, Gender and Location variables at levels of 9.5% of F_1 score, when compared to demographic-agnostic word embeddings.

Finally, although all demographic variables improve on classification, the Gender variable seems to have the smallest impact on the overall results. Indeed, at each inclusion it slightly improves results, while Location is the most productive variable, as hypothesized by Chaudhry (2015). In particular, note that the demographic-aware continuous model with the single Gender variable is outperformed by the model built on general word embeddings increased by discrete context variable (row 8 in Table 4).

Tweet Representation	Prec.	Rec.	F_1
Uni.	65.3	61.5	63.3
Uni. + Age + Loc. + Gen.	66.7	62.4	64.4
Uni. + Bi.	65.8	60.7	63.1
Uni. + Bi. + Age + Loc. + Gen.	66.2	62.3	64.1
Ch. ngrams	64.2	65.6	64.8
Ch. ngrams + Age + Loc. + Gen.	65.0	67.2	66.0

Demo. W.2V. (Age + Gen. + Loc.)	79.0	77.4	77.1

Table 5: Precision (Prec.), Recall (Rec.), and F_1 Score (F_1) for 10-fold cross-validation.

Results of the 10-fold cross-validation are presented in Table 5 and show similar conclusions,

but following the original distribution of the learning data sets, oppositely to the first experiment, where we forced the test data to be balanced. The only small difference is that in these conditions the character ngrams representation seems to take advantage of the introduction of contextual variables reaching the best results in terms of discrete text representation.

Note that all improvements in Table 4 and Table 5 are statistically significant. In particular, we adopted a bootstrap-sampling test similarity to Hovy (2015) with a standard cutoff of $p < 0.05$.

Effect of Training Data Size: The size of the training data set is an important concern in supervised learning methods as lots of manual efforts are required to tag learning instances. Thus, we want to evaluate the impact of the training data set size on the performances of two different word embeddings configurations: (1) W.2V. + Age + Gen. + Loc. (Baseline) and (2) Demo. W.2V. (Age + Gen. + Loc.).

For that purpose, we randomly select $d\%$ (by steps of 20%) of the training data set to train the classifiers and test them on the test data set. Note that for each $d\%$, we generate the training set 20 times and the averaged performance is recorded. F_1 scores for both approaches over the test data are presented in Table 6.

Data size	Baseline	Demo. W.2V. (Age+Gen.+Loc.)
1k	63.4	68.3
2k	65.2	70.2
3k	68.5	73.8
4k	69.9	75.5
5.1k (all)	70.5	76.3

Table 6: Classification performances (F_1 score) with different sizes of training data.

Results show that our proposed framework performs consistently better than its counterpart. In particular, the results show that with 3k training examples better results can be obtained by our approach than relying on 5.1k training examples for the state-of-the-art supervised machine learning approach (Baseline) based on common word embeddings for racist tweet detection.

5.3 Qualitative Results

In order to better understand figures given in section 5.2, we examined different qualitative criteria.

Error Analysis We performed a manual error analysis of the instances where our best performing configuration and manual annotation differed. We noticed that some of the tweets were difficult to classify because of their ambiguity with respect to racism classification. For example, tweets such as “*adam 15 boy prob bi whitey is an irl egg*” or “*@... but the pakis are still trying to get across the border*” could be “racist” tweets, but without the context it is difficult to judge even for humans. Part of our future work will be to extract the context (e.g. previous tweets, threads) of tweets and use it for (i) annotation purposes and (2) classification issues.

Lexical Distribution. Table 7 represents the top ten most frequent racial slurs occurring in automatically tagged racist tweets broken down by Age and Gender. Results show that majority of racial slurs discuss about Islam. Considering that many tweets are issued from the USA or India rather than other countries, it is not surprising that several of the terms are in line with the Indian and American political discourses orientations.

Overall	U.35	O.35	M	F
islam	nigger	islam	islam	nigga
nigger	muslims	hebe	muslims	islam
muslims	paki	muslims	paki	nigger
white boy	islam	white boy	white boy	desi
mohammed	prophet	nigger	chinki	mohammed
pedophile	bihari	negro	mohammed	pedophile
paki	white boy	pedophile	nigger	whitey
prophet	pedophile	whitey	whitey	muslims
whitey	gook	paki	bihari	hebe
bihari	whitey	coon	mallu	coon

Table 7: Ten most frequently occurring racial slurs in racist tweets broken down by age and gender.

Demographic Distribution. The distributions by Age and Gender of the automatically tagged racist tweets are presented in Table 8. It can be seen that the Gender distribution is skewed towards men. This goes in line with an earlier study made by (Roberts et al., 2013) who found that the majority (more than 70%) of the offenders of hate crimes were men. The results also demonstrate that people under the age of 35 years-old seem to be more racist than people with the age over 35. Note that 40.2% of the Twitter users are less than 35 years old¹⁵, which indicates a clear bias towards racism by youngers. We further analyzed the racist tweets and found that roughly 35% of total racist offenders are aged under 25. So, it seems

¹⁵<http://goo.gl/qH1IQq>. Last Accessed on 6-06-2017.

that younger adults are more likely to be involved in racist offenses than older adults.

Variable	Value	% Racist tweets
Gender	Men	64.7%
	Women	35.3%
Age	Under 35	67.2%
	Over 35	32.8%

Table 8: Distribution of tweets by Gen. and Age.

Usage Patterns of Racial Slurs. Finally, we analyzed the set of automatically tagged racist tweets and categorized the patterns of usage of racial slurs into four main categories:

- *Group Demarcation:* The user’s intention is to demarcate group boundaries (people as in or out) as in the following example “*Dirty Jews, Im Hitler, Ill kill the Jews.*”.

- *Directed Attack:* Here, an attack is directed at an individual or group known personally to the sender. Tweets in this pattern use racial/ethnic slurs directly such as in “*@*** why you rotten nigger bitch, how dare you.*”.

- *Unnecessary Use:* In this case, the main discourse of the tweet may not be race or ethnicity, but rather the use of a given slur in an offhand or casual fashion, e.g. “*@: disgusting Indian shops that charge you for paying by card.*” ;

- *Ideological:* Here, authors consciously use racial/ethnic slurs within a political statement that would justify an action in the real world, such as in “*Leftist have no right view. They have an agenda for Paki and muslim. Support BJP.*”.

6 Conclusions

In this paper, we proposed to build demographic-aware word embeddings for the classification of racist tweets. We showed that such models outperform strategies based on discrete text representations and demographic-agnostic word embeddings. However, overall performance ($F_1 = 76.3\%$) is still insufficient confirming that hateful speech detection is a hard task. To improve initial results, future works will aim to (1) incorporate additional context (such as connected tweets) to leverage tweet ambiguity, (2) build demographic-aware sequence embeddings to better capture text semantics, (3) combine both discrete and continuous representations to build semi-supervised models, as weak detection of racist tweets in large amount is possible and (4) test new character-based word embeddings (Bojanowski et al., 2017).

Abstract

Social media texts, such as tweets from Twitter, contain many types of non-standard tokens, and the number of normalization approaches for handling such noisy text has been increasing. We present a method for automatically extracting pairs of a variant word and its normal form from unsegmented text on the basis of a pair-wise similarity approach. We incorporated the acquired variant-normalization pairs into Japanese morphological analysis. The experimental results show that our method can extract widely covered variants from large Twitter data and improve the recall of normalization without degrading the overall accuracy of Japanese morphological analysis.

1 Introduction

Social media texts contain many non-standard tokens (lexical variants), e.g., by lengthening (“gooooood” for “good”) or abbreviating them (“tmrw” for “tomorrow”). Current language processing systems often fail to analyze such non-standard tokens, so normalizing them into standard tokens as a preprocess is promising for analyzing such noisy texts robustly (Cook and Stevenson, 2009; Han et al., 2012; Li and Liu, 2012, 2014). The normalization task mainly consists of two components. One is detecting variant words and generating normalization candidates. The other is constructing a word lattice from possible normalization candidates and decoding to select the best normalized word sequences. Early work on normalization focused on supervised approaches using labeled text, e.g., an approach based on a statistical machine translation

(Aw et al., 2006; Pennell and Liu, 2011). However, social network service (SNS) text has a dynamic nature, and large SNS text is costly to annotate. Recent work has been focused on unsupervised approaches. For example, Han et al. (2012) proposed generating variant-normalization pairs automatically on the basis of distributional similarity and string similarity. Hassan and Menezes (2013) developed the approach by using a graph-based approach. Yang and Eisenstein (2013) introduced a highly accurate unsupervised normalization model. As just described, unsupervised methods have been developed for English normalization tasks.

Japanese SNS text also contains variant words, and several normalization methods have been proposed (Sasano et al., 2013; Kaji and Kitsuregawa, 2014; Saito et al., 2014). The basic framework of Japanese normalization is quite similar to that of English normalization. However, the problem is more complicated in Japanese normalization because Japanese words are not segmented using explicit delimiters, so we have to estimate word segmentation simultaneously in the decoding step. Variant words are also more difficult to extract automatically in Japanese than in explicitly segmented languages such as English. Unlike English normalization, the approaches for generating normalization candidates in Japanese are based on manually created rules or supervised training using annotated text. Japanese normalization contains problems to which the English unsupervised approach is simply applied. Although the English unsupervised approach assumes that there are explicit word segmentations, conventional analyzers often fail to segment non-standard words in Japanese. Therefore, to extract variants in an unsupervised fashion, we have to introduce an idea to generate correct word segmentation of variant words.

*Present affiliation: Future Architect, Inc.

Our idea for this problem is to use short sentences and phrases in SNS text. SNS text, like tweets from Twitter, contains many short sentences and phrases consisting of a single word or several words. For Example, “おっはよーん！ (ohayon, Good Morning)” is a variant form of “おはよう！ (ohayou),” and “ちょーさみー (cho samii, It is very cold)” is a variant form of “超 (cho, very)/寒い (samui, cold).” Since these short sentences often contain variant words, they can be used as efficient cues for extracting a variant word. Our idea is to not extract a variant-normalization pair in one step. Instead, we present a two-step normalization approach. In the first step, we extract coarse candidates for variant-normalization pairs from unlabeled text, and in the second step, we incorporate the extracted pairs into Japanese morphological analysis and normalization. The appropriate normalization candidates are selected in the second step. We use training data for morphological analysis in the second step but do not use annotated data in the first step. Therefore, we can efficiently extract many types of variant-normalization pairs that appear in real text.

The contributions of this study are summarized as follows.

- We developed a new method for extracting pairs of variant and normal forms from tweets, which have no explicit delimiters, by focusing on short phrases and sentences in Twitter.
- We incorporated the variant-normalization pairs extracted by our method from tweets into a Japanese morphological analysis method and statistically significantly improved the accuracy for variant words without degrading the overall accuracy for Japanese morphological analysis.

2 Background

2.1 Japanese Morphological Analysis

As we mentioned above, we have to consider Japanese normalization tasks with Japanese morphological analysis. In this section, we describe the basic idea of Japanese morphological analysis. Japanese Morphological analysis can be interpreted as ranking while using a word lattice and scores of each path (Kaji and Kitsuregawa, 2013). There are two points to consider in the analysis procedure: how to generate the

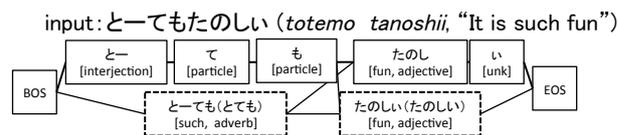

Figure 1: Example of Japanese morphological analysis and normalization

word lattice and how to formulate the score of each path. In Japanese morphological analysis, the dictionary-based approach has been widely used to generate word lattices (Kudo et al., 2004; Kaji and Kitsuregawa, 2013). To calculate the score of each path, two main scores are widely used: the score for a candidate word and the score for a pair of adjacent parts-of-speech (POs). We can consider other various scores by using discriminative model (Kudo et al., 2004; Kaji and Kitsuregawa, 2013).

2.2 Related Work

Several studies have been conducted on Japanese morphological analysis and normalization. The approach proposed by Sasano et al. (2013) developed heuristics to flexibly search by using a simple, manually created derivational rule. Their system generates a normalized character sequence based on derivational rules and adds new nodes when generating the word lattice using dictionary lookup. Figure 1 presents an example of this approach. If the non-standard written sentence “とーでもたのしい (totemo tanoshii, It is such fun)” is input, the traditional dictionary-based system generates nodes that are described using solid lines, as shown in Figure 1. Since “とーでも (totemo, such)” and “たのしい (tanoshii, fun)” are Out Of Vocabulary (OOVs), the traditional system cannot generate the correct word segments or POS tags. However, their system generates additional nodes for the OOVs, shown as broken line rectangles in Figure 1. In this case, derivational rules are used that substitute “ー” with “null” and “い (i)” with “い (i)”, and the system can generate the standard forms “とても (totemo, such)” and “たのしい (tanoshii, fun)” and their POS tags. If we can generate sufficiently appropriate rules, these approaches seem to be effective. However, there are many types of derivational patterns in SNS text, and they are difficult to all cover manually. Moreover, how to set the path score for appropriately

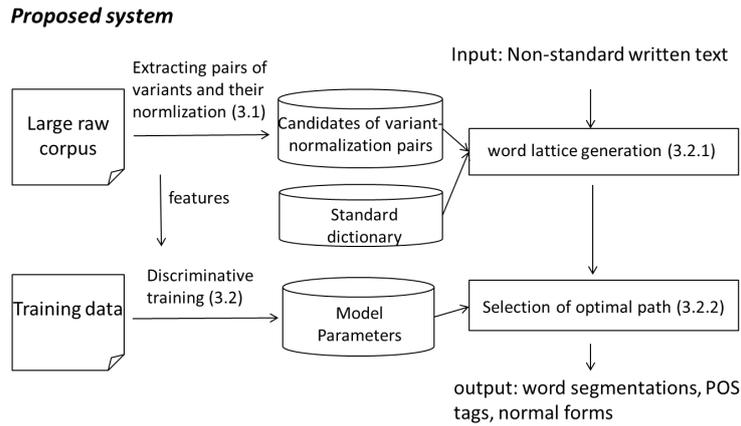

Figure 2: Overview of proposed system

ranking the word lattice when the number of candidates increases becomes a serious problem.

Saito et al. (2014) proposed supervised extraction of derivational patterns (we call them transformation patterns), incorporated these patterns into a word lattice, and formulated morphological analysis and normalization using a discriminative model. Although this approach can generate broad-coverage normalization candidates, it needs a large amount of annotation data of variant words and their normalization. Kaji and Kitsuregawa (2014) also proposed morphological analysis and normalization based on a discriminative model and created variant words on the basis of hand-made rules. As far as we know, automatic extraction of variant-normalization pairs has not been researched. If we can extract variant-normalization pairs automatically, we can decrease the annotation cost and possibly increase accuracy by combining our method with other conventional methods.

Several studies have applied a character-based approach. For example, Sasaki et al. (2013) proposed a character-level sequential labeling method for normalization. However, it handles only one-to-one character transformations and does not take the word-level context into account. The proposed method can handle many-to-many character transformations and takes word-level context into account, so it has a wider scope for handling non-standard tokens.

Many studies have been done on text normalization for English; for example, Han and Baldwin (2011) classifies whether or not OOVs are non-standard tokens and estimates standard forms on the basis of contextual, string, and

phonetic similarities. Han et al. (2012) and Hassan and Menezes (2013) developed the method of extracting variant-normalization pairs automatically for English. Yang and Eisenstein (2013) introduced a highly accurate unsupervised normalization model using log-linear model. In these studies, clear word segmentations were assumed to exist. However, since Japanese is unsegmented, the normalization problem needs to be treated as a joint normalization, word segmentation, and POS tagging problem.

Thus, we propose automatically extracting normalization candidates from unlabeled data and present a method for incorporating these candidates into Japanese morphological analysis and normalization. Our method can extract new variant patterns from real text.

3 Proposed Method

Our method consists of two parts. The first involves extracting normalization candidates and their normal forms from unlabeled data. The second involves a morphological analysis and normalization using extracted variants. Basically, we use a previously proposed dictionary based approach (Sasano et al., 2013; Saito et al., 2014; Kaji and Kitsuregawa, 2014), but the method for generating normalization candidates and some features used in a discriminative model are new. The proposed system is illustrated in Figure 2.

In the first part, we generate a coarsely segmented corpus and calculate the pairwise similarity of two arbitrary nodes that appear in the segmented corpus. In a previous study (Han and Baldwin, 2011), the nodes were assumed to be single words. On the other hand, our

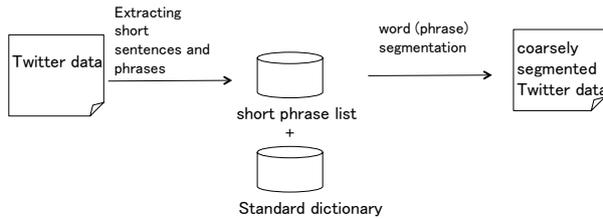

Figure 3: Flow of generating coarsely segmented corpus

method assigns a node to not only single words but also short phrases (See. 3.1). To calculate similarity between two nodes, we use semantic similarity and phonetic similarity. After calculating similarity, we filter the pairs that do not exceed a similarity threshold. We use word embeddings as a semantic similarity measure. We describe this more precisely in 3.1.2.

In the second part, the problem is how to incorporate extracted variants into Japanese morphological analysis. We use a discriminative model and Viterbi decoding for estimating word segmentation, POS tagging, and normalization. To prevent degradation induced by incorporating extracted variants, we introduce many types of features. We describe this more precisely in 3.2.

3.1 Extracting Candidates of Variant-Normalization Pairs from Twitter Texts

3.1.1 Preparation of Coarsely Segmented Corpus Using Short SNS Sentences and Phrases

We have to prepare a segmented corpus for generating normalization candidates and calculating similarity. The flow of generating coarsely segmented corpus is shown in Figure 3. As we mentioned above, we cannot determine the explicit word segmentation of unlabeled data, especially for variant words. However, we can assume that there are some explicit segmentations in text: the left and right ends of sentences and symbols such as punctuation, brackets, pictographs, emoticons, linefeed characters, commas, and spaces. SNS text contains many short sentences and phrases consisting of a word or several words. Our idea is to use the units of short sentences and short phrases delimited in symbols in SNS text as cues for extracting variant words.

More specifically, we first segment large Twitter

text with several predefined symbols, extract character sequences consisting of ten or fewer characters, and insert them into a standard dictionary. Then we segment the large twitter corpus using an expanded dictionary and conventional analyzer. An example of a segmented sentence using an expanded dictionary is “おっはよーう (*ohhayou*)! (Good morning!)”, whereas the result using a standard dictionary is “おっ(*o*)/は (*ha*)/よー (*yo*)/う (*u*)! ” Since this segmented text contains several segmentation errors and noise, we extract reliable candidates using a similarity threshold described in the next subsection.

3.1.2 Similarity Measures

To calculate the similarity between two nodes w_i and w_j appearing in a segmented corpus (3.1.1), we mainly use two similarity measures: semantic and phonetic.

Semantic Similarity We calculate semantic similarity between w_i and w_j by inducing dense real-valued low-dimensional embeddings from large unlabeled text (Mikolov et al., 2013). We use the tool `word2vec`¹ to calculate embeddings of each node. Semantic similarity is defined as

$$sem.sim(w_i, w_j) = \cos(\text{vec}(w_i), \text{vec}(w_j)) \quad (1)$$

This semantic similarity is used as a feature of a normalization and morphological analysis model (3.2.3). We set the embedding size is 200.

Phonetic Similarity We first convert a surface string into pronunciations (Japanese Kanji to Hiragana) and calculate the edit distance. We use two types of edit distance: standard and modified. For calculating modified edit distance, we set the substitution cost of two strings 0.5 when two strings have the same vowels, two strings have the same consonant or two strings are vowels. We also set insertion and deletion cost of vowels 0.5, while the standard cost of substitution, insertion and deletion is 1.

We use standard edit distance and modified edit distance as a threshold of candidate filtering (3.1.3) and modified edit distance as an element of a feature of a normalization and morphological analysis model (3.2.3). For a feature and threshold, we set the phonetic similarity $psim(w_i, w_j)$ as follows:

$$psim(w_i, w_j) = \prod_{m_i, m_j} p(m_i, m_j) \quad (2)$$

¹<http://code.google.com/p/word2vec/>

$$p(m_i, m_j) = 1 - MED(m_i, m_j) / OC(m_i, m_j) \quad (3)$$

Where $OC(m_i, m_j)$ indicates the total number of operations for calculating edit distance of m_i and m_j and $MED(m_i, m_j)$ indicates the modified edit distance. m_i and m_j indicate the morphemes in w_i and w_j , respectively.

To calculate morphological-level features, we analyzed w_j using conventional morphological analyzer and make morphological-level alignment using character-level alignment of w_i and w_j and morphological information of w_j . Here, w_j and w_i are regarded as a normal form and a variant form, respectively. Here is an example of $w_i = \text{“たんじょーび”}$ (birthday)” and $w_j = \text{“たんじょうび”}$ (birthday)”. In this case, morphological-level alignment is (たんじょー/たんじょう, び/び) since character-level alignment is (た/た, ん/ん, じ/じ, よ/よ, ー/う, び/び) and word segmentation of w_j is (たんじょう, び).

3.1.3 Candidate Filtering using Similarity Measures

We calculate the pairwise similarity between two nodes appearing in a segmented corpus (3.1.1) and their filter using a similarity measure we defined (3.1.2). The set of nodes N consists of all tokens w that appear in the segmented corpus. Since there is a huge number of node pairs and most are irrelevant, we have to filter the pairs that have low similarities. Here, we set the threshold of *sem.sim* to 0.4, and the threshold of standard phonetic edit distance is 2. Moreover, we filter the pairs in which the consonants of the beginning phonetic symbols of each morphemes are different or morphological-level phonetic similarity $p(m_i, m_j)$ is lower than 0.6. We also filtered the candidates when the number of consonants and all characters in a variant form (except for “っ”, “ん”, and lower case letters) are larger than that of a normal form at morphological level. If a variant word is already exists in a standard dictionary, we filtered the candidate. Note that this filtering is not intended to exactly identify whether the pair has the relationship of variant and normalization. Since we use only two similarities, simple phonetic information and the coarsely segmented corpus in this phase, we only extract candidates of variants and their normal forms coarsely in the first step. Then, we exactly identify the word segmentation and normalization simultaneously in the

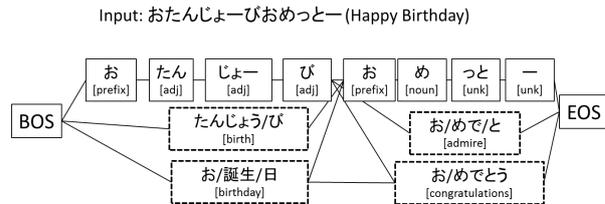

Figure 4: Example of proposed lattice

second step (3.2).

3.2 Normalization and Morphological Analysis

3.2.1 Incorporating Normalization Candidates in Japanese Morphological Analysis

We generate the word lattice using extracted candidate for variant-normalization pairs and dictionary lookup (See Figure 4). The broken line rectangles in Figure 4 are nodes added by the proposed method. We exploit dictionary lookup by using the possible character sequence of the extracted normalized character sequences when variant character sequences match the input character sequences. For example, we exploit dictionary lookup for input character sequences such as “おたんじょーびおめっとうー (happy birthday)” and add the possible normalized word sequences such as “お/誕生日 (birthday)” and “お/めでと (congratulations)” which are from extracted variant-normalization candidates. The proposed method is intended to generate normalized word sequences. In the first step, appropriateness of word segmentation is not taken into account, but in this phase, we can exactly evaluate whether the acquired pair is appropriate for normalization or not by considering the morphological connectivity.

3.2.2 Objective Function

We used a discriminative model for incorporating many features. The decoder selects the optimal sequence \hat{y} from $L(s)$ when given the candidate set $L(s)$ for sentence s . This is formulated as follows (Jiang et al., 2008; Kaji and Kitsuregawa, 2013):

$$\hat{y} = \arg \max_{y \in L(s)} \mathbf{w} \cdot \mathbf{f}(y) \quad (4)$$

Where \hat{y} is the optimal path, $L(s)$ is the lattice created for s , $\mathbf{w} \cdot \mathbf{f}(y)$ is the dot product between

Name	Feature
Word unigram score	$f_{m_i p_i}$
POS bi-gram score	f_{p_{i-1}, p_i}
Character sequence score	$1/\log(p'_{t_i}/p'_s)$ if $p'_{t_i} > p'_s$ otherwise 0. where, $p'_x = p_x^{1/\text{length}(x)}$, $p_x = \prod_{j=1}^k p(c_j c_{j-5}^{j-1})$, $x \in (s, t_i)$
Character similarity score	$\log(\text{psim})$
Semantic similarity score	$\log(\text{semsim})$
Character frequency score	$\log(\text{freq}_w + 1)$
Character and morph transformation score	$\log(\text{freq}_{ct} + 1)$, $\log(\text{freq}_{mt} + 1)$, ϕ_{ct} , ϕ_{mt}

Table 1: Feature list

weight vector \mathbf{w} and feature vector $\mathbf{f}(y)$. The optimal path is selected in accordance with the $\mathbf{w} \cdot \mathbf{f}(y)$ value. For estimating parameters, we used the averaged perceptron, which is widely used (Collins, 2002).

3.2.3 Features

The proposed lattice generation method generates a lattice larger than that generated in traditional dictionary-based lattice generation. Therefore, we need to introduce appropriate normalization scores into the objective function to prevent degradation. Table 1 lists the features we used. Let m_i be the i th word candidate and p_i be the POS tag of m_i . p_{i-1} and m_{i-1} are adjacent POS tag and word, respectively. We used the word unigram score $f_{m_i p_i}$, the cost for a pair of adjacent POSs f_{p_{i-1}, p_i} that are estimated by MeCab², and additional scores.

The character sequence score reflects the character sequence probability of the normalization candidates (Saito et al., 2014). Here, s and t_i are input string and transformed string, respectively (e.g., in Figure 4, for the normalized node ”お誕生日 (birthday)”, s is ”おたんじょーびおめつとー” and t_i is ”お誕生日おめつとー”. Then p_s and p_{t_i} are calculated by using the character 5-gram of a news corpus. c_j is the j th character of character sequence. We also used character sequence score as a candidate filter. We filtered the candidates that did not satisfy the pre-defined condition that $p'_s \leq p'_{t_i}$.

The character similarity score is calculated using psim (see 3.1.2). The semantic similarity score is calculated using semsim (see 3.1.2). The Character frequency score is a frequency of surface character sequences of variant nodes appeared in news data. Since vari-

ant words rarely appear in the news data, we use this feature to identify variant words and standard words. The character and morph transformation score is related to transformation patterns. $\log(\text{freq}_{ct} + 1)$ and $\log(\text{freq}_{mt} + 1)$ are the frequency of transformation patterns ct (character-level) and mt (morphological-level) that are extracted from variant-normalization candidates, respectively. ϕ_{ct} and ϕ_{mt} are 1 if a node contains transformation patterns ct and mt , otherwise 0, respectively. The scale of features were adjusted.

Since all those features can be factorized, the optimal path is searched by using the Viterbi algorithm.

3.2.4 Candidate Expansion

Although our method can extract many variants, we expand the variants to achieve higher recall. We use a simple rule for adding simple variation in the decoding step. For example, first, repetitions of more than one character of “ー”, “〜” and “っ” are reduced to one character and repetitions of more than three characters of Japanese Hiragana and Katakana are reduced to three characters and one character. Moreover, we use the patterns of deletions of “ー”, “〜”, “っ” and lowercase characters (Saito et al., 2014).

4 Experiments

4.1 Data and Settings

We prepared the Balanced Corpus of Contemporary Written Japanese (BCCWJ) (Maekawa et al., 2014), which is a commonly used dataset in Japan and Twitter data. For unsupervised variant extraction, we used about 70 million unlabeled Twitter corpora. We used 2,000 sentences of BCCWJ text for training the decoder and Twitter data for the test. Twitter data contain manually annotated

Table 2: Example of extracted pair of variants-normalization candidates

word segmentations, POS tags, and normal forms for variant words and consist of 7,213 sentences and 995 variant words. We used Unidic (unidic-mecab)³ as a standard dictionary.

4.2 Baselines and Evaluation Metrics

We compared the three methods listed in Table 3 in our experiments. Conventional means a method that generates no normalization candidates and only uses the word cost and the cost for a pair of adjacent POSs, so we can consider it as a conventional Japanese morphological analysis. Rule-based means the conventional rule-based method proposed by Sasano et al. (2013). The rule-based method considers insertion of long sound symbols and lowercase characters and substitution with long sound symbols and lowercase characters. We basically use the transformation rule of Sasano et al. (2013) and use three features for the model of Rule-based method: the word score, score for a pair of adjacent POSs, and character transformation score. The character transformation score is constant for all transformation rules. Proposed is our method. We used extracted variant-normalization pairs and all features described in 3.2.3.

We evaluated each method on the basis of precision, recall, and the F-value for the overall system accuracy and the recall for normalization. Since Japanese morphological analysis simultaneously

estimates the word segmentation and POS tagging, we have to assess whether or not adding the normalization candidates negatively affects a system.

4.3 Results

4.3.1 Results of Extracted Variant-Normalization Candidates

Table 2 lists examples of the extracted variant-normalization candidates. Our method automatically extracted well-known transformation patterns such as substitution of lowercase characters, insertion of lowercase characters, and insertion of “ー” and “っ” such as “うれしーい (*ureshii*)”.

Our method also extracted more variant phonetic transformation patterns such as substitution of “shi” with “pi,” “ji,” or “hi” and these combinations such as “うれちい (*uretii*)”. We also list examples of extracted multi-word variant-normalization pairs. The phrase “お/ねげー/します (*o/nege/shi/masu*)” is a variant pattern of the original phrase “お/ねがい/します (*o/negai/shi/masu*)”. Our method extracted these multi-word mappings.

Moreover, our method can extract typing errors such as “お/めでとう (*o/medetou*)” with “お/めでとー (*o/meteto*)” and slang such as “うれしす (*ureshishu*)” with “うれしい (*ureshii*)”. Such relatively less frequent patterns were often excluded from normalization targets. Our method also extracts many paraphrases: semantically and phonetically similar pairs that are not variant-normalization

“/” indicates the estimated word segmentation. Words in parentheses “()” are estimated normal forms. Underlined words are variant words.

Table 4: Example of morphological analysis and normalization outputs

pairs. This often degrades the results of morphological analysis. We use a discriminative model to prevent such paraphrase pairs appearing in the decoding step.

4.3.2 Morphological Analysis and Normalization Results

Tables 3 and 4 list the results for the Twitter text. The F-value of the proposed method is significantly higher than those of the conventional method and rule-based method. Our method was able to extract broad-coverage variant words, and these candidates also improve the recall of normalization without degrading the overall accuracy of morphological analysis.

Table 4 show examples of the system output. In the table, slashes indicate the positions of the estimated word segmentations, and the correctly analyzed words are written in bold. Examples (1) to (5) are examples improved by using the proposed method. Examples (6) and (7) are examples that were not improved.

Error Analysis There were roughly two types of errors. The first occurred as a result of a lack of

variant-normalization candidates, and the second was search errors. Example (6) shows an example of a case in which our method could not generate the correct normalized form because we could not extract the correct normalized form. Because we extract normalization candidates by phrase level, some patterns are difficult to extract as a word unit. To increase recall, we need to extract character-level and morph-level transformation patterns that occur frequently from phrase-level patterns and add them into morphological analysis and normalization. Example (7) shows an example of a case in which a normalized candidate was generated but a search failed. We will need to develop a more complicated model or introduce other features into the current model to reduce the number of search errors.

Besides the above errors, there are some errors in which correct normalization candidates were filtered. In this study, we filtered many candidates to eliminate noise. Some normalization candidates are filtered, and the correct normalization candidates cannot be generated in the word lattice. To increase recall further, we have to filter functions

or calculate similarity scores more precisely. Also, some errors are associated with unknown words. Twitter data contain many unknown words such as names, and our system sometimes treats these names as other nouns. Non-standard and standard words needs to be more precisely discriminated between for higher accuracy.

5 Conclusion and Future Work

We introduced a new idea for extracting variant words from an unsegmented corpus and incorporated it into morphological analysis. The proposed method can effectively analyze noisy words without manual annotation. The limitation of this work is that this method is based on phonetic similarity. Although our method can extract many variant patterns, it cannot extract a pair of words that have quite low phonetic similarity. In addition, our method is based on a heuristic segmentation method for extracting normalization candidates. Though it works well in practice, we want to extend this idea for a more general framework.

In future work, we would like to increase the coverage of variant-normalization pairs. For this, we have to extract the character- and morph-level transformation patterns from the acquired phrase level variant-normalization pairs.

Abstract

In this paper, we model the document revision detection problem as a minimum cost branching problem that relies on computing document distances. Furthermore, we propose two new document distance measures, word vector-based Dynamic Time Warping (wDTW) and word vector-based Tree Edit Distance (wTED). Our revision detection system is designed for a large scale corpus and implemented in Apache Spark. We demonstrate that our system can more precisely detect revisions than state-of-the-art methods by utilizing the Wikipedia revision dumps¹ and simulated data sets.

1 Introduction

It is a common habit for people to keep several versions of documents, which creates duplicate data. A scholarly article is normally revised several times before being published. An academic paper may be listed on personal websites, digital conference libraries, Google Scholar, etc. In major corporations, a document typically goes through several revisions involving multiple editors and authors. Users would benefit from visualizing the entire history of a document. It is worthwhile to develop a system that is able to intelligently identify, manage and represent revisions. Given a collection of text documents, our study identifies revision relationships in a completely unsupervised way. For each document in a corpus we only use its content and the last modified timestamp. We assume that a document can be revised by many users, but that the documents are not merged together. We consider collaborative editing as revising documents one by one.

¹<https://snap.stanford.edu/data/wiki-meta.html>

The two research problems that are most relevant to document revision detection are plagiarism detection and revision provenance. In a plagiarism detection system, every incoming document is compared with all registered non-plagiarized documents (Si et al., 1997; Oberreuter and Velásquez, 2013; Hagen et al., 2015; Abdi et al., 2015). The system returns true if an original copy is found in the database; otherwise, the system returns false and adds the document to the database. Thus, it is a 1-to-n problem. Revision provenance is a 1-to-1 problem as it keeps track of detailed updates of one document (Buneman et al., 2001; Zhang and Jagadish, 2013). Real-world applications include GitHub, version control in Microsoft Word and Wikipedia version trees (Sabel, 2007). In contrast, our system solves an n-to-n problem on a large scale. Our potential target data sources, such as the entire web or internal corpora in corporations, contain numerous original documents and their revisions. The aim is to find all revision document pairs within a reasonable time.

Document revision detection, plagiarism detection and revision provenance all rely on comparing the content of two documents and assessing a distance/similarity score. The classic document similarity measure, especially for plagiarism detection, is fingerprinting (Hoad and Zobel, 2003; Charikar, 2002; Schleimer et al., 2003; Fujii and Ishikawa, 2001; Manku et al., 2007; Manber et al., 1994). Fixed-length fingerprints are created using hash functions to represent document features and are then used to measure document similarities. However, the main purpose of fingerprinting is to reduce computation instead of improving accuracy, and it cannot capture word semantics. Another widely used approach is computing the sentence-to-sentence Levenshtein distance and assigning an overall score for every document pair (Gustafson et al., 2008). Neverthe-

less, due to the large number of existing documents, as well as the large number of sentences in each document, the Levenshtein distance is not computation-friendly. Although alternatives such as the vector space model (VSM) can largely reduce the computation time, their effectiveness is low. More importantly, none of the above approaches can capture semantic meanings of words, which heavily limits the performances of these approaches. For instance, from a semantic perspective, “*I went to the bank*” is expected to be similar to “*I withdrew some money*” rather than “*I went hiking*.” Our document distance measures are inspired by the weaknesses of current document distance/similarity measures and recently proposed models for word representations such as word2vec (Mikolov et al., 2013) and Paragraph Vector (PV) (Le and Mikolov, 2014). Replacing words with distributed vector embeddings makes it feasible to measure semantic distances using advanced algorithms, e.g., Dynamic Time Warping (DTW) (Sakurai et al., 2005; Müller, 2007; Matuschek et al., 2008) and Tree Edit Distance (TED) (Tai, 1979; Zhang and Shasha, 1989; Klein, 1998; Demaine et al., 2007; Pawlik and Augsten, 2011, 2014, 2015, 2016). Although calculating text distance using DTW (Liu et al., 2007), TED (Sidorov et al., 2015) or Word Mover’s Distance (WMV) (Kusner et al., 2015) has been attempted in the past, these measures are not ideal for large-scale document distance calculation. The first two algorithms were designed for sentence distances instead of document distances. The third measure computes the distance of two documents by solving a transshipment problem between words in the two documents and uses word2vec embeddings to calculate semantic distances of words. The biggest limitation of WMV is its long computation time. We show in Section 5.3 that our wDTW and wTED measures yield more precise distance scores with much shorter running time than WMV.

We recast the problem of detecting document revisions as a network optimization problem (see Section 2) and consequently as a set of document distance problems (see Section 4). We use trained word vectors to represent words, concatenate the word vectors to represent documents and combine word2vec with DTW or TED. Meanwhile, in order to guarantee reasonable computation time in large data sets, we calculate document distances at the paragraph level with Apache Spark. A distance

score is computed by feeding paragraph representations to DTW or TED. Our code and data are publicly available.²

The primary contributions of this work are as follows.

- We specify a model and algorithm to find the optimal document revision network from a large corpus.
- We propose two algorithms, wDTW and wTED, for measuring semantic document distances based on distributed representations of words. The wDTW algorithm calculates document distances based on DTW by sequentially comparing any two paragraphs of two documents. The wTED method represents the section and subsection structures of a document in a tree with paragraphs being leaves. Both algorithms hinge on the distance between two paragraphs.

The rest of this paper is organized in five parts. In Section 2, we clarify related terms and explain the methodology for document revision detection. In Section 3, we provide a brief background on existing document similarity measures and present our wDTW and wTED algorithms as well as the overall process flow. In Section 4, we demonstrate our revision detection results on Wikipedia revision dumps and six simulated data sets. Finally, in Section 5, we summarize some concluding remarks and discuss avenues for future work and improvements.

2 Revision Network

The two requirements for a document \bar{D} being a revision of another document \tilde{D} are that \bar{D} has been created later than \tilde{D} and that the content of \bar{D} is similar to (has been modified from) that of \tilde{D} . More specifically, given a corpus \mathcal{D} , for any two documents $\bar{D}, \tilde{D} \in \mathcal{D}$, we want to find out the yes/no revision relationship of \bar{D} and \tilde{D} , and then output all such revision pairs.

We assume that each document has a creation date (the last modified timestamp) which is readily available from the meta data of the document. In this section we also assume that we have a *Dist* method and a cut-off threshold τ . We represent a corpus as network $N^0 = (V^0, A)$, for example

²<https://github.com/XiaofengZhu/wDTW-wTED>

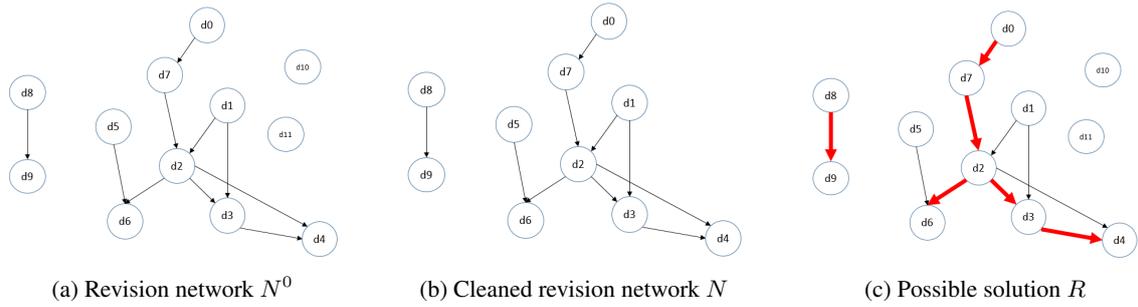

Figure 1: Revision network visualization

Figure 1a, in which a vertex corresponds to a document. There is an arc $a = (\bar{D}, \tilde{D})$ if and only if $Dist(\bar{D}, \tilde{D}) \leq \tau$ and the creation date of \bar{D} is before the creation date of \tilde{D} . In other words, \tilde{D} is a revision candidate for \bar{D} . By construction, N^0 is acyclic. For instance, d_2 is a revision candidate for d_7 and d_1 . Note that we allow one document to be the original document of several revised documents. As we only need to focus on revision candidates, we reduce N^0 to $N = (V, A)$, shown in Figure 1b, by removing isolated vertices. We define the weight of an arc as the distance score between the two vertices. Recall the assumption that a document can be a revision of at most one document. In other words, documents cannot be merged. Due to this assumption, all revision pairs form a branching in N . (A branching is a subgraph where each vertex has an in-degree of at most 1.) The document revision problem is to find a minimum cost branching in N (see Fig 1c).

The minimum branching problem was earlier solved by Edmonds (1967) and Velardi et al. (2013). The details of his algorithm are as follows.

- For each node select the smallest weighted incoming arc. This yields a subgraph.
- If cycles are present in the selected subgraph, then recursively find the replacing arc that has the minimum weight among previously non-selected arcs to eliminate cycles.

In our case, N is acyclic and, therefore, the second step never occurs. For this reason, Algorithm 1 solves the document revision problem.

The essential part of determining the minimum branching R is extracting arcs with the lowest distance scores. This is equivalent to finding the most similar document from the revision candidates for every original document.

Algorithm 1 Find minimum branching R for network $N = (V, A)$

- 1: **Input:** N
 - 2: $R = \emptyset$
 - 3: **for** every vertex $v \in V$ **do**
 - 4: Set $\delta(u)$ to correspond to all arcs with head u .
 - 5: Select $a = (v, u) \in \delta(u)$ such that $Dist(v, u)$ is minimum
 - 6: $R = R \cup a$
 - 7: **end for**
 - 8: **Output:** R
-

3 Distance/similarity Measures

In this section, we first introduce the classic VSM model, the word2vec model, DTW and TED. We next demonstrate how to combine the above components to construct our semantic document distance measures: wDTW and wTED. We also discuss the implementation of our revision detection system.

3.1 Background

3.1.1 Vector Space Model

VSM represents a set of documents as vectors of identifiers. The identifier of a word used in this work is the tf-idf weight. We represent documents as tf-idf vectors, and thus the similarity of two documents can be described by the cosine distance between their vectors. VSM has low algorithm complexity but cannot represent the semantics of words since it is based on the bag-of-words assumption.

3.1.2 Word2vec

Word2vec produces semantic embeddings for words using a two-layer neural network. Specifically, word2vec relies on a skip-gram model that

uses the current word to predict context words in a surrounding window to maximize the average log probability. Words with similar meanings tend to have similar embeddings.

3.1.3 Dynamic Time Warping

DTW was developed originally for speech recognition in time series analysis and has been widely used to measure the distance between two sequences of vectors.

Given two sequences of feature vectors: $A = a_1, a_2, \dots, a_i, \dots, a_m$ and $B = b_1, b_2, \dots, b_j, \dots, b_n$, DTW finds the optimal alignment for A and B by first constructing an $(m + 1) \times (n + 1)$ matrix in which the $(i, j)^{th}$ element is the alignment cost of $a_1 \dots a_i$ and $b_1 \dots b_j$, and then retrieving the path from one corner to the diagonal one through the matrix that has the minimal cumulative distance. This algorithm is described by the following formula.

$$DTW(i, j) = Dist(a_i, b_j) + \min(\\ DTW(i - 1, j), \quad //insertion \\ DTW(i, j - 1), \quad //deletion \\ DTW(i - 1, j - 1)) //substitution$$

3.1.4 Tree Edit Distance

TED was initially defined to calculate the minimal cost of node edit operations for transforming one labeled tree into another. The node edit operations are defined as follows.

- **Deletion** Delete a node and connect its children to its parent maintaining the order.
- **Insertion** Insert a node between an existing node and a subsequence of consecutive children of this node.
- **Substitution** Rename the label of a node.

Let L_1 and L_2 be two labeled trees, and $L_k[i]$ be the i^{th} node in L_k ($k = 1, 2$). M corresponds to a mapping from L_1 to L_2 . TED finds mapping M with the minimal edit cost based on

$$c(M) = \min\{ \sum_{(i,j) \in M} cost(L_1[i] \rightarrow L_2[j]) \\ + \sum_{i \in I} cost(L_1[i] \rightarrow \wedge) \\ + \sum_{j \in J} cost(\wedge \rightarrow L_2[j]) \}$$

where $L_1[i] \rightarrow L_2[j]$ means transferring $L_1[i]$ to $L_2[j]$ based on M , and \wedge represents an empty node.

3.2 Semantic Distance between Paragraphs

According to the description of DTW in Section 3.1.3, the distance between two documents can be calculated using DTW by replacing each element in the feature vectors A and B with a word vector. However, computing the DTW distance between two documents at the word level is basically as expensive as calculating the Levenshtein distance. Thus in this section we propose an improved algorithm that is more appropriate for document distance calculation.

In order to receive semantic representations for documents and maintain a reasonable algorithm complexity, we use word2vec to train word vectors and represent each paragraph as a sequence of vectors. Note that in both wDTW and wTED we take document titles and section titles as paragraphs. Although a more recently proposed model PV can directly train vector representations for short texts such as movie reviews (Le and Mikolov, 2014), our experiments in Section 5.3 show that PV is not appropriate for standard paragraphs in general documents. Therefore, we use word2vec in our work. Algorithm 2 describes how we compute the distance between two paragraphs based on DTW and word vectors. The distance between one paragraph in a document and one paragraph in another document can be pre-calculated in parallel using Spark to provide faster computation for wDTW and wTED.

Algorithm 2 DistPara

Replace the words in paragraphs p and q with word2vec embeddings: $\{v_i\}_{i=1}^e$ and $\{w_j\}_{j=1}^f$
Input: $p = [v_1, \dots, v_e]$ and $q = [w_1, \dots, w_f]$
Initialize the first row and the first column of $(e + 1) \times (f + 1)$ matrix $DTW_{para} + \infty$
 $DTW_{para}(0, 0) = 0$
for i in range $(1, e + 1)$ **do**
 for j in range $(1, f + 1)$ **do**
 $Dist(v_i, w_j) = ||v_i - w_j||$
 calculate $DTW_{para}(i, j)$
 end for
end for
Return: $DTW_{para}(e, f)$

4 wDTW and wTED Measures

4.1 Word Vector-based Dynamic Time Warping

As a document can be considered as a sequence of paragraphs, wDTW returns the distance between two documents by applying another DTW on top of paragraphs. The cost function is exactly the DistPara distance of two paragraphs given in Algorithm 2. Algorithm 3 and Figure 2 describe our wDTW measure. wDTW observes semantic information from word vectors, which is fundamentally different from the word distance calculated from hierarchies among words in the algorithm proposed by Liu et al. (2007). The shortcomings of their work are that it is difficult to learn semantic taxonomy of all words and that their DTW algorithm can only be applied to sentences not documents.

Algorithm 3 wDTW

Represent documents d_1 and d_2 with vectors of paragraphs: $\{p_i\}_{i=1}^m$ and $\{q_j\}_{j=1}^n$

Input: $d_1 = [p_1, \dots, p_m]$ and $d_2 = [q_1, \dots, q_n]$

Initialize the first row and the first column of $(m + 1) \times (n + 1)$ matrix $DTW_{doc} + \infty$

$DTW_{doc}(0, 0) = 0$

for i in range $(1, m + 1)$ **do**

for j in range $(1, n + 1)$ **do**

$Dist(p_i, q_j) = \text{DistPara}(p_i, q_j)$

 calculate $DTW_{doc}(i, j)$

end for

end for

Return: $DTW_{doc}(m, n)$

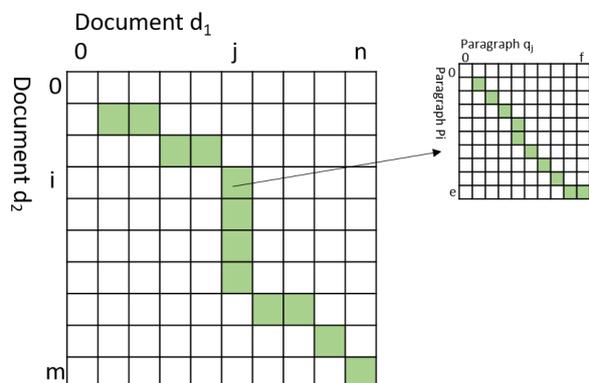

Figure 2: wDTW visualization

4.2 Word Vector-based Tree Edit Distance

TED is reasonable for measuring document distances as documents can be easily transformed to tree structures visualized in Figure 3. The document tree concept was originally proposed by Si et al. (1997). A document can be viewed at multiple abstraction levels that include the document title, its sections, subsections, etc. Thus for each document we can build a tree-like structure with title \rightarrow sections \rightarrow subsections $\rightarrow \dots \rightarrow$ paragraphs being paths from the root to leaves. Child nodes are ordered from left to right as they appear in the document.

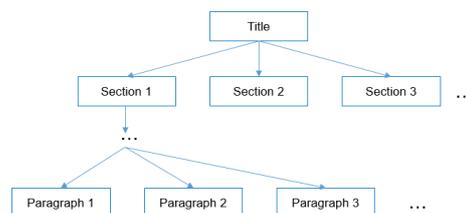

Figure 3: Document tree

We represent labels in a document tree as the vector sequences of titles, sections, subsections and paragraphs with word2vec embeddings. wTED converts documents to tree structures and then uses DistPara distances. More formally, the distance between two nodes is computed as follows.

- The cost of substitution is the DistPara value of the two nodes.
- The cost of insertion is the DistPara value of an empty sequence and the label of the inserted node. This essentially means that the cost is the sum of the L2-norms of the word vectors in that node.
- The cost of deletion is the same as the cost of insertion.

Compared to the algorithm proposed by Sidorov et al. (2015), wTED provides different edit cost functions and uses document tree structures instead of syntactic n-grams, and thus wTED yields more meaningful distance scores for long documents. Algorithm 4 and Figure 4 describe how we calculate the edit cost between two document trees.

Algorithm 4 wTED

- 1: Convert documents d_1 and d_2 to trees T_1 and T_2
 - 2: **Input:** T_1 and T_2
 - 3: Initialize tree edit distance $c = +\infty$
 - 4: **for** node label $p \in T_1$ **do**
 - 5: **for** node label $q \in T_2$ **do**
 - 6: Update TED mapping cost c using
 - 7: $cost(p \rightarrow q) = \text{DistPara}(p, q)$
 - 8: $cost(p \rightarrow \wedge) = \text{DistPara}(p, \wedge)$
 - 9: $cost(\wedge \rightarrow q) = \text{DistPara}(\wedge, q)$
 - 10: **end for**
 - 11: **end for**
 - 12: **Return:** c
-

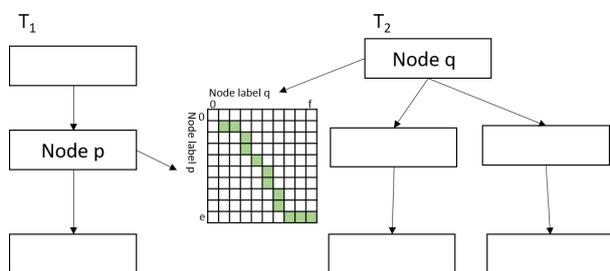

Figure 4: wTED visualization

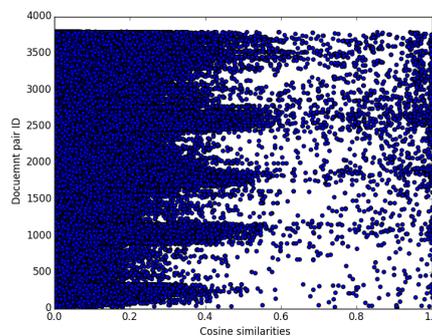

4.3 Process Flow

Our system is a boosting learner that is composed of four modules: weak filter, strong filter, revision network and optimal subnetwork. First of all, we sort all documents by timestamps and pair up documents so that we only compare each document with documents that have been created earlier. In the first module, we calculate the VSM similarity scores for all pairs and eliminate those with scores that are lower than an empirical threshold ($\tilde{\tau} = 0.5$). This is what we call the weak filter. After that, we apply the strong filter wDTW or wTED on the available pairs and filter out document pairs having distances higher than a threshold τ . For VSM in Section 5.1, we directly filter out document pairs having similarity scores lower than a threshold τ . The cut-off threshold estimation is explained in Section 4.4. The remaining document pairs from the strong filter are then sent to the revision network module. In the end, we output the optimal revision pairs following the minimum branching strategy.

4.4 Estimating the Cut-off Threshold

Hyperparameter τ is calibrated by calculating the absolute extreme based on an initial set of documents, i.e., all processed documents since the moment the system was put in use. Based on this set, we calculate all distance/similarity scores and create a histogram, see Figure 5. The figure shows the correlation between the number of document pairs and the similarity scores in the training process of one simulated corpus using VSM. The optimal τ in this example is around 0.6 where the number of document pairs noticeably drops.

As the system continues running, new documents become available and τ can be periodically updated by using the same method.

Figure 5: Setting τ

5 Numerical Experiments

This section reports the results of the experiments conducted on two data sets for evaluating the performances of wDTW and wTED against other baseline methods.

5.1 Distance/Similarity Measures

We denote the following distance/similarity measures.

- wDTW: Our semantic distance measure explained in Section 4.1.
- wTED: Our semantic distance measure explained in Section 4.2.
- WMD: The Word Mover’s Distance introduced in Section 1. WMD adapts the earth mover’s distance to the space of documents.
- VSM: The similarity measure introduced in Section 3.1.1.

- PV-DTW: PV-DTW is the same as Algorithm 3 except that the distance between two paragraphs is not based on Algorithm 2 but rather computed as $\|PV(p_1) - PV(p_2)\|$ where $PV(p)$ is the PV embedding of paragraph p .
- PV-TED: PV-TED is the same as Algorithm 4 except that the distance between two paragraphs is not based on Algorithm 2 but rather computed as $\|PV(p_1) - PV(p_2)\|$.

Our experiments were conducted on an Apache Spark cluster with 32 cores and 320 GB total memory. We implemented wDTW, wTED, WMD, VSM, PV-DTW and PV-TED in Java Spark. The paragraph vectors for PV-DTW and PV-TED were trained by gensim.³

5.2 Data Sets

In this section, we introduce the two data sets we used for our revision detection experiments: Wikipedia revision dumps and a document revision data set generated by a computer simulation. The two data sets differ in that the Wikipedia revision dumps only contain linear revision chains, while the simulated data sets also contains tree-structured revision chains, which can be very common in real-world data.

5.2.1 Wikipedia Revision Dumps

The Wikipedia revision dumps that were previously introduced by Leskovec et al. (2010) contain eight GB (compressed size) revision edits with meta data.

We pre-processed the Wikipedia revision dumps using the JWPL Revision Machine (Ferschke et al., 2011) and produced a data set that contains 62,234 documents with 46,354 revisions. As we noticed that short documents just contributed to noise (graffiti) in the data, we eliminated documents that have fewer than three paragraphs and fewer than 300 words. We removed empty lines in the documents and trained word2vec embeddings on the entire corpus. We used the documents occurring in the first 80% of the revision period for τ calibration, and the remaining documents for test.

5.2.2 Simulated Data Sets

The generation process of the simulated data sets is designed to mimic the real world. Users open

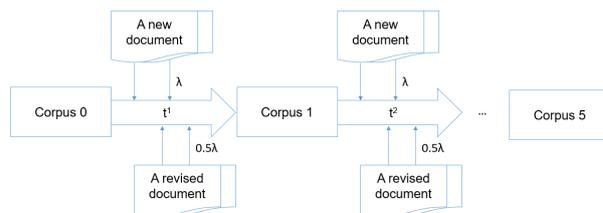

Figure 6: Corpora simulation

some existing documents in a file system, make some changes (e.g. *addition*, *deletion* or *replacement*), and save them as separate documents. These documents become revisions of the original documents. We started from an initial corpus that did not have revisions, and kept adding new documents and revising existing documents. Similar to a file system, at any moment new documents could be added and/or some of the current documents could be revised. The revision operations we used were *deletion*, *addition* and *replacement* of words, sentences, paragraphs, section names and document titles. The *addition* of words, ..., section names, and new documents were pulled from the Wikipedia abstracts. This corpus generation process had five time periods $\{t^1, t^2, \dots, t^5\}$. Figure 6 illustrates this simulation. We set a Poisson distribution with rate $\lambda = 550$ (the number of documents in the initial corpus) to control the number of new documents added in each time period, and a Poisson distribution with rate 0.5λ to control the number of documents revised in each time period.

We generated six data sets using different random seeds, and each data set contained six corpora (Corpus 0 - 5). Table 1 summarizes the first data set. In each data set, we name the initial corpus Corpus 0, and define T_0 as the timestamp when we started this simulation process. We set $T_j = T_{j-1} + t^j$, $j \in [1, 5]$. Corpus j corresponds to documents generated before timestamp T_j . We extracted document revisions from Corpus $k \in [2, 5]$ and compared the revisions generated in (Corpus k - Corpus $(k - 1)$) with the ground truths in Table 1. Hence, we ran four experiments on this data set in total. In every experiment, τ^k is calibrated based on Corpus $(k - 1)$. For instance, the training set of the first experiment was Corpus 1. We trained τ^1 from Corpus 1. We extracted all revisions in Corpus 2, and compared revisions generated in the test set (Corpus 2 - Corpus 1) with the ground truth: 258 revised doc-

³<https://radimrehurek.com/gensim/models/doc2vec.html>

uments. The word2vec model shared in the four experiments was trained on Corpus 5.

Table 1: A simulated data set

Corpus	Number of documents	Number of new documents	Number of revision pairs
0	550	0	0
1	1347	542	255
2	2125	520	258
3	2912	528	259
4	3777	580	285
5	4582	547	258

5.3 Results

We use precision, recall and F-measure to evaluate the detected revisions. A true positive case is a correctly identified revision. A false positive case is an incorrectly identified revision. A false negative case is a missed revision record.

We illustrate the performances of wDTW, wTED, WMD, VSM, PV-DTW and PV-TED on the Wikipedia revision dumps in Figure 7. wDTW and wTED have the highest F-measure scores compared to the rest of four measures, and wDTW also have the highest precision and recall scores. Figure 8 shows the average evaluation results on the simulated data sets. From left to right, the corpus size increases and the revision chains become longer, thus it becomes more challenging to detect document revisions. Overall, wDTW consistently performs the best. WMD is slightly better than wTED. In particular, when the corpus size increases, the performances of WMD, VSM, PV-DTW and PV-TED drop faster than wDTW and wTED. Because the revision operations were randomly selected in each corpus, it is possible that there are non-monotone points in the series.

wDTW and wTED perform better than WMD especially when the corpus is large, because they use dynamic programming to find the global optimal alignment for documents. In contrast, WMD

relies on a greedy algorithm that sums up the minimal cost for every word. wDTW and wTED perform better than PV-DTW and PV-TED, which indicates that our DistPara distance in Algorithm 2 is more accurate than the Euclidian distance between paragraph vectors trained by PV.

We show in Table 2 the average running time of the six distance/similarity measures. In all the experiments, VSM is the fastest, wTED is faster than wDTW, and WMD is the slowest. Running WMD is extremely expensive because WMD needs to solve an x^2 sequential transshipment problem for every two documents where x is the average number of words in a document. In contrast, by splitting this heavy computation into several smaller problems (finding the distance between any two paragraphs), which can be run in parallel, wDTW and wTED scale much better.

Combining Figure 7, Figure 8 and Table 2 we conclude that wDTW yields the most accurate results using marginally more time than VSM, PV-TED and PV-DTW, but much less running time than WMD. wTED returns satisfactory results using shorter time than wDTW.

6 Conclusion

This paper has explored how DTW and TED can be extended with word2vec to construct semantic document distance measures: wDTW and wTED. By representing paragraphs with concatenations of word vectors, wDTW and wTED are able to capture the semantics of the words and thus give more accurate distance scores. In order to detect revisions, we have used minimum branching on an appropriately developed network with document distance scores serving as arc weights. We have also assessed the efficiency of the method of retrieving an optimal revision subnetwork by finding the minimum branching.

Furthermore, we have compared wDTW and

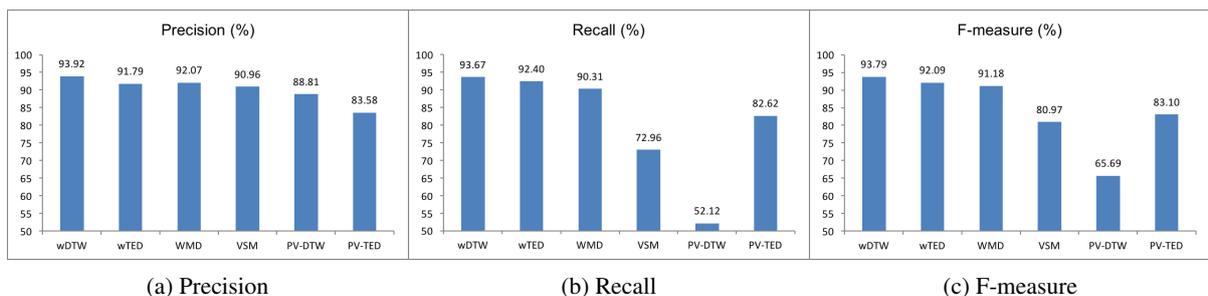

Figure 7: Precision, recall and F-measure on the Wikipedia revision dumps

wTED with several distance measures for revision detection tasks. Our results demonstrate the effectiveness and robustness of wDTW and wTED in the Wikipedia revision dumps and our simulated data sets. In order to reduce the computation time, we have computed document distances at the paragraph level and implemented a boosting learning system using Apache Spark. Although we have demonstrated the superiority of our semantic measures only in the revision detection experiments, wDTW and wTED can also be used as semantic distance measures in many clustering, classification tasks.

Our revision detection system can be enhanced with richer features such as author information and writing styles, and exact changes in revision pairs. Another interesting aspect we would like to explore in the future is reducing the complexities of calculating the distance between two paragraphs.

Abstract

Reading comprehension (RC) is a challenging task that requires synthesis of information across sentences and multiple turns of reasoning. Using a state-of-the-art RC model, we empirically investigate the performance of single-turn and multiple-turn reasoning on the SQuAD and MS MARCO datasets. The RC model is an end-to-end neural network with iterative attention, and uses reinforcement learning to dynamically control the number of turns. We find that multiple-turn reasoning outperforms single-turn reasoning for all question and answer types; further, we observe that enabling a flexible number of turns generally improves upon a fixed multiple-turn strategy. We achieve results competitive to the state-of-the-art on these two datasets.

1 Introduction

There is an old Chinese proverb that says: “*Read a hundred times and the meaning will appear.*” Several recent reading comprehension (RC) models have embraced this kind of multiple-turn strategy; they generate predictions by making multiple passes through the same text and integrating intermediate information in the process (Hill et al., 2016; Dhingra et al., 2016; Sordoni et al., 2016; Shen et al., 2016). While state-of-the-art results have been achieved by these models, there has yet to be an in-depth analysis of the impact of the multiple-turn strategy to reasoning. This paper attempts to fill this gap.

We provide empirical results and analysis on two challenging RC datasets: the Stanford Question Answering Dataset (SQuAD) (Rajpurkar et al., 2016), and the Microsoft Machine Reading

Comprehension Dataset (MS MARCO) (Nguyen et al., 2016). Given a question Q , the RC model is to read passages P and produce an answer A , which could be free-form text or one of the possible candidate spans in the passage.

The following example from SQuAD illustrates the need for synthesis of information across sentences and multiple turns of reasoning:

Q : What collection does **the V&A Theator & Performance galleries** hold?

P : **The V&A Theator & Performance galleries** opened in March 2009. ... **They** hold the UK’s biggest national collection of material about live performance.

To infer the answer (the underlined portion of the passage P), the model needs to first perform coreference resolution so that it knows “**They**” refers “**V&A Theator**”, then extract the subspan in the direct object corresponding to the answer. This process can be modeled by the repeated processing of intermediate states and input in a neural net.

To perform the analysis, we adopt the ReasonNet model of Shen et al. (2016). This is an end-to-end neural network that uses an iterative attention mechanism to simulate multiple-turn reasoning in RC. It has achieved strong results on cloze-style RC tasks like CNN/DailyMail (Hermann et al., 2015) and we extend it to SQuAD and MS MARCO tasks. The advantage of using ReasonNet for our purpose is that it uses reinforcement learning to dynamically determine the number of turns for each question-passage pair. This enables us to analyze the behavior of multiple-turn reasoning in neural network models.

We find that multiple-turn reasoning outperforms single-turn reasoning across the board for various types of question and answer types. Furthermore, the flexibility to dynamically decide the

Table 1: Dataset characteristics

number of turns generally improves over a fixed multiple-turn strategy, where the number of turns are set a priori. As an additional contribution, our extension to the ReasonNet model achieves results competitive with the state-of-the-art on SQuAD and MS MARCO.

In the following, Section 2 describes our two RC tasks, Section 3 explains the model we used for analysis, and Section 4 discusses results.

2 Reading Comprehension Tasks

We focus this study on two RC tasks which we believe require sophisticated reasoning.

SQuAD: SQuAD is a machine comprehension dataset constructed on 536 Wikipedia articles (23K paragraphs), with more than 100,000 questions. In contrast to prior datasets such as (Richardson et al., 2013; Hermann et al., 2015), SQuAD does not provide a multiple choice list of answer candidates. Instead, the RC model must select the answer from all possible spans in the passage. Crowdsourced workers are asked to read each passage (a paragraph), come up with questions, and then mark the answer spans.

There is a variety of questions and answers. The authors of SQuAD described several types of reasoning required to answer questions: (a) lexical variation between question (Q) and answer (A) that can be solved by understanding synonyms, (b) lexical variation that could be solved by world knowledge, (c) syntactic variation between Q and A sentence, and (d) multiple sentence reasoning that require anaphora or higher-level fusion.

The 100K (question, passage, answer) tuples is randomly partitioned into a training (80%), a development (10%) and test set splits (10%). Two evaluation metrics are used: Exact Match (EM), which measures the percentage of span predictions that matched any one of the ground truth answer exactly, and Macro-averaged F1 score, which measures the average overlap between the prediction and the ground truth answer. Human performance on the test set is 82.3% EM and 91.2% F1.

MS MARCO: MS MARCO is a large scale real-world RC dataset that contains 100,000 queries collected from anonymized user logs from the Bing search engine. The characteristic of MS MARCO is that all the questions are real user queries and passages are extracted from real web documents. The data is constructed as follows: for each question/query Q , up to approximately 10 passages P are extracted from public web documents and presented to human judges. These passages might potentially have the answer to the question, and are selected through a separate information retrieval system. The judges write down answers in free-form text, and according to the authors of MS MARCO, the complexity of answer varies from a single “yes/no” or entity name (e.g. Q : “What is the capital of Italy”; A : Rome), to long textual answers (e.g. Q : “What is the agenda for Hollande’s state visit to Washington?”). Long textual answers may need to be derived through reasoning across multiple pieces of text.

The dataset is partitioned into a 82,430 training, a 10,047 development, and 9,650 test tuples. Since the answer is free-form text, the evaluation metrics of choice are BLEU (Papineni et al., 2002) and ROUGE-L (Lin, 2004). To apply the same RC model to both SQuAD (where answers are text spans in P) and MS MARCO (where answer are free-form text), we search for spans in MS MARCO’s passages that maximizes the ROUGE-L score with the raw free-form answers. Our training data uses these spans as labels, but we evaluate our model with respect to the raw free-form answers; this has an upper bound of 94.23 BLEU and 87.53 ROUGE-L on the dev set. By this construction, there are multiple number of passages to read for each question, but the answer span might only involve a few passages (i.e. the ones that include the max ROUGE substring). We describe techniques to handle this case in Section 3.2.

3 Model: ReasonNet++

The reading comprehension task involves a question/query $Q = \{q_0, q_1, \dots, q_{m-1}\}$ and a passage $P = \{p_0, p_1, p_{n-1}\}$ and aims to find an answer span $A = \langle a_{start}, a_{end} \rangle$ in P . Here, m and n denote the number of tokens in Q and P , respectively, while a_{start} and a_{end} indicate the indices of tokens in P . The learning process for reading comprehension is to learn a function $f(Q, P) \rightarrow A$ trained on a set of tuples $\langle Q, P, A \rangle$.

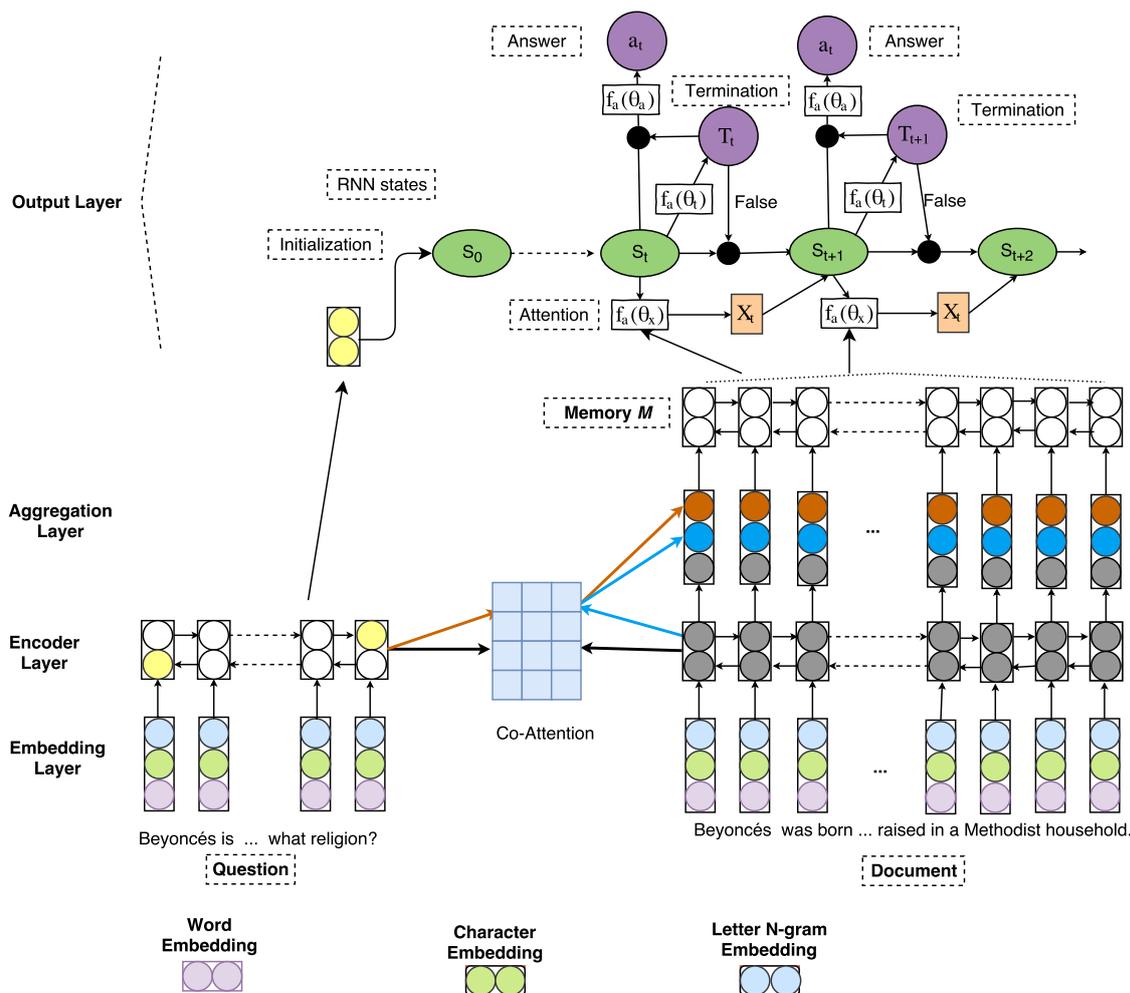

Figure 1: **Architecture of ReasoNet++:** The embedding/encoder layers compute representations for the question Q and the passage document P . The aggregation layer uses co-attention to compute question-aware passage information and passage-aware question information. Then a GRU combines these information into memory cells and feeds them to the output layer. The output layer models the multiple-turn reasoning mechanism, where intermediate results are stored in S_t and the answer is generated only when the termination signal is triggered. Each S_t is a recurrent network state and models one turn of reasoning.

Our model **ReasoNet++**, is an extension of ReasoNet (Shen et al., 2016) with three enhancements: (1) In the input layer, we added character and letter 3-gram embeddings to improve robustness to rare words. (2) We implemented co-attention (Seo et al., 2016) in the aggregation layer to focus on relevant words in both Q and P . (3) For the MS MARCO task, which needs to handle multiple passages, we incorporated an extra passage ranker component. The architecture is shown in Figure 1. In brief, the embedding/encoder layers first build representations of Q and P . The aggregation layer uses co-attention to fuse information from the Q - P pair. The output layer is a recurrent net that maintains intermediate state and dynamically decides at which turn to generate the answer.

3.1 Detailed description of ReasoNet++

Embedding Layer: We adopt three types of embeddings to represent input word tokens in Q and P . For word embeddings, we use pre-trained GloVe vectors (Pennington et al., 2014). To address the out-of-vocabulary problem, we also include character and letter 3-gram embeddings. Character embeddings are fed into a convolutional neural network (CNN) as in (Kim, 2014), then max-pooled to form a fixed-size vector for each token. For letter 3-gram embeddings, we follow Huang et al. (2013) by first *hashing* each word as a bag of letter 3-gram, then feeding them into another CNN. The concatenation of all embeddings are then fed to a two-layer Highway Network (Srivastava et al., 2015). Therefore, we obtain the

final embedding for the words in Q as a matrix $E^q \in \mathbb{R}^{d \times m}$, and words in P as $E^p \in \mathbb{R}^{d \times n}$, where d is the dimension of the embedding.

Encoding Layer: On the top of embedding layer, we utilize a bidirectional Gated Recurrent Unit (GRU), a variety of the Long Short-Term Memory Network (LSTM) (Hochreiter and Schmidhuber, 1997), to encode the words in context. We obtain $H^q \in \mathbb{R}^{2d \times m}$ as the representation of Q and $H^p \in \mathbb{R}^{2d \times n}$ as the representation of P .

Aggregation Layer: In this layer, we construct the memory, a summary of information from both the Q and P , for each word in P . A co-attention mechanism (Seo et al., 2016), which attends to Q and P simultaneously, is applied by first computing an alignment matrix in two directions: from Q to P and from P to Q . The alignment matrix C measures the similarity between Q and P :

$$C = f_{match}(H^q, H^p) \in \mathbb{R}^{m \times n} \quad (1)$$

The element at i -th row and j -th of the alignment matrix, C_{ij} , indicates the similarity between i -th word in the question and j -th word in the passage. In detail, $C_{ij} = f_{match}(H_{:i}^q, H_{:j}^p)$ is a trainable scalar function that measures the similarity between two input vectors, $H_{:i}^q$, which is the i -th column vector of H^q , and $H_{:j}^p$, which is the j -th column vector of H^p . We parameterize $f_{match}(a, b) = w_C^T[a; b; a \circ b]$, where \circ denotes the Hadmard product, $[\cdot; \cdot]$ indicates vector concatenation across rows, and $w_C \in \mathbb{R}^{6d}$ is a trainable weight vector. We normalize C row-wise to produce the attention weight across the passage for each word of the question:

$$C^q = softmax(C) \in \mathbb{R}^{m \times n}. \quad (2)$$

To measure which context words in the P have the closest similarity to the words in the Q , we define an attention weight on the words in passage as:

$$c^p = softmax(max_{col}(C))^T \in \mathbb{R}^n. \quad (3)$$

The final context representation of the P is:

$$U = f_{agg}(H^p, H^q C^q, \sum_{i=0}^{i=m-1} H_{:i}^p c^p) \in \mathbb{R}^{8d \times n}. \quad (4)$$

In our experiment, we define $f_{agg}(B, C, D) = [B; C; B \circ C; B \circ D]$. Note that B, C, D are matrices with the same dimension, \circ denotes the Hadmard product and $;$ indicates matrix concatenation across columns. Note that since

$H^p, H^q C^q, \sum_{i=0}^{i=m-1} H_{:i}^p c^p$ are all $2d$ by n matrices, U is a $8d$ by n matrix. Finally, to incorporate the full context, the ‘‘memory cells’’ of the passage are computed by a bidirectional GRU on top of U :

$$M^p = BiGRU(U) \in \mathbb{R}^{2d \times n} \quad (5)$$

Output Layer: This layer dynamically decides when to stop reasoning and output the answer. A recurrent neural network (Rumelhart et al., 1986; Elman, 1990) is adopted to maintain the states of the reasoning process. Formally, the t -th time step of inference state is denoted as S_t , and the next state is defined by $S_{t+1} = GRU(S_t, X_t)$. Note that the X_t is an attention vector generated based on the current state and the memory of the passage: $X_t = f_a(S_t, M^p)$ as in (Shen et al., 2016). Specifically, the attention score $a_{t,i}$ on a memory vector $m_i \in M^p$ given a state S_t is computed as $a_{t,i} = softmax_{i=1, \dots, |M^p|} \lambda \cos(w_1 m_i, w_2 S_t)$, where λ is set to 10 in our experiments and the projection matrices w_1 and w_2 map the memory vector and state into the same space, they are learned during training. The attention vector X_t can be written as $X_t = \sum_i^{i=|M^p|} a_{t,i} m_i$. The initial state S_0 of the inference is from the encoding representation of the question (we pick the last state of the forward GRU and the backward GRU in the H^q).

The *termination gate* will produce a stochastic random variable according to the current inference state: $T_t \sim p(\cdot | f_t(S_t))$, where f_t is modeled by a $2d \times 10 \times 10 \times 10 \times 1$ feed-forward neural network. Note T_t is a binary random variable: if T_t is true, the recurrent net will stop and the answer model will execute; otherwise it will generate an attention vector X_{t+1} and update the next state S_{t+1} .

The answer module needs to output a span in passage. We do this with two feedforward networks, one predicting the start point of the span and the other predicting the end point, so predicted answer at turn t is $a_t = (y_s^t, y_e^t)$:

$$y_s^t = softmax(w_s^T [M^p, (w_{ps}^T M^p) \circ S_t]) \quad (6)$$

$$y_e^t = softmax(w_e^T [M^p, (w_{pe}^T M^p) \circ S_t]). \quad (7)$$

where w_s, w_e, w_{ps} and w_{pe} are trainable model parameters. Since the termination state is discrete and is not connected to the final output directly, we use the Contrastive Reward method (Shen et al., 2016) inspired by deep reinforcement learning (Weissenborn, 2016; Mnih et al., 2014) for training.

3.2 Passage ranking extension

The MS MARCO dataset provides multiple passages per question/query. Our architecture in Figure 1 is built for a single passage-question pair, so we need to extend it to handle multiple passages. We propose a solution using passage ranking. Assume there are J passages, $P^{(1)}, \dots, P^{(J)}$. First, our model runs independently on every $(P^{(j)}, Q)_{j=1, \dots, J}$ pair, generating J different answer spans (empty spans are possible). Then, we multiply the probability of each answer span with a score $r(P^{(j)}, Q)$ provided by a passage ranker, and output the answer with the maximum combined score, similar to EpiReader (Trischler et al., 2016). The passage ranker is a information retrieval model (Shen et al., 2014).¹ It can be trained on the same RC data, where documents with answers are considered relevant and those that do not are considered irrelevant.

All our MS MARCO results use the passage ranking extension, unless otherwise mentioned.

4 Experiments

We seek to answer the following questions:

1. Is multiple-turn reasoning beneficial for RC? (Section 4.1)
2. What types of questions/answers benefit most from multiple-turn reasoning? (Section 4.2)
3. How many turns are employed in practice by ReasoNet++, and what are the implications for dynamic versus fixed strategies in multiple-turn reasoning? (Section 4.3)

In addition to the above analyses, we also demonstrate that our ReasoNet++ achieves state-of-the-art results (Section 4.4) and discuss some ablation studies on model variants (Section 4.5).²

¹Our implementation first hashes words into letter 3-gram (50K dimension), then use a CNN with 256 hidden nodes and the size of window 5, and lastly optimizes the similarity between the vector representations of P and Q .

²A note on hyperparameters: Throughout all experiments, we use NLTK to tokenize P and Q , and employ pre-trained case-sensitive 300 dimension GloVe embeddings³. A one layer CNN with 100 dimensions and window size of 5 is used to compute the character embeddings; a one layer CNN with 100 dimension and window size of 1 is used for letter 3-gram embeddings. The size of hidden nodes of all GRU’s is set to 128. A five layers feedforward network ($2d(256) \times 10 \times 10 \times 10 \times 1$) is used for the terminate network and the maximum number of reasoning turns in the recurrent net is capped at 5. To avoid overfitting, we adopt 0.15 dropout rate over the letter 3-gram and character embeddings,

	SQuAD	MS MARCO
Single model	EM/F1 Score	BLEU/ROUGE-L
Single turn	67.8/76.7	33.65/36.54
Fixed 5-turn	70.1/78.9	34.93/36.67
ReasoNet++	70.8/79.4	38.62/38.01

Table 2: **Main results**—Comparison of single turn to multiple turn reasoning strategies on SQuAD and MS MARCO dev sets. Both multiple turn strategies (fixed at 5, or dynamically decided based on ReasoNet++) outperform Single turn in all metrics. The dynamic strategy further improves upon the fixed multiple 5-turn strategy.

P: Forces act in a particular direction and have sizes dependent upon how strong the push or pull is. Because of these characteristics, forces are classified as “vector quantities”... For example, when determining what happens when two forces act on the same object, it is necessary to **know both the magnitude and the direction of both forces to calculate the result**. If both of these pieces of information are not known for each force, the situation is ambiguous... Associating forces with vectors avoids such problems.

Q: How do you avoid problems when determining forces involved on an object from two or more sources?

(Turn 1): when determining what happens when two forces act on the same object
(Turn 2): two forces act on the same object
(Turn 3): it is necessary to know both the magnitude and the direction of both forces

Figure 2: Case study from SQuAD of answers from multiple turns. In Turn 1, the model identifies a span similar to the question. This is refined and at Turn 3 a better answer becomes attainable.

4.1 Is multiple-turn reasoning beneficial?

In summary, yes. We compare three systems:

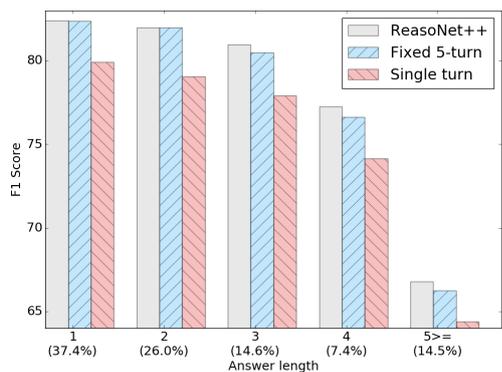

Single turn: the RC model only has one turn of reasoning. This corresponds to a model like Figure 1 without termination nodes, where the output layer always stops at $S_{t=1}$.

Fixed 5-turn: the RC model runs 5 turns of iterative attention. This is Figure 1 without termination nodes, where output layer always stops at $S_{t=5}$.

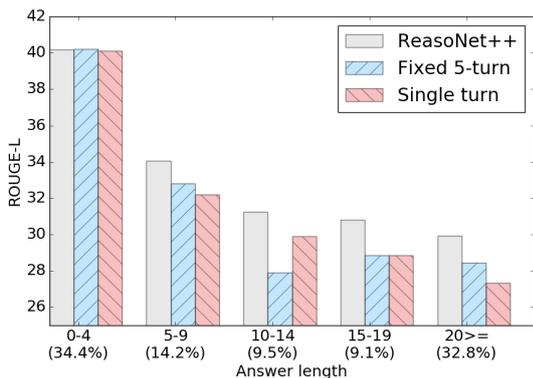

ReasoNet++ (Dynamic multiple-turn reasoning): this is the RC model in Figure 1, which can decide from 1 to T turns based on the termination probability on each Q - P pair at test time. We set $T = 5$ to compare with the Fixed 5-turn system.

The main results are shown in Table 2. We observe that both multiple turn strategies (either fixed at 5 turns, or dynamically decided based on ReasoNet++) outperform the single turn system in all metrics. The dynamic strategy further improves upon the fixed multiple 5-turn strategy. For ex-

and 0.25 dropout rate (Srivastava et al., 2014) over GRU network. The model is optimized with AdaDelta (Zeiler, 2012) with an initial learning rate 0.5.

(a) SQuAD

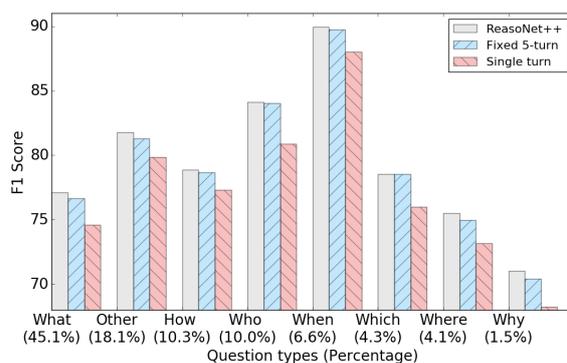

(b) MS MARCO

Figure 3: Score breakdown by answer length

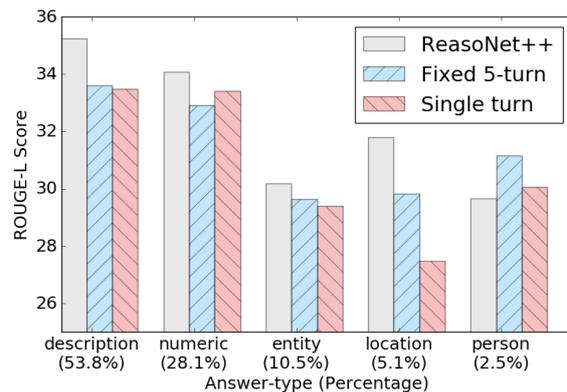

ample, the F1 score on SQuAD improves from 76.7 to 78.9 when increasing the number of turns from 1 to 5, and further improves to 79.4 with dynamic multiple turns. On MS MARCO, we see a ROUGE improvement from 36.54 (1-turn) to 36.67(5-turn) and 38.62 (dynamic multi-turn). These results convincingly show that multiple-turn reasoning is helpful for SQuAD and MS MARCO tasks. Figure 2 shows a case study of how answers improve with each turn.

4.2 What types of questions/answers benefit most from multiple-turn reasoning?

We find that improvements from multiple-turn reasoning is generally seen across the board, but particularly helps questions with longer answers. Figure 3 shows the score breakdown of Table 2 according to answer length (# of words). For SQuAD, both ReasoNet++ and Fixed 5-turn outperform Single turn for all answer lengths, and ReasoNet++ outperforms Fixed 5-turn for answer lengths > 3 . For MS MARCO, ReasoNet++ outperforms Fixed 5-turn for answer lengths > 5 ; on the other hand, there is almost no difference among systems for short answers (0-4). We hy-

(a) SQuAD

(b) MS MARCO

Figure 4: Score breakdown by query/answer type

pothesize there is a correlation between answer length and the difficulty of the question; for difficult questions there may be more potential for multiple-turn reasoning to improve results.

We also visualize the score breakdown according to question/answer type (Figure 4). For MS MARCO, the questions are annotated by the type of the correct answer: description (e.g. Q: “How to cook a turkey”), numeric (e.g. Q: “Xbox one release data”), entity, location, person. There is no such annotation for the entire SQuAD dev data, but we can classify questions by their first word: What, Who, When, Which, etc. Similar to the answer length results, we observe that multiple-turn reasoning outperforms single turn for SQuAD across the board, regardless of question type. For MS MARCO, ReasoNet++ gave large improvements over single turn in particular for description and location types. Descriptions tend to be lengthy, so this again corroborates our hypothesis that there may be more potential gains for questions requiring long answers.

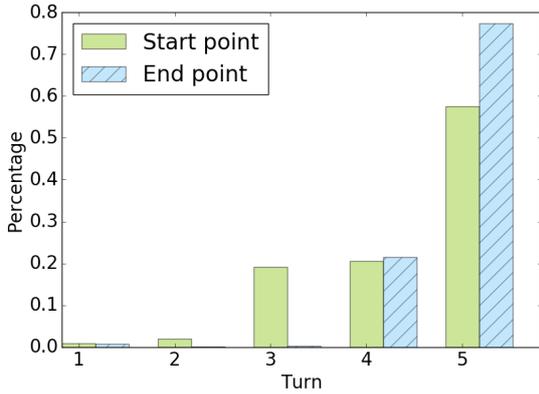

Figure 5: Distribution on the number of turns by ReasoNet++ on the SQuAD dev set. Note that start points are often decided before end points, and most answer spans are generated after 3 turns.

4.3 How many turns of reasoning are employed in practice?

We are interested in understanding the number of turns determined by ReasoNet++. When does it decide to terminate? In Figure 5, we plot the distribution of turns until the model decides on start points and end points (of the answer span).

First, note the start point is often decided before the end point, e.g. the start is already determined at turn 3 for approximately 20% of the questions, but the end does not get predicted until turn 4 or 5. Intuitively, we think it is easier to first identify the start of an answer, then use that signal as intermediate state S_t to identify the end point.

Second, there is almost no termination at turns 1 or 2, implying the model prefers more iterations of reasoning. Most terminations are done at step 4 or 5, which explains the relatively close performance results between Fixed 5-turn and ReasoNet++.

4.4 Comparison with state-of-the-art

Our ReasoNet++ model, which is an extension of ReasoNet (Shen et al., 2016), achieves scores competitive with state-of-the-art results. The official leaderboard results are shown in Table 3 (MS MARCO) and Table 4 (SQuAD) Results are divided by whether we use an individual model or an ensemble of models. For SQuAD, the ReasoNet++ ensemble model achieves the best EM and F1 test score among all published works, and places second if we include r-net. Similarly, the ReasoNet++ individual model results are in the top 1 or 2 ranks, competitive with published works like Zhang et al. (2017) and Weis-

System	BLEU/ROUGE-L	
	Dev Set	Test Set
ReasoNet++ <i>Individual</i>	38.62/38.01	39.86/38.81

Human Performance	-/-	46/47

Table 3: Official MS MARCO leaderboard performance on April 5, 2017.

senborn et al. (2017). For MS MARCO (Table 3), ReasoNet++ ranks first in test ROUGE and second in test BLEU (after Match-LSTM (Wang and Jiang, 2016)). Note that some of the models on the leaderboard use multiple-turn reasoning, while others do not. But we refrain from drawing conclusions about multiple-turn reasoning by comparing across models, due to other confounding variables, e.g. different embeddings and network architectures.

4.5 Ablation studies and model variants

We now present some ablation studies to demonstrate the differences between our ReasoNet++ and the original ReasoNet (Shen et al., 2016) in which we are based on.⁴

First, Table 5 shows the improvement from adding sub-word level modeling to ReasoNet, which only used word embeddings. We observe marked improvements of update number +1.1 F1 in SQuAD and +0.9 ROUGE in MS MARCO. Although these improvements are not as large as those we achieved with multiple-turn reasoning, they are still considerable and imply that robust representations of words is an important building block to strong RC models.

Secondly, Table 6 shows the impact of passage ranking—this is only relevant for MS MARCO, which contains multiple passages for each question/query. Recall that the RC model needs to read approximately 10 passages to answer each query, and on average only one or two passage contain answer spans. ReasoNet++ extracts answer spans from each passage independently, then combines with an IR model to output the final answer. If we assume oracle ranking from the IR model, we can achieve 62 BLEU / 63 ROUGE, suggesting that

⁴Due to time constraints, we only perform ablation studies on the embedding and passage ranking enhancements, and leave the study of the impact of co-attention to future work.

Passage ranking	38.62/38.01

Table 6: Effect of multiple passages per query in MS MARCO.

better passage ranking models (e.g. via joint training with RC models) is fruitful as future work.

5 Conclusion

This paper empirically investigates the performance of single-turn and multiple-turn reasoning on two challenging reading comprehension tasks: SQuAD and MS MARCO. To perform the analysis, we adopt the neural network model of Shen et al. (2016), which employs iterative attention and uses reinforcement learning to dynamically control the number of turns. We find that multiple-turn reasoning outperforms single-turn reasoning for all question and answer types; further, we observe that enabling a flexible number of turns generally improves upon a fixed multiple-turn strategy. While our analysis is based on a single model, we believe the conclusions will be valuable for most RC methods using attention-based neural network. Our model extension to (Shen et al., 2016) achieves results competitive to the state-of-the-art on both tasks. As future work, we plan to investigate the impact of even deeper layers of reasoning and explore fast training methods to make such methods practical for large-scale datasets.

Abstract

This paper presents a hybrid approach to the verification of statements about historical facts. The test data was collected from the world history examinations in a standardized achievement test for high school students. The data includes various kinds of false statements that were carefully written so as to *deceive* the students while they can be disproven on the basis of the teaching materials. Our system predicts the truth or falsehood of a statement based on text search, word co-occurrence statistics, factoid-style question answering, and temporal relation recognition. These features contribute to the judgement complementarily and achieved the state-of-the-art accuracy.

1 Introduction

The proliferation of social media in the Internet drastically changed the status of traditional journalism, which has been an indispensable building block of modern democracy. News are now produced, propagated, and consumed by people in quite a different way than twenty years ago (Pew Research Center, 2016). The downside is that fake news and hoaxes spread through the social network as quickly as those from trustable sources. A mechanism for *fact-checking*, i.e., finding a support or disproof of a claim in a credible information source, is thus needed as a new social infrastructure.

The sheer amount of the information flow as well as the decentralized nature of the social media calls for support to the fact-checking by information technology (Cohen et al., 2011a,b). Although its full automation seems to be beyond current technology (Vlachos and Riedel, 2014; Has-

Context: ... During the period of the Carolingian dynasty of Francia, the Roman Catholic Church preached that the religious cleansing of sins was necessary in order to achieve salvation after death. ...

Instruction: From (1)-(4) below, choose the one correct sentence concerning events during the 8th century when the kingdom referred to in the underlined portion was established.

Choices:

- (1) Pepin destroyed the Kingdom of the Lombards.
- (2) Charlemagne repelled the Magyars.
- (3) The reign of Emperor Taizong of Tang was called the Kaiyuan era.
- (4) The reign of Harun al-Rashid began.

Figure 1: Example of a True-or-False question

san et al., 2015), even its partial automation would greatly enhance the power of the current fact-checking services.

As a step towards this direction, we take up the automatic verification of a statement about historical facts against credible information sources. The test statements are collected from the world history examinations in a standardized achievement test for high school students in Japan (the National Center Test for University Admissions, NCTUA). Approximately 60% of the NCTUA world history exams are “True-or-False” questions. A question in this format consists of a paragraph of text that provides the context of the question, an instruction sentence, and four choices (Fig. 1)¹. One has to choose a correct or incorrect statement from the four choices according to the instruction.

The test statements in the True-or-False questions are thoroughly tuned and checked by the examining board so that they are not too easy nor too difficult for human, and their truth or falsehood can be objectively determined on the basis

¹The questions are posed in Japanese but we use English in the examples for the sake of readability.

of the teaching materials written according to the official curriculum guidelines. The automatic verification of these statements hence serves as an idealized but still difficult test-bed for the basic fact-checking technologies.

In previous studies, three main approaches for answering True-or-False questions were presented: passage retrieval (Kano, 2014), conversion to factoid-style question answering (Kanayama et al., 2012), and textual entailment recognition (Tian and Miyao, 2014). In these approaches, the fact-checking task is directly converted to another, existing problem setting. We however show that the test statements in the True-or-False questions have compound characteristics through an analysis of past exams (§3). Thus, direct conversion alone does not suffice for solving this task satisfactorily, because each method is built on its own problem setting, which does not fully cover the variety of the test statements, especially the false ones. In this work, to overcome this difficulty, we attempt to decompose the problems according to our observations of past exams and design a solver that integrates the ideas behind the existing methods as the features of a statistical classifier (§4). Experimental results show that our decomposition of the task of historical fact-checking is successful in that the features work complementarily and the solver achieved the state-of-the-art accuracy (§6). An analysis of the remaining errors indicates a room for further improvement by the incorporation of linguistic and domain-specific knowledge into the system (§7).

Our essential contributions to this problem are as follows.

- Careful observations of past exams were conducted, based on which hypothetical characterizations of the task were formulated. Evidences were then collected to support these hypotheses.
- According to the observed evidences, five features that range over text search, statistics, and logical entailment were designed. They were combined as the features of a classifier and yielded state-of-the-art results on the task.

2 Related Work

Fact-checking can be framed as a question-answering (QA) task in a broad sense. However, it has not been studied as intensively as other

QA tasks such as factoid-style question-answering (Ravichandran and Hovy, 2002; Bian et al., 2008; Ferrucci, 2012). Kanayama et al. (2012) proposed to convert a fact-checking question into a set of factoid-style questions. In the conversion, the named entities in a test statement are in turn replaced with an empty slot. The answer, i.e., the most appropriate word that fills the slot, was obtained by an open-domain factoid QA system. They define a confidence score that decreases when the QA system’s answer differs from the hidden named entity (i.e., the one replaced with the empty slot). They experimented the idea by *manually* converting the test statements to factoid questions. We follow their idea in designing one of the features. We however fully automatized the conversion and defined another confidence score based on a simple document retrieval system instead of a full-fledged factoid QA system (§4.2.2).

Textual entailment recognition (RTE) (Dagan et al., 2013) has been extensively studied in the field of language processing. RTE can be seen as a quite restricted form of fact-checking where two sentences t and h are given and a system judges whether t is an evidence of (i.e., it entails) h or not. Tian and Miyao (2014) showed the effectiveness of their logic-based RTE system on the True-or-False questions of NCTUA history exams cast in the form of RTE (i.e., a test statement *and* an evidence sentence are given to the system).

Recent effort pursued a more realistic task setting for RTE, in which a system is given a sentence h and a large number of candidates of its evidence $\{t_i\}$ that are drawn from a document collection in advance. The system tests the entailment relation between each of t_i s and h (Bentivogli et al., 2010, 2011). In the RITE-VAL shared task in NTCIR-2014 conference (Matsuyoshi et al., 2014), the participating RTE systems were evaluated both in the traditional RTE task setting and one that fully integrates the document retrieval and entailment recognition (i.e., only h and a document collection are given to the systems). The test sentences (i.e., h s) included those taken from NCTUA world history exams and hence the latter task setting is close to ours. The performance degradation between the two task settings was around 14% (absolute) for the case of the best-performing system. It indicates the difficulty of our task setting of the historical fact-checking.

In a series of recent papers, elementary science

questions are used as a benchmark of AI systems (Khot et al., 2015; Jansen et al., 2016; Clark et al., 2016; Khashabi et al., 2016). The questions, all in the form of multiple-choice questions, were collected from 4th grade science tests. In the majority of the questions, the choices are nouns rather than sentences as in the following example taken from (Khashabi et al., 2016):

Q. In New York State, the longest period of daylight occurs during which month?
 (A) December (B) June (C) March (D) September

The majority of them can hence be regarded as a factoid-style question with hints (i.e., the answer is one of the four). Clark et al. (2016) and Khashabi et al. (2016) demonstrated that the system performance was boosted by multi-step inference that combines, e.g., taxonomic knowledge (“N.Y. is in the northern hemisphere”) and general law (“The summer solstice in the northern hemisphere is in June”). A special kind of logical relation, temporal inclusion, is considered in our system (§4.3). The intention is however on the detection of the falsity of a statement that is not in a temporal inclusion relation with an evidence sentence. The feature based on the conversion to factoid questions is also designed for the detection of falsehood by finding a counter-evidence. The different orientations, i.e., proof of a scientific fact vs. disproof of a historical non-fact, reflect the different natures of the problems.

3 Observation of Task

We examined past True-or-False questions prior to implementing the solver. The observation targets were the NCTUA world history exams 2005, 2007, 2009, 2011, and 2013s (supplementary exam). We used four sets of high school textbooks of world history and Wikipedia as knowledge resources.

From the observations, we formulated three hypotheses as follows. First, to verify most of the test statements (i.e., the choices), it is not necessary to gather several evidence sentences across different paragraphs in the resources; usually there is sufficient information in a local portion, such as a paragraph or a sentence in a knowledge resource. This is a natural consequence of the fact that most of the test statements describe a single historical event. Second, the knowledge resources include a

Knowledge resource	Count (ratio)
Textbook	111/137 (0.81)
Wikipedia	118/137 (0.86)
Textbook + Wikipedia	129/137 (0.94)

Table 1: Ratio of correct statements that can be evidenced by a single paragraph in the knowledge resource

	Count (ratio)
NE change	163 / 275 (0.59)
Time change	47 / 275 (0.17)
NE or Time change	210 / 275 (0.76)

Table 2: Ratio of incorrect statements in which one named entity or time expression is the reason of the falsity

more detailed time expression than the questions, e.g., “1453” as compared to “15th Century,” and “1945” as compared to “1940s.” Third, the falsity of many incorrect statements is attributed to a single named entity (NE) or time expression in them. For example, Choice (2) in Fig. 1, “Charlemagne repelled the Magyars.” is an incorrect statement created by changing “Avars” to “Magyars” in a correct sentence “Charlemagne repelled the Avars.”

To support these hypotheses, we gathered evidences from past exams. First, we examined the correct statements (137 in total) to determine whether: (1) a single paragraph in the knowledge resources includes all the NEs in the statement and (2) the knowledge resources include a more detailed time expression than the statement. Table 1 shows that, in most cases, a single paragraph includes sufficient information to allow the solver to verify the truth of a statement. Among the 137 correct statements, 48 of them included a time expression. The knowledge resources provided a more detailed time for 45 out of these 48 statements (94%). It is thus important to resolve the level of detail of the time expressions. Next, we counted the incorrect statements (275 in total) which can be turned into a correct one by changing one NE or time expression in it. Table 2 shows that to detect the falsity of an incorrect statement, detection of the changed NE is crucial.

4 Features and their Combination

Based on the above observations, we designed the following five features to score the confidence of truth. This section describes them in turn and explains how they are combined as the features of a

statistical classifier.

These features are defined using several statistics collected on a set of documents. We created three document sets, D_s , D_p , and D_m , all from Wikipedia and four high school textbooks of world history, as follows. We first segmented the Wikipedia pages and the textbooks in two ways: one into a set of sentences D_s and the other into a set of paragraphs D_p . D_m is the union of D_s and D_p .

4.1 Text Search Feature

The observations revealed that, in most cases, the NEs in a correct statement are fully included in one paragraph or one sentence in the knowledge resources. The text search feature of the statement S is defined as the number of documents in D_m which include all NEs and content nouns in S . The solver expects that the greater the number is, the more likely the statement is true.

4.2 Statistical Features

The observations showed that an incorrect statement is created mainly by changing one NE in a correct sentence. To detect such a conversion, the solver estimates the strength of relatedness among the NEs in the statement. The solver uses two statistical features, which are respectively defined using global and local statistics collected on the document set.

4.2.1 Pointwise Mutual Information (PMI) Feature

The first statistical feature is PMI (Church and Hanks, 1989), which is defined for a pair of words as,

$$pmi(w_1, w_2) \equiv \log \frac{p(w_1, w_2 | D_s)}{p(w_1 | D_s)p(w_2 | D_s)},$$

where $p(w_i | D_s)$ denotes the probability of observing the word w_i in a sentence that is randomly chosen from D_s and $p(w_1, w_2 | D_s)$ denotes the probability of observing both w_1 and w_2 in a randomly chosen sentence. A low PMI score indicates the independence of the two words. The solver expects that a low PMI score indicates that two NEs are not related to each other and suggests that the statement is incorrect.

The solver calculates PMI for the pairs of an NE and the subsequent NE or a content word that appears before the subsequent NE in the statement, because the two words positioned close to

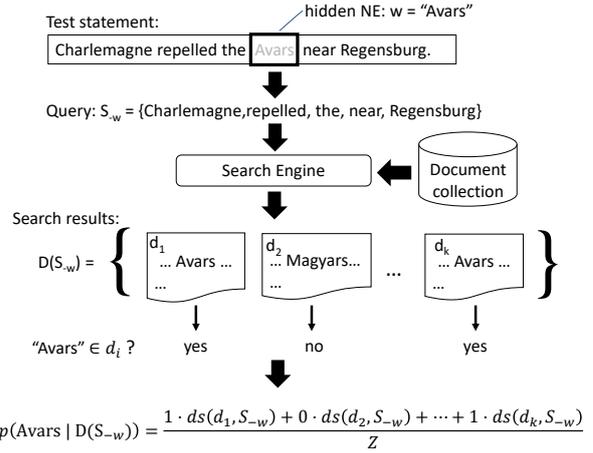

Figure 2: Calculation of the probability $p(w | D(S-w))$ of finding w in the search results $D(S-w)$

each other tend to have strong relation. We write $WP(S)$ for the set of such pairs of words in S excluding the pairs of synonymous words. The final PMI feature of the statement S is defined by the average of $pmi(w_i, w_j)$.

$$\overline{pmi}(S) = \frac{1}{|WP(S)|} \sum_{(w_i, w_j) \in WP(S)} pmi(w_i, w_j).$$

4.2.2 Virtual Question Answering (VQA) Feature

The second feature is based on the result of a search that approximates the process of factoid QA. It directly attempts to detect the changed word in an incorrect statement (Fig. 2). The solver hides each NE w in a statement S in order and makes a VQA query $S-w$, which is the set of words in S excluding w . If the statement is correct, the hidden word is expected to be found in the search results of the query $S-w$ at high probability.

For a hidden NE w , we first calculate the ratio $vqa(w)$ of the probabilities of finding w in the search results $D(S-w)$ of the query $S-w$ and in a randomly chosen document in the collection D_m :

$$vqa(w) = \log \frac{p(w | D(S-w))}{p(w | D_m)}.$$

In the numerator, we consider the probability of finding w in a document $d \in D(S-w)$ that is sampled according to the confidence on the search result d against the query $S-w$, rather than assuming

a uniform distribution on $D(S_{-w})$:

$$p(w|D(S_{-w})) = \sum_{d \in D(S_{-w})} [w \in d] \cdot p(d|D(S_{-w})), \quad (1)$$

where $[w \in d]$ is the binary indicator function that takes value 1 if d includes w , and 0 otherwise. The confidence factor $p(d|D(S_{-w}))$ is assumed to be proportional to a document score $ds(d, S_{-w})$ and we only consider top- k search results. That is, letting d_i denote the document ranked i -th in the search results according to $ds(d, S_{-w})$, we assume

$$p(d_i|D(S_{-w})) = \begin{cases} ds(d_i, S_{-w}) \cdot Z^{-1} & (1 \leq i \leq k) \\ 0 & (k < i) \end{cases} \quad (2)$$

where $Z = \sum_{j=1}^k ds(d_j, S_{-w})$ is the normalization factor. From (1) and (2), we have

$$p(w|D(S_{-w})) = \sum_{\substack{i=1 \\ w \in d_i}}^k \frac{ds(d_i, S_{-w})}{\sum_{j=1}^k ds(d_j, S_{-w})}.$$

We set $k = 30$ in our experiments.

The document score ds is defined by Term Frequency-Inverse Document Frequency (TF-IDF), which is written as

$$ds(d, S_{-w}) = \frac{1}{\ell(d)} \sum_{w' \in S_{-w}} tf(w', d) \cdot idf(w'),$$

where $tf(w', d)$ is the frequency of the word w' in the document d , $idf(w')$ is the inverse document frequency of the word w' , and $\ell(d)$ is the length of d .

The VQA feature uses document-local statistics (except for IDF) and counts only in the top- k search results. However, in this feature, all the query words jointly contribute through the document score ds , in contrast to the case of PMI where only the pairwise relations are considered. The final VQA feature is defined as the average of $vqa(w)$.

$$\overline{vqa}(S) = \frac{1}{|\text{NE}(S)|} \sum_{w \in \text{NE}(S)} vqa(w),$$

where $\text{NE}(S)$ is the set of NEs in the statement S .

4.2.3 Length Feature

We also use the length of the statement (number of words) as a feature. PMI and VQA features of a long statement tend to have low values regardless of the correctness of the statement. The length feature adjusts this bias.

4.3 Time Feature (Logical Entailment)

The observations revealed that the level of detail of the time expressions in the choice sentences differs from that in the knowledge resources. The time information is a key factor of historical events. Therefore, the solver needs a more rigorous inference about temporal relations than about the matching of other NEs. We implemented a module that logically determines the inclusion relation between two time expressions. The time expressions in the statements and the knowledge resources are extracted and converted to ranges of date (e.g., “19th century” \rightarrow 1801-01-01 ... 1900-12-31) by NormalizedNumexp². If the range of a time expression in a statement includes one in the knowledge resources, they are judged as “matched”. The solver hides the time expression t from the statement S and makes the VQA query S_{-t} . The time feature of the statement S is defined as the number of documents in the top- k search results of query S_{-t} ($k = 30$) that include a time expression that matches the hidden time expression t .

4.4 Combination of Features (Machine Learning)

The solver combines the above five features using statistical binary classifiers. In our settings, N training samples $\{(x_1, y_1), \dots, (x_N, y_N)\}$ are given, where x_i is a five-dimensional feature vector and $y_i \in \{1, 0\}$ indicates the truth or falsehood of the sample. We used the “scikit-learn” toolkit³ and created an ensemble of three classifiers, by simply averaging their $[0, 1]$ probabilistic outputs to reduce variance of each classifier (Pedro, 2012). As the classifiers, we used logistic regression, gradient boosting classifier, and support vector machine. The hyperparameters of each classifier are determined by cross validation.

5 Resources and Common Modules

This section describes additional modules that were used in the experiments described in §6.

²<https://github.com/nullnull/normalizeNumexp>

Dataset	# test statements	%correct	%incorrect
DEV	412	33.3%	66.7%
TEST	1112	35.3%	64.7%

Table 3: Size of development and test data

5.1 Custom Dictionary

We use a named entity dictionary and a synonym dictionary, both of which were manually compiled based on textbooks and Wikipedia. The named entity dictionary was created by mainly using the index of textbooks. In the dictionary, approximately 20,000 NEs are categorized into various classes (time, person, etc.) by human experts. The synonym dictionary was created based on Wikipedia redirect and bracketed expressions after NEs (e.g., “Charlemagne (Charles I)”). Additionally, the solver uses Nihongo Goi-Taikai⁴, a Japanese thesaurus, to discriminate NEs from common nouns.

5.2 Retrieval Module

The retrieval module of the solver is based on Apache Solr⁵. We used the Solr defaults (TFIDF-weighted cosine similarity) and the Kuro-moji Japanese morphological analyzer⁶ to tokenize Japanese sentences. As mentioned in §4, all knowledge resources are indexed at overlapping levels of the sentence and the paragraph, and retrieval is executed across fields of both levels by means of the ExtendedDisMax Query Parser⁷.

5.3 Matching of Words

When two words are compared in the solver, some suffixes are ignored to absorb orthographical variants (e.g., “Japan” and “Japanese” are considered to be the same). The suffix list is made from high frequency morphemes (Okita and Liu, 2014). We examined the frequency of morphemes in the textbooks, and then from the top, if the morpheme is a suffix of NE, we added to the list.

Additionally, if a word w in a question has a synonym in a document retrieved from the knowledge resources, the word w is considered to be included in the document.

5.4 Complementing the Lack of Information

The truth or falsehood of a choice sentence is often indeterminable without the information pro-

⁴<http://www.iwanami.co.jp/hotnews/GoiTaikai/>

Context: Coexistence between Christians and Muslims was seen on the Iberian Peninsula in the Middle Ages, ...

Instruction: From (1)-(4) below, choose the most appropriate sentence that describes the history of Spain in the 20th century related to the underlined portion.

Choices:

- (1) The French army suffered in guerrilla warfare in Spain.
- (2) In the Spanish Civil War, Germany and Italy maintained a policy of non-intervention.
- (3) Franco established a dictatorial regime.
- (4) The Philippines were seized from it by the U.S.A.

Figure 3: Question 31 in the 2011 data set

vided in the context and the instruction. For instance, (1), (3), and (4) in Fig. 3 all describe historical facts but the condition in the instruction, “in the 20th century,” turns (1) and (4) to false since they happened in the 19th century. Meanwhile, the context and the instruction also include irrelevant information that does not affect the truth of the choices. For instance, the underlined portion, “Iberian Peninsula,” is redundant since the instruction asks more restrictively about “Spain.” Furthermore, “the Middle Ages” in the context is not relevant to any of the choices.

The instruction tends to include a condition that applies to all choices, such as the location and the time of the historical events described in them. The context usually provides relevant condition only when it is explicitly indicated so.

We utilize these observations as well as the category of the NEs to extract only relevant keywords from the instruction and the context. First, the location names and time expressions are extracted from the instruction if a choice includes no such phrases. The NEs in the underlined portion of the context are then extracted if the instruction includes none of the phrases in a pre-defined set of cue phrases, such as “related to,” that indicate the context is not so relevant to the determination of the truth of the choices. Finally, among the NEs extracted from the context, we discard those categorized as an abstract concept in the NE dictionary, such as “social phenomena” and “social role.” For the choice (1) in Fig. 3, “the 20th century” in the instruction is extracted since (1) does not include a time expression but “Iberian Peninsula” in the context is not extracted since the instruction refers to the underlined portion using the cue phrase “related to.”

6 Experiments

6.1 Experimental Setup

We exhaustively extracted the True-or-False questions from past NCTUA world history exams held from 2005 to 2015 and evaluated the accuracy of the true-or-false (T/F) binary predictions individually made on each of the choice sentences⁸. The data was divided into two disjoint subsets, DEV and TEST. DEV consists of the questions used in the preliminary analysis described in §3. TEST consists of the rest of the questions. Table 3 provides the number of the test statements (i.e., the choice sentences) and the distributions of the correct and incorrect statements. Approximately 20% of the questions ask to choose a false statement in four choices, which include three correct statements. For reference, we also report the accuracy on the 4-way multiple-choice questions. The answer to a multiple-choice question is the choice on which the ensemble of the classifiers yielded the maximum or minimum score.

For the evaluation, we adopted cross validation. DEV and TEST were divided into 20 subsets, each of which was taken from the questions in the same exam. We applied 20-fold cross validation on the subsets. We summarized the results with DEV and TEST respectively.

6.2 Experimental Results

To evaluate the importance of each feature, we tested two feature combination patterns. In the

⁸ Although the instruction sentences indicate either (i) only one of the choices is correct (“choose the correct one”) or (ii) only one of them is incorrect (“choose the incorrect one”), our solver does not utilize this information in any form when it makes binary T/F prediction.

System	T/F binary acc.	4-way acc.
Kanayama et al. (2012)	79% (73/92)	65% (15/23)
This paper (VQA only)	73% (67/92)	52% (12/23)
This paper (all features)	84% (77/92)	83% (19/23)

Table 6: Comparison with manual question conversion on NCTUA 2007 questions

first pattern, the classifiers were trained excluding one feature (Table 4) and in the second one the classifiers were trained with only one feature (Table 5). These results show that the VQA and Text search features are more important than the others. The highest T/F judgement accuracy, 80.8% on DEV and 74.2% on TEST, was obtained using all the features. On the DEV set, the ablation of one of the five features resulted in a loss of 0.2-6.8 points in the T/F judgement accuracy and 0.0-11.6 points in the 4-way multiple-choice accuracy (Table 4). It suggests that the combination of the features is more effective for comparing the confidence on the truth of four statements rather than for the T/F judgement on a single statement. Comparison of the results in Table 5 with ‘All’ in Table 4 further supports it; the effect of combining the five features compared with the result by a single feature is far more evident in the accuracy on the multiple-choice format. These results show the five features worked complementarily and validates our decomposition of the task into the five features.

Table 6 presents a comparison with Kanayama et al. (2012)’s result based on the conversion of T/F judgement to factoid-style questions. The test questions were taken from NCTUA 2007 exam. This comparison is not strict in a few regards. First, Kanayama et al. used English translations of the questions while we used the original questions in Japanese. Second, they manually supplied the choice sentences with necessary information extracted from the instruction and the context. Finally, they converted the choice sentences to factoid-style questions also manually, while our system is fully automated. The results of VQA feature are slightly worse than Kanayama et al.’s which is based on a similar idea. The addition of the other four features boosted the accuracy and it surpassed their result.

Finally, Table 7 presents the accuracy of our system in comparison with previously reported results by fully automatic systems (Shibuki et al., 2014, 2016). We compared the accuracy on the

System	4-way acc. NCTUA 2007
This paper	83% (19/23)
Okita and Liu (2014)	74% (17/23)
Kano (2014)	57% (13/23)
Sakamoto et al. (2014)	52% (12/23)

System	4-way acc. NCTUA 2011
This paper	90% (18/20)
Kobayashi et al. (2016)	80% (16/20)
Takada et al. (2016)	60% (12/20)
Sakamoto et al. (2016)	60% (12/20)

Table 7: Comparison with previous automatic systems

True-or-False questions in the 4-way multiple-choice format. Our system achieved a higher accuracy than the best previous results on NCTUA 2007 and 2011 exams.

7 Error Analysis

We now show some examples that cannot be solved by our current approach and describe the cause of the errors.

Antonym of Verbs (10 sentences) Some incorrect statements in the choices are created by changing a verb to its antonym. For example, in Question 8 in the 2009 exam, the falsity of the sentence “The Agricultural Adjustment Act (AAA) resulted in the prices of agricultural produce being lowered,” is attributed to the verb “lowered” because the sentence becomes correct if we replace “lowered” with “raised.” To properly recognize such false sentences, we need to utilize lexical knowledge about the antonymy and synonymy relations among verbs.

Semantic Roles (five sentences) Many historical events involve two or more participants. For example, in Question 3 in the 2007 exam, the sentence “The Almohad Caliphate, which advanced into the Iberian Peninsula, was overthrown by the Almoravid dynasty.” includes the two participants, “The Almohad Caliphate” and “the Almoravid dynasty.” The sentence is incorrect because the truth was “The Almoravid dynasty was overthrown by the Almohad Caliphate.” To detect this kind of falsity, we need to recognize the semantic roles (e.g., agent and patient) of the participants in the event denoted by the verb. It is beyond the expressiveness of the VQA and PMI features that are largely based on word cooccurrence.

Indirect Description of Time (four sentences)

In Question 15 in the 2007 exam, the instruction includes the following phrase: “choose the one term that correctly describes the religion that was established after the time of Genghis Khan.” The current system cannot extract any temporal information from “after the time of Genghis Khan,” which is equivalent to “after the *death* of Genghis Khan” and thus to “after 1227.” To this end, we need to analyze the combination of the temporal expression (e.g., the time before/after/during of X) and the entity type (e.g., X : Person) and utilize domain-knowledge such as birth/death or establishment/abolishment years of historical entities.

8 Conclusion and Future Work

As a step towards the goal of automated fact-checking, we have worked on the task of true-or-false judgement on the statements about historical facts. We scrutinized the characteristics of the task and designed five confidence metrics according to the observations, which are integrated as the features in a statistical classifier. Experimental results showed that the five features complementarily contributed to the discrimination between a true statement and a false one. Our system achieved the state-of-the-art accuracy on a few datasets. An analysis of the remaining errors indicated a room for improvement by the incorporation of linguistic knowledge such as antonymy of verbs and semantic roles of the events, and extraction of temporal information based on linguistic patterns and domain-knowledge.

Abstract

This paper presents an approach to identify subject, type and property from knowledge base for answering simple questions. We propose new features to rank entity candidates in KB. Besides, we split a relation in KB into type and property. Each of them is modeled by a bi-directional LSTM. Experimental results show that our model achieves the state-of-the-art performance on the SimpleQuestions dataset. The hard questions in the experiments are also analyzed in detail.

1 Introduction

With the popularity of the Internet, more and more new information is generated every day. The information may be stored in unstructured data, such as Wikipedia, which is presented as an article or web page, or in the form of structured data. Knowledge base (KB), such as Freebase (Bollacker et al., 2008) and DBpedia (Lehmann et al., 2015), is very popular. The information in the KB is a description of the relationship between two entities and is stored in the form of (subject, relation, object) triple. In KB, each entity is represented by a unique id, for example, J.K. Rowling's mid (Machine ID) in Freebase is "m.042xh".

With these large-scale open-domain KBs, it is important to access the knowledge efficiently and effectively to meet what users need. The most direct and close to people's life is question answering (QA) system in natural language. People can ask any questions in their familiar languages, and then

use the QA system to get answers from the web resources. Current QA research is often based on KB to find appropriate triples for answering question, which is called QA over KB.

QA systems can be classified by the form of the question. There are two categories of questions in QA system, i.e., simple questions and complex questions. Simple questions can be answered by exactly one triple in the KB. For example, the question "Who is the author of Harry Potter?" can be answered by triple "(Harry Potter, author, J.K. Rowling)". Although this category is "simple" question, retrieving a triple from the KB is not a trivial task due to the billions of facts in the KB. Complex questions contain more restrictions. These questions may involve two or more triples in the KB, or have other semantic constraints to restrict the answers to a smaller set. For example, "the first" in the question "What is the name of the first Harry Potter novel?" restricts that there is only one answer. Previous researches showed that simple questions are the more common category in community QA websites (Fader et al., 2013). This paper focuses on factoid simple question-answering over Freebase.

Simple question can be answered with the object of one KB triple. Thus, the systems only need to find the subject and relation of the triple which can describe the question properly. The issues of simple QA are the identification of the subject entity in a question, and the resolution of the gap between the natural language expression in the question and the relation description in the KB. After a QA system receives users' questions, it needs to transform a question into a KB query, e.g. SPARQL. The question can then be transformed into the KB query, which can access KB to get the answer.

Previous simple QA model often adopts a two-step paradigm. Entity-linking step identifies the subject entities in questions, and forms the candidate entity set and relation set. The candidate relation set is formed by all the relations which have connections with any entity in candidate entity set. Relation-finding step further identifies a proper relation from the candidate relation set. Dai et al. (2016) propose a neural-network based two-step approach to simple QA over Freebase, and formulate the task into a probabilistic form. Given a question q , the first step is to find the candidate relation r with high probability $P(r|q)$. The second step is to find the subject s with high $P(s|r, q)$. As a result, the object in the KB triple which contains the subject s and the relation r with the highest $P(s, r|q)$ is the answer.

The relation in KB triple has hierarchical structure: domain-type-property. For example, in “people.person.place_of_birth”, “place_of_birth” is the property used to present the birth place of a person. The type of this relation is “person”, and the domain is “people”. In Freebase, many relations have the same property, but are in different types. For example, both “film.film.genre” and “music.artist.genre” have the property “genre”, but they are under different domains and types. These two relations are regarded as the same if we only consider the property. The major issue is: they are different relations although they have the same meaning. On the other hand, if the whole relation is considered as a class, the distribution of relations is getting sparser. The past two-step approaches cannot distinguish the subtlety in the structured relation.

In this paper, we will propose a novel three-step approach, including subject, type and property identification steps, to deal with the hierarchical structure of the relation. Our approach introduces new features in subject identification to distinguish similar entities from different aspects. Moreover, splitting relation into type and property predicts relation more precisely. Experimental results show our model outperforms the existing models and achieves a state-of-the-art accuracy of 76.7%.

This paper is organized as follows. Section 2 introduces related works of QA system. Section 3 presents our three-step paradigm. Section 4 shows the experiments on the SimpleQuestions dataset

(Bordes et al., 2015) and compares ours with previous works. We also discuss the importance of each component of our system. Section 5 analyzes the errors in the experiments. Section 6 concludes the remarks.

2 Related Works

Previous simple QA models can be divided into two categories. The first one is based on semantic parsing, which maps a question to its logical form. Then, the logical form can be transformed to SPARQL for KB retrieval.

Berant et al. (2013) present a semantic parser that does not need to be trained through the annotated logical form. They construct a lexicon that maps natural language phrases to KB relations by aligning large text corpus with Freebase. Candidate logical forms can be obtained by this lexicon and the other bridging operations.

Berant and Liang (2014) propose a semantic parser via paraphrasing. They use the intermediate question to deal with the problem of the mismatch between input question and its logical forms.

Yih et al. (2015) treat a question as a query graph, which can be directly mapped to its logical form. Semantic parsing is then equivalent to finding a sub-graph of the KB which can represent the question.

The semantic parsing approach which often requires the human annotated logical form may increase the cost of obtaining training data. Although the use of rule-based method to generate logical forms can reduce the use of annotated data, it limits the application domain. The second approach is information extraction, which needs only question-answer pairs for training. This method retrieves some candidate answers from KB for each question, and ranks the candidates through several features. Deep neural network models are often employed for deriving the vector representations of questions and the KB elements.

The Memory Network based QA system is proposed by Bordes et al. (2015). By embedding all of the KB elements and questions in the same vector space, the system can deal with the relationship between input language and the KB language.

Glob and He (2016) propose a character-level, attention-based encoder-decoder QA model. Their

model embeds the questions and KB elements by a long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) encoder and a CNN-based encoder, respectively. And a LSTM decoder with attention mechanism is used to predict the appropriate answer entity and relation.

Dai et al. (2016) formulate the QA problem into a probabilistic form. Given a question, the answer is the triple in KB containing the subject and relation with the highest conditional probability. They first use a focused pruning method to tag the span in question which is most probable to be the subject entity and gets the candidate answer triples. Then they use a relation network and a subject network, both are a two-layer bidirectional-GRU model, to get the similarity scores between candidate triples and question. We modify their probabilistic form with the splitting of the relation part r into type t and property p .

Dong et al. (2015) introduce a multi-column CNNs (MCCNNs) to analyze the question in three different aspects: answer path, answer context and answer type. The system represents the question in three low-dimensional vectors, each of them then matches to one of the answer aspect to derive the scores of candidates.

Yin et al. (2016) also use the CNN-based approach to implement the QA system. They use a word-level CNN with attentive max-pooling to model the relationship between KB relations and question pattern. They also add an active linker, which is similar to the focused pruning method in Dai et al. (2016), to reduce the number of candidates and improve the performance significantly.

3 Methodology

Our method includes subject identification, type identification, and property identification steps, as shown in Figure 1. We first give an overall picture and then describe each of them in deep in the following sections.

3.1 A Three-Step Paradigm

The relation in a Freebase triple has a hierarchical structure in three levels: domain, type, and property. Many relations have the same property but they are in different types and domains. For example, both

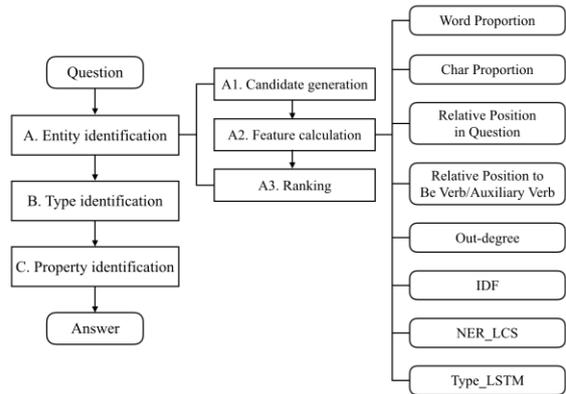

Figure 1: System Overview.

the relations “wine.wine.color” and “roses.roses.color” are used to describe the color of things, but they are in type “wine” and “roses”, respectively. We separate a relation into type and property parts to understand the question meaning more precisely.

Given a KB \mathcal{K} and a question q , the three-step paradigm aims at finding a KB triple containing s , t , and p with the highest probability $P(s, t, p|q)$, where s is a subject, and t and p are type and property of a structured relation, respectively. The process is formulated by Equations (1) and (2). The answer of the question is the object o of the triple (s, r, o) in \mathcal{K} .

$$P(s, t, p|q) = P(s|q) \cdot P(t|s, q) \cdot P(p|s, t, q) \quad (1)$$

$$s^*, t^*, p^* = \operatorname{argmax}_{s, t, p \in \mathcal{K}} P(s, t, p|q) \quad (2)$$

3.2 Entity Identification

The first step is to find potential entities in the question, and link them to KB. We use the Freebase subset FB5M in the SimpleQuestions dataset as the KB. We retrieve all candidate subject entities in question from the KB and calculate their entity linking scores on account of eight features, as in steps A1-A3 of Figure 1.

To find candidate entities for a question, we extract mentions in the question by maximum string matching. A mention that matches an entity name or an entity alias is extracted. When multiple matches are found in an overlapped span, the longest one is taken. And the mention is filtered if it is a stop word or a number that contains less than four

digits. All the entities in \mathcal{K} that have the same names or aliases as the mentions form the candidate entity set.

After obtaining all the candidate entities, we assign each of the candidates a linking score. The score is measured by a learning-to-rank model with eight features in different aspects. The eight features are described as follows.

Word Proportion (Yin et al., 2016): We compute the proportion as the length of candidate entity divided by the length of the question. The length is measured by the number of words. The longer the matched entity name is, the more likely it is a subject.

Char Proportion: Similar to word proportion, the length is computed by the number of characters instead.

Relative Position in Question (Yin et al., 2016): The relative position of a candidate entity is the position of its last token divided by the length of the question (in words). That models an observation: most entity is far from the beginning of the question.

Relative Position to Be Verb/Auxiliary Verb: Subject entity tends to be close to and behind Be verb/auxiliary verb in a question. We take the subtraction of the Be verb/auxiliary verb position and the first token of candidate entity position as α . If the candidate entity position is before the Be verb/auxiliary verb, this feature is α , which is a negative number. Otherwise, this feature is $1/\alpha$, which is a positive number. If no such verbs exist, this feature is set to 0

Out-degree: The number of out-going links of the entity in the KB is taken as Out-degree feature. The more the number of links the entity has, the higher the feature value is and the entity in the KB is more informative. The direction of links from subject to object represents the impact of the entity.

IDF: We take each question in SimpleQuestions training set as a document, and compute the inverse document frequency of the entity. The higher the value is, the more specific the entity is.

NER_LCS: We use the LSTM-CRF named entity recognition (NER) tagger¹ (Lample et al., 2016) to find the span from the question that is most

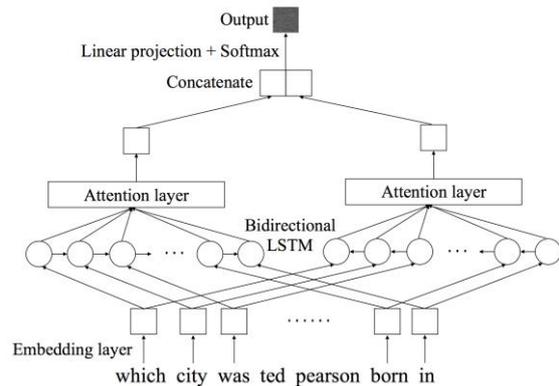

Figure 2: Structure of Type_LSTM in entity identification.

likely to be a subject entity, and compute the length of the longest common subsequence (in characters) between the candidate entity and the words in the tagged span. The tagger consists of an embedding layer, a bidirectional-LSTM layer, and a conditional random field layer to predict the label for each word. The higher the NER_LCS value is, the more possible the candidate is a subject entity.

Type_LSTM: Each entity has entity types in Freebase to describe its characteristics, e.g., entity “Alex Golfis” belongs to types “person”, “actor”, and “deceased_person”. There are total 500 types for entities in FB5M. For a question, we estimate the types of its subject. A bidirectional-LSTM with attention is trained to derive the probability distribution of each question over the 500 types. The structure of the network is shown in Figure 2. The training input of the LSTM is the whole questions and the types of their ground truth entities, and the training objective is categorical cross entropy. The test input is a question, and the output is a probability distribution of the question over the 500 types. We can get the type information of the candidate entity from Freebase, and sum over all dimensions corresponding to the types to get this feature. It means how probable the question is in some types.

With the above eight features, support vector machine for ranking (SVM^{rank}) (Joachims, 2006) is trained to combine these features and derive a score $u_1(s, q)$ for each candidate entity s in the question q . Then each entity has the probability $P(s|q)$:

¹ <https://github.com/glample/tagger> .

$$P(s|q) = \frac{\exp(u_1(s, q))}{\sum_{s'} \exp(u_1(s', q))} \quad (3)$$

where s' is an entity in the candidate entity set. For the entities in the KB but not in the candidate entity set, their $P(s|q) = 0$.

3.3 Type Identification

Given a question q , the type network determines the type of the relation most likely to be answered. We use $E(t)$ to represent the embedding of the type t , and use $g_1(q)$ to represent the vector of question q . Our goal is to make the cosine similarity between $g_1(q)$ and the correct type embedding $E(t^*)$ higher than the cosine similarities between $g_1(q)$ and the other types.

The network structure is shown in Figure 3. First, the question vector $g_1(q)$ is generated by a bidirectional-LSTM model. We change the words in q to lowercase and remove the punctuation. Then we put the words into the embedding layer. After the bidirectional-LSTM layer, the two vectors in left and right directions are concatenated together. The concatenated vector is put into a linear projection layer with sigmoid, and the question vector $g_1(q)$ is generated. After that, we calculate the similarity between $g_1(q)$ and different type embeddings $E(t)$. The embedding $E(t)$ is trained with the bidirectional-LSTM model, and has the same dimension as $g_1(q)$. $E(t)$ and $g_1(q)$ are in the same space so that the cosine similarity $u_2(t, q)$ can be computed by Equation (4).

$$u_2(t, q) = \cos(g_1(q), E(t)) \quad (4)$$

The probability of type t given the question q and the candidate entity set is defined as follows:

$$P(t|s, q) = \begin{cases} \frac{\exp(u_2(t, q))}{\sum_{t'} \exp(u_2(t', q))}, & \text{if } t \text{ has link with } s \\ 0, & \text{otherwise} \end{cases} \quad (5)$$

where t' is a type in the candidate type set. To reduce the computation and the number of candidate types, only those types which have links with an entity in the candidate entity set is chosen into the candidate type set. $P(t|s, q)$ is set to 0 for those types which are impossible to be the correct answer due to the lack of links with any candidate entity.

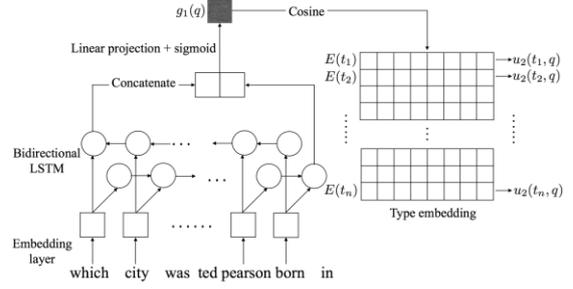

Figure 3: Type identification network.

For training the type network, the hinge loss with negative samples is the objective function to be minimized.

$$\ell(\theta_t) = \sum_{i=1}^{N_t} \max(0, m_t - u_2(t^*, q) + u_2(t_i, q)) \quad (6)$$

where θ_t is the parameters to learn, N_t is the number of negative samples, m_t is the margin, t^* is the correct type, and t_i is the type randomly sampled from all types except t^* .

3.4 Property Identification

Given a question q , property identification determines the property of the relation most likely to be answered. We use $E(p)$ to represent the embedding of the property p , and $g_2(q)$ to represent the vector of question q . Similar to the type network, our goal is to make the cosine similarity between $g_2(q)$ and the correct property embedding $E(p^*)$ higher than the cosine similarities between $g_2(q)$ and the other properties.

The structure of the property network is the same as that of the type network, which is shown in Figure 3, but all the weights and embedding matrixes are not shared with the type network. After deriving $g_2(q)$ and $E(p)$, we compute the cosine similarity $u_3(p, q)$:

$$u_3(p, q) = \cos(g_2(q), E(p)) \quad (7)$$

The probability of property p given question q , candidate entity s , and candidate type t is defined as follows:

$$P(p|s, t, q) = \begin{cases} \frac{\exp(u_3(p, q))}{\sum_{p'} \exp(u_3(p', q))}, & \text{if } p \text{ has link with } s, t \\ 0, & \text{otherwise} \end{cases} \quad (8)$$

where p' is a property in the candidate property set. To reduce the computation and the number of candidate properties, only the properties which have links with an entity in the candidate entity set and

belongs to a type in the candidate type set are chosen into the candidate property set. $P(p|s, t, q)$ is set to 0 for those properties which are impossible to be the correct answer due to the lack of links with any candidate entity and type.

For training property network, the hinge loss with negative samples is the objective function to be minimized.

$$\ell(\theta_p) = \sum_{i=1}^{N_p} \max(0, m_p - u_3(p^*, q) + u_3(p_i, q)) \quad (9)$$

where θ_p is the parameters to learn, N_p is the number of negative samples, m_p is the margin, p^* is the correct property, and p_i is the property randomly sampled from all properties except p^* .

4 Experiments

The SimpleQuestions² dataset (Bordes et al., 2015), which contains 75,910 training data, 10,845 validation data, and 21,687 test data, is adopted in the experiments. The evaluation is the same as in Bordes et al. (2015). The predicted answer is correct when the subject-relation pair is the same as the correct answer. We train our model on the training set. The validation set is used for early stop and parameter tuning. The test set is used for evaluation.

4.1 Experimental Setup

The number of negative samples used in SVM^{rank} is set to 5. Other parameters for SVM^{rank} are $C = 0.1$, $\text{epsilon} = 0.01$, and $\text{loss function option} = 2$. The word embeddings used in each neural network is initialized with the pre-trained GloVe (Pennington et al., 2014) with the dimension of 300. All the networks are optimized by mini-batch and Adam (Kingma et al., 2014) with the learning rate 0.001.

The TYPE_LSTM in entity identification step has a drop rate of 0.2. The hidden size of LSTM is

N	(Yin et al., 2016)		Our approach
	Passive	Active	
1	56.6	73.6	80.9
5	71.1	85.0	90.2
10	75.2	87.4	92.2
20	81.0	88.8	93.7
50	85.7	90.4	95.1
100	87.9	91.6	96.0

Table 2: Hit rates of the ground-truth entity.

500. Batch size is 128. The parameters of type network and property network are the same. Maximal question length is 25. Mini-batch size is 100. The type and property embeddings are 500-dimensional with randomly initialized. The hidden size of LSTM is 500. Both hinge loss margins m_t and m_p are 0.4. The numbers of negative samples N_t and N_p are 65.

4.2 Overall Results

Table 1 shows the performances of our model compared with the other four methods. Bordes et al. (2015) use a memory network. Dai et al. (2016) employ a conditional focused neural-network based approach. Yin et al. (2016) apply attentive convolutional neural network with the passive or active linker. Golub and He (2016) use the character-level encoder-decoder framework. In our approach, “probability” means the outcome is the triple with the highest probability computed by Equation (1). We find that the subject entity and the property are more important than the type. The approach “sum” combines the scores $u_1(s, q)$, $u_2(t, q)$, and $u_3(p, q)$ by weighted summation, and selects the triple with the highest weighted sum. The weights are $\text{entity:type:property} = 4:1:3$, which are tuned on the validation data.

Our “probability” approach outperforms all previous models on FB5M, including the previous best model by Yin et al. (2016). The “sum” approach even significantly outperforms the “probability” approach on McNemar’s test ($p < 0.01$).

4.3 Entity Identification Results

This section discusses the performance of the entity identification step. The hit rates of the top N entities are shown, which means the coverage of

² <https://research.fb.com/downloads/babi/>.

the ground truth entity by top- N results. $N \in \{1,10,20,50,100\}$. Entity linker proposed by Yin et al. (2016) has two versions, passive and active linker. The difference between them is that they use the longest consecutive common subsequence between question and KB entity names to get candidates in the passive linker. On the other hand, the active linker first gets the span from the question that is most likely to be a subject entity by sequential labeling, and the linker uses the labeled span to search the candidate entity from KB. The number of the candidates in the active linker is less than the passive linker, because the active linker uses specific span in question to search candidates, and entities not in this span are filtered out.

Table 2 shows our performance in entity identification compares to Yin et al. (2016). Our entity linker outperforms their approach by over 7% in top-1 result using FB5M as background KB. We have six new features to score the entities in different aspects. The features “Char Proportion” and “Relative Position to Be Verb/Auxiliary Verb” can analyze the entities by their surface form in question, e.g., name and relative position. The features “Out-degree” and “Type_LSTM” can distinguish entities even if they have the same name. The “IDF” feature can kick out common entities and keep the more important ones. And “NER_LCS” feature has the similar effect to the active linker of Yin et al. (2016), but our feature can withstand the wrong subject entity prediction in sequential labeling, because we do not filter out any candidates, we give them the lower score instead.

4.4 Importance of Entity Identification Features

In this section, we discuss the importance of each feature in entity identification in three ways. We first show the performances with a single feature. And then, we consider the performances with one feature or a group of features being removed.

Performance with Single Feature

Table 3 shows the hit rates of the top N entities generated by a single feature. The feature “NER_LCS” has the best performance because this feature contains a part of information from the four surface

Features	N					
	Hit rates @ N					
	1	5	10	20	50	100
Word Prop.	41.0	62.7	70.5	77.6	85.8	90.3
Char Prop.	55.5	73.7	78.9	83.4	88.9	91.7
Rel. Position in Q	16.7	36.5	47.7	60.9	77.0	86.4
Rel. Position to BeV./AuxV.	30.2	44.2	52.6	61.4	75.7	84.2
Out-degree	15.0	39.6	52.5	67.2	82.6	89.5
IDF	43.4	68.9	76.4	82.5	88.5	91.6
NER_LCS	59.5	77.0	81.5	85.5	90.1	92.6
Type_LSTM	44.1	68.8	77.0	85.3	91.6	94.4

Table 3: Hit rates generated by a single feature in entity linker.

form features: “Word Proportion”, “Char Proportion”, “Relative Position in Question”, and “Relative Position to Be Verb/Auxiliary Verb”. The NER tagger labels the span of possible position of the subject entity in a question, and thus “NER_LCS” contains the position information. Moreover, the length of the longest common subsequence between the candidate entity and the words in the span gives the length proportion information.

The feature “Out-degree” has the lowest performance in $N=1$ hit rate, because the entities with many out-going links sometimes represent that they are general entities. For example, the entity “album (m.02lx2r)” in question “Which genre of album is harder.....faster?” has 323,467 out-going links in FB5M, but the subject entity “harder.....faster (m.01jp8ww)” has only 5 links. Although this feature sometimes highlights the general entities, it can distinguish entities that have the same names with the help of other features.

Table 3 also shows that the performance of “Relative Position to Be Verb/Auxiliary Verb” is almost twice the performance of “Relative Position in Question”. It shows that the observation about position “subject entity tends to be close to and behind Be verb/auxiliary verb in a question” is more appropriate, and the Be verb/auxiliary verb plays an important role in identifying entities.

Performance without One of the Features

Table 4 shows the hit rates of the top N entities generated by removing one of the eight features from the entity linker. First, we can see that the performances without one of the first four features are

only reduced by about 1%, because the feature “NER_LCS” contains a part of the information from them, and it can make up for the removal of them. And then, we can find that although the performance of the feature “Out-degree” has the lowest accuracy in Table 3, its removal affects the performance by more than 2%.

The removal of “Type_LSTM” has the greatest impact. The result with this feature outperforms the result without it by 6%. The comparison shows the importance of the entity types which can help us get deeper meanings of an entity. And the “Type_LSTM” is difficult to make up by other features.

Performance without a Group of Features

Table 5 shows the hit rates and overall accuracy of our “probability” approach generated by removing a group of features from the entity linker. We group the features with similar effect together. The first four features in Table 3 are about surface forms of entities, and thus they are put together. The “Individual features” group contains features “Out-degree” and “Type_LSTM”, which can distinguish entities with the same name. The features “IDF” and “NER_LCS” are grouped into “features of specificity”, which can identify the more likely subject entities in the question and kick out common entities.

The removal of individual features reduces the performance of entity identification by more than 20%. This result shows the importance of identifying entities with the same name. Otherwise, these entities would have the same score. However, the removal of these features only reduces the overall accuracy of 0.7%, because type identification step can make up a part of the removed “Type_LSTM” information. For example, the entity with name “Estonia” can be a country or a book, if one “Estonia” is a “book”, it may not have a property in type “location”, and thus we can distinguish these two types of “Estonia” a bit.

The removal of features of specificity affects the overall accuracy by 2.7%. These two features focus on more specific words and make the scores of the general entities, such as “album” or “movie”, become lower. This behavior is important and cannot be replaced by the rest of the system.

4.5 Importance of Type Identification

Table 6 shows the importance of our type identification step. The models with type identification significantly outperform the models without type network on McNemar’s test ($p < 0.01$), and increases the accuracies by at least 1%, no matter the final score is by probability or weighted sum. This shows that the type identification step can effectively handle the hierarchical structure of Freebase relations, and can better understand the semantics of the question.

Features \ N	Hit rates @ N					
	1	5	10	20	50	100
All features	80.9	90.2	92.2	93.7	95.1	96.0

Probability w/o type identification	75.1
Sum w/ type identification	76.7
Sum w/o type identification	75.2

Table 6: Gain by the addition of the type identification step.

5 Error Analysis

We categorize some errors into the following types.

- **Entities with the same name:** The subject entity of the question “What is the place of birth of Sam Edwards?” is “Sam Edwards”. Both entities “m.03kt3y” (an actress) and “m.042gjt” (a physicist) have the same name. This question does not have enough information to distinguish the two entities.
- **Deleted entity in Freebase:** Some questions’ subject entities are deleted in the Freebase dump.
- **Similar properties:** Some relations are very similar, e.g., both “music.release.track” and “music.release.track_list” indicate tracks in an album.
- **Incomplete question:** Some questions in the dataset are not complete. For example, the question “What production company produced?” does not provide any entities.
- **Question from object-relation pair:** There are some questions formed by object-relation pairs of the triple. E.g., the question “Name a lawyer.” is from triple (Charlie Herschel, people.person.profession, lawyer). We cannot find the subject of the triple from the question.
- **Typo:** Some questions contain typo. For example, the question “What is Roger Moliens gender?” should be “What is Roger Mollien’s gender?”
- **Wrong answer:** Some answers are wrong. For example, the answer of the question “Where was David Armstrong born?” is the triple (Undisputed Comedy Series: Lil Rel, film.film.language, English). Obviously, it is not a correct answer to the question.
- **Controversial answer:** E.g., the relation of the question “Leo Bertos was born in what country?” is “people.person.nationality”, but the more appropriate relation should be “people.person.place_of_birth”, because people can have the naturalized citizenship.

6 Conclusion

We propose a three-step approach to identify subject, type and property from knowledge base (KB)

for answering simple questions. Our ranking model with additional features outperforms the previous models in subject entity identification. The experiments also show that all entity features are important. Besides, by splitting the structured relation into type and property, our model benefits from understanding the question meaning more precisely. Our model achieves the state-of-the-art performance on the SimpleQuestions dataset. Error analysis shows that most errors come from the problematic questions in the dataset. Extension to complex questions will be explored.

DailyDialog: A Manually Labelled Multi-turn Dialogue Dataset

†**Yanran Li**,* †,§**Hui Su**,* ‡**Xiaoyu Shen**, †**Wenjie Li**, †**Ziqiang Cao**, §**Shuzi Niu**
†Department of Computing, The Hong Kong Polytechnic University, Hong Kong
§Institute of Software, Chinese Academy of Science, China
‡Spoken Language Systems (LSV), Saarland University, Germany

Abstract

We develop a high-quality multi-turn dialog dataset, **DailyDialog**, which is intriguing in several aspects. The language is human-written and less noisy. The dialogues in the dataset reflect our daily communication way and cover various topics about our daily life. We also manually label the developed dataset with communication intention and emotion information. Then, we evaluate existing approaches on DailyDialog dataset and hope it benefit the research field of dialog systems¹.

1 Introduction

Developing intelligent chatbots and dialog systems is of great significance to both commercial and academic camps. A good conversational agent enables enterprises to provide automatic customer services and thus reduce human labor costs. For academia, it is challenging yet appealing to build up such an intelligent chatbot which involves a series of high-level natural language processing techniques, such as understanding the underlying semantics of user input utterance, and generating coherent and meaningful responses.

However, the training datasets for this research area are still deficient. Traditional dialogue systems are often trained with domain-specific spoken dialogue datasets (Ringger et al., 1996; Petukhova et al., 2014), which are often small-scale and oriented to complete a specific task. More recent work feed their conversational models with open-domain datasets. Switchboard (Godfrey et al., 1992) and OpenSubtitles (Jörg Tiedemann, 2009) datasets

*Authors contributed equally. Correspondence should be sent to Y. Li (csyli@comp.polyu.edu.hk).

¹The dataset is available on <http://yanran.li/dailydialog>

A: I'm worried about something.
B: What's that?
A: Well, I have to drive to school for a meeting this morning, and I'm going to end up getting stuck in rush-hour traffic.
B: That's annoying, but nothing to worry about. *Just breathe deeply when you feel yourself getting upset.*
A: Ok, I'll try that.
B: Is there anything else bothering you?
A: Just one more thing. A school called me this morning to see if I could teach a few classes this weekend and I don't know what to do.
B: Do you have any other plans this weekend?
A: I'm supposed to work on a paper that'd due on Monday.
B: *Try not to take on more than you can handle.*
A: You're right. I probably should just work on my paper. Thanks!

Figure 1: An example in **DailyDialog** dataset. Some text is shortened for space. Best viewed in color.

comprise approximately 150 turns in a “conversation” and thus are too disperse to capture the main topic. Twitter Dialog Corpus (Ritter et al., 2011) and Chinese Weibo dataset (Wang et al., 2013) are comprised of posts and replies on social networks, which are noisy, informal and different from real conversations.

In this work, we develop a high-quality multi-turn dialogue dataset, which contains conversations about our daily life. We refer to it as **DailyDialog**. In our daily life, we communicate with others by two main reasons: *exchanging information* and *enhancing social bonding*. To exchange and share ideas, we often communicate with others following certain dialog flow. Typically, we do not rigidly answer others' questions and wait for the next ques-

tion. Instead, humans often first respond to previous context and then propose their own questions and suggestions. In this way, people show their attention others' words and are willing to continue the conversation. Another reason why people communicate is to strengthen their social bonding with others. Therefore, daily conversations are rich in emotion. By expressing emotions, people show their mutual respect, empathy and understanding to each other, and thus improve the relationship between them.

We demonstrate the above two phenomena by an example conversation as in Figure 1. The *words in Italic* are speaker B's own ideas that are new for the other speaker A. The underlined words in purple explicitly indicate the emotions. In the fourth speaker turn, speaker B first expresses his/her feeling on what he/she has heard from speaker A, which reveals his/her understanding. Then, speaker B suggests by saying *Just breathe deeply when you feel yourself getting upset*. Following the direct response towards A, B's suggestion is original yet context-dependent. It shows that B builds up a connection link by responding to forgoing context and proposing new suggestions.

We describe the dataset construction process and annotation criteria in Section 2, present and analyze the detailed characteristics in Section 3. We then evaluate existing mainstream approaches, including retrieval-based and generation-based approaches on the developed datasets in Section 4.

2 Dataset Construction

2.1 Basic Features and Statistics

To construct a multi-turn dialog dataset, we crawl the raw data from various websites which serve for English learner to practice English dialog in daily life. That's why we refer it as **DailyDialog** dataset. The dialogues in the dataset preserve the following three appealing properties.

First, the language in DailyDialog is human-written and thus is more formal than those datasets like Twitter Dialog Corpus (Ritter et al., 2011) and Chinese Weibo dataset (Wang et al., 2013). The latter are constructed by posts and replies on social networks, which are noisy, short and different from real conversations.

Second, the conversations in DailyDialog often focus on a certain topic and under a certain physical context. For example, a conversation happens in a shop is often between a customer looking for

suitable goods and a salesman who is willing to help for purchasing. Another typical conversation happens between two students talking about their summer vacation trips.

The third desirable feature is that the crawled dialogues usually end after reasonable speaker turns. This makes DailyDialog distinguished from existing dialog datasets such as Switchboard (Godfrey et al., 1992) and OpenSubtitles (Jörg Tiedemann, 2009), which often have 150+ and 1,000+ speaker turns in one "conversation". By examining some examples, we find that in such a conversation, people often talk about three or more topics (or scenes). Compared with them, our dataset has in average approximate 8 turns, which is more suitable to train compact conversational models.

After crawling, we de-duplicate the raw data, filter out those dialogues involving more than two parties (three or more speakers) and automatically correct the misspelling using autocorrect package². Finally, the DailyDialog datasets contain 13,118 multi-turn dialogues. We also count the average speaker turns and tokens to give a brief view of the dataset. The resulting statistics are given in Table 1. From the statistics we can see, the speaker turns are roughly 8, and the average tokens per utterance is about 15.

Total Dialogues	13,118
Average Speaker Turns Per Dialogue	7.9
Average Tokens Per Dialogue	114.7
Average Tokens Per Utterance	14.6

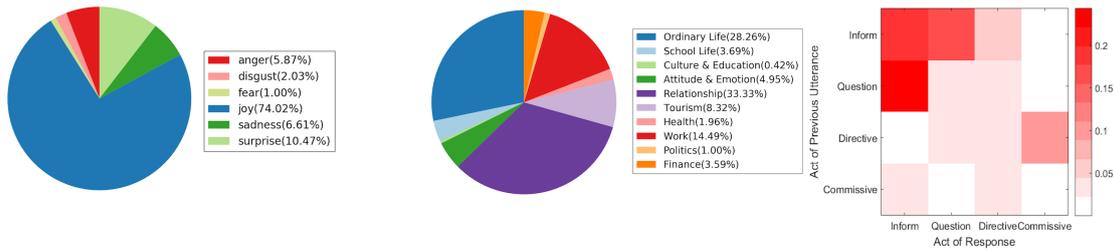

Table 1: Basic Statistics of DailyDialog.

2.2 Annotation Criteria and Procedure

Because the dialogues in DailyDialog datasets are written to reflect our daily conversations, they mainly conform certain communication ways. As stated before, the purpose of the dialogues are *exchanging information* and *enhancing social bonding*. To allow further research on our daily communication behaviors, we manually label the DailyDialog dataset to reflect the two purposes.

The communication purpose of exchanging information is related to the communication intentions. This factor has been extensively explored under the name of dialog act and speech act. In general, dialog acts represent the communication

²<https://github.com/phantpiglet/autocorrect/>

(a) Emotion distributions in DailyDialog. (b) Topic distributions in DailyDialog. (c) Interactions of dialog acts in each utterance pairs.

Figure 2: Statistics in DailyDialog.

functions when people saying something. To label the dialog acts in DailyDialog, we follow the criteria in Amanova et al. (2016) because it is adaptive to mainstream annotation criteria ISO 24617-2 (Petukhova, 2011) and consistent with existing annotated dataset such as Trains (Ringger et al., 1996) and DBox (Petukhova et al., 2014). Following Amanova et al. (2016), we label each utterance as one of four dialog act classes: {Inform, Questions, Directives, Commissive}. The **Inform** class contains all statements and questions by which the speaker is providing information. The **Questions** class is labeled when the speaker wants to know something and seeks for some information. The **Directives** class contains dialog acts like request, instruct, suggest and accept/reject offer. The **Commissive** class is about accept/reject request or suggestion and offer. The former two classes are information transfer acts, while the latter two are action discussion acts. Detailed explanations can be found in Amanova et al. (2016). Thereafter, in the DailyDialog dataset, we have four intention classes.

The second communication purpose, enhancing social bonding, is highly correlated with human emotion. Following (Wang et al., 2013), we adopt the “BigSix Theory” (Ekman, 1992) to label each utterance in DailyDialog. Ekman (1992) thinks that there are six primary and universal emotions in human beings: {Anger, Disgust, Fear, Happiness, Sadness, Surprise}. Besides the main six categories of emotions, we find it necessary to add additional category to represent other emotions. Hence, we have seven emotion categories in DailyDialog.

To guarantee the annotation quality, we recruit three experts who have good knowledge in dialog and communication theory. After teaching them the criteria, we sample 100 dialogues for them to annotate and reduce the discrepancy by discussion among them. Then, they independently annotate

the whole dataset and achieve the inter annotator agreement of 78.9%. When the disagreement happens, we follow the majority rule or let them re-annotate to find a “common” annotation. The detailed statistics of the final annotation information are given in the following section.

3 Characteristics

In this section, we delve deeply into DailyDialog datasets, and show our datasets are beneficial in several aspects:

- *Daily Topics*: It covers ten categories ranging from ordinary life to financial topics, which is different from domain-specific datasets.
- *Bi-turn Dialog Flow*: It conforms basic dialog act flows, such as Questions-Inform and Directives-Commissives bi-turn flows, making it different from question answering (QA) datasets and post-reply datasets.
- *Certain Communication Pattern*: It follows unique multi-turn dialog flow patterns reflecting human communication style, which are rarely seen in task-oriented datasets.
- *Rich Emotion*: It contains rich emotions and is labeled manually to keep high-quality, which is distinguished from most existing dialog datasets.

3.1 Daily Topics

The dialogues in the developed dataset happens in our everyday life, and that’s why we name it **DailyDialog**. They cover a wide range of daily scenarios: chit-chats about holidays and tourisms, service-dialog in shops and restaurants, and so on. After looking into its topics, we cluster them into ten categories. The statistics for each category is summarized in Figure 2(b).

The largest three categories are: Relationship (33.33%), Ordinary Life (28.26%) and Work (14.49%). This is also consistent with our real experience that we often invite people for social activities (Relationship), talk about what happened recently (Ordinary Life) and what happened at work (Work).

3.2 Bi-turn Dialog Flow

Because the dialogues are assumed to happen in daily life, they follow natural dialog flow. It makes DailyDialog dataset quite different from existing QA datasets such as SubTle dataset (Dodge et al., 2015) which are improperly used for training dialog systems. DailyDialog dataset also distinguishes from those post-reply datasets such as Reddit comment (Al-Rfou’ et al., 2016), Sina Weibo (Shang et al., 2015) and Twitter (Ritter et al., 2011) datasets. The latter datasets comprise post-reply pairs on social networks where people interact with others more freely (often more than two speakers) and results in ambiguous dialog flows.

Instead, the dialog act flows in Dailydialog are more consistent with our daily communication. For example, we usually do not leave others’ question and just tersely change the topic. Instead, we will answer others’ questions politely. By the definitions we introduce in Section 2.2, this reflects a *Questions-Inform* bi-turn dialog flow. This is a frequent circle phenomena because it represents a information transfer between the two speakers in the dialog. Another example is that when someone proposes a idea, such as going out for dinner, the other speaker in the dialog usually responds to this proposal. This reflects a *Directives-Commissives* dialog flow and captures the speakers’ suggestions and commitments to conduct certain acts. By labeling each utterances in dialogues, Dailydialog datasets contain more than ten thousands examples of approximately 8-turn dialog act flows. We hope this is beneficial for the research in dialog management. The distributions of these four dialog acts are given in Table 2. We also demonstrate the interactions between each four dialog acts in Figure 2(c).

Inform	Questions	Directives	Commissive
46,532	29,428	17,295	9,724
45.2%	28.6%	16.8%	9.4%

Table 2: Intention Statistics in DailyDialog.

3.3 Certain Communication Pattern

Besides the basic *Questions-Inform* and *Directives-Commissives* bi-turn dialog flows, we also find two unique multi-turn flow patterns in DailyDialog dataset.

Pattern 1: In human-to-human communication, people are inclined to both answer the questions and then initiate a new question to let the dialog last. In other words, a speaker can change from information-provider to information-seeker in a single speaker turn. We find 2,398 (18.3%) dialogues in DailyDialog exhibits this patterns, which is quite frequent.

Pattern 2: When someone is proposing an activity or offering a suggestion, the other speaker usually comes up with another idea. This is sensible because the two speakers often have different views about a topic and by exchanging different proposals, they persuade and influence the other. This results in a *Directives-Directives-Commissives*-like pattern in dialog flows, which happens totally 1,203 times (9.2%) in our dataset.

The two patterns shed light on our daily communications style, which are merely found in single-turn datasets or task-oriented datasets like Ubuntu (Lowe et al., 2015) and restaurant reservation datasets (Bordes and Weston, 2016).

3.4 Rich Emotion

As discussed before, the other main purpose of our daily communication is *enhancing social bonding*. Hence, people tend to express their emotions during communication. When hearing from others’ miseries, we often say “I’m sorry to hear that” or “What a poor guy”. And when we appease others, the listener often feels better. Such emotional words are rich in DailyDialog dataset. Because automatic emotion classification is difficult (Zhou et al., 2017), we manually label the emotion for each utterance to make them as accurate as possible. This distinguishes DailyDialog datasets from most existing dialog datasets. Similarly, we summarize the basic statistics on labelled emotion in Table 3.³

Additionally, we observe in our daily life, a healthy and pleasant conversation often ends with positive emotions. Therefore we examine our Dai-

³The imbalanced emotion categories suggest that it might be improper to label the emotion following “BigSix” Theory (Ekman, 1992). However, we keep it in this work to follow previous work (Wang et al., 2013). To propose a novel emotion theory is beyond this work.

	Count	of EU	of Total
Anger	1022	5.87	0.99
Disgust	353	2.03	0.34
Fear	74	1.00	0.17
Happiness	12885	74.02	12.51
Sadness	1150	6.61	1.12
Surprise	1823	10.47	1.77
Other	85572	-	83.10

Table 3: Emotion Statistics in DailyDialog. EU denotes for utterances that contain the main six categories of emotion, while Total denotes for all utterances in the dataset. Numbers are multiplied by 100%.

lyDialog dataset by how many conversations are ending or positive emotions (i.e., happy), and find 3,675 (28.0%) “happy” dialogues. We also count how many conversations have changed to positive emotions even though they begin with negative emotions (e.g., sad, disgust, anger) and find 113 (0.8%) such examples. We hope our dataset facilitates future research on developing conversational agents able to regulate the conversation towards a happy ending.

4 Evaluating Existing Approaches

In this section, we evaluate existing mainstream approaches on the proposed DailyDialog. We mainly compare five categories of approaches: (1) Embedding-based Similarity for Response Retrieval (Luo and Li, 2016); (2) Feature-based Similarity for Response Retrieval (Jafarpour et al., 2010); (3) Feature-based Similarity for Response Retrieval and Reranking (Luo and Li, 2016; Otsuka et al., 2017); (4) Neural network-based for Response Generation (Shang et al., 2015; Sorboni et al., 2015); (5) Neural network-based for Response Generation with Labeling Information (Zhou et al., 2017). All the evaluated approaches are implemented by TensorFlow (Abadi et al., 2015).

4.1 Experimental Setup

We randomly separate the DailyDialog datasets into training/validation/test sets with 11,118/1,000/1,000 conversations. We tune the parameters on validation set and report the performance on test sets. In all experiments, the vocabulary size is set as 25,000 and all the OOV words are mapped to a special token UNK. We

set word embeddings to size of 300 and initialize them with Word2Vec embeddings trained on the Google News Corpus⁴. The encoder and decoder RNN in the following experiments are 1-layer GRU with 512 hidden neurons (Cho et al., 2014). All the trained model parameters are then used as an initialization point. We set the batch size as 128 and fix the learning rate as 0.0002. Models are trained to minimize the cross entropy using Adam optimizer (Kingma and Ba, 2014).

4.2 Retrieval-based Approaches

4.2.1 Compared Approaches

First, we choose three categories of four retrieval-based approaches, i.e., (1) Embedding-based Similarity (Luo and Li, 2016); (2) Feature-based Similarity (Jafarpour et al., 2010; Yan et al., 2016); (3)(4) Feature-based Similarity with Intention and Emotion Reranking (Luo and Li, 2016; Otsuka et al., 2017). We aim to see whether classical embeddings-based, feature-based and reranking-enhanced approaches are effective on DailyDialog.

Embedding-based The embedding-based approach is using basic neural networks as described in Section 4.1 and denoted as {Embedding} below. We measure the distance between embeddings as the average of cosine similarity, Jaccard distance and Euclidean distance. At test time, candidates whose context embedding is closer to the test context embedding are ranked higher. Similar approaches have been adopted extensively on response retrieval task, such as Luo and Li (2016). **Feature-based** We then evaluate the performance of feature-based retrieval approach. We adopt several linguistic features: TF-IDF and three fuzzy string matching features, i.e., QRatio, WRatio, and Partial ratio. We first use TF-IDF to select 1,000 candidates and rank them with the fuzzy features. These fuzzy features is implemented with fuzzywuzzy package⁵. We denote this feature engineering approach as {Feature}. Similar approaches have been demonstrated effectively on response retrieval task and duplicate question detection task⁶, such as Yan et al. (2016); Luo and Li (2016).

Reranking By Intention We also examine reranking-enhanced retrieval approaches, which

⁴<https://code.google.com/archive/p/word2vec/>

Feature	0.258	0.204	0.194
+ I-Rerank	0.204	0.189	0.181
+ I-E-Rerank	0.190	0.174	0.164

Table 5: BLEU scores of retrieval-based approaches.

encourages the retrieved response to follow a certain rules. Luo and Li (2016) provides a simplest way to realize it. Because intention has shown as a beneficial factor in response selection (Otsuka et al., 2017), we first examine reranking-enhanced retrieval approach based on the intention (dialog act) label in DailyDialog dataset. We compare the intention history of the test example with that of the candidate example, and use the compared similarity as reranking feature. For example, if the test intention history is $\{2,1,3\}$, then the candidate response whose intention history is also $\{2,1,3\}$ will be reranked higher. Based on the feature-based retrieval approach, we denote the reranking by intention as $\{+I\text{-Rerank}\}$.

Reranking By Intention & Emotion The last retrieved-based approach we evaluate is similar with $\{+I\text{-Rerank}\}$, with the only difference that the candidate responses are reranked by both intention and emotion labels. We denote it as $\{+I\text{-E-Rerank}\}$.

Because the groundtruth responses in the test set are not seen in the training set, we can not evaluate the performance using ranking-like metrics such as Recall-k. We instead report the BLEU scores achieved by retrieval-based approaches in Table 5.

We also evaluate them by calculating the ‘‘Equivalence’’ percentage between the labels (i.e., intention, emotion) of the retrieved responses and those

of the groundtruth responses. The results are reported in Table 6. Though subtle improvements can be seen when using labels, we speculate it as not a very strong evaluation metric. It is unsafe to conclude that the higher the ‘‘equivalence’’ percentage is, the better (more coherent, more suitable) the retrieved response will be.

	Feature	+I-Rerank	+I-E-Rerank
Intention	46.3	47.3	46.7
Emotion	73.7	72.3	74.3

Table 6: ‘‘Equivalence’’ percentage (%) of retrieval-based approaches.

4.2.2 Intention And Emotion Matters

In dialog response generation, word-level overlap metrics such as BLEU are inadequate (Liu et al., 2016). To provide insights on whether intention and emotion are beneficial, and how they works, we conduct several case studies in Table 7.

In the first block, we give a example of how intention helps to find more proper response. The intentions in the test context (U1 & U2) are $\{3, 3\}$, meaning $\{\text{Directives}, \text{Directives}\}$. The gold answer (GA) in the test set is ‘‘Thanks.’’ Although both three retrieved responses are not exactly same with GA, the approaches that reranking by intention (+I) and reranking by intention and emotion (+I-E) find more suitable response than the feature-based approach without reranking (F). It is because, the context corresponding to the retrieved response ‘‘About how long will it take me to get there?’’ is ‘‘Excuse me, but can you tell me the way... Just go straight... You can t miss it’’, whose dialog act flow $\{3, 3\}$ is consistent with the context test. On the contrary, the response found by feature-based approach has the context ‘‘Can you direct me to

Test Context	Retrieved Response
U1: <i>Can you direct me to Holiday inn ?</i> (3) U2: <i>Cross the street... You can't miss it.</i> (3) GA: Thanks.	F: <i>Well, we've got some great mangoes on sale.</i> +I: <i>About how long will it take me to get there?</i> +I-E: <i>About how long will it take me to get there?</i>
U1: <i>No way... You can't keep it here.</i> (1) U2: <i>Please...it's so cute and tame.</i> (0) U3: <i>All right. But you have to...</i> (0) GA: I will. Thank you, Mummy.	F: <i>Is there somewhere you wanted to go eat at?</i> +I: <i>Sprite with ice, please.</i> +I-E: <i>Now we get along very well. It makes me feel...</i>

Table 7: Case Study of Reranking-enhanced Retrieve Approaches. Context words are shortened for space.

Test Context	Generated Response
U1: <i>I have to check out today.</i> <i>I'd like my bill ready by 10 in morning.</i>	Attn: <i>all right, sir.</i> Pre+Attn: <i>how long will it take to get there?</i>
U2: <i>You can be sure of that, sir .</i>	HRED: <i>here you are.</i>
GA: Thank you.	Pre+HRED: <i>how long will it take to get there?</i>

Table 8: Case Study of Generation-based Approaches.

some fresh produce that's on sale?", which should be attributed to the poor result.

Similar cases are given in the second block where emotion history information benefits. The emotions in the test context (U1, U2 & U3) are {1, 0, 0}, meaning {Anger, Others, Others}. The most proper retrieved responses are from the reranking approach by intention and emotion (+I-E) that finds "Now we get along very well. It makes me feel that I'm someone special. It makes me feel that I'm someone special." The context history for this response is "oh, really? so you just took home a stray cat? // Yes. It was starving and looking for something to eat when I saw it. // Poor cat." whose emotion history is {6, 0, 0}.

4.3 Generation-based Approaches

4.3.1 Compared Approaches

Seq2Seq The simplest generation-based approach we adopt is a vanilla Seq2Seq with GRU as basic cell, as described in Section 4.1. Such approach is widely selected as baseline models in dialog generation (Shang et al. (2015); Lowe et al. (2015); Al-Rfou' et al. (2016)).

Attention-based Seq2Seq We then evaluate the Seq2Seq approach with attention mechanism (Bahdanau et al., 2014) which has shown its effectiveness on various NLP tasks including dialog response (Hermann et al., 2015; Luong et al., 2015; Mei et al., 2017). We denote this approach as {Attn-Seq2Seq}.

HRED The third generation-based approach

we evaluate is hierarchical encoder-decoder (HRED) (Sordoni et al., 2015). Due to its context-aware modeling ability, HRED has shown better performances in previous work (Sordoni et al., 2015).

Intention and Emotion-enhanced To utilize the intention and emotion labels, we follow Zhou et al. (2017) to incorporate the label information during decoding. The intention and emotion labels are characterized as one-hot vectors. We denote the label-enhanced approaches as {L+} and the performances are given in the second box in Table 4.

Pretrained We also examine whether pre-training with other dataset will boost the performance of the first three generation-based approaches. Following Li et al. (2016, 2017), we use the OpenSubtitle dataset (Jörg Tiedemann, 2009)⁷. Because it has no clear and concise segmentation for each conversation, we treat each of three consecutive utterances as context, and the foregoing one as response. Finally, 3,000,000 three-turn dialogs are randomly sampled and used to pre-train the compared models for 12 epochs. We denote the approaches using pre-training as {Pre+}.

According to BLEU scores from Table 4 (last four columns), we can see that in general attention-based approaches are better than vanilla Seq2Seq model. Among the three compared approaches, HREDs achieve highest BLEU scores because they take history information into consideration.

⁷<https://github.com/jiweil/Neural-Dialogue-Generation>

Furthermore, label information is effective even though we utilize them in the simplest way. These findings are consistent with previous work (Sordoni et al., 2015; Serban et al., 2016b).

On the other hand, the first three columns in Table 4 show that models pretrained by OpenSubtitle converge faster, achieving lower Perplexity (PPL) but poorer BLEU scores. We conjecture it as a result of domain difference. OpenSubtitle dataset is constructed by movie lines, whereas our datasets are daily dialogues. Moreover, OpenSubtitles has approximately 1000+ speaker turns in one conversation, while our dataset has in average 8 turns. To pretrain a model by corpus from different domain will harm its performance on the target domain. Hence, it is less optimal to simply pretrain models with large-scale datasets such as OpenSubtitle, which is domain different from the evaluation datasets. We further examine this issue by comparing the generated answers by models trained solely on DailyDialog with and without pre-training.

4.3.2 Case Study

We give a case study in Table 8. It can be seen the two pre-trained models (the second and the fourth row) generate responses that are irrelevant with the context. In contrast, the corresponding model without pre-training produce more reasonable responses.

5 Related Work

5.1 Domain-Specific Datasets

The research on chatbots and dialog systems is still new and developing. Literature on traditional dialog system primarily relies on template-based and retrieval-based approaches and applies to specific-domain of data.

Popular datasets for this research area include TRAINS (Ringger et al., 1996), DBOX (Petukhova et al., 2014), bAbI synthetic dialog (Bordes and Weston, 2016) and Movie Dialog datasets (Dodge et al., 2015). These datasets feature different types of dialogues happening in different physical contexts. For example, the TRAINS corpus contains problem-solving dialogues and the dialog systems trained with TRAINS are performing as task-oriented assistants. The tasks are often about the shipping of railroad goods and thereafter it is called TRAINS. The bAbI (Bordes and Weston, 2016) and Movie Dialog dataset (Dodge et al., 2015) contain dialogues about movies and the tasks

in these datasets are movie question answering, movie recommendation and so on. Another popular dataset is Ubuntu dataset (Lowe et al., 2015) which extracts the user posts and replies in Ubuntu forums and the task is to answer users' computer-related questions.

5.2 Open-Domain Datasets

More recent work concentrates on generation-based approaches, which are mainly based on the sequence-to-sequence encoder-decoder architecture (Sordoni et al., 2015; Serban et al., 2016b). These generation-based approaches are often trained with large-scale open-domain datasets.

In Shang et al. (2015), the authors propose a neural responding machine (NRM) and examine their approach on Sina Weibo dataset (Wang et al., 2013). The Sina Weibo dataset is constructed by crawling users' posts and replies on a Chinese social network. Similar dataset is constructed by Ritter et al. (2011) who provides a Twitter dataset. Besides social network, Al-Rfou' et al. (2016) constructs a dialog training dataset with Reddit Forum posts. Existing work based on neural networks has examined their approaches on these datasets (Zhou et al., 2017; Wang et al., 2013; Sordoni et al., 2015; Serban et al., 2016b). Although these datasets are large-scale, the dialogues in them are often noisy and short. Even worse, the artificially constructed post-reply pairs are different from our real conversations.

To train neural network based conversational models, researchers often pre-train their models by using movie subtitles which are large-scale and conversation-like. The most widely adopted dataset is OpenSubtitle (Jörg Tiedemann, 2009) which is used in Li et al. (2016, 2017). Other similar datasets are SubTle dataset (Bordes and Weston, 2016) which is then used to build up MovieQA sub-dataset and MovieTriples (Serban et al., 2016a).

6 Conclusions and Future Work

In this work, we develop the dataset DailyDialog which is high-quality, multi-turn and manually labeled. We show the proposed dataset is appealing in four main aspects. The dialogues in the dataset cover totally ten topics and conform common dialog flows such as Questions-Inform and Directives-Commissives bi-turn flows. In addition, DailyDialog contains unique multi-turn dialog flow patterns, which reflect our realistic communication

ways. And it is rich in emotion. The evaluation results in Section 4 are initial but indicative.

In the future we plan to design advanced mechanisms to explore the unique multi-turn dialog flows described in Section 3. It is also promising to utilize the topic information in our dataset by domain adaptation and transfer learning. Our dataset is available on <http://yanran.li/dailydialog>, and we hope it is beneficial for future research in this field.

Inference is Everything: Recasting Semantic Resources into a Unified Evaluation Framework

Abstract

We propose to unify a variety of existing semantic classification tasks, such as semantic role labeling, anaphora resolution, and paraphrase detection, under the heading of Recognizing Textual Entailment (RTE). We present a general strategy to automatically generate one or more sentential hypotheses based on an input sentence and pre-existing manual semantic annotations. The resulting suite of datasets enables us to probe a statistical RTE model’s performance on different aspects of semantics. We demonstrate the value of this approach by investigating the behavior of a popular neural network RTE model.

1 Introduction

The Recognizing Textual Entailment (RTE) task aims to assess a system’s ability to do textual inference—i.e. derive valid conclusions from textual clues (Dagan et al., 2006, 2013; Bar-Haim et al., 2006; Giampiccolo et al., 2007, 2009; Ben-tivogli et al., 2009, 2010, 2011). In this task, a system judges whether “typically, a human reading [the sentential context, or *text*] T would infer that [the sentential hypothesis] H is most likely true” (Dagan et al., 2006).

Recent efforts in textual inference have focused on the Stanford Natural Language Inference (SNLI) dataset. SNLI is made up of hundreds of thousands of text-hypothesis pairs, wherein the texts are image captions drawn from the Flickr30k corpus (Young et al., 2014) and the hypotheses are elicited from crowdsourcing workers based on those captions (but not the corresponding image). While SNLI has led to significant methodological improvements, its collection protocol does not lend itself to understanding the types of semantic knowl-

edge necessary for properly understanding a particular example. Researchers compete on which system achieves the highest score on a test set, but this itself does not lead to an understanding of which linguistic properties are better captured by a quantitatively superior system.

In contrast, datasets such as FraCaS (Cooper et al., 1996) are precisely designed to illustrate a range of semantic phenomenon that a text understanding system should handle. But though this careful design enables fine-grained probes into a system’s semantic capabilities, FraCaS-like datasets tend not to be large-scale enough for recent work in data-driven computational semantics. Asking experts, such as those who constructed FraCaS, to author hundreds of thousands of examples is not practical, just as the existing elicitation protocol behind SNLI will not lead to cleanly partitioned sets of examples that focus specifically on certain kinds of semantic inference.

Our proposal is to leverage existing large-scale semantic annotation collections as a source of targeted textual inference examples. This strategy requires only minor effort in developing dataset-specific generation capabilities to recast annotations into a shared universal representation: natural language sentences.

We demonstrate the use of this strategy in two steps. First, we construct three recasted datasets from three existing semantic resources that target three distinct semantic phenomena:¹ (i) the Semantic Proto-Roles v1 (SPR) dataset (Reisinger et al., 2015), which contains likelihood judgments about the semantic *proto-role* properties (Dowty, 1991) of verbal arguments found in PropBank (Palmer et al., 2005), (ii) the FrameNet Plus (FN+) dataset, which contains likelihood judgments about the paraphrase validity of *frame triggers* (Pavlick et al., 2015), and

¹These recasted datasets are made publicly available at <http://decomp.net>.

(iii) the Definite Pronoun Resolution (DPR) dataset, which contains annotations relevant to complex anaphora resolution (Rahman and Ng, 2012). We use these recasted datasets to train a recent neural RTE model (Bowman et al., 2015) and measure its performance. We show that complex anaphora is the most difficult semantic phenomenon for neural RTE models to capture, followed by predicting thematic proto-role properties. Perhaps unsurprisingly, given the nature of the RTE task, paraphrasing seems to be the easiest phenomenon to model.

In the next section (§2), we discuss previous work in RTE, focusing in particular on the development of RTE datasets. We then discuss our data creation process (§3) as well as the results of a small validation (§4). Finally, we report on the setup and results of our three experiments (§5) and then conclude (§6).

2 Background and Prior Work

The current paper touches on both the broad theme of understanding continuous approaches to natural language understanding as well as the more narrow focus on textual entailment. We begin by discussing how the current paper fits within the broader context and then specify its place within textual entailment.

2.1 Approaches to logical form

All approaches to natural language understanding utilize intermediate logical forms that are interpretable to varying degrees. On one end of the spectrum are approaches that utilize declarative logical forms. In such approaches, semantic parsers first convert a sequence into a meaning representation that expresses the semantics needed for inference. In this case, each individual component of the logical form is clearly interpretable. Tremendous energies within computational linguistics have been spent on building declarative, component-wise-interpretable logical forms such as Hobbsian Logic (Hobbs, 1985), Discourse Representation Theory (Kamp et al., 2011), the Rochester Interactive Planning System (Allen et al., 2007), Minimal Recursion Semantics (Copestake et al., 2005), Episodic Logic (Schubert and Hwang, 2000), Combinatory Categorical Grammar (Steedman, 2000), Semantic Role Labeling (Gildea and Jurafsky, 2002), Framenet Parsing (Fillmore et al., 2003) and Abstract Meaning Representation (Banarescu et al., 2013).

Opposite the above approaches are methods that utilize vector space-based logical forms. Recent work on word and string embeddings (Mikolov et al., 2013; Pennington et al., 2014) has produced vector space representations that can be induced from large corpora in an unsupervised manner that have been used to initialize the training of neural networks for tasks as complex as English-to-French machine translation (Sutskever et al., 2014). Vector space-based intermediate forms are not commonly recognized as logical forms but in light of recent work (Bouchard et al., 2015) it seems worthwhile to reconsider this view.

An argument in favor of declarative, interpretable logical forms is that one can directly observe the specific mistakes made by a system in the interpretive process of mapping natural language strings to logical forms—e.g., it is possible to find out whether a prepositional phrase was attached incorrectly, or the wrong sense of a particular word was selected, causing a cascade of downstream errors. Neural systems that use vector space representations for textual inference, instead of logical forms, lack such modularity and interpretability, and therefore it is very difficult to figure out the cause of a particular error in a neural network.

Much prior work has aimed to improve the interpretability of neural networks, focusing in particular on extracting rules from the activations of feed forward networks (Towell and Shavlik, 1993; Thrun, 1993; Fu, 1994; Thrun, 1995). In recent years, this focus has shifted to understanding and visualizing other architectures such as Convolutional Neural Networks and Recurrent Neural Networks (Zeiler and Fergus, 2014; Karpathy et al., 2015), though the guiding principle remains the same: understanding the behavior of neural networks in terms of its activations.

The current paper also presents a strategy for understanding the behavior of neural RTE systems used for solving the task of RTE, but we take a different route. Instead of explaining the behavior of neural networks in terms of its parameters and activations, we benchmark their performance on datasets that each require distinct types of semantic reasoning for high performance. In this sense, our motivation and strategy is similar to the reasoning behind the bAbI dataset for question answering (Weston et al., 2016). Weston et al. argue that, in order to measure the progress towards building dialogue agents, it can be useful to evaluate the

ID	Dataset	Label	Text	Hypothesis
1	SPR	entailed	The network must refund money to the advertisers and loses considerable revenue and prestige.	The network was altered or somehow changed during or by the end of the losing.
2	SPR	entailed	He turned himself in to authorities in New York earlier this year.	He changes location during the turning.
3	SPR	not-entailed	Later, he marketed glue.	He changes location during the marketing.
4	SPR	not-entailed	So he asked the IRS if the plan would work.	The asking caused a change in the IRS.
5	FN+	entailed	An agreement is to be signed in late 10/92.	An agreement is to be inked in late 10/92.
6	FN+	entailed	So our work must continue.	So our labor must continue.
7	FN+	not-entailed	Friday had beautiful weather.	Friday had beautiful forecast.
8	FN+	not-entailed	Your support will help them go to work.	Your support will allow them go to work.
9	DPR	entailed	The bird ate the pie and it died.	The bird ate the pie and the bird died.
10	DPR	not-entailed	The bird ate the pie and it died.	The bird ate the pie and the pie died.
11	DPR	entailed	The bird ate the pie and it was ruined.	The bird ate the pie and the pie was ruined.
12	DPR	not-entailed	The bird ate the pie and it was ruined.	The bird ate the pie and the bird was ruined.

Table 1: Examples of *text-hypothesis* pairs generated from the SPR, FN+, and DPR datasets.

ability of systems to perform different kinds of question answering tasks that require specific types of reasoning. Our strategy for building specific datasets that can probe the ability of machine learning systems to perform specific types of reasoning is similar to theirs; however, instead of constructing completely artificial datasets, we *recast* datasets constructed on top of natural text.

2.2 Approaches to textual entailment

Research in textual entailment, at least in its most recent form, was catalyzed by the RTE shared task (Dagan et al., 2006; Bar-Haim et al., 2006; Giampiccolo et al., 2007, 2009; Bentivogli et al., 2009, 2010, 2011). With each iteration of this shared task, manually annotated examples were created for testing competing systems. But even after multiple iterations, the amount of available data for RTE was still small. The Sentences Involving Compositional Knowledge (SICK) corpus was released with the goal of alleviating this problem (Marelli et al., 2014).

A significant further contribution was made with the Stanford Natural Language Inference (SNLI) corpus, which uses crowdsourcing to gather two orders of magnitude more examples than all previous datasets (Bowman et al., 2015). SNLI enabled fully supervised training of powerful machine learning models like neural networks. A number of researchers have pursued this direction by applying completely supervised neural models for sequential data to the problem of textual entailment (Rocktäschel et al., 2015; Mou et al., 2015; Shuohang and Jing, 2015; Liu et al., 2016; Cheng et al., 2016; Parikh et al., 2016; Munkhdalai and Yu, 2016).

But though the state of the art performance of neural sequential models has steadily increased over the past year, it appears that this area has reached a point where the paradigm of training and evaluating on a single general-purpose RTE dataset has become insufficient for reaching the next level of improvements. It is still informative to measure the performance of a new RTE model on the SNLI dataset, but this black-box evaluation does not help us understand the fine-grained aspects of a model’s capability in performing particular types of natural language inference, such as its ability to handle coreference, paraphrasing, or its ability to judge thematic properties of a named entity. The issue of lack of understandability is especially important for neural models, which are notoriously difficult to interpret.

To address this issue, we take inspiration from the FraCaS dataset (Cooper et al., 1996) and construct a suite of targeted datasets that separately test a system’s ability to perform individual bits of interpretation such as paraphrasing, semantic role labeling, and coreference. In contrast to the original FraCaS data set, which is relatively small and which could not support the training of purely lexical neural RTE classifiers, we pursue the strategy of automatically converting *semantic classifications*—i.e., human judgments about semantic properties—into labeled examples for textual entailment. This strategy allows us to construct textual entailment datasets that are of the same order of magnitude as SNLI—and hence support data-driven training of large neural networks—but that are also focused on specific semantic properties.

With our strategy we can also quantify the types of semantic phenomenon that an existing *semanti-*

cally *undifferentiated* dataset contains. For example, if a neural model trained on the SNLI dataset performs poorly on a test set from another domain that exercises the trained model’s ability to perform anaphora resolution, then it can be inferred that either the original dataset did not contain enough examples of anaphora resolution, or that the statistical model failed to capture that phenomenon.

Finally, we note that the idea of converting question-answer pairs into text-hypothesis pairs is not novel: the RTE dataset for the second RTE Shared task was created by manually converting existing Information Extraction, Information Retrieval and QA pairs from manually curated datasets such as ACE, MUC, TREC and CLEF (Bar-Haim et al., 2006). The main contribution of the current work is to show that such conversion need not be done manually; automatic conversion of some semantic datasets can be done with a high enough quality to create large-scale RTE datasets.

3 Data Creation Process

In order to create annotated RTE datasets that can probe specific aspects of understanding, our strategy is to rewrite semantic classifications into the form of textual entailment pairs. As mentioned above, we define a semantic classification dataset to be a text corpus, along with manual annotations of a particular meaning-related aspect of the data. Here, we describe how to apply this strategy to the SPR, FN+, and DPR datasets, but there exist many further datasets to which this strategy can be applied.

The SPR dataset Semantic Proto-Role Labeling (SPRL) is the problem of assigning a likelihood value for a particular *proto-role property* holding of a particular argument of a particular predicate (Reisinger et al., 2015; White et al., 2016; Teichert et al., 2017). These proto-role properties are inspired by the *thematic proto-role* theory proposed by Dowty (1991), who argued that, for the purpose of determining the mapping from predicates’ semantic roles to its syntactic arguments, semantic roles should be viewed not as categories, but rather as sets of entailments that arguments must satisfy in the context of an event kind.

For purposes of recasting, we use the SPR1 dataset, which was collected by Reisinger et al. (2015) and contains likelihood judgments for the twelve *proto-role properties* listed in Table 2.

Role property	How likely or unlikely is it that...
instigation	ARG caused the PRED to happen?
volition	ARG chose to be involved in the PRED?
awareness	ARG was/were aware of being involved in the PRED?
sentient	ARG was/were sentient?
change of location	ARG changed location during the PRED?
exists as physical	ARG existed as a physical object?
existed before	ARG existed before the PRED began?
existed during	ARG existed during the PRED?
existed after	ARG existed after the PRED stopped?
change of possession	ARG changed possession during the PRED?
change of state	ARG was/were altered or somehow changed during or by the end of the PRED?
stationary	ARG was/were stationary during the PRED?
location of event	ARG described the location of the PRED?
physical contact	ARG made physical contact with someone or something else involved in the PRED?
was used	ARG was/were used in carrying out the PRED?
pred changed arg	The PRED caused a change in ARG?

Table 2: Questions posed to SPR annotators.

These judgments were collected by providing the annotator with a sentence in which a predicate and an argument of that predicate were highlighted and asking them to answer, on a five-point scale from 1 (very unlikely) to 5 (very likely), how likely or unlikely each property was to hold of the argument in the context of the predicate.²

For example, given (1), with *the antibody* as the highlighted argument and *killed* as the highlighted predicate, the annotator’s job was to answer questions like the one in (2).

- (1) The antibody killed the virus.
- (2) How likely or unlikely is it that the antibody caused the killing to happen?

For the purposes of SPRL task, Teichert et al. (2017) propose to collapse the five-point scale to a binary variable by mapping response 1–3 to *not-entailed* and 4–5 to *entailed* and predicting the resulting binary variable. Collapsing across properties, the current state-of-the-art F1 for the resulting task of predicting this binary variable is reported by Teichert et al. (2017) at 81.7.

Binarized proto-role property judgments can be readily converted to text-hypothesis pairs by simply treating the original sentence as the text and converting the questions listed in Table 2 to statements for use as hypotheses. For example, (1) would be treated as a text, and (3) would be treated as a hypothesis generated from (2).

- (3) The antibody caused the killing to happen.

In this case, the annotator gave a 5 (very likely) response to (2), and so in our recasted dataset, the resulting pair is labeled *entailed*.

²Annotators were also given the option of saying that the question was *not applicable* (NA). We filter these these responses from our dataset.

▶	Three women enjoying a balloon joyride. Three women are on a balloon ride.
▶	A woman sings into a microphone indoors. a women sings
▶	The kid is sliding down a tan plastic slide. The kid is sliding.
▶	A black dog is playing in water with a green toy. the dog has a toy
▶	A woman with glasses and a pink hat rides her bike. A woman with glasses and a pink hat rides her bike

Table 3: Examples of artifacts in the SNLI dataset that promote hypothesis sentences to be substrings of the evidence sentences, specially in case of entailments. The bullet marked sentences are the *evidence* sentences and the *hypothesis* sentences below them.

This is a simple and inexpensive way of creating entailment pairs, with the benefit that this annotation scheme probes for fundamental semantic information from an annotator. Also, note that, since Reisinger et al. collect annotations for the twelve types of proto-role properties mentioned above, the errors made by a neural RTE model can be automatically subcategorized into these 12 categories, further aiding in interpretation.

One potential criticism of our method is that, because our hypothesis sentences are constructed by filling in templates, they do not have the same syntactic diversity as the free elicitation method used by Bowman et al.. We suggest that this is not a problem for two reasons.

First, since our goal is to distinguish between the kinds of semantic phenomenon that can be accurately modeled by statistical RTE models, the lack of diversity is not an obstacle as long as the particular phenomenon that we wish to probe is being covered properly. Second, even the method used by Bowman et al. of enlisting workers on the Amazon Mechanical Turk (AMT) Platform to write hypotheses sentences in response to an image caption is not without its drawbacks since their method introduces artifacts such as the fact that the *hypotheses* sentences in SNLI are on average half the length of the *text* prompts. We believe that this happens because workers on AMT have an incentive to spend the least amount of time possible in constructing their responses. In Table 3, we list a few such examples.

The FN+ dataset In Frame Semantics (Fillmore et al., 2003), the primary unit of lexical analysis is the *frame*, which captures the central properties of a concept, situation, or event. The largest resource for frame annotated sentences with information about evoked frames, their *trigger* phrases,

Dataset	Sentences	Label Percentage	
		Entailed	Not-Entailed
FN+	154,605	43.45	56.55
SPR	154,607	34.80	65.20
DPR	3,661	49.99	50.01
Total	312,873	39.13	60.87
SNLI [†]	569,033	33.41	66.59

Table 4: Number of *text-hypothesis* pairs generated from each dataset along with percentage of entailing v. non-entailing sentences. SNLI included for comparison.

and frame arguments is the FrameNet dataset (Fillmore and Baker, 2001), which despite its scale, still suffers from lexical sparsity.

In order to alleviate this problem of lexical sparsity Rastogi and Van Durme (2014) use the Paraphrase Database (Ganitkevitch et al., 2013) to automatically paraphrase *trigger* tokens that evoke frames inside sentences from the FrameNet dataset. These paraphrases are noisy, and their quality is not high enough for our use. However, these paraphrases were subsequently manually rated by Pavlick et al., who asked annotators to “judge each paraphrase in terms of how well it preserved the meaning of the original sentence” (Pavlick et al., 2015). These ratings were collected on a scale from 1 to 5, where 5 meant that the paraphrase retained all of the meaning of the original sentence and 1 meant that paraphrase did not mean anything close to the original phrase. We generate our *text-hypothesis* pairs using the manual judgments of meaning retention on these *sentence-paraphrase* pairs collected by Pavlick et al..

While the *sentence-paraphrase* pairs that are labeled *entailed* and rated 3.0 and above are usually grammatically correct, the sentences with an average rating below 3 and labeled *entailed* sometimes contain a grammatical errors, and some are rated *neutral* or contradictory. Therefore, we remove sentences with an average rating less than or equal to 3.0 and greater than 2.5. All of the sentence pairs that were rated less than 2.5 were not valid entailments and they were labeled as *not-entailed*.

As an example, consider (4), which is a sentence from FrameNet.

(4) So our work must continue.

The word *work* triggers a frame and is replaced by its paraphrase *labor* by Pavlick et al. to create (5).

(5) So our labor must continue.

We consider the first sentence to be the text and the second sentence to be the hypothesis. The annota-

Dataset	Accuracy	Grammaticality
FN+	85	77
SPR	94	92
DPR	98	96
SNLI	91	96

Table 5: Accuracy of the labels assigned to the RTE pairs and the grammaticality of the hypothesis sentences. 100 random RTE pairs from each dataset were selected and each pair was assigned a value of 1 if it was correctly labeled/grammatical and 0 otherwise. We report the average score as a percentage in two separate columns for each dataset.

tors on Mechanical Turk gave this pair of sentences an average rating of around 4, and so we consider this pair of sentences as an instance of the *entailed* relation.

The DPR dataset Definite Pronoun Resolution is the problem of identifying the correct antecedent for a definite pronoun—e.g. *helhim, shelher, it*, etc.—in one clause, given two potential antecedents in a preceding clause. Data generation for this task is done manually and relies on the concept of *twin sentences*. Twin sentences are (minimally) biclausal sentences that share a (linearly) initial clause containing at least two non-pronominal referring expressions but differ on a non-initial clause containing a pronoun that could corefer with either of the two referring expressions in the initial clause but which is biased to corefer with only one.

This concept is exemplified in (6), where *the bee* and *the flower* are the two referring expressions in the initial clause for both (6a) and (6b), and *it* is the pronoun.

- (6) The bee landed on the flower because...
- ...it wanted pollen.
 - ...it had pollen.

In (6a), *it* is biased to corefer with *the bee*, and in (6b), *it* is biased to corefer with *the flower*.

In order to assign the correct antecedent of *it* in both sentences, a computational system would presumably need world-knowledge about bees and flowers. The DPR dataset is a collection of such problems and their solutions, collected by Rahman and Ng (2012) as a step towards solving the Winograd Schema Challenge (Hector et al., 2012). The ranking-based system that Rahman and Ng present obtains an accuracy of 73.1% on their dataset. This result—which, to our knowledge, remains the best posted on this dataset—outperforms a random baseline as well as various systems based on the Stanford resolver (Lee et al., 2011).

Dataset	Sentence
FN+	12:06 a.m. hrh: i was per the berkeley main library when it hit.
SPR	Me existed as a physical object.
DPR	John could not understand his waiter, because the his waiter spoke Spanish.
SNLI	A person in on concrete.

Table 6: Examples of ungrammatical hypothesis sentences from each of our datasets and SNLI.

Each DPR coreference problem-solution pair can be converted to two annotated entailment problems by substituting the target pronoun with the two expressions that it could corefer with. Thus, two RTE pairs are generated for each DPR pair: one that is entailed and one that is not entailed.

For example, (6a) is rewritten to (7a) and (7b).

- (7) a. The bee landed on the flower because the bee wanted pollen.
b. The bee landed on the flower because the flower wanted pollen.

The two RTE pairs are then (7a)–(8a), which is paired with the output *entailed*, and (7a)–(8b), which is paired with the output *not-entailed*.

Statistics Table 4 summarizes the constructed datasets as well as number of sentences and the class category breakdown of the SNLI dataset.³

4 Data Validation

Since our data is automatically generated, we performed manual validation to ensure that the generated data was high quality. To conduct this validation, we assessed a small subset of our recasted datasets as well as the SNLI dataset.

We randomly sampled 100 RTE pairs from each of the four datasets, and then a single annotator rated those 400 RTE pairs on two criteria of grammaticality and correctness. The results of the manual validation presented in Table 5 show that the data quality of the DPR and SPR datasets is on par with the quality of the RTE pairs in the SNLI datasets. The grammaticality of the hypothesis sentences in the FN+ dataset is worse than the other three datasets, but its accuracy is reasonably high.

Tables 6 and 7 show examples of ungrammatical hypothesis sentences and incorrectly labeled

³For the SNLI statistics, we map the two categories of *contradiction* and *neutral* to *not-entailed*.

Assigned Category	Text and Hypothesis
(FN+) Not Entailed	► The steps passed along the path on the other side of the wall under which i crouched. the steps passed along the path on the other outboard of the wall under which i crouched.
(SPR) Not Entailed	► The machine employs reduced instruction-set computing, or RISC, technology. Reduced instruction-set computing, or RISC, technology existed after the employing stopped.
(DPR) Entailed	► A series of injections are used to battle a type of cancer in patients because they have a special type of drug which counteracts this sickness. A series of injections are used to battle a type of cancer in patients because patients have a special type of drug which counteracts this sickness.
(SNLI) Neutral	► two guys playing music with a band The guys play music

Table 7: Examples of incorrectly labeled RTE pairs from each of our datasets and SNLI.

RTE sentence pairs to illustrate the types of errors that we make in comparison to the errors made by mechanical turkers.

5 Experiments and Results

We now conduct experiments to measure the variation in performance of neural RTE models trained using the datasets described above. The driving idea is that, by analyzing the variation in accuracy of a neural RTE model trained on different datasets on the same test set, such as the SNLI dataset, we can gain insights into the behavior of the model and potentially reveal interesting information about the SNLI dataset itself.

We first split our three datasets into train, validation, and test sets in the proportion of 80:10:10. Prior to training we convert the SNLI test set to a binary scheme by replacing both *neutral* and *contradiction* class labels with *not-entailed*.

For our model, we use the LSTM-based neural RTE model described by Bowman et al. (2015) which was their best performing individual neural model. This model first embeds the words using 300 dimensional word embeddings created using the Glove method (Pennington et al., 2014). Then, two LSTM neural networks (Hochreiter and Schmidhuber, 1997) independently encode the text and hypothesis sentences into 100 dimensional vectors. These representations are concatenated and input to a 3-layer deep 200 dimensional neural network classifier. The entire network is trained by maximizing the cross-entropy of the input-output pairs over the entire dataset using the AdaDelta (Zeiler, 2012) update rule with L2-regularization and Dropout. We evaluated each of our models on all the test sets to obtain the results in Table 8.

These results show that when the neural RTE model is trained and tested on the same dataset, the

performance on the test set is high (above 80%) for FN+, SPR, and SNLI. This suggests that these three tasks are relatively amenable to the application of neural sequence models, with the FN+ and SPR dataset being comparable in their difficulty.

Moreover, we see that the performance of the model trained on all four datasets is equal to chance performance on the DPR dataset. Further, it is consistently lower than other cross-evaluation results shown on the off-diagonals of Table 8. This suggests that complex anaphora resolution is difficult for our model to capture, especially when its training data are not focused on demonstrating correct coreference resolution. And since the performance of the SNLI trained model is the least on the DPR dataset, this may suggest that the phenomenon of anaphora resolution occurs less often than paraphrasing or proto-role resolution in the SNLI dataset.

This is corroborated by a small manual analysis. In our random sample of 100 sentences from the SNLI dataset, we did not find a single example where pronoun coreference resolution was required to predict the label correctly. In fact, in this analysis, we found that the only text that might plausibly have been rewritten as a pronoun resolution problem (8a) was not; the hypothesis for (8a) is (8b).

- (8) a. A man speaking to a woman in a grocery store as he selects a carton of juice.
b. A man is complimenting a woman on her jacket.

Finally, we can see that the SNLI trained model achieves 62.0% on the FN+ test set. While better than a most frequent label baseline (56%), this is still considerably worse than the FN+ model (80.5%), optimized for paraphrastic inference under single word replacement. We believe this is because the sentences in FN+ contain language that is rarely seen. Thus, they contain more subtle

Train Set	FN+	SPR	DPR	SNLI
FN+	80.5	60.0	49.5	62.0
SPR	65.8	80.6	50.7	52.3
DPR	19.2	65.2	49.5	65.7
SNLI	62.0	57.6	48.8	85.3

Table 8: Accuracy under 0-1 loss of predicting the entailment relation. Each cell describes the accuracy of a model trained on the corresponding row’s training set and tested on the corresponding column’s test set

differences compared to the differences between the text and the hypothesis in the SNLI dataset. This may also be why the model trained on SNLI does not perform well on any of the other datasets.

As a second illustration, we analyzed the SNLI trained RTE model’s performance on the SPR test set by dissecting the overall performance of the model by the proto-role properties that the entailment pairs were generated from. Note that all the categories appear equally in the test data. The results, shown in Figure 1, show that entailments belonging to the *change of State* category caused the highest number of errors. Based on manual inspection of examples, such as sentence 4 in Table 1, we believe that this happens because such entailments are not easily captured using lexical patterns. On the other hand information about *stationarity* and *change of possession* may be captured by neural models because the entailments are tightly coupled to the argument tokens.

6 Conclusion

We argue for constructing a suite of large-scale textual inference datasets that probe specific aspects of semantics, in order to analyze a statistical RTE model’s ability of “understanding” distinct semantic phenomena. To construct such datasets we presented a general strategy of converting semantic classification examples to annotated textual inference pairs that can be used to create large datasets for free on which even neural models for RTE can be trained. Further we used these datasets to gain insights into the behavior of a popular neural RTE model and the SNLI dataset itself. The variation in the performance of that model on the three datasets showed that neural models for natural language understanding recognise lexical variations or paraphrasing much better than anaphora resolution. Recently (Chen et al., 2016) also presented a similar conclusion after manually analyzing the errors made by neural systems on a reading comprehen-

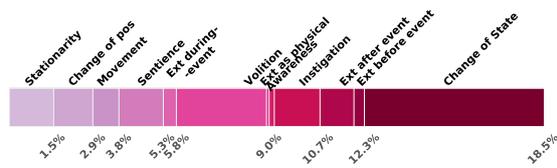

Figure 1: Percentage of errors of RTE model by *proto-role* properties on the SPR test set. The percentage numbers at the bottom are the contribution of the category above to the total errors. Error percentages that are close to each other are omitted for clarity.

sion task. Our approach can be thought of as an automatic way of automating the manual error analysis so that it can be used iteratively in a larger system and it can remove the requirement of a human in the loop. Our results also strongly suggested that the SNLI dataset does not contain examples of anaphora resolution which we validated manually. Our datasets and annotations are available at <http://decomp.net>.

In future work, we plan to execute our strategy on labeled data for Word Sense Disambiguation and Prepositional Phrase attachment resolution, among other semantic resources, because we believe that such diverse datasets will require sophisticated RTE models that combine world knowledge with the pattern recognition abilities of neural networks. For example, given the sentence *The dog wagged its tail* and a known sense of the dog the following hypotheses sentences can be generated: *The dog is a domestic dog* and *The dog is a wiener*. The former hypothesis is *entailed* but the latter is not. Disambiguating between word senses and deciding the correct governor of a prepositional phrase requires world knowledge and RTE examples generated from such sources, even though they are generated automatically unlike the FraCaS dataset, will help researchers build robust statistical models for RTE since each semantic classification dataset highlights a particular type of semantic phenomenon that a robust system for RTE must model.

Abstract

In this paper we present a novel approach to the automatic correction of OCR-induced orthographic errors in a given text. While current systems depend heavily on large training corpora or external information, such as domain-specific lexicons or confidence scores from the OCR process, our system only requires a small amount of relatively clean training data from a representative corpus to learn a character-based statistical language model using Bidirectional Long Short-Term Memory Networks (biLSTMs). We demonstrate the versatility and adaptability of our system on different text corpora with varying degrees of textual noise, including a real-life OCR corpus in the medical domain.

1 Introduction

Recently, Optical Character Recognition (OCR) technology has improved substantially, which has allowed for a large-scale digitization of textual resources such as books, old newspapers, ancient hand-written documents, etc. (Romero et al., 2011). The quality of the subsequent digital corpora can vary substantially, depending on factors such as quality of the original paper, ink quality, differences in fonts, etc. The amount of noise in digital collections can have a severe negative impact on the accuracy of subsequent text mining processes (e.g., Named Entity Recognition, Information Extraction, etc.).

OCR post-correction techniques are used to improve the text quality of OCR output. Traditionally, they rely on domain-specific lexicons (de Does and Depuydt, 2013) and character-based errors statistics obtained from a corrected

training set (Kumar and Lehal, 2016). However, they have some drawbacks that limit their usefulness for specific, low-resource domains. Such resources are expensive to create and for highly specialized texts (e.g., medical domain) not always possible to obtain. The recent advances in neural network models, based on textual context and needing no external resources, provide new opportunities for OCR post-correction. Character-level sequence modeling architectures are especially suited for this task (Chrupała, 2014; Schmaltz et al., 2016), as they reduce the complexity at output time. Moreover, current systems are often limited to processing texts with a limited degree of OCR corruption, i.e., so-called single-error word corrections (Kissos and Dershowitz, 2016) and correction of OCRed corpora that have been generated by older OCR engines can prove too challenging. The correct recognition of historical texts remains an open challenge (Kluzner et al., 2009). A general-purpose OCR post-correction tool should be adaptable to the ratio of error that is present in the OCR output in order to deal with both types of errors.

In this paper, we propose a novel approach to OCR post-correction using bidirectional recurrent neural networks for learning a robust character-based language model that (i) captures the domain-specific vocabulary of a text and (ii) which is able to detect and correct noise in corrupted text in the same time. In order to overcome the problem of producing manually annotated data, our system requires zero pre-annotated training material. Rather than using a large corrected training corpus to learn an error model, we propose a method of generating our own training material from clean text. This has multiple advantages: it allows us complete control over the learning process, and we can train on larger and more diverse corpora.

First, we demonstrate the flexibility of the proposed model by evaluating it on artificially created test sets with varying degrees of noise. We also show how variation inherent in the texts influences training rates. Second, we explore a more realistic setting in which very little clean training data is available to learn a language model. We test our method on a real-life OCRed corpus of French medical reports. Our method outperforms the baseline by 14.3% on domain-specific noisy data, even when the latter is supplemented with a domain-specific lexicon.

2 Background

The problem of OCR post-correction has been studied since the seventies (Kukich, 1992). While traditional OCR error detection systems focused on constructing ‘confusion matrices’ of likely character (pairs) to detect corruptions of existing words into non-words, recent systems improve accuracy using information on the language context in which the error appears (Evershed and Fitch, 2014), using bigrams (Kissos and Dershowitz, 2016), large-scale word n-grams and character n-grams from the web (Bassil and Alwani, 2012) or associating confusion scores into a Bayesian model (Tong and Evans, 1996) or a HMM model (Borovikov et al., 2004) to select the optimal word candidate. These systems are explicitly or implicitly limited to cases in which an erroneous word appears in an otherwise clean context. For serious degrees of corruption (e.g., historical texts), the common approach aims to optimally combine an ensemble of multiple OCR engines (Nakano et al., 2004; Lund and Ringger, 2009).

‘Noisy channel paradigm’ aims to learn error models describing the OCR output generation from the reference text, and as such combine error and language models. Kolak and Resnik (2005) used finite state machines on a small set of training material while Llobet et al. (2010) combined all OCR process hypotheses for each recognized character. Such models need a large amount of training material which is costly and not always easily available. In response, the Text-Induced Corpus Clean-up (TICCL) system (Reynaert, 2011) was developed to run with no annotated training data. It takes noisy texts and extracts the high-frequency word variants through statistical analysis and clusters typographical word variants within a user-defined Levenshtein distance.

Recently, Neural Network Language Models have proven to be extremely effective in complex NLP tasks. For spelling errors correction, systems either include auto-encoders to detect nearest neighbor matches of spelling errors with correct words (Raaijmakers, 2013) or learn edit operations from labeled data while incorporating features induced from unlabelled data via character-level neural text embeddings (Chrupała, 2014). Contrary to Azawi (2015) which makes use of LSTM based on character-aligned strings, our method does not require annotated training data (gold standard) to learn the character-based language model. Moreover, our method does not capitalize on learning character transformation rules based on frequently occurring errors, as done in Azawi (2015), but learns a robust character-based language model.

3 Method

The model we proposed consists of a many-to-many character sequence learning network using long short term memory (LSTM) nodes.

3.1 Definition

LSTM are a special type of Recurrent Neural Network (RNN), a neural network hierarchy designed to model times series or other sequences. Standard RNNs have trouble capturing long-distance sequential dependencies, as the error signal during back propagation tends to disperse or blow up over time, which is known as the problem of vanishing or exploding gradients (Hochreiter, 1991; Bengio et al., 1994). This problem is typically addressed by replacing the standard RNN cell with a long short-term memory cell, which allows for a constant error flow along the input sequence (Hochreiter and Schmidhuber, 1997).

Technically, the LSTM architecture is given by the following equations,

$$\begin{aligned}
 i^{(t)} &= \sigma(W^{ix} \cdot x^{(t)} + W^{ih} \cdot h^{(t-1)} + b_i) \\
 f^{(t)} &= \sigma(W^{fx} \cdot x^{(t)} + W^{fh} \cdot h^{(t-1)} + b_f) \\
 o^{(t)} &= \sigma(W^{ox} \cdot x^{(t)} + W^{oh} \cdot h^{(t-1)} + b_o) \\
 g^{(t)} &= \tanh(W^{gx} \cdot x^{(t)} + W^{gh} \cdot h^{(t-1)} + b_g) \\
 c^{(t)} &= f^{(t)} \odot c^{(t-1)} + i^{(t)} \odot g^{(t)} \\
 h^{(t)} &= \tanh(c^{(t)}) \odot o^{(t)}
 \end{aligned}$$

in which σ is the sigmoid function, i stands for the input gate (a selection of information coming from a previous cell state, given the new informa-

tion contained in x); f stands for the forget gate, which select which parts of the information to forget and which to retain; g creates a vector of new candidate values that are used to update the cell state; o stands for the output gate which decides what parts of the cell state should be outputted.

A bidirectional LSTM (biLSTM) is a combination of two unidirectional LSTM layers, the first of which encodes the input string from left-to-right, the second from right-to-left. This ensures that errors that occur at the beginning of the input string have enough context (on the right-hand side) to be corrected.

3.2 Encoder-Decoder Model: biLSTM model

We stack two bidirectional LSTM layers on top of each other: the first hidden level is an encoder that reads the source character sequence and the other is a decoder that functions as a language model and generates the output. Figure 1 shows the layers in their unrolled forms as they read in the input.

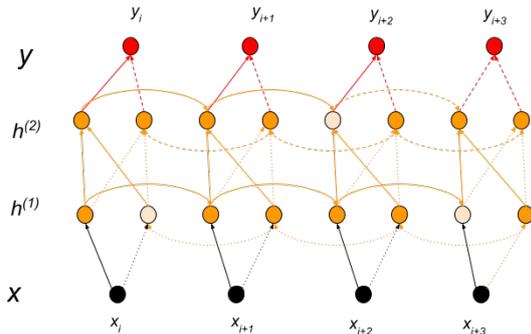

Figure 1: Hierarchy of bidirectional 2-layer many-to-many sequence learning network; lighter nodes in the hidden layers refer to disconnected nodes due to dropout

Architecture We first define a character vocabulary $V = \{v_1, v_2, \dots, v_{|V|}\}$ which contains all the characters that are present in the training corpus. Each input string of 20 characters is padded on the right-hand side to a maximum length of 23, which allows for differences in string length due to insertions in the training phase (see Section 3.3). For an input string we define a 23-dimensional vector x in which each element corresponds to the index of the corresponding character in vocabulary V , thus preserving the order. The input x is then passed to an embedding layer that returns the sequence $S = \{c_j | j = x_1, x_2, \dots, x_{23}\}$ where c_j is the character embedding (by a hyperparameter $d = 64$) for

the characters in the initial string. This sequence is then passed to the first biLSTM, which combines two unidirectional LSTM layers that process the input from the left-to-right and right-to-left hand side, respectively. Each LSTM layer H consists of k LSTM memory units, and its output is a matrix $H = \{h_t \in \mathbb{R}^k | t = 1, 2, \dots, 23\}$. We set k at 512. The output of the individual LSTM layers is concatenated and given as input for the second biLSTM layer. The last hidden layer then projects unto a $|V|$ -dimensional output layer. Finally, we apply the softmax function to select the character with the highest probability for a given timestep and obtain a 23-dimensional vector y with the characters indices for the corrected string.

We also added two drop-out layers to the hidden layers, each set at 0.5, since this has been shown to improve performance (Srivastava et al., 2014). The model was implemented in Keras, a python library for deep learning.

3.3 Training strategy

During training, the neural network is fed corrupted input strings and provided the original non-corrupted string as output labels. In this way, the network learns the domain-specific character-based language model that underlies the text in the training documents, while at the same time it learns to detect and eliminate noise introduced by OCR errors. Following the observations that OCR-induced variation is generally much less systematic than spelling errors (Reynaert, 2008), we generate corrupted strings by randomly deleting, inserting and substituting one or two characters for a given string (cf. algorithm 3.1).

We used a random number generator to determine if and which edit operations were selected. Character substitutions were performed at random with characters from the character set. Since a string could be submitted to multiple corrupting edits, this results in both single-error as well as multi-error words and environments in the corrupted string. Since the if-statements are independent, multiple edits on one string are possible, which can result in longer consecutive errors (three or more consecutive characters can be corrupted for a given string). In our script, the ratio of noise is set by the user, which corresponds to a fixed level of corruption in the training data.

Algorithm 3.1: CORRUPTSTRING(*str*, *noiseRatio*)*len* = *len*(*str*)*chars* = set of characters in corpus**comment:** Randomly delete a character**if** *rand*() < (*noiseRatio* * *len*):**then** $\begin{cases} pos = randInt(len) \\ str = str[: pos] + str[pos + 1 :] \end{cases}$ **comment:** Randomly insert a character**if** *rand*() < (*noiseRatio* * *len*):**then** $\begin{cases} pos = randInt(len) \\ str = str[: pos] + randChoice(chars) \\ + str[pos :] \end{cases}$ **comment:** Randomly replace 1 or 2 characters**if** *rand*() < (*noiseRatio* * *len*):**then** $\begin{cases} numChars = randChoice([1, 2]) \\ pos = randInt(len) \\ do\ numChars\ time \begin{cases} str = str[: pos] \\ + (randChoice(chars)) \\ + str[pos + 1 :] \\ pos ++ \end{cases} \end{cases}$

Table 1 shows the generated input strings for a given string for the different noise ratios we used. In this table, the second row shows the percentage of strings with at least one OCR error in the real-life test set. We split the initial text into windows of 20 characters with an overlap per 3 characters. This length was empirically determined on training experiments w.r.t. accuracy and training speed.

Table 1: Percentage and examples of corrupted strings w.r.t. the noise ratio on the clean corpus. Bold highlights generated errors

noise ratio	corrupted strings	strings (20 characters length) original: n oven for 15 minute
0.001	5%	
0.003	17%	
0.005	30%	
0.01	48%	n o5en for 15 minute
0.02	76%	
0.03	92%	no ven f Q r 15 minute #
0.04	99%	n o e en for 1% min ü te

4 Corpora

In our experiments, we used a few corpora, both ‘clean’ (digital corpora that contain no OCR or orthographic errors) and ‘real-life’ corpora (that contain varying degrees of OCR errors). They were selected according to two criteria: (i) text genre, either ‘structured text’ or ‘free text’, and

(ii) domain, ‘general domain’ or ‘specialized domain’, more particularly the medical domain.

Table 2 gives an overview of the different corpora and their attributes. We give the sizes of the corpora in number of characters, rather than words since the varying degrees of OCR errors make the latter an unreliable metric.

Table 2: Overview of used corpora

	text style & language	domain	size train/test
CURD	structured English	general	150K 44K
LM	free text French	general	2M 100K
Handbook	free text French	foetopath	1M -
medical reports	structured French	other medical	1M -
foetopath reports	structured French	foetopath	500K 57K

We generate several artificial test sets for two clean corpora. Artificially corrupted strings are created using the same methodology as used for training. We generated two types of artificial test sets:

- test sets with a set noise ratio, which contain both corrupted and uncorrupted strings
- and test sets that contain only corrupted strings of a set Levenshtein Distance (LD)

4.1 Clean corpora

CURD corpus The Carnegie Mellon University Recipe Database corpus (Tasse and Smith, 2008) contains 260 structured cooking recipes in English: a list of ingredients followed by short descriptive sentences. This corpus closely resembles the real-life OCRed corpus of medical reports presented in the next section. Unlike medical reports, we consider it to be ‘general domain’. We did not use the semantic annotations in the original CURD corpus but extracted only the plain text.

LM corpus We used documents from the *Le Monde* newspaper from 2000 to 2005 on as training material, and created test sets on a subset of articles from 2006.

Handbook on foetopathology We used an electronic copy of a comprehensive French handbook of foetopathology (Bouvier et al., 2008) to train a domain-specific language model of free text for the foetopathological domain.

Medical reports This set of in-house French medical reports were written in the same reporting style as the real-life OCRed foetopathological reports presented in Section 4.2. While medical, they do not treat the foetopathological domain but rather cancer and gastro-internal illnesses.

4.2 Real-life OCR corpora

The foetopathological reports corpus is a data set of French patient notes from the domain of foetopathology, spanning 22 years. In total, the corpus contains the files from 2476 individual patients. The files were processed with a custom-trained commercial OCR engine, and later de-identified with an in-house de-identification tool (Grouin and Zweigenbaum, 2013).

Since the model of the OCR engine used to convert the entire corpus was trained on a subset of documents of more recent years (implying good paper quality, clear font, etc.), the OCR quality of the OCRed documents decreases substantially for the older documents (D’hondt et al., 2016).

All evaluations in this paper were carried out on an annotated set of 53 files, for which reference texts have been created manually by one annotator in two passes.¹ We extracted two sets of training material from the corpus. One set has a reasonable OCR quality,² the second set is taken randomly from the corpus and contains texts with varying degrees of OCR quality. Both training sets have the same size.

5 Evaluation

5.1 Evaluation metrics

For evaluation, we use the CER metric (formula 1), as defined in OCR post-correction evaluations:

$$CER = \frac{S + D + I}{S + D + C} \quad (1)$$

where S refers to the number of substituted characters in the OCR text (w.r.t. the reference

¹These reference texts were later verified by a second annotator. The role of the second annotator was to check that the existing annotations were correct and consistent. Ergo the annotations were not done independently.

²Based on the proportion of out-of-vocabulary words present in a document for a given lexicon.

texts), D to the number of deleted characters, I to the number of inserted characters and C to the number of ‘correct’ characters. We use the CER metric when comparing to the baseline system (see Section 6.4), using the `ocrevalUation`³ package (Carrasco, 2014).

Since our models use overlapping⁴ windows of 20 characters, a purely character-based metric is not ideal to evaluate. We want to measure the systems performance per input, rather than per character. We therefore introduce two complementary accuracy-based evaluation metrics, which evaluate on the level of the character window:

- detection accuracy (`detAcc`) shows the proportion of correctly detected errors and non-errors in the evaluated set of 20-character strings
- correction accuracy (`corrAcc`) reflects the ability of the language model to accurately correct corrupted strings without overgenerating and editing non-corrupted strings

These metrics are calculated as follows:

$$detAcc = \frac{(TP + TN + incorrectEdit)}{(TP + TN + FP + FN + incorrectEdit)}$$

$$corrAcc = \frac{(TP + TN)}{(TP + TN + FP + FN + incorrectEdit)}$$

Table 3 illustrates the different elements of the formulae.

5.2 Baseline model

We compare our system against the only other approach which requires zero annotated training material and no external resources, the TICCL system (Reynaert, 2011). As explained in Section 2, this system is word-based and uses anagram hashing to handle lexical variation in a large, noisy text collection. The system analyses a corpus to select high-frequency word variants, and then aims to map near-neighbours (in terms of edit distance) to those forms in order to reduce global variation in the corpus.

³<https://github.com/impactcentre/ocrevalUation>

⁴Allowing this overlap is a deliberate choice to maximize the ability to learn language models over a small corpus.

Table 3: Example of evaluation categories for the detection accuracy (detAcc) and correction accuracy (corrAcc) metrics, given the reference string ‘n oven for 15 minute’

	input string	output string
True Positive (TP)	n o5en for 15 minute	n oven for 15 minute
incorrectEdit	n o5en for 15 minute	n oven for 15 m1nute
True Negative (TN)	n oven for 15 minute	n oven for 15 minute

We used the system available for French with pretrained character confusion models with its default settings.⁵ For the foetopathological reports test corpora, we provided TICCL with the full available corpora to extract word variants but calculated CER only on the test sets. TICCL performs specific preprocessing to limit the size of its character vocabulary (all numbers and digits are mapped unto the character ‘3’).

6 Experiments and Discussion

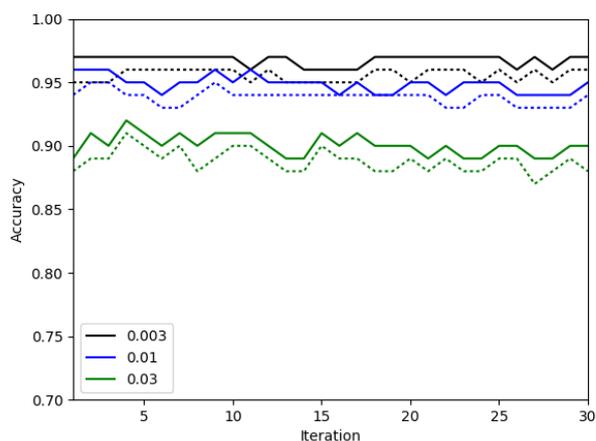

Since our system does not use annotated data, the language and error models learned from the training data are approximations of what will be encountered in the test set. In Sections 6.1 and 6.2, we examine how the error model (the prior probability of encountering an error in a given input string) learned during training corresponds to the (expected) noise ratio in the test set, and how the text genre and size of the training corpus influence performance. Section 6.3 presents how Language Models can be learned when no clean training material is available for a given test set. Section 6.4 shows a comparison with the word-based baseline.

⁵Online TICCL interface for French with default settings: <http://ticclops.clarin.inl.nl/ticclops/>

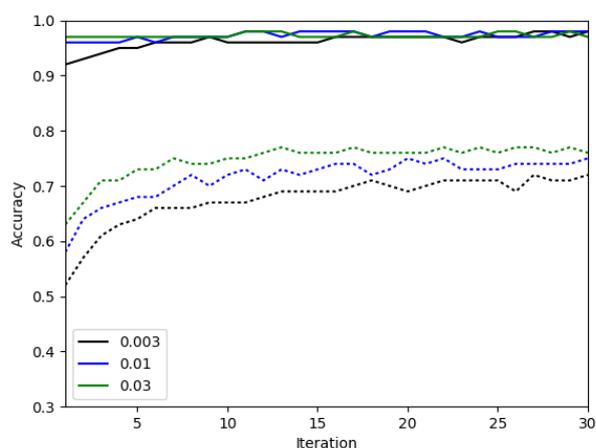

6.1 Adaptability to different degrees of noise

One of the advantages of our approach is its adaptability to different levels of expected noise. It suffices to train the model with a noise ratio that corresponds to the noise found in the test set.

The upper subfigure in Figure 2 shows the detection accuracy (full line) and correction accuracy (dotted line) on a test set with a 0.005 noise ratio for three different models which were trained in 30 iterations on the CURD training data with 0.003, 0.01 and 0.03 noise ratio, respectively.

(a) 0.005 noise ratio

(b) 0.03 noise ratio

Figure 2: Performance of models trained with different noise ratios on the CURD corpus for the 0.005 noise ratio test (upper) and 0.03 noise ratio test (lower), in terms of detection accuracy (full line) and correction accuracy (dotted line)

A 0.005 noise ratio is a fairly easy test set, with few errors, as is evidenced by the overall high scores. We do see that the model which was trained to expect a lot of noise (0.03) underperforms compared to its more conservative counterparts. For the same models on the 0.03 test set,

however, the more aggressively trained model performs the best. The high detection accuracy scores in both figures (full lines) show that the models are correctly identifying errors (i.e., unlikely character sequences) and have little tendency to ignore errors (FN) or incorrectly edit a correct string (FP). The difference between the detection accuracy (full lines) and correction accuracy (dotted lines) in Figure 2 shows the increased difficulty for the language models to make correct edits when the input strings have multiple corruptions.

Figure 3 examines this more closely. Here, the training model has been fixed (trained with noise ratio 0.03) and we examine its performance on test sets where each corrupted string has the same Levenshtein distances to its reference string. Here as well, overall detection accuracy is quite high, but the increasingly lower correction accuracy scores show the increased difficulties of the language model to propose correct edits for a given corrupted string. Since the 0.03 model is trained to expect moderate corruption, it performs best on corrupted strings with a Levenshtein distance of 2.

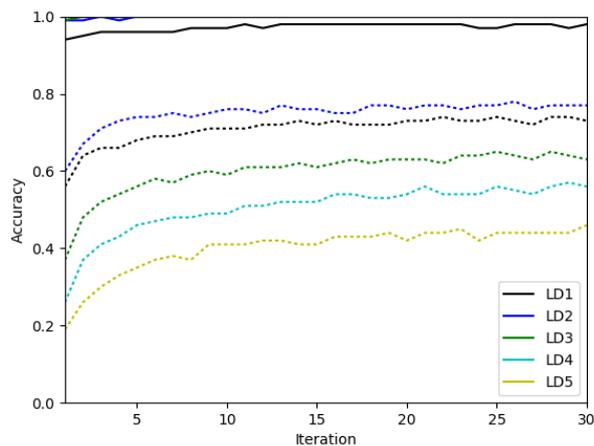

Figure 3: Performance of best model (ratio 0.03) on test sets which contain only corrupted substrings, with a fixed Levenshtein Distance (LD), in terms of detection accuracy (full line) and correction accuracy (dotted line)

6.2 Impact of text variability on training

The previous experiments were carried out on the CURD corpus, a small corpus with relatively fixed vocabulary and structured text, which makes it easy to learn a comprehensive model. Figure 4 shows the performance of a corpus with more inherent variation, the journalistic LM corpus.

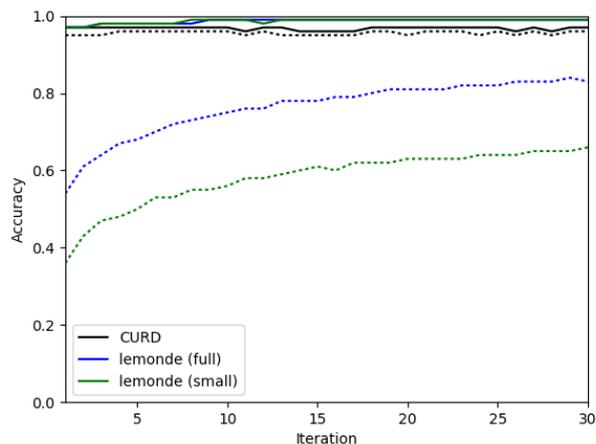

Figure 4: Performance of best-performing models on the CURD and LM 0.005 test set, in terms of detection accuracy (full line) and correction accuracy (dotted line)

As expected, the language model of a more variable corpus has a slower learning rate and needs more training data to achieve good performance. The green lines (lemonde (small)) refer to a subset of the LM corpus of exactly the same size as the CURD corpus (150K characters), which is clearly not enough training material to learn a language model on free text.

6.3 Adaptation to a real-life corpus

While the previous experiments only used artificial test sets, a more realistic setting is that in which an OCR'd test set needs to be corrected but no clean data is available to train the system on.

Table 4 presents the results we achieved on the real life test set while training our model on different types of text that are either similar to the test set w.r.t. text genre or domain. We also compared these to the performance of models that were trained on noisy training data from the same corpus as the test set. For the foetopathological reports, we trained models on two test sets of similar size, one which contained data with relatively few OCR errors, and one whose text quality was mixed.

Overall, we find that the language model of the structured foetopathological reports is fairly easy to learn, as evidenced by the high correction scores. The scores in the first two rows of Table 4 show the impact of noisy training data. While relatively clean training data pose little problem, training on the mixed set leads to a more corrupted language model. Interestingly, we find that training

Table 4: Performance of different models trained on different training data (with 0.003 noise ratio) on real-life test set of foetopathological reports

	detAcc	corrAcc
foet. reports (fairly clean)	0.87	0.82
foet. reports (mixed)	0.86	0.76
medical reports (clean)	0.85	0.79
foet. handbook (clean)	0.87	0.81
LM corpus (clean)	0.60	0.52

on similar corpora, both in text genre (medical reports) and domain (Handbook) leads to almost as good correction accuracy as training on the original corpus. The language model trained on the LM corpus, whilst having seen the most training data, has the worst performance since the text in this corpus is too far removed from foetopathological reports, both in domain and text genre.

6.4 Comparison with baseline

To compare against our baseline system, we transformed the output of the two best performing systems from the experiments in Section 6.3 to a single final output string. Where two characters differed in the overlapping output strings from our system, we used majority vote to construct the final output string.

Table 5 shows the results against the TICCL baseline system, using the CER metric. TICCL-lex refers to a setting in which it was provided with a French, domain-specific lexicon of frequent terms in the foetopathology domain. We find that our system significantly outperforms the baseline on the structured, domain-specific data, by 14.3%.

Table 5: Comparison of baseline system (TICCL) with best performing systems on the foetopathological real-life test set

	Character Error Rate (CER)
original text	34.3
biLSTM	7.1
TICCL	34
TICCL-lex	21.4

7 Conclusion

In this paper we proposed a novel zero-annotated data approach to OCR post-correction. We used biLSTMs to build an encoder-decoder model.

Rather than learning from annotated data, we developed a method to generate our own training material. Our model is trained on clean or moderately clean data in order to produce a robust character-based language model.

We have evaluated our method on different text genres and domains. We found that our method is especially suited to correct domain-specific, structured text, even when no training text from the same corpus is available.

Abstract

Hierarchical attention networks have recently achieved remarkable performance for document classification in a given language. However, when multilingual document collections are considered, training such models separately for each language entails linear parameter growth and lack of cross-language transfer. Learning a single multilingual model with fewer parameters is therefore a challenging but potentially beneficial objective. To this end, we propose multilingual hierarchical attention networks for learning document structures, with shared encoders and/or shared attention mechanisms across languages, using multi-task learning and an aligned semantic space as input. We evaluate the proposed models on multilingual document classification with disjoint label sets, on a large dataset which we provide, with 600k news documents in 8 languages, and 5k labels. The multilingual models outperform monolingual ones in low-resource as well as full-resource settings, and use fewer parameters, thus confirming their computational efficiency and the utility of cross-language transfer.

1 Introduction

Learning word sequence representations has become increasingly useful for a variety of NLP tasks such as document classification (Tang et al., 2015; Yang et al., 2016), neural machine translation (NMT) (Cho et al., 2014; Luong et al., 2015), question answering (Chen et al., 2015; Kumar et al., 2015) and summarization (Rush et al., 2015). However, when data are available in multiple languages, representation learning must ad-

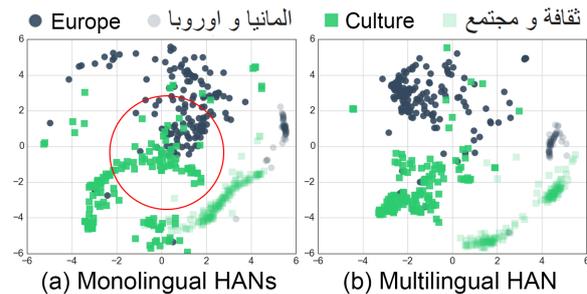

Figure 1: Vectors of documents labeled with ‘Europe’, ‘Culture’ and their Arabic counterparts. The multilingual hierarchical attention network separates topics better than monolingual ones.

dress two main challenges. Firstly, the computational cost of training separate models for each language, which grows linearly with their number, or even quadratically in the case of multi-way multilingual NMT (Firat et al., 2016a). Secondly, the models should be capable of cross-language transfer, which is an important component in human language learning (Ringbom, 2007). For instance, Johnson et al. (2016) attempted to use a single sequence-to-sequence neural network model for NMT across multiple language pairs.

Previous studies in document classification attempted to address these issues by employing multilingual word embeddings, which allow direct comparisons and groupings across languages (Klementiev et al., 2012; Hermann and Blunsom, 2014; Ferreira et al., 2016). However, they are only applicable when common label sets are available across languages which is often not the case (e.g. Wikipedia or news). Moreover, despite recent advances in monolingual document modeling (Tang et al., 2015; Yang et al., 2016), multilingual models are still based on shallow approaches.

In this paper, we propose *Multilingual Hierarchical Attention Networks* to learn shared doc-

ument structures across languages for document classification with disjoint label sets, as opposed to training language-specific training of hierarchical attention networks (HANs) (Yang et al., 2016). Our networks have a hierarchical structure with word and sentence encoders, along with attention mechanisms. Each of these can either be shared across languages or kept language-specific. To enable cross-language transfer, the networks are trained with multi-task learning across languages using an aligned semantic space as input. Fig. 1 displays document vectors, projected with t-SNE (van der Maaten, 2009), for two topics and two languages, either learned by monolingual HANs (a) or by our multilingual HAN (b). The multilingual HAN achieves better separation between ‘Europe’ and ‘Culture’ topics in English as a result of the knowledge transfer from Arabic.

We evaluate our model against strong monolingual baselines, in low-resource and full-resource scenarios, on a large multilingual document collection with 600k documents, labeled with general (1.2k) and specific topics (4.4k), in 8 languages from Deutsche Welle’s news website.¹ Our multilingual models outperform monolingual ones in both scenarios, thus confirming the utility of cross-language transfer and the computational efficiency of the proposed architecture. To encourage further research in multilingual representation learning our code and dataset are made available at <https://github.com/idiap/mhan>.

2 Related Work

Research on *learning multilingual word representations* is based on early work on word embeddings (Turian et al., 2010; Mikolov et al., 2013; Pennington et al., 2014). The goal is to learn an aligned word embedding space for multiple languages by leveraging bilingual dictionaries (Faruqui and Dyer, 2014; Ammar et al., 2016), parallel sentences (Gouws et al., 2015) or comparable documents such as Wikipedia pages (Yih et al., 2011; Al-Rfou et al., 2013). Bilingual embeddings were learned from word alignments using neural language models (Klementiev et al., 2012; Zou et al., 2013), including auto-encoders (Chandar et al., 2014). Despite progress at the word level, the document level remains comparatively less explored. The approaches proposed by Hermann and Blunsom (2014) or Ferreira et al.

(2016) are based on shallow modeling and are applicable only to classification tasks with label sets shared across languages, which are costly to produce and are often unavailable. Here, we remove this constraint, and develop deeper multilingual document models with hierarchical structure based on prior art at the word level.

Early work on *neural document classification* was based on shallow feed-forward networks, which required unsupervised pre-training (Le and Mikolov, 2014). Later studies focused on neural networks with hierarchical structure. Kim (2014) proposed a convolutional neural network (CNN) for sentence classification. Johnson and Zhang (2015) proposed a CNN for high-dimensional data classification, while Zhang et al. (2015) adopted a character-level CNN for text classification. Lai et al. (2015) proposed a recurrent CNN to capture sequential information, which outperformed simpler CNNs. Lin et al. (2015) and Tang et al. (2015) proposed hierarchical recurrent NNs and showed that they were superior to CNN-based models. Recently, Yang et al. (2016) proposed a hierarchical attention network (HAN) with bi-directional gated encoders which outperforms traditional and neural baselines. Using such networks in multilingual settings has two drawbacks: the computational complexity increases linearly with the number of languages, and knowledge is acquired separately for each language. We address these issues by proposing a new multilingual model based on HANs, which learns shared document structures and to transfer knowledge across languages.

Early examples of *attention mechanisms* appeared in computer vision, e.g. for optical character recognition (Larochelle and Hinton, 2010), image tracking (Denil et al., 2012), or image classification (Mnih et al., 2014). For text classification, studies which aimed to learn the importance of sentences included those by Yessenalina et al. (2010); Pappas and Popescu-Belis (2014); Yang et al. (2016) and more recently those by Pappas and Popescu-Belis (2017); Ji and Smith (2017). For NMT, Bahdanau et al. (2015) proposed an attention-based encoder-decoder network, while Luong et al. (2015) proposed a local and ensemble attention model. Firat et al. (2016a) proposed a single encoder-decoder model with shared attention across language pairs for multi-way, multilingual NMT. Hermann et al. (2015) developed attention-based document readers for question an-

¹Germany’s news broadcaster: <http://dw.com>.

swering. Chen et al. (2015) proposed a recurrent attention model over an external memory. Similarly, Kumar et al. (2015) introduced a dynamic memory network for question answering and other tasks. We propose here to share attention across languages, at one or more levels of hierarchical document models, which, to our knowledge, has not been attempted before.

3 Background: Hierarchical Attention Networks for Document Classification

We adopt a general hierarchical attention architecture for document representation, displayed in Figure 2, which is derived from the one proposed by Yang et al. (2016). Our architecture is general in the sense that it defines only the hierarchical structure, but accommodates different types of individual components, i.e. encoders and attention models. We consider a dataset $D = \{(x_i, y_i), i = 1, \dots, N\}$ made of N documents x_i with labels $y_i \in \{0, 1\}^k$. Each document is represented by the sequence of d -dimensional embeddings of their words grouped into sentences, $x_i = \{w_{11}, w_{12}, \dots, w_{KT}\}$, T being the maximum number of words in a sentence, and K the maximum number of sentences in a document.

The network takes as input a document x_i and outputs a document vector u_i . In particular, it has two levels of abstraction, word vs. sentence. The word level is made of an encoder g_w with parameters H_w and an attention model a_w with parameters A_w , while the sentence level similarly includes an encoder and an attention model (g_s, H_s and a_s, A_s). The output u_i is used by the classification layer to determine y_i .

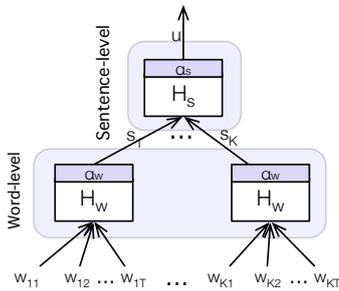

Figure 2: General architecture of hierarchical attention neural networks for modeling documents.

3.1 Encoder Layers

At the word level, the function g_w encodes the sequence of input words $\{w_{it} \mid t = 1, \dots, KT\}$ for

each sentence i of the document, noted as:

$$h_w^{(it)} = \{g_w(w_{it}) \mid t = 1, \dots, K\} \quad (1)$$

At the sentence level, after combining the intermediate word vectors $\{h_w^{(it)} \mid t = 1, \dots, T\}$ to a sentence vector s_i (as explained in 3.2), the function g_s encodes the sequence of sentence vectors $\{s_i \mid i = 1, \dots, K\}$, noted as $h_s^{(i)}$.

The g_w and g_s functions can be any feed-forward or recurrent networks with parameters H_w and H_s respectively. We consider the following networks: a fully-connected one, noted as DENSE, a Gated Recurrent Unit network (Cho et al., 2014) noted as GRU², and a bi-directional GRU which captures temporal information forward or backward in time, noted as biGRU. The latter is defined as a concatenation of the hidden states for each input vector obtained from the forward GRU, \vec{g}_w , and the backward GRU, \overleftarrow{g}_w :

$$h_w^{(it)} = [\vec{g}_w(h_w^{(it)}); \overleftarrow{g}_w(h_w^{(it)})]. \quad (2)$$

The same concatenation is applied for the hidden-state representation of a sentence $h_s^{(i)}$.

3.2 Attention Layers

A typical way to obtain a representation for a given word sequence at each level is by taking the last hidden-state vector that is output by the encoder. However, it is hard to encode all the relevant input information needed in a fixed-length vector. This problem is addressed by introducing an attention mechanism at each level (noted α_w and α_s) that estimates the importance of each hidden state vector to the representation of the sentence or document meaning respectively. The sentence vector $s_i \in R^{d_w}$, where d_w is the dimension of the word encoder, is thus obtained as follows:

$$\frac{1}{T} \sum_{t=1}^T \alpha_w^{(it)} h_w^{(it)} = \frac{1}{T} \sum_{t=1}^T \frac{\exp(v_{it}^\top u_w)}{\sum_j \exp(v_{ij}^\top u_w)} h_w^{(it)} \quad (3)$$

where $v_{it} = f_w(h_w^{(it)})$ is a fully-connected neural network with W_w parameters. Similarly, the document vector $u \in R^{d_s}$, where d_s is the dimension of the sentence encoder, is obtained as follows:

$$\frac{1}{K} \sum_{i=1}^K \alpha_s^{(i)} h_s^{(i)} = \frac{1}{K} \sum_{i=1}^K \frac{\exp(v_i^\top u_s)}{\sum_j \exp(v_j^\top u_s)} h_s^{(i)} \quad (4)$$

²GRU is a simplified version of Long-Short Term Memory, LSTM (Hochreiter and Schmidhuber, 1997).

where $v_i = f_s(h_s^{(i)})$ is a fully-connected neural network with W_s parameters. The vectors u_w and u_s are parameters which encode the word context and sentence context respectively, and are learned jointly with the rest of the parameters. The total set of parameters for a_w is $A_w = \{W_w, u_w\}$ and for a_s is $A_s = \{W_s, u_s\}$.

3.3 Classification Layers

The output of such a network is typically fed to a softmax layer for classification, with a loss based on the cross-entropy between gold and predicted labels (Tang et al., 2015) or on the negative log-likelihood of the correct labels (Yang et al., 2016). However, softmax overemphasizes the probability of the most likely label, which may not be ideal for multi-label classification because each document should have more than one likely labels independent of each other, as we verified empirically in our preliminary experiments. Hence, we replace the softmax with a sigmoid function, so that for each document i represented by the vector u_i we model the probability of the k labels as follows:

$$\hat{y}_i = p(y|u_i) = \frac{1}{1 + e^{-(W_c u_i + b_c)}} \in [0, 1]^k \quad (5)$$

where W_c is a $d_s \times k$ matrix and b_c is the bias term for the classification layer. The training loss based on cross-entropy is computed as follows:

$$\mathcal{L}(\theta) = -\frac{1}{N} \sum_{i=1}^N \mathcal{H}(y_i, \hat{y}_i) \quad (6)$$

where θ is a notation for all the parameters of the model (i.e. H_w, A_w, H_s, A_s, W_c), and \mathcal{H} is the binary cross-entropy of the gold labels y_i and predicted labels \hat{y}_i for a document i . The above objective is differentiable and can be minimized with stochastic gradient descent (SGD) (Bottou, 1998) or variants such as Adam (Kingma and Ba, 2014), to maximize classification performance.

4 Multilingual Hierarchical Attention Networks: MHANs

When multilingual data is available, the above network can be trained on each language separately, but in this case the needed parameters grow linearly with the number of languages. Moreover, this does not exploit common knowledge across languages or to transfer it from one to another. We propose here a HAN with shared components across languages, which has slower

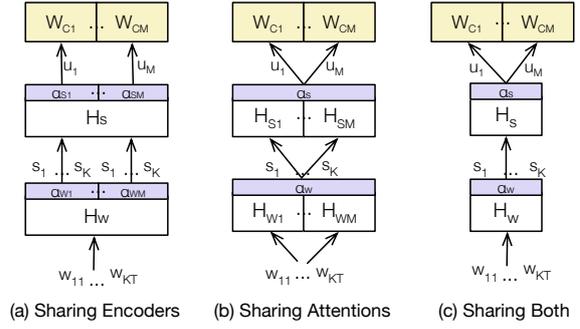

Figure 3: Multilingual hierarchical attention networks for modeling documents and classifying them over disjoint label sets.

parameter growth (hence sublinear) compared to monolingual ones and enables knowledge transfer across languages. We now consider M languages noted $L = \{L_l \mid l = 1, \dots, M\}$, and a multilingual set of topic-labeled documents $D_l = \{(x_i^{(l)}, y_i^{(l)}) \mid i = 1, \dots, N_l, l = 1, \dots, M\}$ defined as above (Section 3).

4.1 Sharing Components across Languages

To enable multilingual learning, we propose three distinct ways for sharing components between networks in a multi-task learning setting, depicted in Figure 3, namely: (a) sharing the parameters of word and sentence encoders, noted $\theta_{enc} = \{H_w, W_w^{(l)}, H_s, W_s^{(l)}, W_c^{(l)}\}$; (b) sharing the parameters of word and sentence attention models, noted $\theta_{att} = \{H_w^{(l)}, W_w, H_s^{(l)}, W_s, W_c^{(l)}\}$; and (c) sharing both previous sets of parameters, noted $\theta_{both} = \{H_w, W_w, H_s, W_s, W_c^{(l)}\}$. For instance, the document representation of a text for language l based on a shared sentence-level attention would be computed based on Eq. 4 by using the same parameters W_s and u_s across languages.

Let $\theta_{mono} = \{H_w^{(l)}, W_w^{(l)}, H_s^{(l)}, W_s^{(l)}, W_c^{(l)}\}$ be the parameters of multiple independent monolingual models with DENSE encoders, then we have:

$$|\theta_{mono}| > |\theta_{enc}| > |\theta_{att}| > |\theta_{both}| \quad (7)$$

where $|\cdot|$ is the number of parameters in a set. For GRU and biGRU encoders, the inequalities still hold, but swapping $|\theta_{enc}|$ and $|\theta_{att}|$. Excluding the classification layer which is necessarily language-specific, the (a) and (b) networks have sublinear numbers of parameters and the (c) network has a constant number of parameters with respect to the number of languages. The word embeddings are not considered as parameters in our setup because

they are fixed during training. For learned word embeddings, the argument still holds if we consider their parameters as part of the word-level encoder.

Depending on the label sets, several types of document classification problems can be solved with such architectures. First, label sets can be common or disjoint across languages. Second, considering labels as k -hot vectors, $k = 1$ corresponds to a multi-class task, while $k > 1$ is a multi-label task. We focus here on the multi-label problem with disjoint label sets. Moreover, we assume an aligned input space i.e. with multilingual word embeddings that have aligned meanings across languages (Ammar et al., 2016). With non-aligned word embeddings, the multilingual transfer is harder due to the lack of parallel information, as we show in Section 6.2, Table 4.

4.2 Training over Disjoint Label Sets

For training, we replace the monolingual training objective (Eq. 6) with a joint multilingual objective that facilitates the sharing of components, i.e. a subset of parameters for each language $\theta_1, \dots, \theta_M$, across different language networks:

$$\mathcal{L}(\theta_1, \dots, \theta_M) = -\frac{1}{Z} \sum_i^{N_e} \sum_l^M \mathcal{H}(y_i^{(l)}, \hat{y}_i^{(l)}) \quad (8)$$

where $Z = M \times N_e$ and N_e is the epoch size.³

The joint objective \mathcal{L} can be minimized with respect to the parameters $\theta_1, \dots, \theta_M$ using SGD as before. However, when training on examples from different languages consecutively it is difficult to learn a shared space that works well across languages. This is because updates for each language apply only on a subset of parameters and may bias the model away from other languages. To address this issue, we employ the training strategy proposed by (Firat et al., 2016a), who sampled parallel sentences for multi-way machine translation from different language pairs in a cyclic fashion at each iteration.⁴ Here, we sample a document-label pair from each language at iteration. For mini-batch SGD, the number of samples per language is equal to the batch size divided by M .

³In the future, it may also be beneficial to add a γ_l term for each language objective, which encodes prior knowledge about its importance.

⁴We verified this empirically in our preliminary experiments and found that mixing languages in a single batch performed better than keeping them in separate batches.

Languages L	Documents			Labels	
	$ X $	\bar{s}	\bar{w}	$ Y_g $	$ Y_s $
English	112,816	17.9	516.2	327	1,058

5 A New Corpus for Multilingual Document Classification: DW

Multilingual document classification datasets are usually limited in size, have target categories aligned across languages, and assign documents to only one category. However, classification is often necessary in cases where the categories are not strictly aligned, and multiple categories may apply to each document. For instance, this is the case for online multilingual news agencies, which must keep track of news topics across languages.

Two datasets for multilingual document classification have been used in previous studies: Reuters RCV1/RCV2 (6,000 documents, 2 languages and 4 labels), introduced by (Klementiev et al., 2012), and TED talk transcripts (12,078 documents, 12 languages and 15 labels), introduced by Hermann and Blunsom (2014). The former is tailored for evaluating word embeddings aligned across languages, rather than complex multilingual document models. The latter is twice as large and covers more languages, in a multi-label setting, but biases evaluation by including translations of talks in all languages.

Here, we present and use a much larger dataset collected from Deutsche Welle, Germany’s public international broadcaster, shown in Table 2. The DW dataset contains nearly 600,000 documents, in 8 languages, annotated by journalists with several topic labels. Documents are on average 2.6 times longer than in Yang et al.’s (2016) monolingual dataset (436 vs. 163 words). There are two types of labels, namely *general topics* (Y_g) and *specific* ones (Y_s) both described by one or more words. We consider (and count in Table 2) only those specific labels that appear at least 100 times, to avoid sparsity issues.

The number of labels varies greatly across the

Table 1: Full-resource classification performance (F_1) on general (top) and specific (bottom) topic categories using bilingual training with English as target (left) and the auxiliary language as target (right).

8 languages. Moreover, we found for instance that only 25-30% of the labels could be manually aligned between English and German. The commonalities are mainly concentrated on the most frequent labels, reflecting a shared top-level division of the news domain, but the long tail exhibits significant independence across languages.

6 Evaluation

6.1 Settings

We evaluate our multilingual models on full-resource and low-resource scenarios of multilingual document classification on the Deutsche Welle corpus. Following the typical evaluation protocol in the field, the corpus is split per language into 80% for training, 10% for validation and 10% for testing. We evaluate both type of labels (Y_g , Y_s) on a *full-resource scenario* and only the general topic labels (Y_g) on a *low-resource scenario*. We report the micro-averaged F1 scores for each test set, as in previous work (e.g., [Hermann and Blunsom, 2014](#)).

Model configuration. For all models, we use the aligned 40-dimensional multilingual embeddings pre-trained on the Leipzig corpus using multi-CCA from [Ammar et al. \(2016\)](#). The non-aligned embeddings used for comparison purposes are trained with the same method and data. We zero-pad documents up to a maximum of 30 words per sentence and 30 sentences per document. The hyper-parameters were selected on the validation sets. We made the following settings: 100-dimensional encoder and attention embeddings (at every level), relu activation function for all intermediate layers, batch size of 16, epoch size of 25k, and optimization using SGD with Adam until convergence.

All the hierarchical models have DENSE encoders in both scenarios (Tables 1, 4, and 5), and GRU and biGRU in the full-resource scenario for English+Arabic (Table 3). For the low-resource scenario, we define three levels of data availability: *tiny* from 0.1% to 0.5%, *small* from 1% to 5% and *medium* from 10% to 50% of the original training set. We report the average F_1 scores on the test set for each level based on discrete increments of 0.1, 1 and 10 percentage points respectively. The decision threshold for the value of p in Eq. 5 for the full-resource scenario is set to 0.4 for labels such that $|Y_s| < 400$ and 0.2 for $|Y_s| \geq 400$, and for the low-resource scenario it is 0.3 for all sets. For the *ensemble* in the low-resource setting, we train the three proposed multilingual models and choose the optimal one based on the validation data for each language respectively (see Fig. 4).

Baselines. We compare against the following monolingual neural networks, with shallow or hierarchical structures. These networks are based on the state of the art in the field, reviewed in Section 2, and thus represent strong baselines.

- **NN** : A neural network which feeds the average vector of the input words directly to a classification layer, as the common baseline for multilingual document classification ([Klementiev et al., 2012](#)).
- **HNN** : A hierarchical network with encoders and average pooling at every level, followed by a classification layer.
- **HAN**: A hierarchical network with encoders and attention, followed by a classification layer. This model is the one proposed by [Yang et al. \(2016\)](#) adapted to our task.

Our multilingual models with the three sharing

configurations from Section 4.1, are noted as *Enc*, *Att* and *Both*. Their implementation amounts to, first, creating a HAN model for each language, second, sharing components across multiple languages as illustrated in Fig. 3, and, third, training them with the objective of Eq. 8.

6.2 Results

Full-resource scenario. Table 1 displays the results of full-resource document classification using DENSE encoders for general and specific labels. On the left side, the performance on the English sub-corpus is shown when English and an auxiliary sub-corpus are used for training, and on the right side, the performance on the auxiliary sub-corpus is shown when that sub-corpus and the English sub-corpus are used for training.

The multilingual model trained on pairs of languages outperforms on average all the examined monolingual models, namely a bag-of-word neural model and two hierarchical neural models which use average pooling and attention respectively. The best-performing multilingual model bilingually on average is the one with shared attention across languages, especially when tested on English. The consistent gain for English as target could be attributed to the alignment of the word embeddings to English and to the many English labels, which makes it easier to find multilingual labels from which to transfer knowledge. Interestingly, this reveals that the transfer of knowledge across languages in a full-resource setting is maximized with language-specific word and sentence encoders, but language-independent (i.e. shared) attention for both words and sentences.

However, when transferring from English to Portuguese (en→pt), Russian (en→ru) and Persian (en→fa) on general categories, it is more effective to have only language-independent components. We hypothesize that this is due to the underlying commonness between the label sets rather than to a relationship between languages, which is hard to identify on linguistic grounds.

We will now quantify the impact of three important model choices on the performance: encoder type, word embeddings, and number of languages used for training. In Table 3, we observe that when we replace the DENSE encoder layers with GRU or biGRU layers, the improvement from the multilingual training is still present. In particular, the multilingual models with shared atten-

	Encoders	Mono	Multi		
			$Y_{general}$	HAN	Enc
ar→en	DENSE	71.2	70.0	73.8	68.9
	GRU	77.0	74.8	77.5	75.4
	biGRU	77.7	77.1	77.5	76.7
en→ar	DENSE	80.5	79.0	82.1	79.1
	GRU	81.5	81.2	83.4	83.1
	biGRU	82.2	82.7	84.0	83.0

Table 3: Full-resource classification performance (F_1) for English-Arabic with various encoders.

		n_l	f_l	n_l	f_l
Aligned	1	50K –	77.41 –	90K –	44.90 –
	2	40K ↓	78.30 ↑	80K ↓	45.72 ↑
	8	32K ↓	77.91 ↑	72K ↓	45.82 ↑
Non-aligned	8	32K ↓	71.23 ↓	72K ↓	33.41 ↓

Table 4: Average number of parameters per language (n_l), average F_1 per language (f_l), and their variation (arrows) with the number of languages $|L|$ and the word embeddings used for training.

tion are superior to alternatives, regardless of the employed encoders. For reference, using simply logistic regression with bag-of-words (counts) for classification leads to F_1 scores of 75.8% in English and 81.9% in Arabic, using many more parameters than biGRU: 56.5M vs. 410k in English and 5.8M vs. 364k in Arabic.

In Table 4, when we train our multilingual model (MHAN-att) on eight languages at the same time, the F_1 score improves on average across languages – for both types of labels, general or specific – while the number of parameters per language decrease, by 36% for $Y_{general}$ and 20% for $Y_{specific}$. Lastly, when we train the same model with word embeddings that are not aligned across languages, the performance of the multilingual model drops significantly. An input space that is aligned across languages is thus crucial.

Low-resource scenario. We assess the ability of the multilingual attention networks to transfer knowledge across languages in a low-resource scenario, i.e. training on a fraction of the available data, as defined in 6.1 above. The results for seven languages when trained jointly with English are displayed in detail in Table 5 and summarized in Figure 4. In all cases, at least one of the multilingual models outperforms the monolingual one, which demonstrates the usefulness of multilingual training for low-resource document classification.

Moreover, the improvements obtained from our multilingual models for lower levels of availabil-

Table 5: Low-resource classification performance (F_1) with various sizes of training data.

ity (*tiny* and *small*) are larger than in higher levels (*medium*). This is also clearly observed in Figure 4 with our multilingual attention network ensemble, i.e. when we do model selection among the three multilingual variants on the development set. The best performing architecture in a majority of cases is the one which shares both the encoders and the attention mechanisms across languages. Moreover, this architecture also has the fewest number of parameters.

This promising finding for the low-resource scenario means that the classification performance can greatly benefit from the multilingual training (sharing encoders and attention) without increasing the number of parameters beyond that of a single monolingual document model. Nevertheless, in a few cases, we observe that the other architectures with increased complexity perform better than the “shared both” model. For instance, sharing encoders is superior to alternatives for Arabic language, i.e. the knowledge transfer benefits from shared word and sentence representations. Hence, to generalize to a large number of languages, we

may need to consider more dynamic models which are able to choose for each language individually which sharing scheme is the most appropriate for transferring from another language. Lastly, we did not generally observe a negative (or positive) correlation of the similarity between languages with the performance in the low-resource scenario, although the largest improvements were observed on languages more related to English (German, Spanish, Portuguese) than others (Arabic).

Overall, the above experiments pinpointed the most suitable multilingual sharing scheme (Figure 3) for each setting independently of the encoder type, rather than the optimal combination of sharing scheme and encoder. Therefore, as shown in Table 3, increasing the sophistication of the encoders (from DENSE to GRU to biGRU) is expected to further improve accuracy.

6.3 Qualitative Analysis

We analyze the performance of the multilingual model over the full range of labels, to observe on which type of labels it performs better than the monolingual model, and provide some qualitative examples. Figure 5 shows the cumulative true positive (TP) difference between the monolingual and multilingual models on the Arabic, German, Portuguese and Russian test sets, ordered by label frequency. We can observe that the cumulative TP difference of the multilingual model consistently increases as the frequencies of the labels decrease. This shows that labels across the entire range of frequencies benefit from joint training with English and not only a subset, for example only the highly frequent labels.

For example, the top 5 labels on which the multilingual model performed better than the monolingual one for en→de were: *russland* (21), *berlin* (19), *irak* (14), *wahlen* (13) and *nato* (13), while for the opposite direction those were: *germany* (259), *german* (97), *soccer* (73), *football* (47) and *merkel* (25). These topics are likely better covered in the respective auxiliary language which helps

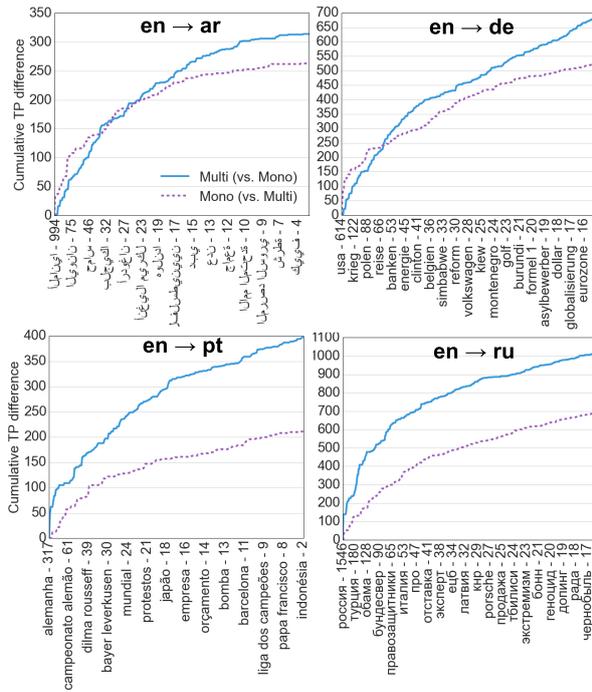

Figure 5: Cumulative true positive (TP) difference between *monolingual* and *multilingual* (ensemble) models for topic classification with *specific* labels, in the full resource scenario.

the multilingual model to better distinguish them in the target language as well. This is also observed in Figure 1 presented in the introduction, through an improved separation of topics using multilingual model vs. monolingual ones.

7 Conclusion

We proposed multilingual hierarchical attention networks for document classification and showed that they can benefit both full-resource and low-resource settings, while using fewer parameters than monolingual networks. In the former setting, the best option was to share only the attention mechanisms, while in the latter one, it was sharing the encoders along with the attention mechanisms. These results confirm the merits of language transfer, which is also an important component of human language learning (Odlin, 1989; Ringbom, 2007). Moreover, our study broadens the applicability of multilingual document classification, since our framework is not restricted to common label sets.

There are several future directions for this study. In their current form, our models cannot generalize to languages without any example, as attempted by Firat et al. (2016b) for neural machine

translation. This could be achieved by a classification layer independent of the size of the label set as in zero-shot classification (Qiao et al., 2016; Nam et al., 2016). Moreover, although we explored three distinct architectures, other configurations could be examined to improve document modeling, for example by sharing the attention mechanism at the sentence-level only. Lastly, the learning objective could be further constrained with sentence-level parallel information, to embed multilingual vectors of similar topics more closely together in the learned space.

Acknowledgments

We are grateful for the support from the European Union through its Horizon 2020 program in the SUMMA project n. 688139, see <http://www.summa-project.eu>. We would also like to thank Sebastião Miranda at Priberam for gathering the news articles from Deutsche Welle and the anonymous reviewers for their helpful suggestions. The second author contributed to the paper while at the Idiap Research Institute.

Abstract

In this work we investigate how role-based behavior profiles of a Wikipedia editor, considered against the backdrop of roles taken up by other editors in discussions, predict the success of the editor at achieving an impact on the associated article. We first contribute a new public dataset including a task predicting the success of Wikipedia editors involved in discussion, measured by an operationalization of the lasting impact of their edits in the article. We then propose a probabilistic graphical model that advances earlier work inducing latent discussion roles using the light supervision of success in the negotiation task. We evaluate the performance of the model and interpret findings of roles and group configurations that lead to certain outcomes on Wikipedia.

1 Introduction

In this paper we explore the discussion strategies and configurations of conversational roles that allow Wikipedia editors to influence the content of articles. In so doing, we contribute both a new public dataset and proposed model that advance work towards induction of latent conversational roles using light supervision.

Online production communities like Wikipedia, an online encyclopedia which anyone can edit, have the potential to bring disparate perspectives together in producing a valuable public resource. Individual Wikipedia editors unavoidably carry their own perspectives; these voices can explicitly or subtly influence the jointly produced article content even when editors strive for neutrality¹.

¹https://en.wikipedia.org/wiki/Wikipedia:Neutral_point_of_view

This work explores the interaction between individual editors and the collaborative process that supervises the development of a Wikipedia article.

Wikipedia editors discuss article improvements, coordinate work and resolve disagreements on talk pages associated with each article (Ferschke, 2014). Pairing talk page discussions with simultaneous edits in shared content, we introduce a task predicting the success of a particular editor’s article edits based on the corresponding discussion.

We propose a lightly supervised probabilistic graphical model of discussion roles and behaviors that offers advances over the prior discussion role modeling work of Yang et al. (2015), which employs a more restricted conceptualization of role taking. While the earlier model only allowed each role to be played by one editor, our extended model learns a distribution over roles for each editor. Furthermore, it can assign roles to an arbitrary number of editors rather than being restricted to a specific number.

This model allows the interpretation of configurations of roles that are conducive or detrimental to the success of individual editors. We find that the greatest success is achieved by detail-oriented editors working in cooperation with editors who play more abstract organizational roles.

2 Related Work

This work investigates influence in discussion as part of the collaborative editing process of Wikipedia, but achieving influence through discussion has also been studied in online environments other than Wikipedia. For example, other work in language technologies has studied the effectiveness of argumentative speech in changing others’ minds (Tan et al., 2016) and revealing subgroups of users with similar attitudes (Hassan et al., 2012).

Our work fits with research on editor behavior on Wikipedia, which is relatively well-studied on article pages and somewhat less studied on talk pages. Wikipedia has been a popular source of data for modeling social interaction and other issues of language behavior from multiple perspectives including collaboration (Ferschke et al., 2012), authority (Bender et al., 2011), influence (Bracewell et al., 2012; Swayamdipta and Rambow, 2012), and collegiality and adversity (Bracewell et al., 2012).

Much work analyzing behavior in Wikipedia has focused on types of edit behavior. Yang et al. (2016) use an LDA-based model to derive editor roles from edit behaviors. They then find correlations between certain editor roles and article quality improvements. Their approach differs from ours in that our model is supervised with an outcome measure and that we define editor roles based on talk page behavior.

Behavior in discussion can be characterized at multiple levels of granularity. Viégas et al. (2007) categorize talk page contributions into 11 classes, and find that the most common function of talk page behavior is to discuss edits to the corresponding article, but that requests for information, references to Wikipedia policies, and off-topic remarks are also commonly found. Bender et al. (2011) annotate authority claims and agreement in Wikipedia talk pages.

Above the level of individual contributions to discussion, the notion of a conversational role is relevant both for characterizing the rights and responsibilities an individual has within an interaction as well as the configuration of conversational behaviors the person is likely to engage in. Therefore, it is not surprising that prior work has revealed that the process of becoming a Wikipedia moderator is associated both with changes in language use and in the roles editors play on the talk pages (Danescu-Niculescu-Mizil et al., 2012).

Attempts have been made to understand roles Wikipedia editors play. Arazy et al. (2017) find self-organizing roles based on the edit behavior of thousands of editors. Editors frequently move in and out of those roles, but on the aggregate the proportions of these roles are relatively stable.

Our work is similar to that of Ferschke et al. (2015), who apply the role identification model of Yang et al. (2015) to Wikipedia talk page contributions. This model learns a predefined number of

user roles, each of which is represented as weights on a set of user behaviors, and assigns the roles to the participants in each discussion. The roles are induced by rewarding latent role representations with high utility in selecting users whose behavior was highly predictive of the task outcome of article quality. We extend this work by predicting an outcome that is specific to one discussion participant, i.e. the editing success of a particular editor within an interaction. We also relax the constraint that every role must be assigned to a single participant and that each participant can take at most one role. Our model is thus more flexible in capturing more nuanced configurations of roles.

3 Data and Task

One of the contributions of this work is the creation of a new public dataset² and task for predicting the influence of editors in Wikipedia discussions. The dataset comprises 53,175 instances in which an editor interacts with one or more other editors in a talk page discussion and achieves a measured influence on the associated article page. In this section we detail the motivation for the conceptualization of the task as an influence prediction task, and the details for the construction of the dataset.

3.1 Task Conceptualization

Wikipedia talk pages are not stand-alone discussion forums. They are explicitly designed to support coordination in editing of their associated article pages. In order to extract task instances, we pair discussions with the record of concurrent edits to the associated article page.

Once a discussion has been paired with a sequence of edits, an assessment can be made for each editor who participated both in the discussion and in article edits of how successful that editor was in making changes to the article page. It is this assessment that forms the class value of our predictive task. In this study we explore negotiation strategies and role configurations that affect article editing; each data point in our task provides both discussion and an article edit success value for each editor involved.

²This dataset is available at <http://github.com/michaelmiller/yoder/wikipedia-talk-scores>

3.2 Data Acquisition

To form our dataset, we extracted all versions (*revisions*) of English Wikipedia articles from 2004 to 2014 and removed much of the Mediawiki markup using the Java Wikipedia Library (JWPL) (Ferschke et al., 2011). The most recent revisions of talk pages corresponding to the articles were split into turns using paragraph boundaries and edit history. We grouped discussion posts under the same section headings as *discussion threads*.

We sampled 100,000 articles with talk page discussions and filtered to include discussion threads with 2 or more participants who made edits to the article page from 24 hours before the discussion began to 24 hours after the discussion ended. Discussion thread beginnings and endings are defined as the time of the first post and last post, respectively. Statistics on our discussion dataset can be seen in Table 1.

number of articles	7,211
number of discussion threads	21,108
number of editor-discussion pairs	53,175
average #editors/discussion	2.52

Table 1: Dataset statistics

3.3 Editor Success Scores

Editors frequently enter into talk page discussions to modify the article page in a particular way or challenge others’ edits. We wish to quantify the success of editors on the article page as related to these goals on the talk page. In prior work, editor success has been measured with respect to the longevity of edits made to a page (Priedhorsky et al., 2007), and we take a similar approach. We define a success score y for each editor in a specific discussion. Intuitively, this measure is computed as the change in word frequency distribution associated with an editor’s edits between the article revision prior to discussion and the article revision when the discussion ends. In particular, this score is the proportion of an editor’s edits—words deleted and words added—that remain 1 day after the discussion ends. Note that this score only reflects changes in word frequencies and does not take word re-ordering into account.

Formally, we consider each edit e as a vector of word frequency changes, both positive (addi-

tions) and negative (deletions) for each word type, stopwords removed. For an example in English, an edit that changed one instance of *suggested* to *insinuated*, as well as adding *old* might be represented as {'suggested': -1, 'insinuated': +1, 'old': +1'}. For each edit e_i , let vector c_i be the changes in word frequencies from that edit to the final revision after the discussion. This change vector represents how many tokens that an editor deleted were put back and how many tokens the editor added were afterward deleted. Let $|e|$ be the number of tokens changed in that edit and $|c|$ be the total word frequency changes (deletions if tokens of the word were added in the edit, or vice versa) in those specific word types from the edit to the final revision. The score y of a particular Wikipedia editor u in thread t across edits $\{e_1, e_2, \dots, e_n\}$ made by u in t is:

$$y(u, t) = 1 - \frac{\sum_{i=1}^n |c_i|}{\sum_{i=1}^n |e_i|}$$

Each editor’s score is the proportion of tokens they changed that remain changed, so $s \in [0, 1]$.

The goal of this editor score is to capture the “ground truth” of an editor’s influence on the article page. To validate this editor success measure, we sampled 20 conversations, read through the corresponding article edits by those editors, and made sure our automated editor success scores were reasonable compared with the success that editors seemed to achieve.

In our experiments, we aim to predict this editor success measure calculated from article revisions with behaviors and interactions simultaneously occurring on the talk page. This assumes that talk page discussions in our data are related to the simultaneous article edits that those same editors are doing. To validate that editors who were editing the article while having a discussion on the talk page simultaneously were talking about those simultaneous article edits, and not something else, we manually went through 20 conversations and simultaneous edits. Nineteen out of the 20 conversations directly related to simultaneous edits, and the only one not specifically about simultaneous edits related to similar content on the article page.

4 Model

We present a model which attempts to learn both discussion behaviors of the target editor (editor we are predicting the success of) and roles of other

discussion participants that influence the success of a particular editor.

4.1 Role Modeling Task

The task of role modeling as described is to identify latent patterns of behavior in discourse which explain some conversational outcome measure. The learned roles can then be intuitively interpreted to better understand the nature of the discourse and the interactions between the participants with respect to the chosen outcome measure.

4.2 Prior Approach: Role Identification Model (RIM)

A similar task was explored by (Ferschke et al., 2015) and (Yang et al., 2015), who represented role modeling as a bipartite matching problem between participants and roles. More specifically, RIM learns conversational roles from discussion behaviors, supervised by discussion outcome. A role is defined as a weight vector over discussion behaviors, where the weights represent the positive or negative contribution of the behaviors toward outcome measures.

However, this approach suffers from several simplifying assumptions which reduce its applicability to realistic conversation settings:

1. All roles are present in every conversation.
2. Each role is played by exactly one editor.
3. Each editor plays exactly zero or one roles.
4. All behaviors from editors with a role contribute to the outcome metric under that role.
5. No behaviors from editors without a role contribute to the outcome metric.

The proposed approach addresses these limitations by using a probabilistic graphical model that encodes a more appropriate hierarchical structure for the task.

4.3 Probabilistic Role Profiling Model (PRPM)

For modeling roles in discourse, we propose a generative model shown in Figure 1, whose generative story is shown in Figure 2.

4.3.1 Inference

Appropriate values for the parameters η , β , and τ may be inferred from data, and represent the settings with which the data is best explained (i.e. has the highest likelihood) under the generative story.

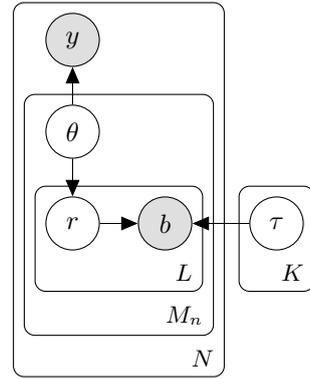

Figure 1: PRPM plate diagram relating for each conversation N the outcome measure y and each user M 's L behaviors b .

- For each role $k \in \{1, \dots, K\}$,
 - Draw behavior distribution $\tau_k \sim \text{Dir}(\alpha)$.
- For each conversation $n \in \{1, \dots, N\}$,
 - For each user $m \in \{1, \dots, M\}$,
 - * Observe user participation z_{nm} .
 - For each user $m \in M_n$,
 - where $M_n = \{m | z_{nm} = 1\}$,
 - * Draw role distribution $\theta_{nm} \sim \text{Dir}(\gamma)$.
 - * For each behavior $l \in \{1, \dots, L\}$,
 - Draw role $r_{nml} \sim \text{Multi}(\theta_{nm})$.
 - Draw behavior $b_{nml} \sim \text{Multi}(\tau_{r_{nml}})$.
 - Draw outcome $y_n \sim \mathcal{N}(\mu_n, \sigma)$,
 - where $\mu_n = \sum_m z_{nm} \theta_{nm} \cdot \beta$.

Figure 2: PRPM generative story

Computationally efficient methods for exact inference will not work for the proposed model due to the model structure, so approximate inference is used to estimate the parameter values.

We implement the model sampler using the JAGS framework (Plummer, 2003), which uses Gibbs sampling to generate dependent samples from the posterior distribution. These samples are used to obtain posterior mean estimates of the model parameters.

5 Features

5.1 Dialogue Act Features

We are interested in linguistic moves that characterize editors in conversation, and so we extract features that represent conversational acts. In particular, we extract dialogue act features from the model of Jo et al. (2017), an HMM-based unsuper-

vised dialogue act identification method that has been found to usefully separate between content-related words that are relatively static across conversations and words more related to dialogue acts, which change over the course of discussion. These features were found to yield better performance with our model than unigrams with tf-idf selection.

The model of Jo et al. (2017) learns separate language models for dialogue acts (DA LMs) and topical content (content LMs), where each word can be generated from either type of language model. This structure helps the model identify content words that are consistent throughout a conversation and separate them out from language models for dialogue acts.

To identify dialogue acts on talk pages that may be related to conversational roles of interest, we ignore content-specific words by providing pre-trained content LMs trained using LDA over the content pages. Each conversation is provided with the topic distribution of the content page of the same article, and in the modified model, each word may come from a different content LM independently chosen from the provided distribution over content LMs.

5.2 Behavior Features

To be used in combination with roles, we extract general discussion features motivated by relevance in other work.

Along with a simple bag of words of each editor's talk contributions and the contributions of all other editors, we consider the following discussion features.

5.2.1 Position of the editor in a discussion.

- Number of editor turns
- Number of other editors' turns
- Whether the editor takes the first turn
- Whether the editor takes the last turn

5.2.2 Style characteristics.

Drawn from (Tan et al., 2016), these may reflect the style and state of editors.

- Number of definite/indefinite articles
- Number of singular/plural personal pronouns
- Examples: number of occurrences of “for example”, “for instance”, and “e.g.”
- URLs: number of URLs that end with “.com”, “.net”, “.org”, or “.edu”

- Questions: number of question marks that follow an alphabetic character

5.2.3 Authority claims.

Bender et al. (2011) define these authority claim categories annotate them in Wikipedia talk pages. For each word type in their annotated data, we calculated the pointwise mutual information for each category. In our data, we scored each sentence with the log sum of the word scores for each category.

The categories used are:

- Credentials: education or occupation
- Experiential: personal involvement
- Forum: policy or community norms
- External: outside authority, such as a book
- Social expectations: expected behavior of groups

5.2.4 Emotion expressed by editors.

For a simple measure of emotion, we use LIWC (Tausczik and Pennebaker, 2010).

- Counts of positive/negative emotion words

6 Experiments

We frame our task as a regression problem, predicting editor scores based on discussion behaviors of the target editor and the other editors. Our outcome measure is the editor success score of a single editor. Since there are multiple editors in a discussion, we have multiple instances per discussion.

We use root mean squared error (RMSE) between the true scores and the predicted scores as an evaluation metric. We hypothesize that in specifying our model with latent roles as mediators between the raw discussion data and the predictive task we can achieve a lower RMSE than from a baseline that takes only the behaviors into account, especially for conversations with a greater number of participants, for which there can be more interaction.

Furthermore, to the extent to which the proposed graphical model better captures a valid conceptualization of roles, we hypothesize that we can achieve a lower RMSE than the model of Yang et al. (2015). In this section we first specify the baselines used for comparison in our experiments, and then explain the testing process with our own model and experimental design.

6.1 Baselines

These two hypotheses suggest different baseline models. Our first hypothesis is that introducing a model with latent roles improves over simply using discussion features, and the second is that PRPM better captures interaction than the prior RIM model.

6.1.1 Linear Regression

The simplest baseline model allows us to evaluate the first hypothesis. This model assumes that the whole is not greater than its parts. In other words, it assumes that the sum total of positive impact the features can achieve on performance is just through their inclusion as separate features. For this baseline, we use a simple linear regression model. We bound the linear regression predictions to be between 0 and 1, the range of the editor scores. The full set of features in this model are included twice, once from the target editor in the discussion, and once from an aggregation across all non-target editors in the discussion.

6.1.2 RIM

We evaluate our model against RIM, introduced by Yang et al. (2015). RIM was originally applied to Wikipedia talk page discussions in Ferschke et al. (2015), who assigned a single success score to each page. In our work, for each discussion, we evaluate the success of each editor in each discussion thread separately. Since there is differential success between editors in the same interaction, the same interaction is associated with multiple different success measures. We handle this by slightly tweaking the original RIM model such that the first role is reserved exclusively for target editors, i.e., editors whose success measure is being evaluated. The other roles represent the roles of other editors in terms of their influence on the success of the target editor. Additionally, for conversations having fewer editors than the number of roles, we leave some of the roles unassigned by adding dummy editors whose behavior values are zero.

To predict the success measure of an editor for a test instance, RIM first assigns the learned roles to the editors. This process is identical to the training process, except that there is only the role assignment step without the weight adjustment step. Specifically, the first role is assigned to the target editor as in training, and the other roles are assigned according to the original model. Once the

roles are assigned, the predicted score is simply the sum over roles of the inner product of a role’s weight vector and the behavior vector of the editor who is assigned the role.

6.2 PRPM

To infer role distributions for each editor in a test instance conversation, we first fix the model parameters to the estimates learned during the training phase. Gibbs sampling is then used to infer the non-target users’ role distributions θ_m and the conversation outcome measure y over the unseen data. The role distributions for each non-target editor are then averaged together and concatenated with the target editor role distribution. Finally, a linear regressor is used analogously to the above baseline to evaluate the predictive power of the PRPM roles in aggregating the information from editor behavior features.

6.3 Experimental Design

In order to evaluate our approach and model, we split our data into a training set of 60%, a development set of 20% to train regression weights on the roles learned from the training set, and a test set of 20%.

For the original and proposed role identification models, we manipulated the number of latent roles the learned models were allowed to include.

7 Results and Discussion

Results from baselines and PRPM are presented in Table 2. We do not include scores with unigram tf-idf counts as features, as this decreases the performance of all models. The pattern of results is consistent with the hypotheses, i.e., role information and our model’s configuration improves performance over both baselines.

First, the relatively high RMSE values indicate the challenging nature of this task. Talk page discussion is only one factor in editor success, and undoubtedly much interaction between editors comes from edit behavior, past interactions between editors, and even the short edit comments that editors leave about their edits. We were not able to find a comprehensive study of the effect of Wikipedia talk pages on article pages, but links from discussion features to outcomes in collaborative editing are often tenuous (Wen et al., 2016).

Our model performs slightly better than the linear regression baseline, though it performs

Model	Setting	2	3	4	5+	All
LinReg	tgt editor	0.286	0.302	0.287	0.302	0.292
LinReg	all	0.287	0.302	0.289	0.301	0.292
RIM	$K=2$	0.316	0.317	0.308	0.342	0.318
RIM	$K=3$	0.307	0.320	0.310	0.337	0.314
RIM	$K=4$	0.307	0.314	0.311	0.327	0.311
RIM	$K=5$	0.309	0.315	0.308	0.321	0.312
PRPM	$K=2$	0.286	0.302	0.288	0.297	0.292
PRPM	$K=3$	0.286	0.302	0.288	0.295	0.291
PRPM	$K=4$	0.286	0.302	0.289	0.295	0.291
PRPM	$K=5$	0.286	0.302	0.288	0.295	0.291

Table 2: RMSE for baselines and models. Rows are model settings. Scores are reported for different numbers of participants, which are the columns headings. (LinReg: editor uses only the target editor’s features, and all uses all participants’ features. RIM and PRPM: K is the number of roles.)

substantially better than the previously proposed RIM model. One advantage of our role-based model above the linear regression baseline is clear when looking at conversations with more editors (columns in Table 2 denote the number of discussion participants in analyzed conversations). This points to the utility of using role information with larger groups, when roles are likely more relevant.

Another advantage of PRPM over the linear regression baseline is that it allows interpretation of both target editor strategies and group dynamics that characterize the success or failure of a target editor. Where linear regression allows only the characterization of behaviors that make individual editors successful, PRPM captures roles in interaction with other roles in group conversation. In this way, PRPM allows a more full interpretation of group interaction.

7.1 PRPM Role Analysis

Our best-performing model classified editors into 5 different roles. We identified the combinations of roles that are predictive of editor success (or failure).

To assess roles, we examined the text and discussion features of editors who scored highly, as well as considered the weights assigned to each feature for each role. The relative frequencies of each behavior for each role are shown in Figure 3. A characteristic example discussion post for each role is given in Table 3. Each role is named and described qualitatively below.

Moderator. This role primarily helps discussion flow without getting too involved, perform-

ing and summarizing the results of administrative tasks. High probability dialogue act features for this role include asking questions of other editors and discussing itemized content. The moderator role is less likely than other roles to have success as a target editor and has the lowest target editor success when paired with other editors playing the moderator role.

Architect: This role is predominantly focused on page hierarchy, with the bulk of its probability focused on the `page_format` dialogue act, which is relevant to discussions of adding new page sections, merging, archiving, and creating new pages. The architect role is moderately likely to have success as a target editor.

Policy Wonk: This role is an knowledgeable Wikipedia user, frequently mentioning source accountability, fair use or copyright policy for images. Dialogue act features which have high probability for the policy wonk include appealing to Wikipedia policy and discussing engagement with other users on user talk pages. The policy wonk role is moderately unlikely to have success as a target editor.

Wordsmith: This role is predominantly concerned with the naming, creation, and wording of pages. Dialogue act features which have high probability for the wordsmith include discussing the spelling, pronunciation, or translation of words and phrases, as well as discussing the (re-)naming of new or existing pages or sections. The wordsmith role is strongly correlated with target editor success, especially when combined with the moderator or architect.

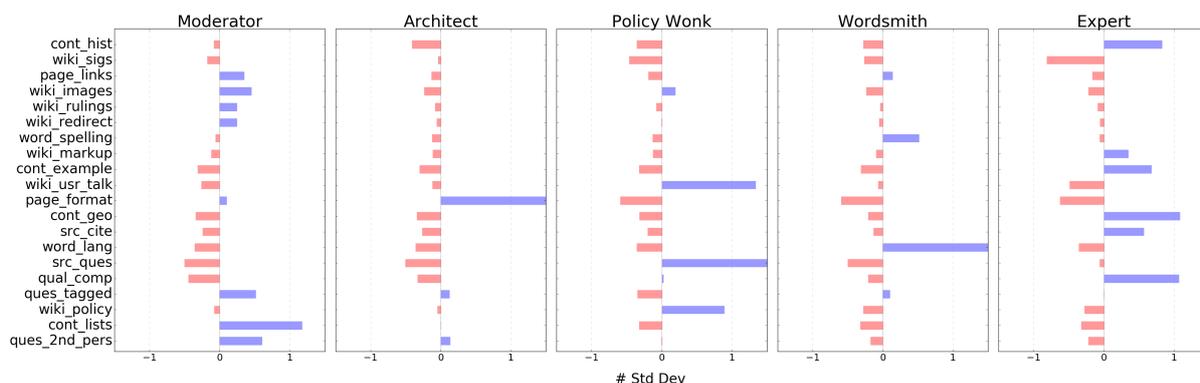

Figure 3: Behavior distributions for each role, expressed for each behavior as the number of standard deviations above the mean.

Role	Example post
Moderator	It was requested that this article be renamed but there was no consensus for it be moved.
Architect	I think a section in the article should be added about this.
Policy Wonk	The article needs more WP:RELIABLE sources.
Wordsmith	The name of the article should be ““Province of Toronto”” because that is the topic of the article.
Expert	There actually was no serious Entnazifizierung in East Germany.

Table 3: Examples of discussion posts from users in certain learned roles

Expert: This role is the most content-oriented role learned by our model. Dialogue act features which have high probability for the expert include making comparisons, discussing historical and geopolitical content, giving examples, and citing sources. The expert role is most strongly correlated with target editor success when combined with other users playing the expert role.

We find that the roles that lend themselves most strongly to target editor success (the Wordsmith and Expert) are more concrete edit-focused roles, while the roles associated with lower target editor success (the Moderator, Architect, and Policy Wonk) are more conceptual organizational roles. Note that it is not necessarily the case that editors that edit more frequently have higher scores. We

find frequent editors across all roles.

Additionally, we find that configurations with multiple conceptual organizational roles lead to diminished outcomes for individual editors, suggesting that individual conceptual editors are unlikely to have their edits universally accepted. This could mean that talk page conversations that have multiple conceptual voices (which could be a measure of interesting discussion) are more likely to result in compromises or failure for a target editor. It is important to recognize that we are focusing on strategies and configurations of roles always in relation to the success of one editor; this editor score does not necessarily refer to a good, well-rounded discussion.

8 Conclusion and Future Work

The nature of collaboration on Wikipedia is still not fully understood, and we present a computational approach that models roles of talk page users with relation to success on article pages. We contribute both a new task with corresponding public dataset and a lightly-supervised graphical model for inducing role-based behavior profiles to predict the success of Wikipedia editors.

The proposed probabilistic graphical role model is unique in its structure of roles in relation to the outcome of one particular participant instead of group performance, and allows flexible mappings between roles and participants, assigning each participant a distribution over roles. The model we present retains one limitation of the RIM model, the assumption that editors in one conversation exist independently from those same editors in other conversations. Future work should address this.

Our model lends interpretability to combinations of talk page discussion roles. We find that detail-oriented roles are associated with success in combination with organizational roles, but that multiple participants taking organizational roles can lessen individual editing success.

We hope that this exploration into role-based discourse analysis will further enable systems to understand group interaction in text.

Acknowledgments

This work is supported in part by NSF GRFP Grant No. DGE1745016, NSF IIS STEM+C 1546393, NIH R01HL12263903, and by seedling funding from the Naval Research Lab.
